Title: A role of lateral connections in the formation of orientation representation efficiently preserving visual information

Authors: ***M. MIYASHITA**[1], S. ISHIKAWA[2], J. HORIKAWA[2], S. TANAKA[3];
[1]Natl. Inst. of Technol., Numazu, Shizuoka, Japan; [2]Toyohashi Univ. of Technol., Toyohashi, Aichi, Japan; [3]The Univ. of Electro-Communications, Chyofu, Tokyo, Japan

Abstract: It has been believed for long time that preferred orientations are arranged tangentially in the mammalian primary visual cortex in an orderly manner, forming orientation maps. Recently, in the rodent visual cortex, however, preferred orientations have been found to be distributed almost randomly in a salt-and-pepper-like manner. These experimental findings raise a question of what functional roles cortical orientation representation plays in visual perception. Very recently, we have successfully reproduced not only orderly but also random orientation representations using our self-organization model of geniculo-cortical afferent inputs only by changing the value of the connection probability of lateral excitation p. The salt-and-pepper-like representation emerged with a large portion of unresponsive cells at $p < p_c$, whereas orderly maps without unresponsive cells appeared at $p > p_c$. In the present study, we examined to what extent visual images are reconstructed from activity patterns of cells in the model cortex that exhibits different types of orientation representations. The reconstruction was made so that the mean square error in activity patterns between a target image and a reconstructed one is minimized. We quantitatively evaluated the similarity of reconstructed images to target images. As a result, the larger the p value is, the higher the similarity is, as expected. In other words, the precision of image reconstruction is higher for denser lateral excitatory connections. Next we examined the similarity in case where simulations of self-organization had been conducted with lateral connections at $p < p_c$ or without lateral connections under the condition of the equal

number of responsive cells. The similarity was found to be conspicuously higher for the orientation representation that had been self-organized with lateral connections than for the representation without lateral connections. This suggests that cortical lateral connections are necessary for the development of the orientation representation that preserves visual information sufficiently to decode visual images, even if the representation is salt-and-pepper-like due to the sparseness of the connections.

Title: Development of orientation selectivity in ferret V1: high cellular and columnar variability visualized through chronic 2-photon imaging

Authors: ***G. B. SMITH**[1], D. E. WHITNEY[1], B. HEIN[2], M. KASCHUBE[2], D. FITZPATRICK[1];
[1]Max Planck Florida Inst. For Neurosci., Jupiter, FL; [2]Frankfurt Inst. for Advanced Studies, Frankfurt am Main, Germany

Abstract: Selectivity for stimulus orientation is a fundamental property of primary visual cortex in primates and carnivores, where it is organized into a smoothly varying columnar map that emerges in an activity-dependent manner during early postnatal life. Numerous theoretical models have been proposed to explain the formation of orientation maps, and this key developmental process has been the subject of extensive experimental work. Despite these efforts, it has remained unclear how the modular structure of an orientation map forms over development and the degree to which individual neurons alter their preferences to produce a smooth map. In the ferret, intrinsic signal imaging shows that orientation maps first emerge around eye-opening and then exhibit a stable columnar pattern. However, this technique both lacks cellular resolution and requires extensive trial averaging, and therefore cannot distinguish between several potential explanations for the early absence of maps, including weak cortical responses, high trial-to-trial variability, and an intermixed ‘salt-and-pepper’ organization of

orientation preferences at the cellular level.
Here we address this limitation through the longitudinal imaging of GCaMP6s at both the columnar and cellular level in developing ferrets. We show that prior to eye-opening, gratings reliably evoke strong responses, which exhibit a highly modular structure with consistent domain size across both cortical locations and visual stimuli. Notably, the spatial location and pattern of domains activated by a single orientation varies greatly across trials, resulting in the absence of a clear orientation map. The high variability of orientation responses on the columnar scale is not a general feature of the immature cortex, as responses to uniform luminance steps are both selective and reliable. Longitudinal imaging shows that trial-averaged columnar orientation responses begin to show similarity to the future mature orientation map in the days immediately prior to eye-opening, despite response variability remaining high until several days following eye-opening. At the cellular level, two-photon imaging reveals that responses are spatially coherent prior to eye-opening, with no evidence of an intermixing of differently tuned populations. Similar to columnar responses, the responses of individual neurons also exhibited high trial-to-trial variability, which declined following eye-opening. Thus, our results suggest that the lack of strong orientation maps prior to eye-opening reflects highly variable responses in an immature cortex already exhibiting strong modular organization.

Title: A model network with clustered connections reproduces the observed dynamics of correlated variability in visual cortex

Authors: *M. HOSEINI[1], N. WRIGHT[1], W. CLAWSON[2], W. SHEW[2], R. WESSEL[1]; [1]Physics, Washington Univ. In St. Louis, Saint Louis, MO; [2]Univ. of Arkansas, Fayetteville, AR

Abstract: The correlated variability (or “noise correlation”) of cortical responses to repeated presentations of the same stimulus originates from the interconnected nature of cortical circuits and impacts population coding. Two questions loom high in our quest to understand cortical signal processing: (1) What are the spatiotemporal dynamics of correlated variability? (2) What mechanisms mediate such dynamics of coordination?
To address the first question, we obtained simultaneous local field potential (LFP) recordings from a visual cortex in response to repeated visual stimulation. Specifically, we inserted a 96-channel microelectrode array into the visual cortex of the ex vivo turtle eye-attached whole-brain preparation and recorded the LFP responses to naturalistic movie clips projected onto the intact retina. We made four key observations with respect to the correlated variability among pairs of LFP recordings. First, correlated variability was small during ongoing activity, significantly increased at stimulus onset, and relaxed back to an intermediate level during continued visual stimulation. Second, correlated variability decreased with increasing inter-electrode distance. Third, correlated variability varied markedly among electrodes, but correlated variability of a pair during ongoing activity was related to the correlated variability during evoked activity. Fourth, LFP recordings featured intermittent oscillations; correlated variability among pairs of LFP recordings was strongly linked to the coherence of such oscillations.
To address the second question, focused on mechanisms, we investigated a model network of excitatory and inhibitory leaky integrate-and-fire (LIF) model neurons, including external inputs and synaptic depression with recovery. We mimicked two-dimensional space by arranging neurons on the surface of a sphere with a mix of mostly clustered and some long-range connections. We defined the simulated LFP as the sum of the synaptic currents within a group of adjacent neurons. Within this model framework, our simulations reproduced the experimentally observed temporal dynamics and the spatial dependence of correlated variability. In contrast, a random network with unstructured connections is not able to reproduce all experimentally observed features.
In conclusion, our work quantifies the spatiotemporal dynamics of correlated variability and emphasizes the role of structured connectivity in shaping the dynamics, thus building a bridge between cortical structure and computation.

Title: Spontaneous emergence of structured responses in a random neural network in-vitro

Authors: *M. SCHOTTDORF[1], J. VOGEL[1], H. SCHROBSDORFF[1], W. STÜHMER[2], F. WOLF[1];
[1]MPI DS, Goettingen, Germany; [2]MPI EM, Goettingen, Germany

Abstract: Neural networks with connections organized by probabilistic rules are conceptually powerful model systems. Among others, random neural networks have been shown to (1) generically exhibit computationally favorable properties for stimulus representation and information processing (e.g. Lukoševičius & H. Jaeger, 2009), (2) dynamically generate a state of sustained irregular spiking activity (van Vreeswijk & Sompolinsky, 1996) and (3) to account for visual cortical orientation selectivity (Ernst et al., 2001). What is left open in these theoretical studies is the question whether such ideas are viable in random networks of living cells.
We address this problem using a dissociated culture of rat cortical neurons. The neuronal connection patterns in such cultures are substantially less organized than neural circuits in the brain. We then drive these neurons optogenetically with spatially complex light patterns, generated by a holographic photostimulation system (Golan et al. 2009) and monitor neural responses optically with a redshifted genetically encoded calcium indicator (Dana et al. 2016 bioRxiv) together with ground truth data from a multielectrode array.
Stimulating the cell culture with moving gratings reveals a substantial degree of orientation tuning. We identify at least 33 out of 430 units from 16 cortical cultures as orientation selective, i.e. they show a circular variance < 0.9. This is highly significant with $p<0.001$**.** Notably, the orientation selectivity described here resembles to some extend cortical orientation selectivity.

Title: The computational tradeoff between dynamic range and stimulus discrimination in neural circuits near criticality.

Authors: *K. L. MCCLANAHAN, D. BOHLMAN, W. L. SHEW;
Physics, Univ. of Arkansas, Fayetteville, AR

Abstract: How the brain processes input from the senses depends crucially the collective interactions among neurons in the cerebral cortex and interactions among cortical regions. One important property of how a neural network encodes input is dynamic range, which quantifies the range of input intensities that lead to distinguishable responses. Previous experiments and computational models show that dynamic range is maximized when the interactions among neurons in the network are tuned to a special regime, called criticality. However, dynamic range is typically defined based on the average response to many repetitions of the same set of stimuli. This is unrealistic, because trial-to-trial variability can be high, especially at criticality, and the brain does not have the luxury of averaging over thousands of repetitions. A more principled approach, which accounts for trial-to-trial variability, is offered by signal detection theory. For a given pair of stimuli, the ability to correctly discriminate between the two stimuli depends on how the two distributions of responses overlap, and can be quantified as the area under the receiver operating characteristic (AUROC). Here, we study this problem using a network-level computational model of binary, probabilistic integrate-and-fire neurons. First, we consider a single network of neurons and show that the true distinguishability (AUROC) of stimuli is not optimal at criticality, but rather is highest in the subcritical regime. However, if we consider a second network of neurons that receives its input from the first network, the optimal regime for stimulus discrimination shifts back towards criticality. Considering the multi-network, hierarchical structure of real sensory systems (e.g. thalamus, primary sensory cortex, association areas, etc.), our results suggest that sensory input may be best distinguished when the system as a whole operates near criticality, but in the slightly subcritical regime. More generally, our results demonstrate a computational tradeoff: maximizing dynamic range comes at the cost of suboptimal stimulus discrimination.

Title: Pulvinar modulates the contrast response function of cortical neurons throughout the visual hierarchy.

Authors: *N. CORTES, B. O. SOUZA, J. LAI, U. KEYSAN, S. THOMAS, C. CASANOVA; Ecole d'optometrie, Univ. De Montreal, Montreal, QC, Canada

Abstract: While the properties of pulvinar cells and their connectivity with cortical visual areas have been described, their exact function are still unknown. Experimental and theoretical data suggest that projections from the pulvinar to the cortex modify the neural gain of the contrast response function (CRF) of cortical cells (Cortes and van Vreeswijk, 2012, 2015). Further, data from our group show that pulvinar inactivation can also shift the CRF of primary cortical neurons along the x-axis. How both gain and shift in the CRF can arise from the pulvinar? We explored this question by creating a network of sequential cortical levels attached to a pulvinar-like structure where each component is in the balanced state, to mimic the flow of neural activity through the visual system. We modeled the interactions between the visual cortices and the pulvinar with both reciprocal and non-reciprocal projections. While reciprocal connectivity was kept constant throughout the cortical chain, the synaptic strength of the non-reciprocal connections decreased as one moves from lower to higher cortical levels. We found that for early levels, reciprocal connections are mainly responsible for shifts in the CRF whereas local processing within the pulvinar together with non-reciprocal connections control the CRF gain across the cortical hierarchy. We compare these findings with experimental data on the CRF of V1 and 21a neurons of the cat prior to and after pulvinar inactivation. The proposed model suggests that both forms of CRF modulation could be managed sufficiently by cortico-pulvino-cortical connections, and does not require changes in cortico-cortical connection strength across the network.

Title: Effect of mean luminance on cortical responses to darks and lights

Authors: *R. MAZADE[1], J. JIN[1], C. PONS[1], H. SWADLOW[2], J. ALONSO[1];
[1]Biol. and Vision Sci., State Univ. of New York Col. of Optometry, New York, NY; [2]Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: The cat primary visual cortex is organized in ON and OFF domains of neurons that show different preferences for light and dark stimuli. OFF domains generate stronger responses and have a more accurate representation of visual space than ON domains. It is currently unclear how this cortical OFF-dominance is affected by the different luminance levels of visual scenes. To better understand the relation between cortical OFF dominance and mean luminance, we performed horizontal penetrations through cat primary visual cortex with multielectrode arrays (32-electrode Neuronexus, 0.1 mm electrode spacing) and measured visual responses to dark and light stimuli with luminance spanning from 0.007 to 70 cd/m^2 (mean luminance was attenuated with neutral density filters placed in front of the eye). Our results demonstrate that, when driven by dark stimuli in light backgrounds, both OFF (dark on) and ON responses (dark off) double their strength as mean luminance increases from 0.007 to 0.7 cd/m^2. However, OFF responses remain consistently stronger than ON responses across the entire luminance range (average OFF vs. ON: 79 vs. 46 spk/sec, $p<0.001$, n=410 vs. 158 recording sites, Wilcoxon test). In turn, when driven by light stimuli in dark backgrounds, OFF responses (light off) are still stronger than ON responses (light on) but only at the higher luminance (ON vs. OFF: 61 vs. 80 spk/sec at 0.7-70 cd/m^2, n=310 vs. 395, $p<0.001$; 65 vs. 64 spk/sec at 0.007-0.7 cd/m^2, n=147 vs. 131, p=0.35; Wilcoxon tests). OFF responses were also stronger than ON responses for all stimulus conditions in mid-gray backgrounds except for lights at 7-70 cd/m^2 (light ON vs. light OFF: 51 vs. 45 spk/sec, n=212 vs. 127, p=0.009, Wilcoxon test). In addition to changes in response strength, increasing stimulus luminance caused a pronounced reduction in ON and OFF response latency, which could be accurately fit with a linear function in a semi-log scale. For each log-unit increase in luminance, ON response latency was reduced by 14.25 msec in dark backgrounds (R^2 = 0.98, n=4 luminance bins, p=0.007) and OFF response latency was reduced by 11.13 msec in light backgrounds (R^2 = 0.99, n=4 luminance bins, p=0.001). Surprisingly, increasing the mean luminance also made OFF receptive fields slightly larger (23% for a luminance increase from 0.07 to 70 cd/m^2 in light backgrounds, n=70 vs. 417, $p<0.001$, Wilcoxon test), an increase that reached half-saturation at 0.09 cd/m^2. These results demonstrate that mean luminance has pronounced effects on the response magnitude, latency and size of OFF cortical receptive fields and reveal a surprising dominance of the OFF pathway across a wide illumination range including low mesopic light.

Title: Gamma oscillations as a marker of collinear horizontal and feedback connectivity in primate primary visual cortex

Authors: *M. BIJANZADEH[1], A. ANGELUCCI[2];
[1]Moran Eye Inst., Neurosci. program, Univ. of Utah, Salt Lake City, UT; [2]Moran Eye Inst., Salt Lake City, UT

Abstract: Orientation tuned surround modulation (SM) is a fundamental property of primary visual cortex (V1) neurons, thought to result from the interaction of horizontal (H) and feedback (FB) connections with local recurrent circuits (Angelucci et al. 2002; Shushruth et al. 2012). We previously proposed that both H and FB connections mediate the modulation from surround regions *near* the receptive field (RF), but only FB mediates *far* SM. H connections link neurons having similar orientation preference along an anisotropic axis in visual space collinear with the orientation preference of the connected neurons (Bosking et al. 1997). We have recently shown that FB connections may have a similar collinear arrangement (Federer et al., SFN 2015). Stimulation of the RF surround with isotropic gratings has been shown to increase the power in gamma oscillations (30-90 Hz) when the RF is simultaneously stimulated (Gieselmann & Thiele 2008). Gamma oscillations are thought to enhance information transmission across different brain regions (e.g. Fries 2009), and to reflect the activity of recurrent circuits (Borgers & Kopell 2008; Xing et al. 2012). If SM results from the interaction of visually anisotropic long-range connections with local recurrent circuits, then gamma oscillations induced by surround stimulation should reflect this anisotropy in connectivity. Here we have tested this hypothesis. Using linear electrode arrays in macaque V1, we recorded local field potential (LFP) responses to small (0.5-1.5°) iso-oriented grating patches flashed at varying distances from the RF center (0.5°-3.4°), in collinear or non-collinear configuration relative to the preferred orientation of neurons in the recorded V1 column. LFPs were filtered (1-100Hz) and their power spectrum was computed using Chronux toolbox (multitaper method, 8 Hz bandwidth, 3 tapers, Mitra & Bokil,

2008). The increase in gamma power was defined as the difference between the logarithm of the power during stimulus presentation (0-200ms) and prior to stimulus onset (-200-0ms).
We found that collinear surround grating patches in the absence of RF stimulation evoked higher gamma power than non-collinear patches in both superficial and deep V1 layers, and this effect decreased with distance from the RF. Moreover, collinear (but not non-collinear) patches in the near surround evoked greater increases in gamma power than far surround patches. These results suggest that collinearity is an important feature of the H and FB connectivity underlying near and far surround modulation, and support a role for recurrent networks in surround modulation.

Title: Layer 6 corticogeniculate neurons in the awake visual cortex: Receptive field properties and effect of alert/non-alert brain states.

Authors: *C. R. STOELZEL[1], Y. I. BERESHPOLOVA[1], J.-M. ALONSO[2,1], H. A. SWADLOW[1,2];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Dept. of Biol. Sci., SUNY-Optometry, New York, NY

Abstract: The lateral geniculate nucleus provides a powerful input to layer 4 (L4) and a less dense but significant input to layer 6 (L6) of the visual cortex. L6 corticogeniculate (CG) neurons provide a feedback projection to the LGN that is thought to shape receptive field (RF) properties and influence spike timing and response gain of thalamic neurons. Here, we examine the RF properties of antidromically identified CG neurons of primary visual cortex of awake rabbits, in both alert and non-alert states, and we compare these findings with recently studied L4 simple cells (Zhuang et al., 2013; 2014). We found that ~ 40% of CG neurons did not respond to visual stimulation in either brain state, and these unresponsive cells had significantly longer corticothalamic axonal conduction times (30.8 ± 1.9 ms) than visually responsive CG neurons (19.0 ± 1.7 ms). All visually responsive CG neurons (n = 42) had simple RFs with either a single

ON or OFF domain, or spatially separate ON and OFF domains, and all but one (97.6%) had an F1/F0 ratio > 1. L4 simple cells and visually responsive CG neurons had similar (low) spontaneous firing rates (CG = 0.45 ± 0.09 spk/s L4 simple = 0.55 ± 0.08 spk/s), visually evoked response rates (F1, CG = 11.9 ± 1.3 spk/s, L4 simple = 15.2 ± 1.5 spk/s) and response linearity (F1/F0, CG = 1.42 ± 0.04, L4 simple = 1.53 ± 0.03). However, L6 CG neurons: 1) preferred lower temporal frequencies (CG = 3.0 ± 0.2 Hz, L4 simple = 5.8 ± 0.9 Hz), 2) had wider RFs (CG = 4.1 ± 0.3°, L4 simple = 3.2 ± 0.1°), 3) had similar preferred spatial frequencies (CG = 0.21 ± 0.02 cpd, L4 simple = 0.20 ± 0.03 cpd), 4) but had a wider SF bandwidth (CG = 1.38 ± 0.16 oct, L4 simple = 0.68 ± 0.07 oct), 5) were less directionally selective (DSI, CG = 0.42 ± 0.05, L4 simple = 0.68 ± 0.03), 6) had longer latencies to visual stimulation (CG = 55.6 ± 2.1 ms,L4 simple = 37.5 ± 2.8 ms), and 7) responded in a more sustained manner to a stationary stimulus. Moreover, the effects of alertness were considerably stronger on layer 6 CG neurons than on layer 4 simple cells. For both cell classes, alertness significantly reduced response variability (Fano factor), enhanced visually evoked responses (F1) to stimuli moving in the preferred direction while also suppressing responses to stimuli moving orthogonal to the preferred direction. However, state effects on CG neurons were greater. Using a population coding model for orientation detection (Zhuang et al., 2014; Hei et al., 2014), we show that these effects of alertness on CG neurons --enhanced reliability, higher gain, and increased suppression to orthogonal orientations-could increase the speed of cortical feature detection, and do so to a much greater degree (~ 2-fold) than was seen for layer 4 simple cells.

Title: Fast spike interneurons in layer 6 of rabbit visual cortex: Comparison with layer 4 and effects of alert/non-alert brain states

Authors: *Y. I. BERESHPOLOVA[1], C. R. STOELZEL[1], J.-M. ALONSO[1,2], H. A. SWADLOW[1,2];

[1]Dept. of Psychology, Univ. of Connecticut, Storrs, CT; [2]Dept. of Biol. Sci., SUNY-Optometry, New York, NY

Abstract: Thalamocortical axons from the lateral geniculate nucleus (LGN) project largely to layer 4 (L4) of primary visual cortex (V1), but also send a significant projection into layer 6 (L6). Here we examine the visual response properties, geniculocortical connectivity, and effects of brain state (awake alert vs. non-alert) of putative fast-spike inhibitory interneurons (suspected inhibitory interneurons, SINs) in L6 of V1, and we compare these findings with those previously obtained (Zhuang et al., 2013; 2014) from SINs of L4. SINs of L6 had similar latencies to electrical and visual stimulation as L4 SINs, and cross-correlation analysis between spike trains of LGN neurons and retinotopically aligned L6 SINs confirmed monosynaptic connectivity. In comparison to L4 SINs, L6 SINs: 1) were less linear (F1/F0 ratios, L6 vs L4: 0.2 ± 0.04 vs 0.53 ± 0.04), 2) had similarly high spontaneous firing rates (L6 vs L4: 17.76 ± 2.03 spk/s vs. 21.96 ± 2.18 spk/s), but significantly lower modulated response amplitudes (F1, L6 vs L4: 10.09 ± 1.87 spk/s vs 32.97 ± 3.73 spk/s), 3) were less sensitive to contrast (C-50 values, L6 vs L4: 24.31 ± 2.41 % vs 10.83 ± 1.94 %), and 4) were far less reliable (Fano Factor, L6 vs L4: 2.03 ± 0.35 vs 1.33 ± 0.08). Receptive field tuning properties for orientation, spatial frequency and temporal frequency did not significantly differ between SINs of L4 and L6. Additionally, the alert state greatly enhanced response reliability and the response amplitude of visually evoked responses during optimal stimulation. In contrast to the diversity of state-dependent effects previously reported for L4 SINs (Zhuang et al., 2014), the effect of state on L6 SINs was stronger, and considerably more homogeneous, demonstrating an enhanced sensitivity to state.

Title: Optogenetic inactivation of V2 feedback to primate V1 affects contrast gain, receptive field size and near surround suppression

Authors: *L. NURMINEN, S. MERLIN, M. BIJANZADEH, F. FEDERER, A. ANGELUCCI; Moran Eye Ctr., Univ. of Utah, Salt Lake City, UT

Abstract: Inter-areal feedback (FB) connections are a prominent feature of the cortex whose role remains hypothetical, due to the difficulty of inactivating FB selectively and rapidly without silencing an entire cortical area. Neurons in primate area V1 receive FB inputs from areas V2, V3 and MT. V2 FB inputs encompass the receptive field (RF) and *near* RF surround of V1 cells, while V3 and MT FB inputs extend to the RF *far* surround (Angelucci et al. 2002). Here, we investigated the impact of optogenetically inactivating V2-to-V1 FB terminals on V1 responses . The inhibitory opsin ArchT was expressed in axon terminals of V2 FB cells by injecting AAV9-CaMKII.Cre and AAV9.CAG.Flex.Arch into V2 of 3 marmosets. After 4-6 wks, linear array recordings (24-channels) were made in V1 of anesthetized animals. Optogenetic silencing of FB terminals in V1 was performed by surface photostimulation with a green (532nm) laser coupled to a 400μm diameter optical fiber or collimator, producing a ~2mm diameter light spot. V2 was shielded from light. For each penetration (n=8), we measured size tuning and contrast response functions with and without FB inactivation. Photostimulation intensity was gradually increased while measuring V1 neurons' size tuning curves using drifting high contrast sinusoidal gratings of increasing size optimized for the recorded cells. The lowest light intensity evoking response changes was chosen for the reminder of the experiment. Each stimulus was presented twice in succession for 500ms (ISI 750ms) with photostimulation (500ms) randomized between the first and second presentation.

In a subset of V1 units modulated by light, V2 FB inactivation caused a shift in the peak of the size tuning curve towards larger grating diameters, and increased spike-rate at the shifted peak, thus effectively increasing RF and surround sizes, and reducing *near* surround suppression. Both RF and RF-surround sizes (grating diameter at peak summation and at plateau, respectively) approximately doubled after FB inactivation. In contrast, the size and strength of *far* surround suppression, which is likely mediated by FB from V3 and MT, were unaffected by V2 FB inactivation. V2 FB inactivation also affected the contrast response of V1 cells by reducing spike-rate at all contrasts, and increasing contrast gain.

We conclude that V2 FB increases near surround suppression and “shrinks” RF size in V1 cells via a contrast gain-dependent mechanism. These results are consistent with a model of surround suppression (Schwabe et al. 2006) in which reduced FB excitatory inputs to V1 RFs allows V1 cells to sum inputs over larger visual field regions, until a threshold for inhibition is reached.

Title: Visual dominance for darks increases with low light and optical blur

Authors: *C. PONS, R. MAZADE, J. JIN, M. DUL, Q. ZAIDI, J.-M. ALONSO;
Biol. Sci., State Univ. of New York, New York, NY

Abstract: We have previously shown that differences in the luminance response function of ON and OFF visual-pathways can explain asymmetries in processing dark versus light features in visual scenes. We now measure dark/light asymmetries in human vision across two orders of magnitude of background luminance by using neutral density filters (0.0136 to 136 cd/m^2), and confirm that differences in ON/OFF luminance responses explain multiple dark/light asymmetries in perception. First, we demonstrate that humans see high spatial frequencies better with full-contrast gratings of dark bars than light bars (14.3% difference in correct responses at 16 cpd, $p<0.001$, Wilcoxon tests here and below), but the difference disappears under low luminance, where high spatial frequencies are no longer visible. Second, we show that, although low light eliminates dark/light asymmetries in grating acuity, it enhances the asymmetries for visual salience of dark/light spots presented in noisy backgrounds (dark-light difference in correct responses of 11.29% increases to 22.01% in low luminance, $p<0.001$). We also show that dark/light asymmetries are enhanced by optical blur (7.95% at focus vs. 18.79% with -5 diopters and 24.68% with +5 diopters, $p<0.001$). Third, we demonstrate that, although visual resolution is higher for gratings of dark bars, full-contrast light dots on dark backgrounds are detected better than dark dots on light backgrounds (-36% dark-light difference in correct responses for dots of 1 monitor pixel $p<0.001$), a difference that disappears or reverses as background brightness increases. Finally, we use a computational model to demonstrate that ON luminance-response saturation explains all the asymmetries tested. The model assumes that ON luminance saturation occurs under different luminance conditions, an assumption that was confirmed with multielectrode recordings in cat visual cortex. In these recordings, reducing luminance from 35 to 0.35 cd/m^2 shifted the luminance that generated 50% of maximum response to light spots (L50) by two orders of magnitude, while keeping it below the middle luminance range available (average L50 in high vs. low luminance: 18.49% vs. 29.29% of maximum luminance, $p=0.003$). Reducing luminance also caused a pronounced increase in the exponent of the luminance response function (1.06 vs. 2.41, $p<0.001$), allowing a more precise sampling of the narrower luminance range. These results support the notion that dark/light asymmetries in vision are a

consequence of ON luminance response-saturation and suggest a possible explanation for the association between low-light/optical-blur and myopia: an under-stimulation of the ON-pathway.

Title: Structure + dynamics lead to function in a new computational model of macaque primary visual cortex

Authors: L. CHARIKER[1], *R. M. SHAPLEY[2], L. YOUNG[1];
[1]Courant Inst., New York Univ., New York, NY; [2]Ctr. for Neural Sci., New York, NY

Abstract: Our overall aim is the development of a coherent dynamical theory that explains cortical function as a direct consequence of known circuitry and neuronal interactions. To this end we constructed a new computational model of layer 4Cα in macaque V1 cortex, modeled as a large network of integrate-and-fire neurons. More than in previous models, we have tried to incorporate realistic neuroanatomy, following closely data on cell density, fraction of Excitatory (E) and Inhibitory (I) cells, connectivity probabilities as well as the fact that connections are isotropic and non-specific. One important new feature of the model was that LGN input to layer 4Cα was very sparse, consistent with what is known about the LGN projection to V1 (Silveira, Perry 1991; Angelucci, Sainsbury 2006). Feedback from layer 6 is also incorporated. Specific modeling goals were: (1) to investigate interrelations between structure and dynamics, and the resulting functions of V1; (2) to show how it is possible that sparse LGN input can lead to V1's visual capabilities; (3) to replicate the known diversity of visual properties across V1; (4) to assess the magnitude of recurrent or feedback excitation compared to feedforward. Goals (1)-(4) were achieved through analysis of model regimes that replicate simultaneously many experimental datasets. We found: (re goals 1, 2) the model generates Orientation-Selective (OS) cells through a complex, nonlinear, dynamic computation involving multiple factors, including strong, recurrent, OS input from neighboring E-cells, and recurrent inhibition that is non-selective for orientation; (3) model neurons show great diversity in many dimensions: firing rates and firing patterns, synchronization with the population gamma rhythm, orientation and spatial

selectivity, and modulation ratio; (4) no more than 15% of the E- input to an E-cell in the model comes from LGN; the rest comes from cortex through lateral interactions with other 4Cα neurons and from feedback via layer 6. Furthermore, like the real cortex, the model generates partially synchronized firing in the gamma band (30-90 Hz) when driven by drifting gratings. The model's temporal synchrony is stimulus dependent: there is very little synchronized firing in background, or at low contrast, but strong synchrony when the stimulus is high contrast, again like the real cortex (Henrie and Shapley 2005). The model's architecture and its dynamical interactions both play key roles in determining its background activity and responses to visual driving. As our model is realistic, we propose that a similar relationship holds in the real cortex.

Title: Feature-specific organization of cortico-cortical feedback connections in mouse visual cortex

Authors: *C. HUH, C. BENNETT, R. M. VEGA, J. P. PEACH, S. HESTRIN;
Dept. of Comparative Med., Stanford Univ., Stanford, CA

Abstract: The visual system consists of lower and higher areas that are reciprocally connected. Although much is known of the role of feedforward pathways in shaping the receptive field properties of neurons, relatively little is known about the role of feedback pathways in visual processing. Nine cortical areas that receive retinotopically-organized input from V1 have been identified in the mouse (Wang and Burkhalter, 2007). In particular, superficial neurons in two areas, AL (anterolateral) and PM (posteromedial), have been shown to possess distinct visual properties in terms of spatial and temporal frequency tuning (Andermann *et al.*, 2011; Marshel *et al.*, 2011). AL neurons respond best to visual stimuli with relatively low spatial and high temporal frequencies, while PM neurons prefer those with relatively high spatial and low temporal frequencies. Both of these areas send significant feedback to V1 (Wang *et al.*, 2011; 2012). It is not yet clear whether feedback connections from these areas convey feature-specific

information to V1 and what functional impact they have on receptive field properties of V1 neurons. To investigate these questions, we employed retrograde viral technology, macroscopic imaging of cortical areas sending feedback to V1, *in vivo* optogenetics and single-unit recordings in awake mice. We used channelrhodopsin-2-assisted targeted recordings to identify AL-to-V1 and PM-to-V1 feedback neurons. Our preliminary results indicate that AL and PM neurons providing feedback to V1 exhibit distinct visual stimulus preferences, similar to previously reported characteristics of superficial neurons in these areas. Using optogenetic silencing of feedback neurons, we found that the effects of feedback on V1 neurons exhibit like-to-like functional impact; V1 neurons whose visual properties are similar to the feedback area being silenced showed the greatest modulation in visual responses. For example, silencing PM feedback suppressed visual responses primarily in V1 neurons tuned to high spatial frequencies. We are currently investigating whether feedback effects on V1 neurons are modulated by the behavioural state of the animal, as indicated by spontaneous running. This study will reveal new insights into the functional organization of feedback connections in the brain and contribute to a greater understanding of the role of top-down pathways in vision.

Title: Somatostatin neurons drive long-range gamma band synchronization in the visual cortex

Authors: ***J. VEIT**[1], R. HAKIM[1], M. P. JADI[2], T. J. SEJNOWSKI[2], H. ADESNIK[1]; [1]UC Berkeley, Berkeley, CA; [2]Salk Inst., La Jolla, CA

Abstract: Rhythmic activity is a ubiquitous feature of brain circuits, and has been linked to many aspects of sensory and cognitive function. Gamma band rhythms, in particular, may synchronize distributed cell assemblies to facilitate information transfer within and across brain areas, yet their underlying mechanisms and functional consequences for neural computation

remain hotly debated. Most circuit models pose that soma-targeting parvalbumin (PV) positive GABAergic interneurons help mediate gamma rhythms through somatic inhibition. In contrast, using cell-type specific manipulations we show that dendrite-targeting somatostatin (SOM) interneurons are critical for visually induced cortical gamma rhythms in awake, behaving animals. Both a computational model based only on prior measurements of connectivity, and a brain slice model using optogenetic activation of horizontal cortical circuits, recapitulated gamma rhythms that depend critically on somatostatin interneurons. In vivo, SOM-mediated oscillations synchronize remote ensembles that process stimuli with common sensory features, implicating them in context-dependent visual perception. Taken together, these data establish a new mechanism for synchronizing distributed cell assemblies. By operating through dendritic rather than somatic inhibition, SOM-mediated oscillations may expand the computational power of gamma rhythms for optimizing the synthesis and storage of sensory perceptions.

Title: Contextual modulation and the cortical hierarchy: inactivating feedback from V2/V3 reveals multiple mechanisms of surround modulation in V1

Authors: *A. TROTT[1], S. G. LOMBER[2], R. T. BORN[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Dept. of Physiol. and Pharmacol., Brain and Mind Institute, Univ. of Western Ontario, London, ON, Canada

Abstract: One of the defining features of cortex is its hierarchical organization, defined by the feedforward and feedback projections that connect distinct cortical areas. Compared to feedforward processing, the functions carried out through cortico-cortical feedback are poorly understood, despite the anatomical abundance of these projections. Previous work from our lab established that feedback contributes to size tuning in V1, a canonical form of surround suppression (Nassi et al. 2013, 2014), and we sought to better understanding this contribution in

order to gain deeper insight into the computational role of feedback. The effects of the stimulus surround on V1 responses to natural stimuli have given rise to two prominent theoretical perspectives on surround modulation: that surround normalization is flexibly and optimally gated to promote the efficient representation of natural images (Coen-Cagli et al. 2015); and, that surround suppression effectively produces input-gain control (Lochmann et al. 2012). These mechanisms are expected to produce distinctive patterns of surround modulation, which we can disentangle through the careful design of parametric stimuli, including center 'plaids' with surround gratings (Trott and Born 2015). Here, we examined the effects of reversibly inactivating feedback from areas V2/V3 to V1 in awake macaque monkeys while recording responses to these parametric stimuli. Our preliminary results suggest that input-gain control remains intact during feedback inactivation, while divisive normalization is affected. We tentatively conclude that multiple underlying surround mechanisms contribute to contextual modulation in V1, potentially consistent with multiple theoretical frameworks, and that feedback contributes to surround mechanisms involved in flexible normalization.

Title: Modelling transient dynamics and attentional modulation in MT cells in a structurally simple model

Authors: L. BOHNENKAMP, D. WEGENER, *U. A. ERNST;
Univ. Bremen, Bremen, Germany

Abstract: In the primate brain, area MT is largely responsible for the processing and perception of motion in visual scenes. MT neurons are tuned for the direction and the speed of moving stimuli and they respond with pronounced firing rate transients upon a change in visual stimulation. These transients increase the neurons' sensitivity and they are directly related to behavioural performances. Therefore, to gain a better understanding of the processing of dynamic visual scenes it is important to understand the neural processes that shape the transients in MT responses. We present a dynamical model of MT cells that takes the cells' speed and direction tuning into account and that is able to reproduce their experimentally observed

transients. In its simplest version, the model consists of only two coupled differential equations, representing an excitatory and an inhibitory population that make up a single direction column. Both populations receive the same external input and additionally the inhibitory population provides divisive inhibition to the excitatory one. Using a simple optimization procedure, we fit the model to find close to perfect fits for the sustained and transient phases in MT single cell responses. Based on the fit for each cell, the model reproduces and predicts neuronal responses to arbitrary accelerations and decelerations of a moving stimulus starting from both low and high base speeds, including experimentally observed deviations of the actual transient as compared to the expected firing rate change as deduced solely from a neuron's speed tuning profile. We also investigated the possible effects of spatial and feature-directed attention in our model and reproduced psychophysical reaction time distributions under different attentional conditions. In particular, we found increasing relative firing rate differences during the transients the stronger the attentional modulation was prior to a stimulus change. This effect reversed in the sustained phase of the neurons' response, where relative activation decreased with increasing attentional modulation. Our finding provides a mechanistic explanation for the shaping and attentional modulation of neuronal response transients, and underlines the importance of this dynamical mechanism for change detection.

Title: Learning dynamic balancing with and without gravitation dependent cues

Authors: ***V. P. VIMAL**, P. DIZIO, J. R. LACKNER;
Brandeis Univ., Waltham, MA

Abstract: Our objective was to compare learning in a dynamic self-balancing task when gravitational cues relevant to position were present or absent. Subjects sat blindfolded in a device that was programmed to behave as an inverted pendulum about the body roll axis, which could be either upright or supine. They used a joystick to align themselves to the direction of balance. Each subject was tested over twenty 100 second trials on two consecutive days in one of four groups (n=10/group). Group 1 had upright balancing on both days; Group 2 had supine balancing

on both days; Group 3 had upright balancing on the first day and supine balancing on the second day, and Group 4 had the opposite order. To quantify learning we used metrics derived from phase portraits and stabilogram diffusion function analysis of roll plane motion and joystick deflections. Subjects tested upright on Day 1 showed significant improvement, learning to reduce the standard deviation of angular position, the frequency of crashes (angular deviations from the direction of balance greater than $\pm 60^0$), the magnitude of joystick deflections, destabilizing joystick deflections, the overall energy of the system; and learning to increase the intermittency of joystick commands and the time interval between short term persistent motion and the long term anti-persistent motion. Subjects tested supine on Day 1 showed minimal improvement, learning to reduce only the frequency of crashes and destabilizing joystick deflections. While a subset of supine subjects showed improvements on Day 1, all supine subjects showed positional drift and most reported uncertainty about their position. Subjects tested on Day 2 in the same condition as Day 1 (Groups 1 and 2) showed retention of their Day 1 learning. Prior exposure to the upright condition did not enhance learning of supine balancing (Group 3), however prior exposure to the supine condition did accelerate learning of upright balancing (Group 4). Our results indicate that in the absence of gravitation dependent otolith and somatosensory cues about dynamic body orientation the ability to balance is significantly impaired.

Title: Successful balance training improves memory and spatial cognition

Authors: *A.-K. ROGGE[1], B. ROEDER[1], A. ZECH[3], V. NAGEL[2], K. HOLLANDER[2], K.-M. BRAUMANN[2], K. HOETTING[1];
[1]Biol. Psychology and Neuropsychology, [2]Human Movement Sci., Univ. of Hamburg, Hamburg, Germany; [3]Human Movement Sci., Univ. of Jena, Jena, Germany

Abstract: Physical exercise has been shown to improve memory and spatial cognition and to induce structural changes in the hippocampus. In humans, these effects have mostly been studied after aerobic exercise. However, it remains unknown whether an increase in cardiovascular fitness is a prerequisite for the beneficial effects of physical exercise on cognition. Some findings

suggest that the vestibular system might mediate this link, as (a) it codes self-motion which is inherent in any physical exercise; (b) it provides direct connections to the hippocampus; and (c) vestibular lesions have been shown to result in memory and spatial cognition deficits. Physical exercises with high demands on balance skills stimulate the vestibular senses while leaving the cardiovascular fitness unaffected. Therefore, we examined the effects of a controlled balance training intervention on memory and spatial cognition. Healthy adults (N=40, 19-64 years) were randomly assigned to a diversified balance training and to a muscle relaxation control group. Both groups trained twice a week for three months. Before and after training, participants were tested with a dynamic balance task on a moveable platform and a stepwise ergospirometry to measure cardiovascular fitness (maximum oxygen uptake, VO_2peak). Memory was assessed by an auditory verbal paired-associate learning task. Spatial cognition was assessed by small scale mental rotation as well as orienting and perspective taking tasks, consolidated into one composite spatial score. The balance training group showed significantly higher scores at post-test than at pre-test for the balance parameter, whereas the control group did not improve across sessions. The increase in balance skills in the balance training group was accompanied by an improvement in memory and spatial performance: Whereas there were no differences between groups prior to training, the balance training group outperformed the control group in the paired-associate learning and in the spatial score after training. There was no change in VO_2peak over time in either group. The present results suggest that successful balance training improves memory and spatial cognition. These findings suggest that a stimulation of the vestibular system might contribute to the beneficial effects of physical exercise on neurocognitive functioning, and that an increase of cardiovascular fitness is not a prerequisite for these effects.

Title: Visual reinforcement of illusory rotation during centrifugation: A novel habituation strategy to motion sickness

Authors: ***G. I. BERTOLINI**[1], J. E. BOS[2], D. BRON[3], T. FRETT[4], E. GROEN[2], R. HEMMERSBACH[4], F. L. WHETS[5];
[1]Dept. of Neurology, Univ. Hosp. Zurich, Zurich, Switzerland; [2]TNO, Soesterberg, Netherlands; [3]Aeromedical Inst., Duebendorf, Switzerland; [4]Inst. of Aerospace Med., German Aerospace Ctr., Cologne, Germany; [5]Antwerp Univ. Res. centre for Equilibrium and Aerospace, Univ. of Antwerp, Antwerp, Belgium

Abstract: Background: Artificial gravity through centrifugation is currently the only countermeasure providing an "Earth-like" solution to weightless health hazards. Every head movement during centrifugation, however, may cause motion sickness due to conflicts between the perceived direction of gravity and the illusory rotations caused by the vestibular activation (Cross-coupling stimulus). Existing habituation protocols are based on repetition of cross-coupling stimuli. Although they successfully abate motion sickness, they also reduce overall responses to rotations. Our aim is to develop a novel habituation strategy to disentangle gravity and rotation perception, reducing motion sickness but retaining response to rotation. Methods: We tested 19 healthy subjects on the ESA Short Arm Human Centrifuge at DLR, Cologne. The control group (CG: 9 subjects, 3 female) performed a normal habituation protocol consisting of repetitive 30° clockwise head rolls during centrifugation at 100°/s (1 g at feet). The test group (TG: 10 subjects, 5 female) performed an identical protocol, with the addition of visual stimuli triggered by head movements providing an illusion of rotation (optokinetic stimuli provided through the Oculus Rift) assumed to reinforce the vestibular activation. Motion sickness was measured using a 1-20 scale, while an eye tracker embedded in the Oculus Rift recorded the vestibulo-ocular reflex (VOR). Habituation measurements were obtained repeating the experiment after 24h. Results: 15 subjects (7 CG, 8 TG) were able to complete the experiment. No difference between groups was observed in the motion sickness score on day 1 or in the reduction of motion sickness from day 1 to day 2 (median [MAD] CG: -4 [2]; TG: -4 [1], p=0.78). The CG, however, had a significantly larger reduction of the VOR duration than the TG (CG: -4 [1] s; TG: -1 [2] s, p=0.05). Conclusions: Subjects habituate to the cross-coupling stimuli during centrifugation even if illusory self-rotation induced by head tilts is sustained by visually induced perception of self-rotation. Visually reinforced habituation may however induce less reduction of oculomotor response to rotation than classical habituation and may therefore better preserve vestibular reflexive responses.

Title: The influence of roll tilt on perceptual verticality in children

Authors: *L. F. CUTURI, M. GORI;
U-Vip, Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Orientation of head and body in the roll plane is known to affect perception of verticality causing the so-called A-effect or E-effect, respectively biases towards or away from the tilt angle. These effects have been extensively studied in adults focusing on the readout of vestibular information and the sensory modality involved in the estimation of verticality. Although previous studies have shown that visual and tactile modalities do not optimally combine until adulthood and they contribute differently to the perception of stimulus orientation, less is known about the role of vestibular information in influencing such perceptual modalities during development. To fill this gap, we investigated how head and body roll tilt of 90° relative to gravity influences perception of verticality in children (5-13 years). We had participants lying on one side and asked them to evaluate stimulus orientation either haptically by touching a plastic bar or visually by observing a luminous bar. Participants had to report whether the stimulus was tilted more clockwise or counterclockwise compared to verticality. In order to control for differences given by age, we performed the same experiment in a group of adult participants. For all groups and conditions, we employed an adaptive procedure to select the stimulus orientation to be presented thus allowing us to quantify participants' biases and variability in the estimation of verticality. Our findings show different patterns of results depending on participants' age and involved sensory modality. Adults and older children tend to show E-effects in the tactile modality whereas the youngest group of participants (5-7 years) shows an opposite tendency. Although visual precision tends not to differ across age groups, these results suggest a stronger role of vision in perception of verticality in line with previous findings showing vision to overcome touch in processing stimulus orientation at the early stages of development. Regardless of age, all participants show A-effects in the visual condition with a tendency for the youngest participants (5-7 years) to show less pronounced biases. These results suggest an effect of age on the processing of vestibular information: idiothetic priors in young children seem to be less influential and their reliance on vestibular sensory information might be higher compared to adults who instead might rely more on prior experience (e.g. standing upright). Overall, these findings throw light on how the brain interprets vestibular sensory

information at different stages of development considering its role in influencing other sensory modalities as visual and tactile.

Title: Effects of chronic Purkinje cell silencing on central processing of vestibular self-motion signals

Authors: ***T. STAY**, J. LAURENS, D. E. ANGELAKI, R. V. SILLITOE;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The vestibular otolith organs physically cannot distinguish between linear inertial acceleration and changes in head position relative to gravity. Previous research advocates that the two types of motion are separated centrally by combining otolith information with signals from the semicircular canals. Notably, neurons in the cerebellum and vestibular nucleus modulate their firing rates to represent linear acceleration or gravitational changes, with a broad range of selectivity. Since experimental evidence suggests that cerebellar circuitry is significantly involved in the creation of internal models, we hypothesized that processing in the cerebellar cortex is necessary for single neurons to differentiate linear translation and gravitational tilt. To test this hypothesis, we adapted motion test protocols previously used for macaques to similarly test a published conditional genetic mouse line, $L7^{Cre};Vgat^{flox/flox}$. Our lab developed this line to constitutively prevent cerebellar Purkinje cells from signaling to their targets through GABA. We recorded extracellular signals from Purkinje cells in awake mutant and littermate mice during combinations of translation and tilt. Our data first indicated that mice typically represent the two types of motion analogous to that reported for monkeys. Intriguingly, $L7^{Cre};Vgat^{flox/flox}$ mice also appear to have Purkinje cells which respond selectively to tilt or translation. This could be because feedback from Purkinje cell target areas into cerebellar cortex is not required for proper self-motion dissociation, or could also be reflecting a functional developmental

compensation. We are currently examining the vestibular circuit at other times and cell types to identify how Purkinje cell signaling shapes proper vestibular sensation.

Title: Second-order statistics of self-motion signals experienced by human subjects during everyday activities: implications for vestibular processing

Authors: ***M. J. CHACRON**[1], J. CARRIOT[1], M. JAMALI[1], K. E. CULLEN[2];
[2]Physiol., [1]McGill Univ., Montreal, QC, Canada

Abstract: Understanding the neural code remains a central problem in systems neuroscience. There is accumulating evidence that the brain's neural coding strategies are constrained by the statistics of the natural environment in which the organism lives. Thus, knowledge of natural stimulus statistics is essential towards understanding the neural code. Here we investigated the statistics of the time varying envelope (i.e. a second-order stimulus attribute that is related to variance) of rotational and translational self-motion signals experienced by human subjects during everyday activities. We found that second-order stimulus attributes can reach large values across all six-motion dimensions (~450 deg/s and ~4 G). Unlike results obtained in other sensory modalities, spectral power decreased slowly for low (< 2 Hz) and more sharply for high (>2 Hz) temporal frequencies and thus was not well-fit by a power law. We further found that this unique structure was not due to biomechanical filtering by the body. Instead, while the power spectra of signals resulting from passive self-motion were well-fit by a power law, those of signals resulting from active self-motion were not. Our findings have important consequences for understanding how natural second-order self-motion signals are processed by the vestibular system.

Title: Transcranial magnetic stimulation (TMS) of supramarginal gyrus tilts perception of upright without changing ocular torsion

Authors: *A. KHERADMAND[1], J. OTERO-MILLAN[2], A. WINNICK[2];
[1]Neurol., Eye Movement/Vestibular Lab., Baltimore, MD; [2]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Torsional position of the eyes or ocular torsion affects our perception of upright. Here we studied the functional role of the right temporal parietal junction (TPJ) in perception of upright by using transcranial magnetic stimulation (TMS). Perception of upright was measured by subjective visual vertical (SVV) during head tilt and ocular torsion was recorded simultaneously by video-oculography. The continuous theta burst stimulation (cTBS) over the posterior aspect of the supramarginal gyrus (SMGp) in 12 right-handed subjects tilted the SVV in the opposite direction of the head tilt without commensurate changes in ocular torsion. These findings suggest that the inhibitory effect of cTBS at the supramarginal gyrus alters perception of upright without changing torsional position of the eyes.

Title: Head movements during locomotion in vestibular schwannoma patients: Decreased variability after unilateral vestibular lesion

Authors: *O. ZOBEIRI[1], C. ZHANG[1], S. KING[2], R. F. LEWIS[2], K. E. CULLEN[1];
[1]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Otolaryngology, Harvard Med. Sch., Boston, MA

Abstract: The vestibular system plays a key role in a wide range of functions from basic reflexes to high-level behavior. By detecting head motion and then generating the appropriate reflexes, the vestibular system is vital for maintaining balance and stabilizing gaze. In turn, it is well known that immediately following unilateral vestibular loss, patients experience impaired balance, postural, and gaze control. However, to date, much less is known about the effects of vestibular loss on voluntary behaviour. Here, to assess how vestibular loss alters voluntary behaviour, we analyzed locomotive behaviour in a group of patients with a diagnosis of vestibular schwannoma (VS) who had undergone a primary surgical resection of their tumor via suboccipital craniotomy and retrosigmoid approach with sectioning of the vestibular nerve. Head movements were recorded before the surgery, as well as 2 and 6 weeks after surgery using a micro-electromechanical systems (MEMS) module (Carriot et al., 2014), which combines three linear accelerometers (recording linear accelerations along the fore-aft, inter-aural, and vertical axes) and three gyroscopes (recording angular velocity about pitch, roll, and yaw). Patients were asked to complete the Functional Gait Assessment, and we focused our analysis on short, 15-30-second-long gait tasks including: normal walking, walking with eyes closed, and walking backwards on a level surface. We then compared pre-operative and post-operative data to determine if and how patient' movements were altered. We quantified gait speed, gait cycle asymmetry, and gait variability. Surprisingly, we found that locomotor speed actually increased six-weeks post-surgery as compared to pre-operative testing, and that movement asymmetry did not change. Furthermore, although previous studies using age-matched controls have found increased variability in gait, we found that this was not the case when using the pre-operative patient as their own control. Instead, movement variability was lower two weeks after the surgery than before the surgery. Specifically, the standard deviation of both linear acceleration and angular velocity in all dimensions (up-down, left-right, fore-aft, roll, pitch, and yaw) consistently decreased after surgery. Variability is often seen as the result of noise in the nervous system, however it has been shown that variability could contribute to motor learning. Taken together, our results suggest that variability is an important indicator of how patients are adapting to altered motion and the recovery process.

Title: Vestibular coding strategies for representing natural selfmotion. Differential integration of canal and otolith Inputs in the vertical and horizontal plane

Authors: *J. CARRIOT[1,2], I. MACKROUS[1], M. JAMALI[1], K. CULLEN[1];
[1]Physiol., McGill Univ., Montreal, QC, Canada; [2]Univ. of Western Ontario, London, ON, Canada

Abstract: During every day activities, self-motion is sensed by the vestibular system, which contributes to an impressive range of brain functions from the most automatic reflexes to spatial perception and motor coordination. It is generally assumed that sensory systems efficiently encode natural stimuli using coding strategies that are adapted to the statistics of the environment in which the organism lives. However, to date, sensory coding has been primarily studied using artificial stimuli. We recently characterized natural vestibular stimuli during everyday activities. One of the characteristic of these stimuli is their multidimensionality and the simultaneous activation of the canals and otolith organs. How these signals are integrated when the head motion is perform in the horizontal plane versus in the vertical plane remain unknown. We characterized the response of the vestibular only (VO) neurons receiving input from otolith and/or semicircular canal afferents. We recorded from central vestibular neurons in response to i) translation (otolith stimulation), ii) rotation in the horizontal plane (horizontal canal stimulation), iii) Tilt-translation (vertical canal stimulation), iv) multidimensional stimuli (in the horizontal and vertical plane), and v) while the monkey was generating comparable self-motion. Consistent with previous results, we found that the firing rate response to unidimensional stimuli was accurately estimated by a typical linear model, which could account for up to ~95% of the variance in the data. In contrast, during multidimensional motion, VO neurons sub-additively integrated the translational and rotational inputs rather than simply adding the otolith and canal afferents information. This sub-additivity was comparable in the vertical and horizontal plane ($p<.05$). Finally, we found that neuronal responses were significantly attenuated (~75%) during self-generated vs passively applied movements. Taken together, these findings provide insights into the underlying processing required for the integration of rotational and translational inputs in the vestibular system and are key for understanding the neuronal mechanisms required for accurate posture and motor control, as well as perceptual stability during everyday life.

Title: Ocular correlates of auditory vection

Authors: *D. GRENET[1,2], A. A. MIGLIACCIO[1,2], R. C. FITZPATRICK[1,2];
[1]Neurosci. Res. Australia, Randwick, Australia; [2]UNSW Australia, Sydney, Australia

Abstract: Sensations of self-motion, whether real or illusory, may be accompanied by reflexive eye-movements or changes in eye position. There are contradictory reports regarding the presence of these ocular correlates during auditory vection or illusory self-motion perception. Both ears (pinnae) from ten subjects were cast in silicone rubber. The silicone ears were mounted on a mannequin head and microphones were placed on the medial side of the silicone auditory canal. The ambient sounds of the laboratory and a variety of preprogramed sound stimuli created a soundscape that was acquired by these microphones, amplified and played to the subject through headphones as they sat in a dark booth within the laboratory to isolate them from other sound. Thus, the subject heard the soundscape as if he or she were at the position of the mannequin head with the sound filtered by their own pinnae. All subjects perceived the sounds as external to their head and could accurately localise their sources. We rotated the mannequin head in yaw at 2 constant speeds (20 and 50 degrees/s) and asked subjects to report their perceptions of self-rotation by clicking a button every time they had rotated 45 degrees. Left eye position was recorded using an EyeSeeCam video-oculography system (EyeSeeTech, Germany). Nine subjects reported feeling some self-motion, all as yaw rotations, in a total of 104/132 trials. Nystagmus was not observed, although eye deviations in the direction of perceived rotation resulted in significant ($p<0.05$) correlation between eye position and perceived rotational velocity in 40 % of the trials where subjects felt movement. These eye position deviations had amplitudes up to 20 degrees and were akin to the “shift of beating field” that often accompanies nystagmus evoked by vestibular or visual stimuli - a phenomenon shown to depend on the orientation strategy used by the subject, but never previously reported in the absence of nystagmus. An alternate explanation may be that perception of rotational motion in the absence of a dynamic vestibular stimulus is interpreted by the vestibular system as a static vestibular stimulus with an ocular response akin to the otolith-mediated head tilt response.
The presence of eye position deviations in the absence of nystagmus suggests that this eye movement is either a residual component of suppressed nystagmus or it is driven by a separate mechanism.

Title: The effect of 30-hr acute sleep deprivation on psychomotor vigilance and a Mars rover simulation

Authors: E. J. BELTRAN[1], S. T. MOORE[2], *S. J. WOOD[3];
[1]Wyle Science, Technol. and Engin. Group, Houston, TX; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Azusa Pacific Univ., Azusa, CA

Abstract: Increases in variability of docking misalignment have been observed in astronauts during a Mars rover simulation following long-duration spaceflight. The objective of this study was to examine the effect of 30-hr acute sleep deprivation on this simulation using ground control subjects to determine the influence of sleep loss independent of post-flight neurosensory adaptation. Nine subjects (39 ± 11 yr; 4F/5M) participated in three baseline laboratory sessions, a 30-hr sleep deprivation period, and a post-sleep deprivation laboratory session. The rover simulation consisted of a serial presentation of tasks that were self-paced to be completed as quickly and accurately as possible. The tasks consisted of (1) perspective-taking, using a map that defined a docking target, (2) navigation toward the target over simulated Martian terrain, and (3) docking a side hatch of the rover to a visually guided target. The simulator used a Stewart-type motion base (CKAS, Australia), a single-seat cabin with triple scene projection, and a joystick controller. Throughout the 30-hr sleep deprivation period, subjects reported subjective sleepiness via the Stanford Sleepiness Scale (SSS) and performed a 3-minute Psychomotor Vigilance Test (PVT) administered on an iPad (Joggle Research). The SSS and PVT were completed at 5-hr intervals during the first 10 hours, 2-hr intervals during the next 10 hours, and 1-hr intervals during the final 10 hours, with the last ones completed in the lab just prior to the rover simulation. There was a significant increase in SSS during the sleep deprivation period. Although mean SSS reported in the lab was slightly reduced from the last one reported at home, this 30-hr SSS was still significantly higher than that reported in the baseline sessions. The PVT mean reaction time (mRT) scores were significantly related to SSS, and were therefore used as the main outcome variable for the PVT. There was a significant increase in the mRT during the sleep deprivation period; however, the mRT at 30 hr in the lab was not different than the first mRT obtained at the beginning of the sleep deprivation period. There was also no significant change in any of the Mars rover simulation parameters between the last baseline session and the

post-acute sleep deprivation session. These results suggest that subjects had remained as vigilant during the lab session following the 30-hr sleep deprivation period as they were during the final baseline session, although they were subjectively more tired. We conclude it is important to control for behavioral alertness when testing for the neurosensory consequences of sleep loss.

Title: Sensory precision limits behavioral precision in a manual control task

Authors: M. J. F. ROSENBERG[1,2], R. GALVAN-GARZA[3], T. K. CLARK[4], D. P. SHERWOOD[3], L. R. YOUNG[3], *F. KARMALI[1];
[1]Otolaryngology, Jenks Vestibular Physiol Lab, Harvard Med. Sch., Boston, MA; [2]NASA Johnson Space Ctr., Houston, TX; [3]Man Vehicle Lab., MIT, Cambridge, MA; [4]Univ. of Colorado at Boulder, Boulder, CO

Abstract: Precise motion control is critical to human survival, whether running from prey on soft ground at night or piloting a spacecraft when landing on the moon. Sensorimotor responses and perception are inherently imprecise, and the sources of imprecision are not well known, nor are the functional implications of this imprecision. For example, there is disagreement about whether sensory imprecision dominates visual tracking, or if motor imprecision also contributes. Likewise, modeling has suggested that vestibular sensory imprecision contributes to postural instability. To more directly address these questions, we determined whether vestibular perceptual thresholds, which have substantial inter-subject variation, predict performance in a "vestibular" manual control task. In this task, subjects attempted to keep themselves upright using a control joystick to null out pseudo-random, head-centered roll tilt motion disturbances in the dark. Furthermore, we examined whether behavioral precision would change in an altered gravity environment. The "G level" was manipulated using rotation of a short-radius centrifuge, with roll tilt motion and the chair configured so that the manual control task occurred relative to centripetal accelerations of 0.5, 1.0, 1.3 G. Manual control performance was quantified by taking

the standard deviation of the chair position (i.e. worse nulling corresponded to less stability in chair position). Vestibular precision was quantified using direction recognition thresholds, the minimum movement that one can reliably distinguish as leftward vs. rightward. Subjects were roll tilted using a single-cycle acceleration trajectory in each of 100 trials. We selected a 5 s motion, with the majority of frequency content at 0.2 Hz, because prior work shows contributions of both the otolith organs sense of tilt angle and semicircular canals' sense of angular rotation at this frequency. Motion amplitudes were selected by a 3-down, 1-up adaptive staircase. Thresholds were estimated by fitting a cumulative Gaussian psychometric curve to subject response. A positive, linear correlation across subjects was found between manual control variability and vestibular thresholds ($p<0.01$) in the 1.0 G baseline. This suggests that sensory precision is a limiting factor in manual control performance. Additionally, manual control performance was 12.7% lower in 1.33 G ($p<0.05$) and 37.5% higher in 0.5 G ($p<0.05$), as compared to 1 G. The increased variability in 0.5 G may be due to decreased otolith shear force causing a decrease in sensitivity to tilt angles, with the converse occurring in 1.33 G.

Title: Does decision-making reflect high-pass filter contributions?

Authors: *D. M. MERFELD[1], F. KARMALI[2], T. LEEDER[2], K. LIM[2];
[1]Otol & Laryngol, [2]Harvard Med. Sch., Boston, MA

Abstract: Decision-making is a crucial aspect of cognition that impacts a broad range of fields. Recent vestibular threshold data showed a pattern of increasing thresholds when the frequency of applied single cycles of sinusoidal acceleration fell below about 1 Hz (1-4). While both perceived rotation measured via magnitude estimation (5) and peripheral transduction (6) show similar high-pass filter characteristics, the variation of thresholds as a function of frequency showed a much higher cut-off frequency (i.e., much lower time constant) than either perceived

rotation or peripheral transduction. These threshold variations as a function of frequency have been hypothesized to be consistent with the contributions of a high-pass filter (i.e., a neural mechanism that filters out low frequency signals) as part of the decision-making process (7-8). But at least two other related mechanisms - the addition of an urgency signal (9) and decision-boundaries that decrease with the passing of time (10) - might contribute to this observed threshold pattern. To test the contributions of these different hypothesized mechanisms, we chose to perform binary fixed-duration forced-choice tasks while rotating subjects about earth-vertical. Specifically, we varied the motion trajectory shape while maintaining the stimulus duration constant at 2 s with the peak stimulus velocity always occurring 1 s after the beginning of the motion. By maintaining stimuli at a constant duration, the impacts of an urgency signal and reductions in decision boundaries would be expected to be similar for different stimulus trajectories (i.e., be independent motion trajectory shape). In contrast, the high pass filter hypothesis forecasts predictable threshold variations as the shape of the motion trajectory is varied. To test these model predictions, we utilized different stimulus trajectory shapes, including bell-shaped velocity trajectories, triangular velocity trajectories, and parabolic velocity trajectories. We found that the thresholds were consistently higher for triangular velocity trajectories than for bell-shaped velocity trajectories. These results are consistent with the contributions of a high-pass filter to the decision-making process. (1) Grabherr, 2008 Exp Brain Res 186: 677-681. (2) Soyka, 2011 Exp Brain Res 209: 95-107. Title: Perception of the visual vertical during linear self-motion

Authors: ***A. POMANTE**, L. P. J. SELEN, W. P. MEDENDORP;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: The vestibular system provides information for spatial stability and the percept of verticality. A stationary subject, seated upright, can align the orientation of a visual line to the direction of gravity with an accuracy better than 1 degree. A complexity arises when subjects are in motion. Because the otoliths sense the gravito-inertial force, they cannot distinguish gravitational and inertial accelerations. As a consequence, prolonged linear acceleration of the head can be interpreted by the brain as a tilt, even though the head does not rotate. In this study, we tested the dynamics of this illusion by probing the percept of the visual vertical (subjective visual vertical, SVV) during passive linear head motion. Human subjects were sinusoidally translated (f=0.4 Hz, 3.5 m^2/s peak acceleration, 60 cm peak-to-peak displacement) along an inter-aural axis using a vestibular sled. While they kept fixation on central body-fixed light, a line was briefly flashed (5 ms) at different phases of the motion. Using a psychometric approach, subjects judged the orientation of this line relative to gravity. So far, we have tested 5 subjects. Their results show a phase- dependent modulation of the SVV, with a stronger bias of the SVV at peak acceleration than at peak velocity. These findings provide evidence that the SVV is modulated by self-motion signals, presumably reflecting the brain's interpretation of the otolith signal. Our observations are consistent with the prediction from the modeling work of Laurens and Droulez, 2007 [1]: the vestibular canals and otolith signals are integrated in a statistically optimal fashion reproducing the rules of Bayesian inference.

Title: Modulation of egocentric spatial frames of references by vestibular

Authors: *N. ABEKAWA[1,2], E. FERRE[3], M. GALLAGHER[2], H. GOMI[1], P. HAGGARD[2]; [1]NTT Communication Sci. Labs., Kanagawa, Japan; [2]UCL, Inst. of Cognitive Neurosci., London, United Kingdom; [3]Royal Holloway, Dept. of Psychology, London, United Kingdom

Abstract: Judging the position of external objects relative to the body is essential for interacting with environments. For instance, a tennis player has to quickly select a forehand or backhand shot based on the location of the ball in respect of the body. Thus, *egocentric* spatial

representations must be processed rapidly for successful control of actions. Clinical reports have suggested vestibular contributions to egocentric spatial representation. However, most of these studies estimated the perceptual "subjective center" of the body. It remains unclear whether vestibular-based egocentric representations also contribute to on-line selection of rapid actions. Importantly, vestibular signals could also affect visual perception and motor execution. This raises further questions regarding which processing stages along the visual-motor processing chain are effectively modulated by vestibular signals. To address this issue, we systematically explored how vestibular inputs contribute to rapid vision-body-motor processing. A visuomotor task was combined with low intensity Galvanic Vestibular Stimulation (GVS, 1mA square-wave). L-GVS (Left anode and right cathode), R-GVS (right anode and left cathode), or sham-GVS were delivered while participants judged whether a briefly-flashed visual stimulus was located to the left or right of their body-midline. They had to press as fast as possible a button located on their left or right side accordingly. To directly examine the effect of GVS on effector selection, the task was performed with hands uncrossed or crossed in different blocks. The results showed that GVS polarity influenced the subjective perception of body midline: L-GVS biased the subjective body midline toward the left, while R-GVS induced a bias in the opposite direction. This bias was not modulated by crossing the hands, ruling out explanations based on GVS affecting the effector selection processes. Explanations based on visual localization were also ruled out in an additional control experiment. Taken together, our results indicate that egocentric representation is strongly modulated by vestibular signals without the actual motion of the body or head. The findings support a model of egocentric representation centered on the body midline, and implemented by the balance between sensory signals in the left and right hemispheres. The vestibular systems *calibrate* an egocentric spatial frame, which allows on-line action selection for rapidly interacting with the external environment.

Title: MT neurons preserve visually selective signals across eye movements

Authors: *A. AKBARIAN AGHDAM[1], M. PARSA[2], N. NATEGH[1], B. NOUDOOST[3]; [1]Electrical and Computer Engin., Montana State Univ., Bozeman, MT; [2]Computer Science, Montana State Univ., Bozeman, MT; [3]Cell Biol. and Neurosci., Bozeman, MT

Abstract: Our perception of visual world stays stable despite substantial retinal image motion due to the thousands of saccades that we make each day. Research suggests that higher-order prefrontal and parietal areas contribute to the maintenance of visual stability across saccades. Because higher-order areas lack the visual feature selectivity of early sensory areas, it has remained unclear how visual representations are preserved during the disruption of retinal input due to eye movements. We measured the receptive fields (RFs) of neurons in the middle temporal (MT) area of two rhesus monkeys before, during, and after a visually guided saccade using brief pseudo-random flashing probes. The flashing probes appeared on the screen in a grid covering both the pre- and post- saccadic RFs, as well as the initial fixation point and the saccade target. Each probe appeared at pseudo-random locations for 7ms enabling us to precisely map the neuron's RF around the brief period of saccade execution. We found that MT neurons exhibit a persistent visual activity during eye movements: when the flashing probe appears within the neuron's RF very near to the time of the saccade onset (-10 to +10 ms) some MT neurons exhibit a response that starts with the usual latency of the MT neuron but persists across the saccade and even after the eyes have landed. Such persistent activity during eye movements could serve as an extrastriate mechanism for preserving visual information across saccades. This activity could contribute to perceptual stability across saccades, maintaining the pre-saccadic representation until the post-saccadic one is formed. In order to examine this idea, we employed an explicit probabilistic model in the generalized linear model (GLM) framework, which enables us to create a readout of the visual scene during eye movements based on MT spike trains. This encoding and readout modeling framework suggests that the persistent activity is necessary for trans-saccadic integration of the visual representation.

Title: Memory for retinotopic locations is more accurate than memory for spatiotopic locations, even when intending to reach.

Authors: *A. SHAFER-SKELTON, J. D. GOLOMB;
Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: In order to successfully interact with objects, we must maintain stable representations of their locations in the world. However, their images on our retina may be displaced several times per second by large, rapid eye movements. Are we able to form a seamless world-centered (spatiotopic) representation of objects' locations across eye movements? Surprisingly, Golomb & Kanwisher (2012 PNAS) found that memory for an object's location is more accurate and precise in gaze-centered (retinotopic) than world-centered (spatiotopic) coordinates, and that the accuracy of spatiotopic but not retinotopic memory deteriorates with each eye movement. This suggests that the native coordinate system of visual memory is retinotopic. We used a human behavioral paradigm to investigate whether the intention of acting on an object's location could improve memory for its spatiotopic location. Twelve participants were asked to remember a spatial location across a short delay. During the delay, they completed a variable number of eye movements (0-2). Participants completed four versions of this task in separate sessions (with session order counterbalanced across participants); they reported either the retinotopic or spatiotopic location, either using a mouse to click on the remembered location (as in Golomb & Kanwisher, 2012) or using their finger to interact directly with the touchscreen. We replicated Golomb & Kanwisher's original results. Critically, we found the same pattern of results in the reaching task. These results further support the hypothesis that spatial memory is natively retinotopic; we found no evidence that the intention to act on an object improves spatiotopic memory across saccades. How, then, do we successfully act on objects in the world? One possibility is that the rich information contained in visual scenes could serve as landmarks that could facilitate the creation of more seamless spatiotopic representations. Further research could explore whether and what types of object and/or scene information might contribute.

Title: Modeling perisaccadic visual representation in MT neurons by incorporating population-level information

Authors: *K. NIKNAM[1], A. AKBARIAN AGHDAM[1], B. NOUDOOST[2], N. NATEGH[1]; [1]Electrical & Computer Engin. Dept., [2]Dept. of Cell Biol. & Neurosci., Montana State Univ., Bozeman, MT

Abstract: How the brain maintains the stability of visual perception across saccades is one of the oldest questions in systems neuroscience; accurately characterizing visual responses in this perisaccadic period is an important step towards understanding how the visual world is represented during saccades. We recently developed a probabilistic model in the Generalized Linear Model (GLM) framework to characterize and predict the pre-, trans-, and post-saccadic responses of single middle temporal (MT) neurons at the level of single-trial spike trains. Here we report an extended form of the model incorporating statistical dependencies of MT responses, such as the correlations between neurons as well as the local field potentials (LFPs). The responses of multiple neurons within the MT cortex of macaque monkeys were simultaneously recorded using linear array electrodes. The animals were performing a visually-guided saccade task while a set of probes flashed in pseudorandom positions around the estimated receptive field (RF) of the MT neurons during fixation and saccade execution. Probe presentations were brief, enabling us to characterize the spatiotemporal RF changes with a temporal resolution higher than the saccade execution time. The responses of these neurons to drifting Gabor gratings were also recorded during a fixation task to determine the motion sensitivity of individual neurons as well as the correlations between neurons. To characterize the time-varying information carried by MT neurons, we fit the spiking response of an MT neuron to an extended GLM, consisting of a set of linear kernels to mimic the spatiotemporal properties of the MT neurons' RFs, a set of saccade kernels to account for the changes in stimulus sensitivity induced by eye movements, an offset kernel to account for time-varying baseline activity relative to the saccade, a post-spike kernel to account for dependencies on spiking history (such as refractoriness, burstiness, and adaptation), and finally, a set of coupling kernels to account for correlations between neurons. In addition to visual information, the input to this extended model includes the spiking response of other neurons and the LFP, which may provide additional information about brain state or cognitive factors. The model allows us to predict the responses of MT neurons to a variety of visual stimuli around the time of the saccade. This in turn enables us to test the contribution of specific perisaccadic changes in neuronal responses to the representation of the visual scene during eye movements.

Title: Modulation of binocular rivalry by stimulus complexity, arousal and caffeine

Authors: *A. C. O. BOATENG[1], D. E. FLEMING[2], S. C. STEFFENSEN[2];
[1]Brigham Young Univ. Hawaii, Laie, HI; [2]Brigham Young Univ., Provo, UT

Abstract: Abstract: The most common form of perceptual rivalry is visual system binocular rivalry (BR), which has been known since the 18th century. Binocular rivalry is characterized by perceptual alternation (BRPA), where perception alternates between stimuli presented separately to the eyes. Binocular rivalry appears to be a stochastic neural process, but under a modicum of dynamic conscious control. While the brain substrate of BRPA is not clearly identified, fMRI studies suggest that it originates in brainstem structures (Pettigrew et al., 2001), but involves neural competition at multiple levels of the visual pathway (Freeman et al., 2005; Wilson et al., 2003). The aim of this study was to determine if BRPA can be modulated by stimulus complexity, arousal and the psychostimulant caffeine. In addition, we also evaluated the effects of caffeine on color afterimages. Experiments were performed in 306 college-age (20-27 yrs) male and female subjects with a program that logged keyboard presses whenever the subject indicated the perception of red or blue arrows vs red or blue generic faces presented to the eyes separately via superimposed images through red/blue 3D anaglyph glasses in a 2 min session. There was no significant difference in BRPA between male and female subjects (28.2 ± 0.8 alternations/min in males vs 29.4 ± 1.1 alternations/min in females). BRPA was significantly slower when the subjects viewed the images of faces vs arrows ($p<0.01$), and significantly faster following hyperventilation for 2 min ($p<0.05$) or 30 min after the consumption of 1 mg/kg caffeine ($p<0.05$). In a separate study, undergraduate students (n=31, age range: 18-24 years) with a history of regular caffeine consumption were tested on opponent color processing (green/red, magenta/cyan, blue/yellow) and BR (arrows vs faces) tasks after three levels of conditions: placebo, low (1mg/kg) and high (5mg/kg) dose of caffeine. The results show a biphasic response with low and high dose caffeine as well as a wavelength sensitivity, with blue-yellow afterimages enduring longer at high dose $F(2,180) = 31.69$, $p < 0.01$, $\eta^2 = 0.26$ and increase in perceptual alternation time $F(4,556) = 6.77$, $p < 0.05$, $\eta^2 = 0.05$ with an overall interaction effect between conditions and color type $F(4,180) = 8.40$, $p < 0.01$, $\eta^2 = 0.15$. Taken together, these findings provide strong evidence that BR is modulated by the complexity of the stimulus and the degree of physiological arousal and that psychostimulants increase the rate of perceptual switching but have a dose-related biphasic effect on the endurance of color afterimages. Studies are ongoing to elucidate electroencephalographic correlates of BR.

Title: Parahippocampal gyrus neurons in the monkey respond to stimuli in the entire visual field except for the foveal region.

Authors: ***M. SEMEWORK**[1], M. E. GOLDBERG[2];
[1]Dept. of Neurosci., Columbia Univesity, New York, NY; [2]Columbia Univ., New York, NY

Abstract: When we enter a new environment we immediately and automatically establish a gist memory of that environment, so that we can, with our eyes closed, point at or look at salient objects in the new space. Patients with parietal cortical lesions can locate objects in the room with their eyes open, but cannot do so with their eyes closed (Levine, 1985). Place cells in the hippocampus (O'Keefe & Dostrovsky, 1971) represent an environmental memory, and neurons in the FEF (Umeno & Goldberg, 2001) and LIP (Steenrod & Goldberg, 2009) demonstrate this environmental memory. One pathway by which the spatial memory signal of the hippocampus could reach the parietal cortex is by way of the parahippocampal gyrus (PHG), area TF. Here we sought to evaluate the spatial properties of neurons in PHG in order to understand what they might contribute to the process of spatial memory.We recorded the activity of neurons in PHG adjacent to visual area TE in an awake Rhesus monkey performing fixation, memory- and visually-guided delayed saccade tasks (electrodes located at +2 AP, +15 ML stereotactically). We found a class of neurons with very fast visual latencies (50-70 ms). In the area in which they were found, every cell in a vertical penetration exhibited the same properties. The cells respond to stimuli throughout the visual field, as far as we could measure (25^0 in the periphery) with the salient exception of the 2.5-5^0 around the center of gaze. The onset of the visual response over trials jitters a few milliseconds (+/- 5 ms). The cells responded to visual stimuli of various sizes, a tiny dot to several degrees diameter - with larger probes evoking larger (higher peak, and a little longer) responses. The cells were not selective for color, orientation, or shape, and gave

equal responses from either eye. There is no systematic variation in the maximums, means and latencies of the visual responses when probes are presented ipsi/contraletrally. They did not distinguish between visual probes in the fixation task and saccade targets, except when the monkeys made a visually guided saccade the saccade target, now in the fovea, suppressed the response.The role of such large receptive fields with a hole around the fovea might be to suppress the response of the PHG to unattended stimuli. The majority of the neurons have 'ambiguous' waveforms according to the Shin and Sommer (2012) criteria for frontal eye field neurons, circumstantial evidence that they might be inhibitory neurons.

Title: Perceptually-driven rightward saccades for detection of lateralized visuospatial attention system

Authors: ***M. SANEFUJI**[1,2], H. YAMASHITA[3], Y. SAKAI[1], D. KATSUKI[3], S. AKAMINE[1], Y. SHIOTSUKA[4], Y. ISHIZAKI[1], K. IRAMINA[4], T. HARA[5], K. YOSHIDA[3];

Abstract: [Introduction] Neuroimaging and psychological studies in neurologically normal adults have demonstrated right-lateralized visuospatial attention system. However, the lateralization remains unknown during early childhood because of methodological constraints. To estimate the lateralization for infants, we have invented a brief task that elicits initially a perceptual-driven saccade and subsequently predictive saccades. To check the task's significance, we examined the association of the task with line bisection test, a lateralization test for perceptual attention, in adult subjects. [Methods] Participants were 57 right-handed adults. A

target steps between two horizontal fixed locations at a fixed time interval. The first saccade was leftward for half of the subjects and rightward for the remaining half. They were just instructed to follow the target. They did not know the timing of the target appearance at the first saccade but, in the following saccades, they began to anticipate the appearance of the target and more rapidly make a saccade towards the expected location. Saccades were monitored using a remote eye-tracker and the latencies were analyzed separately for rightward and leftward saccades. We hypothesized that the first saccade is perceptually driven while the following predictive saccades are more internally generated and less perceptual. Thus, the latency of the first saccades subtracted by that of the following saccades could represent the processing time required for the perception of the target presented in a hemi-field. [Results] As expected, latency rapidly decreased from the first to the following saccades. In line bisection test, participants showed variable biases, but as a whole, a slight left deviation. For rightward saccades, a longer subtracted latency corresponded to a greater deviation toward the left in line bisection. For leftward saccades, there was no such correlation. [Discussion] The longer subtracted latency for rightward saccades indicates that more time is required for the perception of the target in the right-field. Such individuals could have less left hemispheric function than right function, and perceptually underestimate the right-side of the line, bisecting the line with left deviation. In contrast, the absent correlation for leftward saccades may be accounted for by the classical theory that the right hemisphere is not directionally biased compared with left hemisphere. This brief task will reveal whether the hemispheric lateralization of visuospatial function already exists during early childhood.

Title: Electrocorticographic correlates of saccades

Authors: ***A. GELLER**[1], J. BURKE[2];
[1]Neurol., NYU, New York, NY; [2]Neurosurg., UCSF, San Francisco, CA

Abstract: Cortical control is known to be critical in driving horizontal gaze. The frontal eye fields have been studied both in non-human primates, where they have been localized to Brodmann area 8, and in humans, where there remains some debate regarding their precise localization. Cortical control for vertical gaze, if present, remains obscure; the lower motor neurons for cranial nerves 3 and 4 are known to be triggered by the Rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) with support from the Interstitial nucleus of Cajal (iNC). We examined the electrocorticographic correlates of both horizontal and vertical conjugate eye movements in 90 epilepsy patients undergoing invasive monitoring, who performed a task engaging the extraocular muscles in ballistic eye movements as well as smooth pursuit. We found that both tasks activated visual cortex. The horizontal gaze task preferentially activated superior temporal cortex (BA 41 and 22), while the vertical gaze task preferentially activated posterior temporal cortex (BA 37).

Title: The medial ventro-thalamic microconnectomics: cells implicated in a bimodal motor circuit

Authors: *T. VEGA-ZUNIGA, D. TROST, K. SCHICKER, H. LUKSCH;
Technische Univ. Muenchen, Freising, Germany

Abstract: A common feature of the ventral thalamus of birds is the presence of a group of retino-recipient and somatosensory structures located adjacent to each other. This includes the intergeniculate leaflet (IGL), n. geniculatus lateralis pars ventralis (GLv), n. ventrolateral thalami (VLT) and n. intercalatus thalami (ICT). These structures have in common an absence of projections to the telencephalon, together with efferent projections to the pretectum, tegmentum and pontine targets. Although the general connectivity is known, detailed morphology and connectivity pattern is still elusive. Here, by means of intracellular filling technique, we focused on two neural structures, namely, the retino-recipient neuropil (ne) of the GLv, and the adjacent somatosensory nucleus ICT. We found that the GLv-ne cells showed two different neuronal types: projection cells and horizontal interneurons. The projection cells showed a variable morphology and dendritic arborization with axons that target the n. lentiformis mesecephali (LM), griseum tectale (GT) and ICT. The horizontal cells showed a widespread medio-lateral

dendritic arborization throughout the retino-recipient GLv-ne. The ICT cells on the other hand, showed multipolar somata with a projection pattern that targets the GLv-li, n. laminaris precommissuralis (LPC), GT and TeO. Together, these results add more complexity to the tangled connectivity pattern so far described between the GLv, ICT, LM, GT and TeO. Interestingly, the implication of some of these neural structures in visuomotor and somatosensory functions suggests that these nuclei may form part of a bimodal circuit involved, among other tasks, in the generation/modulation of saccades, gaze control and space perception.

Title: Gaze coordination with strides during walking in the cat

Authors: K. M. I. CHU[1], H. N. ZUBAIR[1], J. L. JOHNSON[1], T. J. RIVERS[2], *I. N. BELOOZEROVA[1];
[1]Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [2]Dept. of Ecology & Evolutionary Biol., Univ. of Kansas, Lawrence, KS

Abstract: Vision plays a crucial role in guiding locomotion, especially in complex environments. However, the relationship between gaze behaviors and phases of the stride is not well understood. We investigated gaze behaviors of cats walking in four conditions: (1) on a flat surface in darkness or (2) in the light, (3) on a horizontal ladder or (4) on a pathway cluttered with small stones. We recorded vertical and horizontal eye movements and 3-D head and forelimb movements, and calculated where the cat's gaze intersected the walkway. Movements of the gaze intersect point were classified into four categories: gaze shifts away from the cat, gaze shifts toward, fixations, and constant gaze. Occurrences of gaze behaviors were correlated with phases of the stride.
We found that even during walking on the flat surface in the dark, most gaze behaviors were coordinated with strides. Toward gaze shifts typically began just before the initiation of a forelimb's swing or during the first 1/3 of the swing and ended in the middle of swing phase. Away gaze shifts began throughout the second half of swing of each forelimb and ended when both forelimbs were in stance. Fixations peaked in the middle of each forelimb's swing phase,

roughly between the end of gaze shifts toward and beginning of gaze shifts away. Constant gaze had no clear relation to strides.
Introducing light markedly increased synchronization of gaze behaviors with strides. Toward gaze shifts only started in the first 1/3 of swing phase, while away gaze shifts started in the last 1/3 of this phase. Fixations occurred throughout most of each forelimb's swing phase, except near the end when constant gaze dominated. Few fixations were seen during the transition from swing to stance.
Walking on the horizontal ladder requires vision (Beloozerova and Sirota, 2003). On the ladder, gaze behaviors were even more synchronized with strides. Toward gaze shifts were confined to the beginning of swing phase. They were followed by fixations, which in turn were followed by away gaze shifts. Constant gaze was also highly synchronized with strides in two of three cats, occurring during the transitions from swing to stance phases of each forelimb.
Gaze behaviors during walking on a surface cluttered with many small stones were similar to those observed on the ladder. The most prominent difference was that constant gaze occurred slightly earlier in the cycle, at the end of the swing phase.
We concluded that gaze is synchronized with strides even when vision is unavailable or unnecessary for successful walking. This synchronization increases when vision is available and further increases on a complex terrain when accurate stepping is required.

Title: Visual saliency response in the superficial and intermediate superior colliculus

Authors: *J. Y. KAN[1], B. J. WHITE[1], L. ITTI[2], D. P. MUNOZ[1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Computer Sci., USC, Los Angeles, CA

Abstract: The superior colliculus (SC) is a phylogenetically old midbrain structure that plays a central role in vision, attention, and orienting. The SC has visual representations in the superficial-layers (SCs), and sensorimotor representations linked to the control of eye

movements and attention in the intermediate-layers (SCi). Cognitive and computational neuroscience postulates the existence of a visual saliency map that guides visual orienting towards the most visually conspicuous stimuli, and a priority map that combines bottom-up saliency and top-down relevance to allow internal processes such as goals and expectations to also guide behavior. We hypothesize that the SCs embodies the role of a bottom-up saliency map while the SCi embodies the combined priority map. To test this hypothesis, we compared SCs and SCi activity in response to task-irrelevant salient stimuli. Monkeys viewed a wide-field arrangement of stimuli (210 radially-arranged items spanning ~40-50deg) extending beyond the classic receptive field (RF). The stimuli were oriented color-bars (~0.4x1.2deg) that formed a perceptual "pop-out" array the monkeys had to ignore; i.e., reward was contingent upon maintaining gaze on central fixation. We compared visual representations in SCs and SCi when 1 to 4 salient pop-out stimuli appeared equally spaced within the array. We also compared this to an array of homogenous items with no pop-out. Only SCs neurons showed a reliable preference for the visually salient but goal irrelevant pop-out stimulus. Also, this representation in the SCs was the same in the presence of 1 to 4 pop-out items. It is important to note that the pop-out stimuli in the present task was goal IRRELEVANT. In the SCi, we only observed a response to a single salient pop-out stimulus; this response was absent once there were 2 or more salient pop-out items. Next, we will examine how activity in the SCs and SCi changes when the salient stimuli become also goal RELEVANT by being the target of a saccade that will lead to differing amount of reward.

Title: Functional connectivity within and between the oculomotor and the face-perception networks in the human brain when looking towards or away from faces

Authors: *M.-H. GROSBRAS[1], B. NAZARIAN[2], E. SALVIA[1];
[1]Lab. de Neurosci. Cognitive- CNRS, [2]Inst. des Neurosciences de la Timone- CNRS, Aix Marseille Univ., Marseille, France

Abstract: Faces attract and retain attention more than other objects. Here we used functional magnetic brain imaging (fMRI) to investigate how the functional coupling between oculomotor brain regions and visual brain regions is modulated when participants look towards or away visual stimuli belonging to different categories. We scanned 23 healthy adults volunteers in an event-related design intermixing pro- and antisaccades towards or away either faces or cars. Each individual completed six runs of 40 trials. We also acquired a high resolution We identified regions of the oculomotor network and of the face- perception network using coordinate-based meta-analyses of brain imaging studies. We For each functional region we defined a sphere of 6 mm radius around the coordinate of maximum likelihood activation and computed the average signal across the voxels witin the spahere. Then we used psychophysiological interaction analyses to test how the different conditions affect the functional coupling between nodes within and between these two networks. We observed increased functional connectivity during antisaccades away from faces compared to cars (i) between the frontal eye-field (FEF) and posterior oculomotor regions. (ii) between the insula and the amygdala and middle temporal temporal gyrus (i.e within the face network); (iii) and between the right frontal eye field and a region of the left inferior frontal gyrus.
These data suggest that the functional connectivity within the oculomotor network is increased in presence of a socially salient stimulus such as a face. Likewise the functional organization of the face network and its interaction with the FEF is modulated by the oculomotor task, but mainly with respects to the nodes that are more commonly associated with the perception of emotional facial expressions. These data highlight specific neural bases to the increased attentional demand induced by orienting towards or away from faces as compared to other objects.

Title: New perspectives brought by the study of saccades toward an accelerating target

Authors: ***A. TASSOU**, L. GOFFART;
Inst. De Neurosciences De La Timone, Marseille, France

Abstract: An object moving in the peripheral visual field triggers a saccade which orients the gaze toward its location, even though the target-evoked retinal activity consisted of a brief and transient streak. How does the brain transform time-varying signals into a saccade landing position? A recent study showed that this transformation depended upon the target location, the speed of its motion and the rate of change in speed. When the saccades were made in response to a transient target that accelerated (from 0 to 40 deg/s) in the peripheral visual field, a linear relation was found between the landing positions of saccade and their response times (delay between target onset and saccade end). This relation had a slope which was close to the terminal speed of the target (Quinet & Goffart 2015). We investigated further this dependency by testing in three head-restrained monkeys, the saccades made in response to a target which accelerated to a larger range of maximum speeds (from 20 to 180 deg/s). Like in the previous study, the saccades were initiated from a fixation target located straight ahead that the monkeys had to fixate for a variable interval. Then, a transient moving target (duration=200ms) appeared in the upper or lower visual field (16° above or below the horizontal meridian). The target moved horizontally to the left or to the right, and the monkeys' task was to look at the zone traveled by the target with barely any constraint on the accuracy of their response. As shown previously and in spite of the stealth of the target, the saccade endpoints were not randomly distributed; the horizontal landing position of saccades increased linearly with their response time. However, this linearity was observed up to a maximum. Beyond a delay of approximately 100 ms after the target offset, the horizontal landing position stopped increasing. Below this delay, the relation was linear and its slope was correlated with the terminal speed of the target. The increasing horizontal speed of the target led to discover an asynchrony between the horizontal and vertical components of saccades which had never been reported before: the horizontal component was delayed with respect to the vertical component with an average delay which tended to decrease with the target speed.
Our results suggest that within a bounded time window, the brain performs a derivative function (in the mathematical sense) in response to time-varying signals. The quadratic time function of target position is transformed into a linear function. Moreover, the asynchrony between the horizontal and vertical components of saccades toward accelerating targets calls into question the idea that a single goal command drives saccades.

Title: Visual search and fixational eye movements in amblyopia

Authors: *F. F. GHASIA[1], J. OTERO-MILLAN[2], A. SHAIKH[3];
[1]Cole Eye Inst., Cleveland Clin., Cleveland, OH; [2]Neurol., Johns Hopkins Sch. of Med., Baltimore, MD; [3]Neurol., Case Western Reserve Univ., Cleveland, OH

Abstract: Introduction Miniature eye movements such as microsaccades shift the image on the fovea and counteract visual fading. They also serve as an optimal sampling strategy while viewing complex visual scenes. The goal of our study was to assess visual search and microsaccade production in amblyopia. **Methods**Eye movements were recorded using infrared VOG during amblyopic and fellow eye viewing while the subjects identified picture differences. 24 amblyopes (mild =11;moderate= 9; severe=4) and 9 controls were recruited. **Results**Amblyopic subjects had comparable dwell time in the relevant interest areas during both fellow eye viewing (normal: 49.8%; mild: 48.4%; moderate: 45.9%; severe: 43.6%, ANOVA p=0.5) and amblyopic eye viewing conditions (normal: 49.8%; mild: 45.7%; moderate: 39.8%; severe: 47.3%, ANOVA p=0.5). Amblyopes were able to identify comparable picture differences during fellow eye viewing to controls (normal: 5.7; mild: 5.8; moderate: 5.2;severe: 4.3, ANOVA p=0.3). However, the ability to identify picture differences was diminished during amblyopic eye viewing condition (normal: 5.8; mild: 3.8; moderate: 2.7;severe: 0.8, ANOVA $p<0.05$). In amblyopes who were able to identify the picture differences the reaction time was increased during both fellow and amblyopic eye viewing condition(Fellow eye viewing: normal: 8.5 s; mild: 8.0 s; moderate: 14.9 s; severe: 11.9 s KW ANOVA p=0.03; Amblyopic eye viewing: normal:8.5 s; mild: 7.4 s; moderate: 16.7 s; severe: 11.3 s KW ANOVA p=0.01). There was a decrease in the frequency of microsaccades in amblyopes (normal:0.3 Hz, fellow eye viewing:0.2 Hz, amblyopic eye viewing:0.06Hz).**Discussion**The brain increases the rate of microsaccades to aid visual exploration. The relative increase in production of microsaccades while viewing crowded visual scene is diminished in amblyopes. These results suggest that alteration in micro-saccades could explain the difficulty in perceiving details of a complex picture evident as crowding phenomenon in amblyopia.

Title: Eye movements induced by patterned microstimulation of the frontal eye fields

Authors: *M. A. SMITH, R. O. KONECKY;
Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The frontal eye fields (FEF) are the region of cortex most closely linked to the generation of eye movements, receiving visual inputs and sending descending projections to subcortical regions that control saccades. FEF is functionally identified as the region of prefrontal cortex in which saccades can be generated by electrical microstimulation at low currents. Supra-threshold stimulation at a particular site produces a saccade with a characteristic direction and amplitude (Bruce et al, 1985). Raising the current above the threshold produces little change in the saccade, and extending the duration often produces repeated saccades with the same vector ("staircase saccades"). The relationship between microstimulation strength (current) and behavior has been used to deduce features of the functional organization of visual and motor cortex. Similarly, the behavior of animals under conditions in which both microstimulation and visual input are provided simultaneously has been used to study the integration of sensory activity by downstream targets. Here, we employed microstimulation in FEF at multiple sites simultaneously to determine how the output of FEF is summed to produce behavior. To investigate this question we microstimulated at multiple sites concurrently in the FEF of macaque monkeys. We used a linear array of 16 channels spaced 150 μm apart to microstimulate FEF with small amounts of current (15-150 μA). Using this experimental design, we tested the following hypotheses: (1) do the contributions of multiple neuronal populations in the FEF sum in a predictable way, (2) can their contributions be manipulated by varying the current into these inputs and (3) can their contributions be manipulated by varying the distance between inputs. We found that the direction of evoked saccades resulting from simultaneous stimulation of two contacts is equal to the average saccade vector evoked from stimulation of each constituent contact alone. We were able to shift the resultant saccade vector from one constituent saccade to the other by varying the amount of current on each contact. The ability to produce this graded response saturated at supra-threshold currents. Also, we found that greater inter-contact distances increased the amount of error between the vector average prediction and the actual saccade. Evaluating the effects of patterned microstimulation provides a richer

understanding of the complexities of the oculomotor system. More broadly, these data demonstrate how cortical inputs combine to produce complex outputs and serve as a foundation for the development of neural interfaces to influence perception and behavior with microstimulation.

Title: Eye movement recordings of spontaneous fusion loss in intermittent exotropia

Authors: ***J. C. HORTON**, D. L. ADAMS, J. R. ECONOMIDES;
Beckman Vision Ctr., Univ. California, San Francisco, CA

Abstract: Subjects with intermittent exotropia have normal visual acuity in each eye and intact stereopsis, but a large exophoria that results periodically in spontaneous loss of fusion. The factors that trigger breakdown of fusion are not well understood. No recordings have been made to characterize the type of movement made when the eyes diverge. To address this issue, we tested 10 subjects (mean age 31, range 12 - 61 years) with intermittent exotropia. They fixated a small central target rear-projected onto a tangent screen while the positions of their eyes were monitored with video eye trackers. A cover-uncover test was performed at unpredictable intervals by occluding either eye with a filter mounted on a pneumatic cylinder. The filter transmitted infrared light, so that the position of the covered eye could still be tracked. Between cover-uncover trials, while both eyes were viewing the fixation target, subjects experienced occasional episodes of spontaneous fusion loss. Outwards eye movements, occurring either spontaneously or after monocular occlusion, were compared. The mean exotropia was 17° (range 9 - 32°). Exotropia magnitude showed slight asymmetry, being an average of 14% larger with one eye covered compared with the other. Mean exotropia was nearly identical for spontaneous fusion loss and cover-induced trials. The difference in peak velocity of outwards eye movements occurring spontaneously or after occlusion was 1.1°/sec ($p = 0.59$). In subjects with larger exodeviations, peak velocities tended to be higher. In some subjects, additional testing was

performed by arranging two targets in depth, along the line of sight of either eye. Subjects were asked to shift fixation from the near to the far target. Target distances were chosen to evoke an eye movement that matched the amplitude of the subject's exotropia. The resulting divergence eye movement resembled the eye movement recorded during spontaneous loss of fusion. This similarity suggests that intermittent exotropes make a divergence eye movement when their ocular alignment breaks down. This divergence eye movement is not significantly affected by occluding the drifting eye. Intermittent exotropia appears to be a disorder of the divergence eye movement system.

Title: Sensory prediction errors during saccade adaptation drive cerebellar complex spikes and learning

Authors: ***D. J. HERZFELD**[1], Y. KOJIMA[2], R. SOETEDJO[2], R. SHADMEHR[1];
[1]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Natl. Primate Ctr., Univ. of Washington, Seattle, WA

Abstract: The hypothesis of cerebellar learning suggests that adaptation is driven by prediction errors, communicated via climbing fibers to Purkinje cells (P-cells), resulting in complex spikes (CSs). In this framework, presence of a CS results in synaptic plasticity which changes the simple spike (SS) activity of P-cells and subsequently behavior. Recent attempts to validate this hypothesis during short-term saccade adaptation have failed to find a link between P-cell SS activity and movement parameters. Therefore, adaptation, which entails a change in this

encoding, has been even more difficult to address. However, we recently found that the combined responses of P-cells, organized by their CS tuning properties, reliably predict the real-time velocity of eye movements. Using this result, we have begun to address the question of adaptation.
We trained monkeys to produce saccades to visual targets while recording single-unit P-cell activity from the oculomotor vermis (OMV). In every trial, the monkey made a saccade to a random target. However in some trials, we jumped the target, producing a foveal error.
We found that an unexpected visual event consistently modulated the probability of a CS (Pr[CS]). During fixation, presentation of a random target produced a CS with a probability that was cosine tuned as a function of the foveal direction of the target. Once the saccade was completed, the same P-cell exhibited a cosine tuned Pr[CS], now with respect to foveal direction of error. That is, in both periods of time, a visual sensory prediction error (target location with respect to the fovea) modulated Pr[CS]. Therefore, the complex spikes have a directional preference for sensory prediction errors, regardless of whether the sensory event is associated with a previous movement or not.
Finally, we asked whether Pr[CS] affected SS responses during gain-down adaptation. We functionally organized the P-cells into microclusters wherein all P-cells shared a common CS tuning, and then computed a SS population response. When the post-saccadic prediction error occurred in the preferred CS direction of the P-cells, the SS population activity decreased and accurately predicted the gain of the saccade (R2=0.86). However, when the error occurred in the anti-preferred CS direction, the population response showed little or no changes.
Our results suggest that occurrence of a complex spike is associated with a sensory prediction error, even when that error is not associated with a previous movement. However, when the error occurs following a movement, then the increased Pr[CS] coincides with a reduction in the population SS response, driving plasticity during saccade adaptation.

Title: Interceptive saccades revisited: a comparison of saccades to stationary and moving targets

Authors: K. J. MOHSENIAN[1], B. STEINBERG[2], A. L. CECALA[2], *N. J. GANDHI[1]; [1]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Dept. of Biol., Elizabethtown Col., Elizabethtown, PA

Abstract: Natural environments are dynamic and filled with sensory information that could be used by an organism to guide behaviors necessary for survival. Animals are able to extract relevant information from their environment by aligning their specialized sensory apparatus (e.g. the retinal fovea) with stationary and moving objects. Rapid eye movements have been used to study sensory, motor, and cognitive processes in primates, but most of this research has emphasized the use of stationary targets. Under these circumstances, the metrics and kinematics of saccades have been well characterized (Leigh & Zee, 2015); however, there have been relatively few in-depth descriptions of horizontal, vertical, and oblique interceptive saccades using a large range of target speeds and directions. The current abstract reports data collected from two rhesus monkeys and five human subjects who performed a delayed saccade task in which the delay duration, starting target location, and target speed (range: 10-60 deg/s) and direction (inward, outward, upward, downward) were varied randomly to elicit saccades with different vectors (amplitude and directions). Delay trials using stationary targets placed along moving target paths were randomly interleaved with delay trials using moving targets. Eye position was recorded using magnetic search coils and an eye-tracker system for non-human primates and humans, respectively. Preliminary data are similar for both species. Analyses indicate that saccade metrics between stationary and moving targets may be more similar than previously proposed (Guan et al. 2005, Keller et al. 1996). We observed no differences in the duration, peak velocity, average velocity, latency, and saccadic error between amplitude matched saccades used to foveate stationary and moving targets across directions and speeds. The discrepancies between our observations and those previously reported could be a function of task differences. For instance, we used a delay saccade task and most previously reported data were collected using a step saccade task. We also interleaved many more target trajectories than previous studies. These results suggest that the interceptive saccade vector encoded in the programming pathway is transformed in a similar temporal pattern in the brain stem as traditional saccades.

Title: Frontoparietal functional connectivity in the common marmoset

Authors: *M. GHAHREMANI[1,2], M. HUTCHISON[4], J. S. GATI[2], K. GILBERT[2], R. S. MENON[1,2], S. EVERLING[1,2,3];

Abstract: Interest in the common marmoset monkeys (Callithrix jacchus) is growing rapidly as it is poised to become the leading candidate transgenic primate model. In contrast to the well-established Old World macaque, little is known about the functional organization of the saccade circuitry in these New World primates. Here, we used resting-state ultra-high-field fMRI data collected from 4 lightly anesthetized male marmosets and 12 anesthetized male macaques to examine and compare the brain's functional organization, with emphasis on the saccade system. Macaque data and marmoset data were obtained using custom-built transmit/receive coils on a 7T and 9.4T MR scanner, respectively. Exploratory independent component analysis (ICA) revealed eight resting state networks in marmosets that greatly overlapped with corresponding macaque and human networks including a distributed frontoparietal network. Seed-region analyses of the superior colliculus (SC), a fundamental node in saccadic eye movement control, showed homologous functionally connected areas in both macaques and marmosets. Visualization of surface rendered functional connectivity maps revealed the strongest bilateral connectivity of the SC in frontal areas 6DC, 6DR, 8C, 8B, 8aV, 8aD, 46D, parietal areas PG, PGM, PO, MIP, LIP, and temporal areas MT, MST, FST of marmosets. Considerable functional connectivity was also observed in visual areas V1, V2, V3, V4 as well as cortical face patch areas ML, MF, AL, AF and the amygdala. Functional connectivity of the marmoset frontal eye fields revealed a similar connectivity pattern including a strong functional connectivity with areas 23a, 23b, 23c, 24m, 29a-c and parietal area PF. Furthermore, areas 8aD, 8aV, PG, TPO, TE2, and TE3 were identified as major hubs based on a region-wise evaluation of betweeness centrality, suggesting that these cortical regions make up the functional core of the marmoset brain. The results support an evolutionarily preserved frontoparietal system and provide a starting point for invasive neurophysiological studies in marmosets.

Title: Oculomotor gap effect and reduced saccadic reaction times to faces in the common marmoset

Authors: *K. D. JOHNSTON, S. EVERLING;
Univ. of Western Ontario, London, ON, Canada

Abstract: The common marmoset (Callithrix jacchus) is a New World primate that shows considerable promise as a model animal for neuroscience research. The first primate transgenic lines have been developed in this species, making possible the integration of genetic and neurophysiological tools in primates. Practical advantages, such as a lissencephalic cortex that allows recording with linear and planar electrode arrays, and a clear extant knowledge of the anatomy and physiology of the visual system in this species further support it's value. The oculomotor system is the most thoroughly understood sensorimotor system in the brain, and provides a window into numerous neurodegenerative and neuropsychiatric disorders. To date however, a limited number of studies have evaluated the oculomotor behaviour of the common marmoset. Here, we investigated the performance of the common marmoset on an oculomotor phenomenon well-studied in humans and rhesus macaques, the gap effect. This effect is a decrease in saccadic reaction times (SRTs) observed when the fixation spot is extinguished prior to the appearance of a target in saccade tasks. We trained a common marmoset to make saccades to peripheral white circular targets for liquid reward. In a "step" condition, an initial fixation spot was extinguished simultaneously with the appearance of the target. In a "gap" condition, the fixation spot was extinguished 200ms prior to target appearance. Consistent with previous observations in both humans and macaques, we observed reductions in SRTs in the gap as compared to step condition. In a second series of experiments, we expanded the set of target stimuli in the gap condition to include marmoset faces as well as control stimuli consisting of scrambled faces, to investigate the possibility of an SRT advantage for naturalistic stimuli. Under these conditions, we observed a reduction in SRTs to faces as compared to control stimuli. Taken together, these findings suggest that conserved oculomotor circuits mediate the gap effect in marmosets and Old World primates, and support the use of the common marmoset as a model for investigations of oculomotor neurophysiology. Further, they suggest preferential processing of faces in the marmoset oculomotor system.

Title: Differential effects of saccadic suppression on single-unit activity and local field potentials in the primate superior colliculus

Authors: *C.-Y. CHEN[1,2], Z. M. HAFED[1];
[1]Werner Reichardt Ctr. For Integrative Neurosci., Tübingen, Germany; [2]Grad. Sch. of Neural and Behavioural Sciences, Intl. Max Planck Res. Sch., Tübingen, Germany

Abstract: Saccadic suppression refers to reduced visual sensitivity around the time of saccades/microsaccades. Neuronally, suppression appears as reduced firing rates to visual stimuli, and behaviorally, this translates into, among others, delayed reaction times (RT's). However, the sources of saccadic suppression remain elusive. Here, we compared saccadic influences on both firing rates (single-unit activity; SUA) and local field potentials (LFP's) in primate superior colliculus (SC). We hypothesized that LFP's, a proxy for population and synaptic activity, can reveal movement-related signals at the time of visual burst SUA suppression, which may help constrain the neural sources of a suppressive saccade-related signal. We recorded from 90 SC sites (1-24 deg eccentricity) in 2 monkeys, collecting both SUA and LFP's. Monkeys fixated a white spot over a gray background. Inside RF's at the recorded sites (assessed from SUA and LFP tuning properties), a stationary, vertical Gabor grating (0.56, 1.11, 2.22, 4.44, or 11.11 cpd) appeared. For SUA, we measured peak visual response 20-150 ms after grating onset. For LFP's, we measured peak transient deflection similar to how we measured peak SUA response, and we also collected transient LFP latency defined as the first time at which the LFP was >2 s.d. away from pre-stimulus baseline. We compared trials when gratings appeared <50 ms after microsaccade end (the saccadic suppression trials) to trials when the gratings appeared without microsaccades (baseline). We chose a post-microsaccade interval to ensure that the eye was already stable at the time of grating onset, just like in the baseline trials. Visual-motor neurons showed the strongest visual response suppression, and the suppression was spatial-frequency-dependent; visual-only neurons had only mild and unselective suppression. In the LFP's, opposite to the SUA's, we observed enhanced visually-evoked transient response, and with facilitated latency (regardless of electrode location). This suggests the presence of a movement-related signal that may mediate SUA visual burst suppression. We confirmed this by identifying microsaccade-related LFP modulations, even in the far periphery, in the absence of any visual stimulus. However, the interaction between this movement-related modulation and the

visually-evoked LFP response was supra-additive because the enhanced LFP response could not be explained by a baseline shift caused by the movement-related modulation. Thus, LFP's show opposite saccadic suppression effects from SUA and reveal a putatively movement-related signal at the time of SUA suppression.

Title: Temporal compression of visual perception around microsaccades

Authors: ***M. C. DORRIS**, G. YU, M. YANG, P. YU;
Inst. of Neuroscience, Shanghai Inst. For Biol. Sciences, CAS, Shanghai, China

Abstract: Even during fixation, our eyes are in constant motion. For example, microsaccades are small (typically<1°), rapid eye movements that occur during attempted fixation. Recently researchers have begun to characterize how microsaccades influence visual attention and visual perception. Here we demonstrate that microsaccades can also influence time perception; that is, the perceived temporal interval between transient visual stimuli is compressed around microsaccades. While maintaining central fixation, human subjects reported whether the duration between a pair of successively flashed horizontal bars (test interval) was longer or shorter than the duration between a subsequent pair (probe interval). A total of ~40000 trials were collected from 8 subjects. Trials were separated into those with and without accompanying microsaccades. We found that if spontaneous microsaccades occurred around the time of one of these temporal intervals (test or probe), that temporal interval was judged to be of shorter duration compared to those trials without microsaccades. This temporal compression was consistent across subjects and was not influenced by attributes of microsaccade such as their particular direction or amplitude. Microsaccades exerted their strongest effect when they occurred within 100ms of the temporal interval and significant effects extended for ~250ms both before and after the temporal interval. The magnitude of the temporal compression
was larger if a microsaccade was associated with the later probe interval than if a microsaccade was associated with the earlier test interval. If multiple microsaccades occurred surrounding a temporal interval, this enhanced the temporal compression of that interval. If microsaccades

occurred surrounding both temporal intervals, their temporal compression effects tended to counteract each other. The compression of time surrounding microsaccades resembles the temporal compression associated with voluntary (macro)saccades (Morrone et al., 2005). Considering microsaccades' small and fast nature, this compression effect on visual perception is far-reaching. In the spatial dimension, the flashed visual stimuli were far (~20°) from central fixation. In the temporal dimension, microsaccades exerted an influence for +/- 250ms from their onset. Together these suggest an underlying extra-retinal mechanism rather than a mere retinal impact. Lastly, given the ubiquity of microsaccades (1~2Hz), our results raise questions of how we can maintain accurate time perception in our everyday life and during experimental situations.

Title: Neural activity and saccadic eye movements involved during letter and object stimuli manipulations

Authors: ***N. Z. AL DAHHAN**[1], D. C. BRIEN[1], J. R. KIRBY[2], D. P. MUNOZ[1];
[1]Queen's Univ. Ctr. for Neurosci. Studies, Kingston, ON, Canada; [2]Queen's Univ. Fac. of Educ., Kingston, ON, Canada

Abstract: Although reading is an important and generative skill, it remains controversial how it develops and how dysfunctions lead to reading difficulties. To further understand the processes that are involved during reading, we combined functional magnetic resonance imaging (fMRI) with eye tracking to investigate the neural substrates and cognitive processes underlying performance during letter and object naming speed (NS) tasks. These tasks, which measure how quickly and accurately participants can name sets of familiar stimuli, provide a simplified example of processes involved during reading and are a precursor and concurrent correlate of accurate and efficient reading.
We recruited 19 healthy young adults (ages 21 - 26 years), and employed a block design consisting of a letter NS task and three variants that were either phonologically and/or visually confusing; and an object NS task with a variant in which the object names rhymed with one another, while subjects' eye movements and articulations were recorded. We examined how these manipulations influenced behavioral performance and whether they resulted in differences

in neural activation.
Behavioral analyses revealed that letter NS manipulations were influenced by visual rather than phonological similarity. When the task was both visually and phonologically similar, participants had significantly longer naming times and fixation durations, and made more frequent saccades and regressions. For the object NS tasks participants' performance was not affected when the names of the objects rhymed with one another.
fMRI results indicated that these NS tasks activated key neural structures that are involved in reading, such as: the ventral visual stream (visual word-form area), supramarginal gyrus (grapheme-phoneme mapping), middle temporal gyrus (semantic access), motor cortex (motor planning), supplementary motor and pre-motor areas (articulation), and anterior cingulate (speech monitoring). Activation in the temporoparietal areas of the reading network varied by difficulty of each letter NS task indicating differential neural processes that are associated with each task. There was also significantly greater bilateral activation in the fusiform gyrus and parahippocampal gyrus during the object NS tasks than the letter NS tasks.
These findings further our understanding of the neural substrate required for reading. As further progress is made in understanding these underlying processes, this could lead to establishing biomarkers to help identify children who may be at-risk for developing reading difficulties in order to provide them with early assessments and effective interventions.

Title: Integration of past and current visual information during eye movements in Amblyopia

Authors: ***N. DERAVET**[1], D. YÜKSEL[2], J.-J. ORBAN DE XIVRY[4], P. LEFÈVRE[3];
[2]Inst. of Neurosciences ; Ophtalmology department, [3]Inst. of Neurosciences ; ICTEAM, [1]Univ.

catholique de Louvain, Louvain-la-Neuve, Belgium; [4]Dept. of Kinesiology, Movement Control and Neuroplasticity Res. Group, Katholieke Univ. Leuven, Leuven, Belgium

Abstract: Amblyopia is a neuro-developmental disorder characterized by a reduced acuity of one or both eyes that is not related to a structural, correctible deficit. In addition to acuity and contrast sensitivity deficits, Amblyopia affects perception and eye movements. Furthermore, some of these deficits extend to the fellow eye, excluding loss of acuity as their unique cause. One of the proposed hypotheses is that the integration of visual and extraretinal signals (memory, proprioception…) matures differently in amblyopic patients. In this study, we investigate this hypothesis and the integration of visual signals with memory of target motion during eye movements in amblyopic patients.

Fourteen control subjects and nineteen amblyopic patients, their dominant/fellow eye covered, visually pursued a moving red dot (diameter=0.8°) for a variable number of repetitions (1 to 4 trials). Control subjects had normal or corrected to normal vision, while amblyopic patients had visual acuity of 2/20 to 10/20 Snellen, and exhibited either anisometropic (n=5), strabic (n=9) or anisometropic and strabic (n=5) amblyopia. Repetitions of target motion had the same direction (among 6: 0°±20°, 180°±20°) and the same velocity (among 2: 15°/s, 20°/s), which led to the gradual formation of a memory of target motion. We tested the relative weights of visual and memory signals by presenting, at the last repetition, a catch trial that had the same direction but reduced (-5°/s) or increased (+5°/s) velocity.

Catch trials were compared to control trials that had both the same number of preceding trials and the same velocity. Doing so, the only difference between them was prior information about target velocity.

We found that, for all groups, smooth pursuit eye velocity gain during steady-state was biased towards the target velocity of previous trials ($p<0.05$). Furthermore, the amplitude of catch-up saccades was larger when previous target velocity was higher, and reciprocally ($p<0.05$). Interestingly, the magnitude of the effect did not differ significantly between controls and amblyopic patients (interaction of trial type vs subject type: $p>0.5$), despite obvious differences in visual acuity. It therefore appears that Amblyopia does not significantly affect the weighting of the memory of target motion with visual information during eye movements (within 4 trials). Since we considered a diverse group of amblyopic patients, we intend to pursue this study by increasing our pool of patients and refine the results by type of amblyopia.

Title: Normal correspondence of tectal maps for saccadic eye movements in strabismus.

Authors: *J. R. ECONOMIDES, D. L. ADAMS, J. C. HORTON;
Beckman Vision Ctr., UCSF, San Francisco, CA

Abstract: The superior colliculus is a major brainstem structure for the production of saccadic eye movements. Electrical stimulation at any given point in the motor map generates saccades of defined amplitude and direction. It is unknown how the saccade map is affected by strabismus. Three macaques were raised with exotropia by performing a medial rectus muscle tenotomy in each eye at age 1 month. Once the animals were mature, their ocular motor behavior was tested. The animals showed no evidence of amblyopia; they were able to make saccades to targets with either eye and alternated fixation freely. To probe the organization of the superior colliculus, microstimulation was applied at multiple sites, with the animals either free-viewing or fixating a target. In two animals, microstimulation drove conjugate saccades. They were similar in both amplitude and direction, but separated by the ocular deviation. In the third animal, saccades from microstimulation were the same in amplitude, but differed in direction for the two eyes by 15° of polar angle. This direction difference was due to a strabismic pattern deviation that also caused a 15° rotation during static fixations and smooth pursuit. Given that smooth pursuit is not thought to be mediated by the superior colliculus, the rotation in relative eye motion was unlikely to be caused by a shift in the tectal saccade map for one eye. These data indicate that the map for saccade generation appears normal in strabismus, with no evidence for anomalous correspondence. However, saccades generated by tectal stimulation may be disconjugate in animals with a pattern deviation, presumably due to altered downstream elements. Single cell recordings made in the course of these stimulation experiments showed normal, binocular sensory responses in the tectum, in contrast with the striking loss of binocularity induced in striate cortex by strabismus.

Title: Perceived location of a target flash presented before, during and after smooth pursuit eye movement

Authors: *J. POLA, H. J. WYATT;
Dept. of Biol. and Vision Sci., SUNY Col. Optometry, New York, NY

Abstract: Smooth pursuit eye movements allow one to visually track a target moving against a stationary background field. Of particular interest, the background is perceived as stationary even though its image, as a consequence of the pursuit, moves relative to the retina. One explanation for this perception is that, associated with the motor signal driving smooth pursuit, an extraretinal (exR) signal is generated that serves to cancel out what otherwise would be the appearance of background displacement. A large number of studies have explored this exR signal in a variety of circumstances. However, there have been no studies concerned with the overall temporal features of the exR signal before, during and after smooth pursuit. To investigate the exR signal over time, subjects in the present experiment observed a target flash (10 ms) presented at various times before, during and after smooth pursuit movement. The subjects reported on the location of the flash relative to the location of a fixation target viewed and extinguished shortly before pursuit onset. (The pursuit target moved either to the right or left at 15 deg/sec for 1.2 sec.) By varying target flash location over experimental trials we determined a target flash that appeared to be at the location of the fixation target, i.e., the target point of subjective equality (TPSE), for each time of flash presentation. Generally, the TPSE was not at the actual location of the fixation target: for rightward smooth pursuit, the TPSE was to the left of the fixation target (opposite to pursuit) from about 0.5 sec before pursuit onset until about 0.75 sec after onset. Thereafter, the TPSE was to the right of the fixation target (in the direction of pursuit) during the remainder of pursuit and 2.5 sec of fixation after pursuit. Using the pursuit time course, it was possible to find a *retinal locus* corresponding to each TPSE, i.e., the retinal point of subjective equality (RPSE). In general, the RPSE shifted relative to the retina in a compensatory direction (for retinal image displacement) as a linear function of time. However, the RPSE shift began before pursuit onset, occurred more slowly than the pursuit movement, and reached a final magnitude after the pursuit (during post pursuit fixation) that was smaller than that of the eye movement. In short, the RPSE suggests an exR signal that changes more slowly than pursuit movement with a final signal magnitude that is smaller than that of the movement. The features of the TPSE, RPSE and underlying exR signal are considered in view of the functional dynamics of the smooth pursuit system and the possible influence of target flash visual persistence.

Title: Macaque use of categorical target templates to guide visual search for complex naturalistic stimuli.

Authors: ***B. M. COOPER**[1], H. ADELI[2], G. J. ZELINSKY[2], R. MCPEEK[1];
[1]Biol. Sci., State Univ. of New York Col. of Optometry, New York, NY; [2]Dept. of Psychology, Stoney Brook Univ., Stoney Brook, NY

Abstract: Humans represent objects as higher-level categories. While object category representations have also been demonstrated behaviorally and physiologically in macaques, macaque use of categorical target templates to guide visual search has yet to be demonstrated. Here we investigated target guidance with two search tasks, one in which a target exemplar was previewed (exemplar search) and another in which the target was defined by a category-specific symbol (categorical search). Subjects freely searched for a member of an object category (e.g. teddy bears), among distractors drawn from random non-target categories (e.g. cars, plants, utensils, etc.). Objects were arranged on a circle and displayed at 10 deg. eccentricity from central fixation. Set size was varied over five levels (2-8, evenly spaced). On target-present trials (TP; 50%), the subject was rewarded after making a saccade to the cued target. On target-absent trials (TA; 50%), reward was given after fixation was held at a 'Target Absent Button' in the periphery (18 deg.). Search behavior was also compared to predictions of an image-based model of the superior colliculus (MASC) that generates sequences of saccades as it searches for the same exemplar and categorical targets. We found that the proportion of TP trials in which the target was the first-fixated object was highly above chance and didn't differ between exemplar and categorical search conditions, demonstrating a strong level of target guidance. Similar strong target guidance and set size effects were observed in MASC's fixations. We exploited the fact that thousands of opportunities existed to observe the preferential fixation of distractors, from

which we assembled most-fixated and least-fixated sets. We show that the same distractors that were more/less fixated by the macaque were also more/less fixated by MASC. We interpret these findings as evidence that macaques use categorical features in visual search to guide their overt attention. The fact that these features can be extracted by our model and used to predict fixation behavior may make possible the future prediction of neural activity in oculomotor structures such as the superior colliculus in naturalistic tasks.

Title: Population coding in the superior colliculus may contribute to variability in saccadic reaction time

Authors: ***S. DASH**[1], T. R. PEEL[2], B. D. CORNEIL[2];
[1]Physiol. and Pharmacol., Robarts Res. Institute, Western Univ., London, ON, Canada; [2]Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: In primates, the saccadic reaction time (SRT) to look towards a visual target ranges from below 100ms to above 300ms. What is the neural basis of such variability? Previous research on the activity of single neurons has highlighted the importance of stimulus properties (e.g., contrast, number of targets) on the vigor of the initial sensory response, and the impact of top-down signal (e.g., expectancy or reward) on low-frequency preparatory activity prior to stimulus onset. Here, we examine the potential contribution of population coding in the oculomotor system to SRT variability. To do this, we recorded saccade-related neurons (currently > 100) in the primate superior colliculus (SC) while monkeys made visually-guided saccades into the neuron's response field. As expected, across SC neurons the time of peak saccade-related activity (Peaktime) correlated positively with SRT, being delayed for longer-latency saccades. However, across our sample of neurons we observed substantial variability in the strength and slope of this correlation, meaning that the time of peak activity on an individual neuron basis was an insufficient predictor of SRT. To investigate population coding, we sorted

all the trials across all the neurons based on increasing SRT, and divided this dataset into partially overlapping sub populations(13 sub-populations; 20ms bins; 5ms separation between bins; range 120-200ms). Unlike what was found with individual neurons, the average Peaktime across all neurons and across all bins correlated nearly 1:1 with SRT. However, we observed a monotonic increase in the variability of Peaktime with increasing SRT. As a consequence of such desynchronization, population activity at saccade threshold decreased for longer-latency SRTs. Together, our results suggest that the synchrony of saccade-related activity in the SC population impacts SRT; it takes longer for a more desynchronized population to reach saccade threshold. Our results also show that saccade threshold is not invariant in this simple task, instead decreasing for longer SRTs. This observation can be reconciled if the downstream brainstem burst generator acts as a leaky integrator accumulating activity from a population of SC neurons with a short time constant.

Title: Perceptually driven gain modulation of neuronal activity in the superior colliculus during urgent choices

Authors: ***C. K. HAUSER**, E. ROGERS, T. R. STANFORD, E. SALINAS;
neurobiology and anatomy, Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The superior colliculus (SC) has been implicated in visual target selection, visuospatial attention, and saccade execution. By and large, neural correlates of these processes have been demonstrated in laboratory tasks that, by design, impose serial order to the perceptual decision and motor planning processes that precede saccade execution. While successful in distinguishing purely sensory-contingent from purely motor-related activity, such tasks obscure the dynamics of the perceptual-motor interactions that one would expect in more natural settings. To examine such interactions and their neural correlates, we recorded from single SC neurons

(visual, visuomotor, and motor) while monkeys performed a novel, urgent two-choice task that requires subjects to form a motor plan in advance of receiving a cue that reveals the identities/locations of target and distracter. Crucially, performance on this task varies from chance to near 100% as a function of processing time (PT) — the amount of time available to view the cue before commitment to a saccadic choice. The resulting psychophysical function ("tachometric" curve), which plots success rate as a function of PT, provides an opportunity to examine the relationship between the evolving perceptual decision process and its neural correlates with unprecedented temporal resolution. As we previously demonstrated for the frontal eye field (FEF), the impact of the perceptual judgment was clearly evident as choices progressed from uninformed to informed; i.e., the rising activity associated with target and distracter exhibited characteristic PT dependencies. In addition, we observed an entirely novel form of gain modulation: for most SC neurons, the maximum firing rate either increased or decreased as a function of PT. This PT-dependent gain modulation was observed in all neuronal subclasses in the SC, regardless of their visuomotor properties. Moreover, its magnitude and time course varied across experimental conditions (easy vs difficult), outcomes (correct vs incorrect), and cell classes. The results provide critical insight about how perceptual information is dynamically translated into motor output.

Title: Passive eye movements induced by electromagnetic force (EMF) in anesthetized rats

Authors: Y. YU[1], L. CHEN[1], D. S. SANDLIN[1], J. HUANG[1], S. WANG[1], J. ALLISON[1], H. ZHU[1], *W. ZHOU[1,2];

Abstract: Many important sensorimotor functions (e.g., visual localization and eye movement control) require accurate information of eye position in the orbit, which can be provided by either an efferent copy of the feedforward oculomotor commands or the feedback signals from the extraocular muscle proprioceptive pathways. Whereas the neural substrates for oculomotor commands have been extensively studied, the central processing of extraocular muscle proprioceptive signals remains to be elucidated. A technical barrier to investigate this issue is a lack of noninvasive approaches to induce well-defined passive eye movements that specifically activate eye muscle proprioceptive pathways. In this study, we describe a noninvasive method to generate passive eye movements in isoflurane-anesthetized rats (N=6). A small magnet (<1mm) was attached to the surface of a rat's eyeball nasal to the cornea without blocking the pupil, and a small iron rod (~5mm diameter) surrounded by an electromagnetic coil was placed close to the magnet (<15 mm). By passing currents with different polarities to the electromagnetic coil, attractive or repulsive electromagnetic force was generated upon the magnet attached to the eye, therefore inducing eye movements. A video-based eye tracker (ISCAN ETL-200) was employed to measure horizontal and vertical positions of the stimulated eye at a speed of 240 frames per second with a spatial resolution of 0.1 deg. The results show that the electromagnetic forces generated by the coil induced well-defined eye movements: directions were dependent on current polarity, and amplitudes (1~15 deg) and peak velocities (100~1000 deg/s) were dependent on current intensity (0.1~0.7A) and pulse duration (20~200ms). We further showed that peak velocities of the EMF-induced eye movements were linearly related to their amplitudes, demonstrating consistent main sequences among rats. Besides the slopes, the main sequences of the EMF-induced eye movements were similar to that of saccades in awake rats and that of eye movements-induced by electrical micro-stimulation of the abducens nucleus in anesthetized rats. These results suggest that the EMF method provides an effective noninvasive approach to induce well-defined passive eye movements for investigating the central processing of eye muscle proprioceptive signals and its role in visual localization and eye movement control.

Title: Abstraction of 2D head-centered positions from tracking a moving visual target: A study in the non-human primate

Authors: *C. BOURRELLY[1,2], R. M. ETOUMBE[1,2], P. CAVANAGH[2,3], L. GOFFART[1]; [1]CNRS Inst. Des Neurosciences De La Timone, Marseille, France; [2]CNRS Lab. Psychologie de la Perception, Paris, France; [3]Dartmouth Col., Dept. of Psychological and Brain Sci., Hanover, NH

Abstract: The ability to navigate in an environment involves notions such as places, distances and directions. Many studies have investigated how the brain represents or encodes these spatial parameters in various navigation tasks. However, very few have tried to explain how these parameters were constructed in naive animals. We developed a simple protocol for studying this problem using the oculomotor system as a probe. In this protocol, monkeys were trained to fixate a central fixation target and to track it when it started to move along a triangular path. The target moved with a constant speed (10°/s) for approximately 5000 ms along one of 4 pseudo-randomly selected paths in the upper, lower, left or right visual fields. The target ended its motion when it returned back to the center of the screen, at which time the monkey received its reward. From a head-centered perspective, the target motion was clockwise. The direction of target motion changed abruptly at the vertices of each triangular path and the oculomotor behavior around these inflection points was an indicator of the monkey's spatial knowledge of the trajectory. Three monkeys were used to study the evolution of their oculomotor tracking during this task. During the first days of practice, the tracking was primarily composed of saccades and the monkey did not anticipate the changes in target motion direction. After a few days of learning, pursuit became more frequent and as the eye approached the inflection points, the velocity of the pursuit eye movements and the amplitude of saccades both decreased. These results indicate that the location of inflections points were encoded, and possibly represented within a spatial map. To further examine this location coding, we tested the tracking behavior in response to an increase in target speed, to an increase in the length of the paths and to a change in motion direction (from clockwise to counterclockwise). During these tests, the ocular tracking revealed the properties of the memory of the inflection points. This new protocol can guide fRMI studies to the brain structures involved in the coding of 2D head-centered spatial memory. Altogether, our work demonstrates the critical role played by the oculomotor system in the spatial mapping of the world.

Title: Temporal stability of reference frames in a 3d reaching task in monkey posterior parietal area V6A.

Authors: K. HADJIDIMITRAKIS[1], R. BREVEGLIERI[2], F. BERTOZZI[2], P. FATTORI[2], *C. GALLETTI[2];
[1]Monash Univ., Melbourne, Australia; [2]Univ. Bologna, Bologna, Italy

Abstract: Neurons in the medial posterior parietal area V6A of macaques have been consistently reported to show spatial modulations during all the phases of an instructed delay reaching task. In addition, during the planning and the execution of hand movements in 3D space performed from different starting hand positions, the vast majority of V6A neurons represent targets' location either in body-centered frame of reference, or in mixed body/hand-centred coordinates, with only occasional units showing pure hand-centered coding (Hadjidimitrakis et al, 2014, Cer. Cortex 24(12):3209-20). We here characterized the frames of reference in earlier epochs of the task, i.e. immediately after target fixation and in the subsequent main part of the delay period and examined whether the reference frames in individual neurons are stable across the task epochs. We recorded the activity of single cells in V6A while two *Macaca Fascicularis* performed in darkness a foveal reaching towards 9 targets located at different depths and in different directions. The reaches could start from two different hand positions, one close to the body and the other far from it, at a different depth. We report no evidence of hand-centred coding also in the earlier phases of the task. Shortly after target fixation and throughout the main part of the delay period, V6A neurons used either body-centred, or mixed body/hand-centred reference frames. Most of the cells showed consistent reference frames across epochs. Interestingly, a population trend for a shift from mixed body/hand-centred frames to 'pure' body-centred coordinates was found as the task progressed. These findings suggest that in V6A, similar to other parietal areas, the reference frames show a limited degree of temporal evolution. The stronger presence of mixed coding at early task stages could reflect the early involvement of V6A in eye-hand coordination, whereas the increase in spatiotopic representations towards movement execution could be related to its role in online movement control.

Title: Using sponstaneous behaviour to interrogate the mouse visual system: a proof of concept

Authors: ***R. STORCHI**, R. A. BEDFORD, F. P. MARTIAL, J. WYNNE, R. J. LUCAS; Univ. of Manchester, Manchester, United Kingdom

Abstract: Mouse spontaneous behaviour is strongly affected by visual cues and by ambient light (irradiance). Their natural tendency to explore new environments and follow simple visual stimuli allowed researchers to use them to measure the acuity of visual perception and to assess the effect of genetic treatments [1-3]. However our understanding of how mouse spontaneous behaviour is driven by vision is still limited to locomotion or pre-specified behaviours. A more thourough comprehension would provide fundamental insights into how the visual system integrates and processes complex natural visual stimuli and how mice make use of it to survive outside a laboratory. Moreover it would also be important to increase the sensitivity of behavioural tests to assess the effects of treatments aimed at restoring vision. In the present work we target two fundamental limitations of current behavioural analyses: low dimensionality and reliance on cumulative measures. Low dimensional movement tracking, typically based on a single body point, dramatically reduces the number of behaviours that can be discriminated. We increase the dimensionality by combining non-invasive body markers and nonlinear dimensionality reduction. Reliance on cumulative measures (e.g. total distance travelled or average locomotion speed) provides a single number summary of complicated dynamics and averages out potentially important events which may last only a small fraction of the time windows considered. We use multivariate change point analysis to segment the behavioural time series and identify an optimal set of distinct behavioural modules. We show that our technique allows us to get quick and precise measurements of mouse irradiance responses and spatial acuity. **References:** [1] Abdeljalil J et al (2005). Title: Modulating inter-hemispheric coherence to influence behavior - a TMS-EEG study

Authors: N. THIRUGNANASAMBANDAM, *M. HALLETT;
Human Motor Control Sec, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Inter-hemispheric coherence (IHC) is one of the EEG parameters that measures synchronization of oscillations originating from brain regions of different hemispheres and thereby the functional connectivity between them. We know that IHC is critical for tasks such as midline object recognition that involves merging information obtained from the 2 hemispheres. In a previous study, it was observed that midline object recognition is associated with transient increase in IHC over temporo-parietal areas in the alpha frequency range (Mima et al., 2001). Whether this association is causal, remains unknown. In the current study we aimed at determining the causal association of inter-hemispheric alpha coherence to midline object recognition. Several studies have used TMS as an effective tool to entrain intrinsic brain oscillations. We interfered with the IHC by using unilateral or bilateral, synchronous or asynchronous repetitive transcranial magnetic stimulation (rTMS) pulses. Our hypothesis was that asynchronous rTMS would reduce IHC thereby impairing midline object recognition.
We recruited 13 healthy subjects for the study. All subjects first participated in a screening session where the threshold intensity for blocking object recognition and the optimal coil orientation for TMS were determined using single pulse TMS. In the main experiment session, they were asked to perform the object recognition task in four blocks. During the first block, the individual alpha coherence frequency was determined by recording EEG during object recognition. During the second, third and fourth blocks rTMS was delivered in every trial with simultaneous EEG recording. Trains of 7 TMS pulses were administered over left and/or right lateral occipital gyrus at 80% of threshold intensity blocking object discrimination or 60% maximum stimulator output whichever was smaller.
Our primary outcome measure for the object recognition task was d' (d-prime or sensitivity index). Our results have not shown a significant effect of rTMS on object recognition. The EEG

data is currently being analyzed to look for entrainment effects. We think that this absence of effect on behavior could be due to a ceiling effect in task performance, wrong stimulation site or sub-optimal stimulation paradigm. We are currently performing additional experiments to address the above issues.

Title: Direction-selective units in the frog's basal optic root nucleus and its role in gaze stabilization in prey-catching behavior

Authors: *V. A. BASTAKOV[1], O. Y. ORLOV[1], E. I. KISELEVA[2];
[1]Inst. For Info Transmission Problems RAS, Moscow, Russian Federation; [2]A.N. Severtsov Inst. of Ecology and Evolution RAS, Moscow, Russian Federation

Abstract: Electrophysiological responses from 91 direction-selective (DS) units located in the basal optic root (nBOR) and the adjacent dorsomedial area have been recorded extracellularly in the frog (*Rana temporaria* L.). Based on characteristics of the recorded responses, 23 of the units are considered to be retinal ganglion cells' (RGC; axon terminals). The majority of the remaining 68 units were considered to be DS neurons of the nBOR. The results of our study suggest that in the nBOR area there might be four subtypes of the tegmental and retinal DS units that respond selectively to stimuli moving in the dorso-ventral, ventro-dorsal, caudo-rostral and rostro-caudal directions. The receptive field (RF) sizes of the nBOR DS neurons were estimated to be about 30-60°, while those for the retinal units were significantly smaller - just 6-8°. In response to abrupt darkening within the units' RFs, both the nBOR DS neurons and the RGC DS units respond by a weak discharge. Our results indicate that the frog nBOR DS neurons integrate the inputs from the retinal OFF-type DS units over relatively large segments of the visual field.It will discuss the role of retinal projections to the nBOT in gaze stabilization in frog prey-catching behavior.

Title: Behavioral and cognitive changes following lateral posterior thalamic nucleus lesion

Authors: *R. M. CYSNEIROS[1], L. C. AURORA[2], F. A. SCORZA[2];
[1]Univ. Presbiteriana Mackenzie, Sao Paulo, Brazil; [2]Federal Univ. of São Paulo, São Paulo, Brazil

Abstract: Lateral posterior (LP) thalamic nucleus is part of the cortical–basal ganglia–thalamic–cortical network and appears important for various functions involved with spatial processing related to directed attention, including emotional stimuli. We studied cognitive and behavioral changes in male Wistar rats submitted to unilateral electrolytic lesion of the LP at 60 days post-natal. The behavioral tests started 7 days after surgical procedures. In open field, LP group exhibited higher time of immobility ($F[1,18] = 19.07$; $p = 0.0018$) and self-grooming episodes than SHAM group ($F[1,18] = 15.3$; $p = 0.0036$, respectively). In central zone, LP group exhibited reduced locomotor activity ($F[1,18] = 31.6$; $p = 0.0003$) and time spent ($F [1,18] = 27.29$; $p =0.0005$) as compared to SHAM group. In elevated plus maze, for percentage of time spent and number of entries into the open arms significant differences were observed between groups ($F[1,9] = 132.1$; $p < 0.0001$, $F[1,9]= 7.02$; $p <0.001$, respectively), with no difference for total locomotion ($F[1,9] =0.46$; $p = 0.52$). In the social approach phase of the sociability paradigm, for time spent in the compartments with social and non-social stimuli, significant differences were noted between compartments ($F[1,9]= 83.9$; $p = 0.0001$) and effect of interaction between factors ($F[1,9] = 9.96$; $p = 0.0116$). Both groups exhibited preference for the social stimulus, but LP group showed less discrimination as compared to SHAM group ($t = 4.44$; $p<0.01$ e $t = 8.34$; $p<0.001$, respectively). In the social novelty phase, for time spent in the compartments with familiar and unfamiliar conspecific, significant differences were observed between groups ($F[1,9] = 11.76$ $p =0.0075$) and effect of interaction between factors ($F[1,9] = 11.76$ $p =0.0075$). LP group spent more time with familiar animal as compared with social novelty. For social contacts, it was noted effect of interaction between factors ($F [1, 9] =72.73$; $p < 0.0001$). LP group exhibited more social contacts towards to familiar animals as compared to social novelty, and opposite behavior was observed in SHAM group. In operant conditioning box, SHAM group learned to press the right bar in the first session and the LP group completed the task between the second and fourth sessions, ($\chi^2 = 8{,}049$; $p =0.0046$). For reversal learning, SHAM group learned to press the left bar between first and second session and the LP learned between the third and fourth sessions ($\chi^2 = 9{,}747$; $p =0.0018$). The data suggest that the LP lesion leads to anxiety

related behavior, social behavior impairment, stereotypic behavior, deficits in visual conditional associative learning and the cognitive flexibility.

Title: Neural representation of a threat stimulus in the early visual system

Authors: ***K. LEE**, Z. TURAN, M. MEISTER;
Caltech, Pasadena, CA

Abstract: The mouse shows a rapid, innate defensive response to an overhead expanding black disc that mimics an approaching predator: the animal freezes in place or escapes to a shelter. Driven purely by the visual stimulus, this “looming reaction” provides an opportunity to study how sensory information is transformed to motor output by brain circuits.
Where in the visual system is the looming feature first detected and discriminated from innocuous visual events? It has been suggested that the Off-transient alpha ganglion cell in the retina serves this function (Munch et al. 2009), but recent work shows that this cell type still fires promiscuously during many other episodes encountered in mouse natural vision. Thus the looming detector may lie downstream of the retina, perhaps in the superior colliculus (SC), a layered midbrain area important for sensorimotor transformation.
The superficial layer of the SC serves as the gateway for visual input from the retina but how it represents visual stimuli is poorly understood. Here we study the convergence of retinal input onto the SC by transsynaptic retrograde tracing from genetically identified sSC neurons. We then explore the neural representation of visual stimuli by recording from an awake mouse with silicon neural probes that span all layers of the SC. In the superficial SC we report neurons with diverse visual response properties that collectively encode many different stimulus features. In the deeper layers we find certain neurons with a pronounced response to the onset of the black expanding disc, but not to many innocuous stimuli that fail to elicit a looming reaction. We

suggest that the neural computation of a looming threat emerges in the interlaminar circuitry between the superficial and deeper layers of the SC.

Title: Spatial and temporal extent of single pulse Transcranial Magnetic Stimulation on single-cell activity in alert macaque monkeys.

Authors: ***M. C. ROMERO**, M. DAVARE, P. JANSSEN;
KULeuven, Leuven, Belgium

Abstract: Transcranial Magnetic Stimulation (TMS) is a safe, non-invasive brain stimulation technique that can induce electric currents in the brain. Despite its extensive use both in the clinical practice and cognitive neuroscience, very little is known about the spatial and temporal extent of TMS effects on single neurons. To study the TMS influence on neuronal activity, we performed simultaneous TMS and electrophysiological recordings in parietal area PFG of two macaque monkeys during a visually-guided grasping task (VGG). We measured the changes in neuronal activity in a region located directly under the center of stimulation, and analyzed the spatial (7 mm antero-posterior, 3 mm medio-lateral and 6 mm dorso-ventral) and temporal extent of TMS effects. In the stimulation trials, single TMS pulses were applied either at 60% (low intensity) or at 120% (high intensity) of the motor threshold. With this protocol, we recorded 378 PFG neurons in two animals and quantified the net evoked activity, comparing the average response of all neurons tested with high intensity TMS before (-70 to -30 ms) and after (30 to 70 ms) stimulation to the same intervals in the absence of stimulation. Single pulse TMS caused a short-latency excitation in PFG neurons, which emerged around 20 ms after stimulation, and lasted for approximately 50-80 ms. Surprisingly, this excitatory effect of TMS was significant (t-test post- versus pre-stimulation interval) in only a single recording position in both monkeys. In this center of stimulation, TMS evoked a significant burst of activity in a substantial number of

neurons (t-test, 25/46, 54% in monkey 1; 21/50, 42% in monkey 2). The net TMS-evoked activity averaged 16.7 (monkey 1) and 30.9 (monkey 2) spikes/sec at the center of stimulation. Even in neighboring recording positions (located 1 or 2 mm away from the center of stimulation, both in the anterior-posterior and medio-lateral directions), TMS did not induce a significant change in activity (average evoked activity less than 10 spikes/sec). Finally, behavioral analyses of the VGG task revealed that single-pulse TMS applied over PFG during the reach-to-grasp movement caused a significant increase in the grasping time in both monkeys. Thus, single-pulse TMS over parietal cortex causes a robust, transient burst of activity in single neurons which is remarkably local, providing the first validation of the effect of single-pulse TMS on single neurons during behavior.

Title: The role of the serotonergic system in short-term motor learning in larval zebrafish

Authors: ***T. KAWASHIMA**, C.-T. YANG, B. D. MENSH, M. B. AHRENS;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: To execute accurate movements, animals must continuously adapt their behavior to changes in their body and the environment. Animals can learn changes in the relationship between their locomotor commands and the resulting displacement of the body, then adjust command strength to achieve a desired locomotion. It is largely unknown which circuits implement this form of motor learning. We use whole-brain neuronal imaging and circuit manipulations in larval zebrafish to perform a functional screen of brain regions involved in short-term motor learning. We find that the serotonergic system, in particular the dorsal raphe nucleus, stores a memory of learned motor drive that builds up during training. We identify the motor and sensory signals that drive the formation of this memory, and demonstrate causal relationships between raphe activity and behavior.

Title: Probing a sensorimotor transformation in dorsomedial frontal cortex using electrophysiology and optogenetics

Authors: *E. D. REMINGTON[1], E. A. HOSSEINI[1], M. JAZAYERI[1,2];
[1]McGovern Inst. for Brain Res., [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: A central question in neuroscience is how the brain uses sensory inputs to generate appropriate motor outputs. A recent study used a time interval reproduction task in monkeys to address this question (Jazayeri and Shadlen 2015). Results were consistent with a "preplanning" model in which the brain uses an estimate of elapsed time during the measurement of an interval to compute an ongoing motor plan. However, to test the preplanning model more definitively, it is important assess how the same sensory input can be used to plan different motor responses. Therefore, we designed a variant of the time interval reproduction task in which the relationship between the measurement and production intervals varied between two contexts. In the first context, monkeys had to reproduce the sample interval, similar to the previous study. In the second context, monkeys had to produce an interval that was 50% longer than the sample interval. In other words, the two contexts had similar sensory information but required the animal to apply two different gain factors to compute the appropriate motor plan. We recorded activity in dorsomedial frontal cortex (dMFC) of monkeys measuring and producing time intervals in alternating blocks of trials associated with the two behavioral contexts. dMFC responses in the measurement and production epochs were modulated by elapsed time. Consistent with the preplanning model, the gain factor influenced neural responses during the sensory measurement and the magnitude of the effect was time dependent. To gain further insight into the nature of dMFC signals and to test their causal effect on behavior, we perturbed neural activity in dMFC using optogenetics. We transduced dMFC neurons using a virally mediated red-shifted chloride pump (JAWS, Chuong et al. 2014) that enabled us to modulate activity at multiple time points during the task. In our initial tests with brief optical stimulations, we were able to perturb responses of a substantial fraction of neurons (n = 48/221) in the vicinity of the injection sites. However, these effects were largely limited in time to the stimulation intervals, and stimulation

had no significant effect on task performance. We therefore used a stimulation protocol in which we targeted a larger volume of dMFC for longer durations, which enabled us to influence behavior reliably. Ongoing work aims to use this protocol to further examine how activity in the measurement epoch is used to generate the appropriate motor plan in the production epoch.

Title: Anatomy and function of an inter-hemispheric neural circuit in the zebrafish optic tectum

Authors: ***C. GEBHARDT**[1], T. O. AUER[1], K. DUROURE[1], I. H. BIANCO[2], F. DEL BENE[1]; [1]Ctr. de Recherche, Bat. BDD, Equipe Del Bene, Inst. Curie, Paris, France; [2]Dept. Neurosci., Physiol. & Pharmacol., UCL, United Kingdom

Abstract: The optic tectum is the main retino-recipient brain structure in zebrafish and as such each tectal hemisphere receives direct input exclusively from the contralateral retina respectively. Based on observations of the behavior of zebrafish larvae during capturing of prey, like e.g. paramecia, it is likely that visual signals coming from both eyes of the animal have to be integrated e.g. for efficient hunting (Bianco et al. 2011, Bianco et al. 2015) but the neural substrate for binocular integration is as of yet unknown.
We recently identified a zebrafish line that specifically expresses the trans-activator Gal4 in a novel, previously undescribed neuron population in the visual system of the zebrafish. Using transient UAS:GFP-expression for single-cell labeling in this zebrafish line, we find these neurons to be bilateral-symmetrically distributed directly adjacent to the ventral tectum.

Furthermore, they send their axons through and form arbors in both tectal halves and were thus termed intertectal neurons (ITNs). ITNs are therefore good candidates for the potential transfer and/or the integration of visual signals originating from both eyes.
First, we described the anatomy and temporal development of the ITN neurons and their connections, i.e. their axon trajectories and arbors, potential up- and downstream neurons, the development and distribution of the ITN synapses and also their neurotransmitter type.
Second, to physiologically describe a potential intertectal signal transfer, we performed unilateral eye-ablation at 2dpf and subsequently 2photon-Ca-imaging at 5-6dpf. We observed Ca-transients in the tectal hemisphere not receiving any retinal input that were nevertheless time-locked to the presented visual stimuli. Moreover, these transients were co-localized in the tectum with the position of ITN arbors originating from the contralateral ITNs. Furthermore, we established that ITNs themselves respond to a wide range of visual stimuli including looming stimuli and direction selective bars.
Finally, we tried to understand the role of the ITNs during behavior. To this end we unilaterally ablated genetically stained ITNs using 2photon imaging and subsequently examined free-swimming behavior parameters using a high-speed camera in ablated vs. ctrl fish.
In summary, we anatomically describe novel inter-hemispheric neural connections in the zebrafish visual system and aim to establish their role in inter-tectal visual signal transfer as well as their functional role during behavior.

Title: Probing and modeling the causal role of mouse cortical areas in visual discrimination

Authors: *P. ZATKA-HAAS, N. A. STEINMETZ, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Perceptual decisions depend on an interaction between physical stimuli and internal variables such as bias and sensitivity. To investigate the causal role of cortical regions in this interaction, we performed optogenetic inactivation in multiple regions of mouse cortex during a visual discrimination task.
Mice were trained on a two-alternative unforced choice task (Burgess et al, *bioRxiv* 2016). After an auditory cue, grating stimuli of variable contrast appeared in the left and right hemifields. Mice were rewarded for turning a steering-wheel to indicate which hemifield contained a stimulus of higher contrast, or for refraining from turning the wheel (a "no-go" choice) if no stimulus was present in either hemifield. We implanted a head post and transparent skull cap in mice expressing ChR2 in Pvalb-positive cortical interneurons and trained them on the task. On a random subset of trials, a 473 nm laser mounted on a motorized manipulandum inactivated a single site, randomly chosen out of 52 sites over the cortex.
We quantified the mouse's behavior and the effects of focal inactivations using a generalized linear model. This model fits the probabilities of choosing left, right, or no-go in terms of parameters representing bias (b_L,b_R) and stimulus sensitivity (s_L,s_R). The model was expanded to incorporate additive effects of optogenetic inactivation on the bias and sensitivity parameters at different cortical sites. The parameter fits thus estimate the effect of inactivation on these perceptual attributes.
We found that inactivation in primary and secondary visual areas, and secondary motor cortex, reduced unilaterally the bias terms b_L and b_R. This effect corresponds to a choice bias away from contralateral stimuli. We also found that inactivation of primary visual cortex reduces the sensitivity to contralateral stimuli, reflected in a decrease in s_L and s_R. For other cortical regions there was little effect.
These results demonstrate that visual cortex and a subregion of secondary motor cortex are required for the mouse to discriminate visual stimuli based on contrast. Inactivation of either region caused a bias, but only visual cortex determined sensitivity. These findings prepare us to investigate these areas in greater detail, to further uncover the causal neural structures that drive visual discrimination.

Title: Adaptation of perception of upright during prolonged head tilts is not mediated by changes in torsion

Authors: *J. OTERO-MILLAN[1], A. KHERADMAND[2];
[1]JOHNS HOPKINS UNVIVERSITY, Baltimore, MD; [2]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Torsional eye movements are rotations of the eye around the line of sight and they occur when we tilt our head towards the shoulder. Perception of upright is usually assessed by a psychophysical task known as subjective visual vertical (SVV) which quantifies the orientation of a visual line that a subject perceives as aligned with the direction of gravity. Torsional eye movements change the orientation of the visual stimulus on the retina thus playing a critical role in our perception of upright. Previous studies have shown that both torsion and SVV can drift over time during prolonged head tilts. Here we directly compared the amount of drift of torsion and drift of SVV during continuous recordings of 15 minutes. We used a novel video tracking method to measure torsion and an adaptive paradigm to continuously measure SVV. Both SVV and torsion were also measured after subjects were brought back to upright position to study any aftereffect caused by the prolong head tilt. We found that torsion always drifted towards zero (the eye position during upright) by an average of 0.8 degrees and between 0 and 3 degrees depending on the subject. SVV, on the other hand, was much more variable across subjects with a drift ranging from 0 to 10 degrees and an average of 5 degrees towards the direction of the head tilt. After the head was brought back to upright position, there was a significant SVV aftereffect of 4 degrees in the same direction as the drift. There was a trend in the aftereffect in torsion but was not significant and only 0.2 degrees on average. The amount of drift in torsion and SVV was not correlated across subjects, nor it was the aftereffect. That is, subjects with larger torsional drifts or aftereffects did not necessarily have larger SVV drifts or aftereffects. Our results show that the drift in upright perception during head tilt and the aftereffect are not due to changes in torsional position of the eyes.

Title: Anodal tDCS stimualtion over mIPS improves online control in reaching

Authors: *A. GOETTKER[1], S. XU[2], K. FIEHLER[1], G. BLOHM[2];
[1]Justus-Liebig-University, Giessen, Germany; [2]Ctr. of Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Goal-directed reaches can become inaccurate due to multiple reasons, e.g. sensory noise or changes in the environment. Therefore, the human brain uses an online-control system to correct for movement errors and lead the hand precisely to a target. The posterior parietal cortex (PPC) seems to be crucially involved in online corrections during reaching. When transcranial magnetic stimulation is applied to the PPC, no corrections to sudden changes in target position occur; similar to patients with bilateral lesions in the PPC (Desmurget et al., 1999; Grea et al., 2002).

We wanted to investigate the role of the middle intraparietal sulcus (mIPS) for online corrections during reaching. By using high-definition transcranial direct current stimulation (HD-tDCS) we set out to alter the activity in the mIPS and examined the behavioral effects due to anodal or cathodal stimulation. Subjects took part in the experiment on two days, one with anodal and one with cathodal stimulation. The experiment was divided into 3 sessions: Baseline, Stimulation, Post-Stimulation. Each session included 4 blocks. Each block consisted of 80 trials, 20 each to a left or a right located target and 40 to a central one. On half of the trials to the central target, the target was jumped at hand movement onset to the left or right target location. We measured the curvature of movements to jumping targets and the latency of online correction for hand and eye movements.

The polarity of stimulation significantly changed the curvature of the online correction movements, across sessions. Reaching movements were less curved for anodal stimulation during stimulation and post-stimulation, reflecting better online corrections; they did not change

with cathodal stimulation. In addition, we quantified the influence of stimulation on the online correction latencies for hand and eye movements as the difference between the baseline and each of the upcoming sessions and compared the effects for the polarities. We found that the size and direction of these effects were highly correlated between the hand and eye movements.
In summary, anodal stimulation, which presumably increased mIPS excitability, led to smoother online correction movements. Our results provide further evidence for a crucial role of the mIPS and PPC in general in online correction for reaching. Furthermore, the correlation between the effect of stimulation on the online correction latency of hand and eye movements suggests a common mechanism for both effector systems. This mechanism may be associated with the updating of target locations (Gaveau et al, 2008) or the coupling between effectors during eye-hand coordination (Bowman et al., 2009).

Title: Facilitation of visual-motor response by increasing alpha phase synchronization between visual and motor areas by tACS / tDCS

Authors: *M. KAWASAKI[1,2], Y. HENMI[1];
[1]Univ. of Tsukuba, Ibaraki, Japan; [2]RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Numerous electroencephalograph (EEG) evidence indicates the important role of sensory-motor phase synchronization in integrating several functions on achievement of stimulus related response. However, it is not well known about the causal relationship, namely, whether or not the observed EEG phase synchronization really induces the behaviors. Using transcranial alternative / direct current stimulation (tACS / tDCS) method to manipulate the effective connectivity in oscillatory sensory-motor networks, we estimate the modulation of the EEG synchronization and that of the sensory-motor response time. First, we confirmed the beta (about 20Hz) and alpha (about 10Hz) phase synchronizations between the visual and motor areas, which is consistent with previous findings. Second, the beta and alpha phase synchronization increased

after the 20 Hz and 10Hz tACS was applied to the visual and motor areas, respectively. Interestingly, the response time after the 10Hz tACS was faster than before the tACS, and the facilitated performance was significantly correlated with the enhancements of alpha but not beta phase synchronization. Finally, the electronic current flows from the input visual area to the output motor area (i.e. in case of the cathodal tDCS to the motor area and the anodal tDCS to the visual area) facilitated the alpha phase synchronization and the response time. These results strongly indicate that the alpha phase synchronization is crucial in mediating effective connectivity among oscillatory network and in facilitating the sensory-motor reaction.

Title: Transient representation of pre- and post-saccadic information in motion areas MT and MST: a possible neural basis of chronostasis

Authors: *H. KUMANO[1,2], S. KITAZAWA[1,2,3];
[1]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [2]Ctr. for Information and Neural Networks (CiNet), Osaka, Japan; [3]Dept. of Brain Physiol., Grad. Sch. of Medicine, Osaka Univ., Osaka, Japan

Abstract: During each saccade, visual information is largely lost due to a retinal slip, yet we perceive the visual world as continuous in time. This means that the gap duration is filled with some information. A well-known temporal illusion, chronostasis, suggests that the brain fills the gap duration with post-saccadic visual information (Yarrow et al., 2001). However, this temporal filling-in does not occur when visual information is altered during the saccade. This led us to hypothesize that the brain preserves pre-saccadic visual information until after the saccade for comparison so as to determine whether to fill in the gap or not. In this study, we aimed to test the hypothesis by studying neural responses in motion areas MT and MST around the time of saccades. We recorded extracellular activity of single neurons in areas MT and MST, while two macaque monkeys performed a visually guided saccade task. In each trial, monkeys made a 10-degree saccade toward a visual target that appeared on a tangent display in one of four directions (up, down, left, and right). The display (120 x 90 degrees) was divided into a six-by-nine or five-

by-eight grid of subfields. Within each subfield, a random-dot motion was presented in one of four directions at random: a preferred direction, an anti-preferred direction, and two orthogonal directions. The direction within each subfield was updated every 50 ms. We quantified information about stimulus direction (two bits at a maximum) encoded by spikes of each neuron during a 10-ms time window, which was moved along the peri-saccadic period from -300 ms (before) to +300 ms after the saccade. Neural discharges of MT and MST neurons generally encoded information on motion with a fixed latency of around 50 ms. However, spikes lost any information during an early post-saccadic period from +30 to +70 ms, then at around +80 ms they transiently encoded pre-saccadic information at -80 ms in addition to the default information at +30 ms with the fixed delay. The results clearly show that MT and MST neurons represent visual information just before and just after saccades during the transient post-saccadic period. We infer that the pre- and post-saccadic information during the short post-saccadic period is used for comparison to determine whether to fill in the temporal gap.

Title: Distributed neural prediction of prey motion in amphibians

Authors: *W. R. MOWREY, A. LEONARDO;
Janelia Farm Res. Campus, Ashburn, VA

Abstract: Prediction is a fundamental task of animal nervous systems, but the computations that underlie prediction are largely unknown. Recent work has shown that amphibian tongue projections compensate for phototransduction and head movement delays by extrapolating prey motion (Borghuis and Leonardo, 2015). One hypothesis is that this extrapolation occurs in the retina, as activity in amphibian fast-OFF retinal ganglion cells has been shown to predict object motion (Berry *et al.*, 2013). A tracking estimate to guide the tongue could be extracted from fast-OFF population activity by a population vector average (PVA); if so, tongue projections will have characteristic prey size- and speed-dependent errors arising from fast-OFF cell population dynamics (Leonardo and Meister, 2013). We tested this by presenting toads (*Anaxyrus terrestris*) with artificial prey and recording prey-capture kinematics with high-speed video. Consistent with

fast-OFF/PVA tracking, we find that tongue projections are systematically biased ahead-of-center for prey elongated in the direction of motion. We measured the total visuomotor delay that is compensated by neural prediction by presenting toads with prey that unpredictably reversed direction. The reaction to these reversals shows that prey-capture is not ballistic, as often assumed, but under continuous control from delayed visual signals. Under photopic conditions this reduces the total visuomotor delay by half as compared to ballistic behavior, simplifying prediction. However, toads often hunt under low-light conditions where visual latency can increase dramatically, leading us to ask whether these animals used specific knowledge of the visuomotor delay to predict the prey's future position. We find that dark-adapted animals fail to compensate for increased retinal latency, suggesting that animals can only approximate the system delay. Finally, we tested the ability of toads to use prey velocity information to predict the prey's future position. In contrast to the speed-dependence of the fast-OFF/PVA model, we find that tongue projection accuracy is unchanged over a 4-fold range of prey speeds. Thus, it is likely that additional predictive computation in the brain uses prey velocity information to correct for speed-dependence in retinal tracking. Together, our work shows that distributed neural prediction corrects for prey motion during a visuomotor delay that is minimized by continuous visual control. This prediction accurately corrects for a wide-range of prey velocities, but not for variations in the delay itself.

Title: Contribution of dorsal pulvinar to visuomotor behavior and spatial decision-making

Authors: *I. KAGAN[1], A. U. DOMINGUEZ-VARGAS[1], L. SCHNEIDER[1], L. GIBSON[1], M. WILKE[1,2];
[1]German Primate Ctr., Goettingen, Germany; [2]Dept. of Cognitive Neurol., Univ. Med. Goettingen, Goettingen, Germany

Abstract: Evolutionary history and anatomical connectivity of the thalamic dorsal pulvinar suggest its involvement in visuomotor processing and coordination of eye and hand movements. However, since classical visuomotor tasks rarely have been employed in studies of the pulvinar, little is known about its function in goal-directed behaviors. We investigated spatial and effector specificity of neuronal responses in the dorsal pulvinar in two rhesus monkeys performing visually-guided, delayed/memory saccades and free-gaze/eye-hand dissociated delay reach tasks to instructed and chosen locations. Effective connectivity and effects on spatial tuning in interconnected cortical areas of a given pulvinar site were probed by a combination of electrical microstimulation and fMRI. Pulvinar microstimulation potentiated contraversive BOLD signal representations in frontoparietal and temporal cortices. Correspondingly, it led to spatially-specific reaction time and saccade choice changes consistent with overall contraversive "drive", but contingent upon the timing of stimulation and behavioral state imposed by the task. In saccade and reach tasks, dorsal pulvinar neurons exhibited diverse patterns of spatial tuning in cue, delay/memory, pre-, peri- and post-movement epochs; the tuning, as well as the sign of effect (facilitation or suppression) often differed across task epochs. Notably, many cells were modulated by the gaze position and exhibited spatial tuning only after the saccade execution. In saccade tasks across the sample (N = 404), we found no or weak contralateral spatial tuning for either visual cues or oculomotor responses. Thus, no systematic visual or oculomotor map was derived. Some cells were active during fixation but paused during saccades, similar to cells in the superior colliculus. Neurons investigated with reach tasks (N = 110) often showed left/right hand specificity and/or interaction between space and hand variables. Furthermore, visual and saccade-related responses exhibited hand-specific modulations even when a hand was positioned fixedly on the screen throughout entire trial, implying postural interactions. Taken together, our results suggest that hemifield-specific effects of pulvinar inactivation and stimulation are predominately due to its influence on contralaterally-tuned cortical and subcortical regions. The modulation of pulvinar responses by gaze and hand contingencies supports its contribution to coordination of visually-guided actions and transformations between spatial reference frames.

Abstract: The ferret is an important model for studying brain connectivity due to its elaborate behaviour and well studied physiology. Studies have mapped the cortico-cortical connectivity of the extrastriate cortex and the auditory cortex in the ferret, but none have examined the posterior parietal cortex.
Biotinylated dextran amine (BDA) was injected into the medial and lateral rostral (PPr) and caudal divisions (PPc) of the posterior parietal cortex of the ferret to visualize anterograde and retrograde connectivity of these areas as well as afferent and efferent connections with the dorsal thalamus.
The PPr and PPc in the ipsilateral hemisphere displayed very dense retrograde and anterograde connectivity within these regions as well as the closely surrounding visual regions. The retrograde connectivity tapers off towards the more distal regions while the anterograde connectivity is observed as numerous dispersed clusters of low to moderate terminal networks throughout the cortex. The retrograde and anterograde connectivity of the PPr shows a larger propagation towards the somatosensory and motor cortices than the PPc, which is expected as the PPr receives visual and somatosensory input. The anterograde connectivity of both the PPr and PPc within the contralateral hemisphere displayed the similar extend of weak to moderate 'patchiness' as seen in the ipsilateral hemisphere. Contralateral retrograde connectivity was observed in both the PPr and PPc but the density of these connections were less intense than that observed in the ipsilateral hemisphere and the distribution less dispersed. Furthermore, the distribution of the retrograde connectivity of PPr was confined to the primary motor and somatosensory cortices as well as the posterior parietal cortex whereas that of the PPc extended to the extrastriate cortex. The PPc displayed a more dispersed degree of cortical afferents to the dorsal thalamus than the PPr, however both cortices displayed efferent projections to the thalamus that appeared as bands of moderately dense terminal networks within the lateral posterior, ventral anterior nuclei and pulvinar nuclei. These bands were each enclosed by a halo of weak to moderately dense terminal networks.
Further connectivity studies are necessary to add to the existing cortical 'ferretome' and thus aid modeling of brain connectivity across species.

Title: Transient inhibition of the cerebellum modulates processing of somatosensory input

Authors: *D. ANDREW, R. J. IBEY, W. R. STAINES;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Sensorimotor integration (SMI) enables effective responses to sensory stimuli via performance of appropriate motor actions. Cortical contributions to SMI are well established, however subcortical inputs are often neglected or yield inconsistent activity patterns. The cerebellum is emerging as a principle candidate for evaluation of incoming stimuli prior to relaying this information to the somatosensory cortex. Cortical activity associated with stimuli evaluation can be measured using the mismatch negativity (MMN), a response reflective of pre-attentive detection of changes elicited in the 120-180 ms latency range in response to deviant stimuli interspersed amongst frequent stimuli. Typically this is observed fronto-temporally in response to auditory stimuli. Investigation of this response to somatosensory stimuli (S-MMN) has identified abnormalities in the MMN in unilateral cerebellar lesion patients. While this provides a unique population from which to measure responses in affected and unaffected hemispheres, lesion variability may affect results. Therefore, to validate the presence of cerebellar input in the earliest moments of sensory processing, the MMN to somatosensory stimuli was assessed pre and post transient inhibition of cerebellar output. As a secondary outcome of interest, the N24, an early latency peak hypothesized to have cerebellar inputs, was also measured. To do this, continuous theta burst stimulation (cTBS) was performed on the lateral cerebellum ipsilateral to the dominant hand. Participants received frequent and deviant stimulations to the median nerve and on the 5^{th} digit respectively in an oddball paradigm delivered pre and post cTBS. Post blocks were delivered at 3 time points following cTBS (Post 1,2,3 - 0,10,20 min). Scalp responses were averaged and measured using a 64 channel EEG cap. Preliminary results demonstrate a large negativity in response to deviant stimulation pre cTBS in the 120-180 ms latency range, this appears parieto-occipitally. Following application of cTBS, there is a blunting of the MMN such that responses to frequent and deviant stimuli appear similar; this effect is maximal in the Post 3 block. The N24 demonstrates an amplitude decrease apparent during Post 2 and Post 3 time points. Present data indicate that cerebellar processing is crucial for pre-attentive detection of changes in incoming sensory information; evidence of cerebellar input in early latency peaks is also provided. Validating the presence of cerebellar

input for early sensory processing in a healthy population can provide insights into investigating cerebellar abnormalities in aging and disorders with behavioural anomalies.

Title: Sensorimotor circuit function in orientation and aversion - a common vertebrate plan

Authors: *A. A. KARDAMAKIS, T. WIBBLE, D. SUZUKI, J. PEREZ-FERNANDEZ, S. GRILLNER;
Karolinska Inst., Stockholm, Sweden

Abstract: Sensory-based decisions for redirecting gaze involve the interaction of subcortical and cortical circuits. The optic tectum (superior colliculus in mammals) is central for multisensory integration and motor control of gaze movements (both orienting and aversive). The interaction between multisensory afferent inputs, the basal ganglia and cortex with local tectal circuits play a determinant role in guiding gaze - the synaptic integration of which *remains unknown* on the cellular, synaptic and circuit level.
We have previously shown using the lamprey that the tectal GABAergic system is necessary for generating visual stimulus selection through a process of local excitation and global inhibition for the direct regulation of activity in brainstem projecting neurons (Kardamakis et al., 2015). We found that retinotopic recruitment of GABAergic neurons across the tectum is integrated directly by tectal output cells. Recently, we have also shown that two senses (visual and electrosensory) converge onto the same output neurons with monosynaptic excitatory connections, and that the evoked synaptic currents from the two inputs summate thus potentiating each other when they are aligned in space and time (Kardamakis et al., *review*). Our overarching goal is to map the set of stimuli and afferent synaptic inputs arising from the basal ganglia output nuclei and other forebrain inputs including the pallium (mammalian

homologue of cortex) that selectively activate either contralateral or ipsilateral tectal-brainstem output channel responsible for orienting and aversive gaze movements.
Here, we have developed an isolated preparation that maintains eyes, brain and spinal cord intact enabling us to simultaneously monitor neural responses from the optic nerve, optic tectum, extraocular muscles and ventral roots, while delivering visual stimuli ranging from dots, bars and looming in a computer-controlled environment.
We recorded single units from motoneurons and bursts of ventral root activity in response to dark looming stimuli in the upper visual field in the rostral spinal segments - reflecting episodic fictive head movements that are aversive (*n = 6*). When smaller stimuli are used, phase-tonic activity was recorded unilaterally indicative of an orienting gave movement (*n = 3*). Neural correlates of these gaze reorientation commands were identified by monitoring optic nerve, deep layer tectal and reticulospinal activity during visual stimulation, enabling us to apply pharmacological perturbations to forebrain/midbrain structures including striatum, pallium and pretectum to determine their involvement in shaping this sensorimotor decision-making process.

Title: Near and far response cell activity associated with combined saccade-vergence eye movements

Authors: *A. PALLUS[1], M. M. G. WALTON[2], M. J. MUSTARI[2,1];
[1]Ophthalmology, Univ. of Washington, Seattle, WA; [2]Washington Natl. Primate Res. Ctr., Seattle, WA

Abstract: Accurate control of eye movements is critical for humans and other primates who rely on vision to survive. Saccades are conjugate when they occur between equidistant targets, while vergence eye movements rotate the eyes in opposite directions to effect changes in the depth of fixation. This is essential for accurate binocular vision. Vergence eye movements are typically slow, but during saccades between targets at different depths, the vergence velocity is enhanced compared with similar amplitude movements occurring in the absence of saccades.
It is currently unknown whether the observed enhancement behavior is due to an interaction between the neural mechanisms responsible for saccade and vergence movements. Previous studies have identified neurons that may encode vergence velocity, but the activity of these cells has not been described during saccade-vergence movements, so it is unclear whether they encode the enhanced vergence velocity observed during saccades. In the nucleus reticularis tegmenti pontis (NRTP), neurons have been identified with activity related to saccadic eye movement, static vergence angle as well as vergence velocity, suggesting the region may be well positioned to encode saccade-vergence interactions.
In this study, we investigated the activity of individual neurons in the NRTP while monkeys made combined saccade-vergence eye movements to plus-shaped LED targets displayed at varying depths. Our experimental setup allowed for horizontal, vertical and oblique saccades with or without changes in depth. We recorded the activity 29 near and six far response cells in the NRTP of a rhesus macaque performing this task. Of these, 30/35 also showed a burst of activity during saccades with vergence changing in the preferred direction (29 convergent and one divergent), while 31/35 show a pause during saccades that changed vergence in the opposite direction. Most cells showed both pauses and bursts, with a minority only pausing (5/35) or only bursting (4/35).
We further compare these findings with previous recordings from our lab of 27 near and eight far response cells in the supra-oculomotor area (SOA). Only 5/33 neurons in SOA displayed a burst associated with saccades with on-direction intrasaccadic vergence but 26/33 showed a significant reduction in firing rate (below the post-movement baseline) associated with saccades with off-direction intrasaccadic vergence. These data indicate that the NRTP is more sensitive to intrasaccadic vergence velocity than the SOA, while static vergence angle is more strongly represented in the SOA.

Title: Mapping the polar angle representation of saccades in human superior colliculus

Authors: *R. R. SAVJANI, E. HALFEN, D. RESS;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Purpose: The superior colliculus (SC) is a layered midbrain structure involved in directing eye movements and coordinating visual attention. Electrical stimulation and neuronal recordings in the intermediate layers of monkey SC has revealed a retinotopically organized saccadic eye-movement map. However, the polar angle representation of saccades in ***human*** SC has not been well studied. We used high-resolution fMRI to map the representation of eye movements in human SC. **Methods:** We used a phase-encoding approach similar to previous human studies of saccadic mapping. However, these studies operated with a very low duty cycle (1 saccade every 5 s) and reverse saccades made immediately after forward saccades. We designed a novel paradigm in which subjects performed multiple forward saccades, then returned to the opposite visual field using guided smooth pursuit. Subjects made series of saccades either to left or right (activating primarily the contralateral SC) while we cyclically varied the vertical component of the cue to correspond to saccades in the lower, horizontal, and upper visual field. Attention was engaged via a target discrimination task at the end-point of every saccade and along smooth pursuit. Eight quasi-axial slices covering SC were imaged on a Siemens 3T Trio (2.4 sec/volume, 1.2-mm voxels). Each run consisted of 9, 28.8-s-duration cyclic repetitions of the 3 saccade directions; imaging sessions included 14—16 runs which were subsequently averaged. Sinusoids were fit to the data, yielding phase data that related the fMRI response to saccade angle. Phase encoding with moving-dot stimuli measured the polar-angle representation of the visual field in SC. **Results**: The expected lateral-to-medial phase progression was observed in all subjects (Fig). Also, we found the saccadic maps lie deeper in the SC (intermediate layers) and are in alignment with the more superficial visual-field retinotopy. **Conclusion**: Our techniques in psychophysics and imaging allow us to relate findings in non-human primates to human SC, strengthening our understanding of subcortical vision.

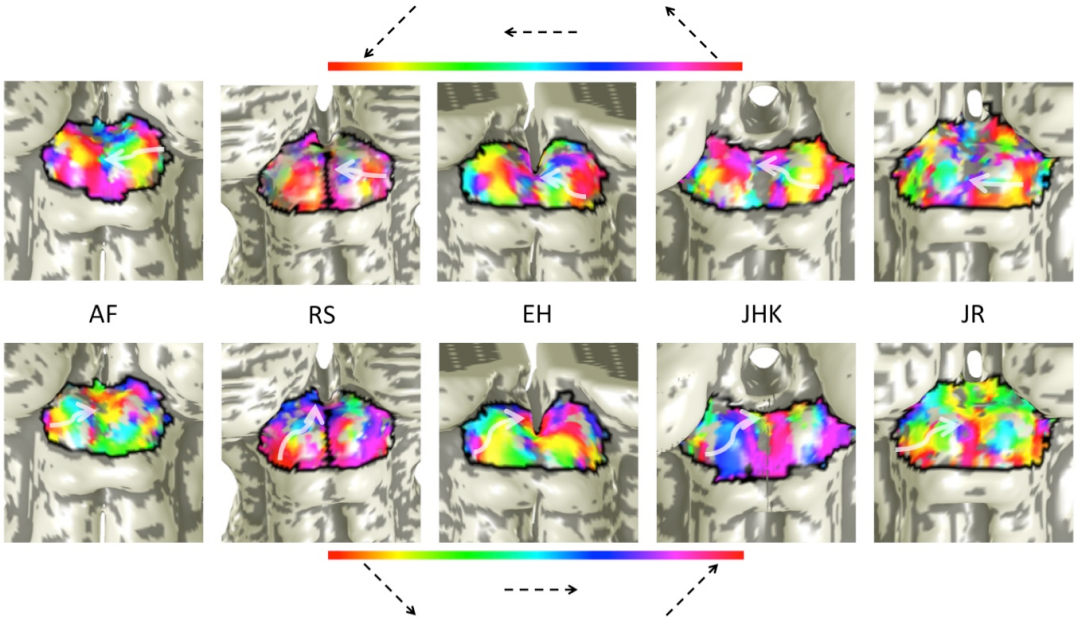

Figure: Data from 5 subjects show eye movements along the inferior-superior visual field axis are mapped along the medial-lateral axis in both SC, consistent with previous studies in alert monkeys.

Title: Unique compartmental role of inferior rectus (IR) muscle in compensation of vertical strabismus

Authors: ***J. L. DEMER**[1], R. A. CLARK[2];
[1]Jules Stein Eye Inst., [2]Ophthalmology, UCLA, Los Angeles, CA

Abstract: Latent vertical eye position imbalances are physiologically compensated by vertical fusional vergence to prevent diplopia. In some people, such imbalances develop early in life and increase gradually so that enhanced vertical fusional vergence can intermittently control vertical

strabismus. In 4 subjects with intermittent hypertropia (HT) averaging 5.3°, we asked if differential compartmental contractility in cyclovertical extraocular muscles (EOMs) underlies vergence mechanisms that control intermittent strabismus. Surface coil magnetic resonance imaging (MRI) was repeated for each orbit in fusing and deviated conditions, with one eye always aligned to distinguish fusion from monocular fixation of the same target. Contractility, indicated by change in posterior partial volume (PPV), was analyzed by automated algorithm in the medial (equatorial insertion, torsion) and lateral (posterior insertion, vertical) superior oblique (SO) compartments, the superior vs. inferior horizontal rectus compartments, and medial and lateral IR compartments. MRI confirmed no significant vertical or horizontal eye position differences between fusion and monocular fixation. Infraduction of the higher eye to monocular central gaze was associated with 6.2±1.0% (SEM) whole IR PPV increase, with further 3.3±5.2% increase from monocular central gaze to central gaze fusion, in both cases with similar behavior in medial & lateral compartments. Supraduction of the lower eye during monocular switch to fixation was accomplished by 8.3±1.7% PPV decrease in whole IR and 5.6±6.1% increase in whole superior rectus, in both cases with similarly in medial & lateral compartments. The SO behaved similarly with 9.6±5.9% PPV decrease, again similar in both compartments. In contrast, shift from monocular viewing to fusion without position change was associated in the lower eye with 10.1±3.7% PPV decrease in the lateral IR, but 3.8±4.8% increase in the medial IR compartment (P=0.008). No other rectus or the SO exhibited significant whole or differential compartmental contractility during change from monocular fixation to fusion. The lateral IR compartment is innervated by a second motor nerve branch supplementing main IR innervation. Supplemental innervation of the lateral IR may be the basis for unique contribution of the lateral IR to vergence compensation of intermittent HT. Differing contractility of the lateral IR during fusion vs. monocular fixation despite identical eye position confirms absence of a final common pathway in the ocular motor system.

Title: New insights on receptive field remapping with evidence from primate area V4

Authors: *S. NEUPANE, D. GUITTON, C. C. PACK;
Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: Neural representations of visual space are classically thought to be determined entirely by the pattern of retinal inputs. From this standpoint it is surprising that receptive fields in multiple visual areas of the primate brain have been found to change their position, before a saccade begins, to the spatial position they will occupy after the saccade (Duhamel et al 1992, Sommer and Wurtz 2006, Neupane et al 2016).While some studies have reported such *forward remapping*, in which receptive fields shift to their postsaccadic locations, others have reported *convergent remapping*, in which receptive fields shift toward the saccade target (Tolias et al 2001, Zirnsak et al 2014). We have found that both mechanisms exist in area V4 (Neupane et al 2016). Here we report new neurophysiological data using an experimental configuration in which both forward and convergent remapping would lead to receptive field shifts in opposite directions. We show that forward remapping is the dominant type of receptive field shift in V4. In a minority of the neurons, receptive fields first shifted towards the forward direction and subsequently reversing direction to follow the convergent direction. Furthermore, remapping seems to require a transient rewiring of position signals matched according to the spatial and temporal properties of each saccade. One candidate mechanism that could support remapping is a change in the coherence of oscillatory LFP signals between distant sites on a retinotopic map. Indeed oscillatory coherence has been shown to support transient rewiring of neural circuits in other contexts (Fries 2015), with different functions being associated with different frequencies. We therefore asked whether the two types of remapping were implemented on a cortical map via coherence at different frequency bands. We recorded from multi-electrode arrays while monkeys performed a saccade task. This allowed us to record simultaneously from two groups of neurons: those encoding the current receptive field and those encoding the post-saccadic future receptive field. We found that the two neural population located on the V4 retinotopic map and separated by a distance specifying the saccade vector, had coherent LFP oscillations in the frequency range of 8-12Hz around the time of saccade execution. At a later time after the saccade, we found coherence in gamma (40-60Hz) frequency range between the neural populations encoding respectively the visual space near fovea and those encoding the periphery. We propose that rapid changes in connectivity on a retinotopic map can be achieved dynamically by changes in synchrony across different neural populations in specific frequency bands.

Title: Saccade metrics reflect decision-making dynamics during urgent choices

Authors: *J. SEIDEMAN, V. E. SCERRA, E. SALINAS, T. R. STANFORD;
Neurobio. & Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Saccadic eye movements are perhaps the most ubiquitous manifestation of the perceptual decision and motor choice mechanisms that underlie visually-guided behavior. Once thought to be highly stereotyped and ballistic in nature, there is evidence to suggest that a signature of the decision-making processes that precede a saccade may exist within its metrics and/or kinematics. However, no study to date has provided a precise account of the impact of perceptual information processing on oculomotor dynamics as they unfold over the time course of saccade preparation. We investigated this using a novel urgent-choice paradigm in which the time available to view stimulus information prior to committing to a saccadic choice varied on a trial-by-trial basis. Our findings demonstrate that saccade velocity, amplitude, curvature, and endpoint precision all vary continuously as a function of perceptual processing time, and changes in these metrics track closely the processing-time-dependent changes in overall choice performance characteristic of the task. Interestingly, the amplitude and peak velocity effects observed are not redundant, as perceptual processing time explains variance in the saccadic main sequence. Our findings provide a unique, moment-by-moment, glimpse into how the state of the perceptual decision-making process at the time of choice commitment impacts the execution of that choice. Said differently, these data suggest that the metrics of any given saccade may reflect — to a much finer level of detail than previously thought — the dynamics of the internal cognitive processes that preceded it.

Title: Beta frequency TMS disrupts top-down cognitive control

Authors: *J. RIDDLE, M. D'ESPOSITO;
Univ. of California Berkeley, Berkeley, CA

Abstract: Neural oscillation theory offers a mechanism of coordinating brain networks for information processing. Neural signals in the beta frequency (20-35 Hz) are proposed to orchestrate top-down cognitive control, while gamma frequency (35-60 Hz) signals are proposed to propagate bottom-up information driven by the environment. Buschman & Miller 2007 tested this hypothesis while monkeys performed a visual search and pop-out saccade paradigm. In this task, a briefly presented cue is remembered over a short delay, followed by an array of 4 targets displayed in the periphery, and the subject is instructed to saccade to the remembered cue item. In the pop-out condition, the distractors in the 4 target array differ from the target in orientation and color. In the visual search condition, the distractors are similar in orientation or color, presumably leading to the need for increased cognitive control. In the pop-out condition, it was found that in gamma frequency signals from parietal cortex to the frontal eye fields (FEF) was associated with bottom-up processing whereas in the visual search condition beta frequency signals from FEF to parietal cortex was associated with top-down processing.
Recent human studies have used rhythmic transcranial magnetic stimulation (rTMS) to disrupt or entrain neural oscillations in a specific frequency band. In this study, we applied 4 pulse trains of rTMS at 50 Hz (gamma) and 20 Hz (beta) to FEF and intraparietal sulcus (IPS) to 20 subjects while they perform the identical paradigm used by Buschman & Miller. On the first day, we collected fMRI data while subjects performed the visual search and pop-out saccade task in order to obtain subject-specific TMS target sites for FEF and IPS. On the following three days, we used rTMS to stimulate right FEF, IPS, and a control region (somatosensory cortex, S1). rTMS was applied at a critical stage for information processing: following the presentation of the target array in the perisaccadic window (just before a saccade is initiated). Beta rTMS was applied 30 ms after the target array appeared whereas gamma rTMS was applied 120 ms after the target array. In both conditions, rTMS was actively applied at the time when criteria for a response is

being formulated as shown in Miller & Buschman 2007.
Following beta rTMS to FEF, as compared to S1, subjects had a faster reaction time and decreased accuracy during the visual search condition only. Our findings provide causal evidence complementing the physiological findings reported by Miller & Buschman 2007, supporting the proposal that beta oscillations emanating from FEF are necessary for cognitive control processes.

Title: A visually-entrained saccade command circuit driving phototaxis in zebrafish.

Authors: *G. DEBREGEAS[1], S. WOLF[2], A. DUBREUIL[3], V. BORMUTH[2], R. CANDELIER[2], R. MONASSON[3];
[1]LJP - UPMC/CNRS, Paris, France; [2]Lab. Jean Perrin - UPMC/CNRS, Paris, France; [3]Lab. de Physique Théorique - ENS, UPMC, CNRS, Paris, France

Abstract: In order to survive and thrive, motile organisms use sensory cues to navigate towards favorable environments. Efficient goal-directed locomotion requires a closed-loop coordination between motor action and sensory perception. Each movement induces a new sensory signal, which in turn modulates the forthcoming motor output. This mechanism is at play in a number of taxes behaviors, in organisms ranging from bacteria to humans. Numerous models have been proposed to account for this complex coordinated motion, but to date, no data are available to understand how these behavioral strategies might be implemented at the neural level in the vertebrate brain.
Here we take advantage of the accessibility of zebrafish larvae to whole-brain imaging to identify and dissect the central neural circuit that subserves positive phototaxis. We first established, through behavioral assays, that saccade-induced gaze shifts and reorientation turn bouts are robustly coordinated, and that the statistics of gaze orientation is biased towards illuminated regions. We then used volumetric functional imaging and optogenetic activation to identify the circuit controlling spontaneous gaze dynamics by direct correlation between gaze-shift sequences and neural activity (see figure). We demonstrated that this self-oscillating network is a substrate for visual integration. Its interaction with the visual pathway however differs from a simple stimulus-response pattern. Visual stimuli exert an action that depends on

the circuit oscillatory phase at which they are delivered, a mechanism that manifests itself in the phase-locked entrainment of the circuit by periodic stimuli. We developed a rate-model of this circuit that reproduced most of our observations, and provides the first comprehensive description of how phototaxis can be implemented in the vertebrate brain.
Projection map showing the neural population tuned to ocular saccades. This image was obtained from volumetric light-sheet based functional imaging.

Title: Visuomotor activity in the frontal eye field is differentially modulated by attentional demands across neuronal types

Authors: *V. SCERRA[1], M. COSTELLO[3], E. SALINAS[2], T. STANFORD[2];
[1]Wake Forest Univ., Winston Salem, NC; [2]Neurobio. and Anat. Dept., Wake Forest Univ., Winston-Salem, NC; [3]Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Perceptual decision making is the process whereby sensory information is used to guide choices and actions. We studied the dynamic interplay between perception, attention, and motor planning that is required for selecting both the action and the target for that action, and which is particularly crucial when time is limited. These processes are thought to have some correspondence with the characteristic visual (V), visuomotor (VM), and motor (M) cells found in the frontal eye field (FEF). Many tasks used for studying the participation of FEF in perceptually-driven choices require subjects to select an oddball stimulus, allowing for perceptual selection to occur before a motor report is imperative. The compelled saccade (CS) task developed in our lab reverses this order by first issuing a movement imperative and then varying the amount of perceptual information available to guide the decision. By applying the same temporal constraints to both a match-to-sample (CS) and an oddball task (CO), we explored how attentional conditions (top-down vs. bottom-up) impacted behavior and neural activity over a continuum of perceptual processing times. We recorded single-unit activity from characteristic FEF cells (V, VM, M) from non-human primates performing a battery of tasks varying in both urgency and attentional demands. We found that while V cells, traditionally thought to "select" targets independently of motor action, do not discriminate target from distracter in the CS task, they do so in the CO task, indicating that their selectivity is driven by bottom-up attention. We also observed that while motor and visuomotor cells faithfully convey saccadic direction in correct trials, their responses in error trials are substantially correlated with target location, demonstrating a direct impact of perceptual information on their activity. Furthermore, such modulation was stronger in the CO task and weaker — but still present — in the CS task, suggesting that both attentional mechanisms (bottom-up and top-down) are associated with traditional FEF choice-related activity.

Title: Effect of allocentric cues on primate gaze behaviour in a cue conflict task

Authors: *J. CRAWFORD[1], J. LI[1], V. BHARMAURIA[1], A. SAJAD[1], R. MARINO[2], X. YAN[1], S. SUN[1], H. WANG[1];

Abstract: The visual system can remember the location of a peripheral target relative to the self (egocentric coordinates) or to an external landmark (allocentric coordinates). The relative influence of each reference frame have been examined for reach (Byrne & Crawford*, J. Neurophysiol.* 2010), but have not been systematically explored in the gaze control system. Here, we utilized a cue conflict paradigm to assess the effect of allocentric cues on gaze behaviour in the rhesus monkey. Two monkeys (M1 and M2) were trained to maintain central fixation while a target was presented for 100ms in one of eight radial directions, along with an allocentric cue presented at one of four oblique directions 11º from the target. This cue was the intersection of two horizontal/vertical lines spanning the visual field. After a 100ms delay, a mask was shown for 100ms during which the allocentric cue was displaced by 8° in one of eight radial directions. After a second delay of 300-700ms, the fixation point extinguished, acting as a 'go' signal for a head-unrestrained saccade towards the remembered target. To examine the effect of the presence of an allocentric cue on gaze behaviour, the allocentric cue was randomly removed in 50% of control trials where the cue did not shift. Overall, there was a significant ($P < 0.01$) influence of the cue on gaze endpoints, with a mean gain of 0.14 in M1 and 0.17 in M2 (where 0 = target location and 1.0 = cue location). In addition, this cue influence was significantly greater when it is closer to the initial gaze position ($P < 0.01$). In shift conditions, the monkeys did not look toward the original target or the cue location, but rather toward a point shifted partially towards a virtual target defined relative to final cue location (i.e., in allocentric coordinates). Overall, there was a significant ($P < 0.01$) allocentric shift in gaze endpoints relative to controls (with no cue shift), with a mean gain of 0.27 in M1 and 0.23 in M2 (where 0 = no shift and 1.0 = complete shift). In addition, the cue had a significantly greater effect when it is closer to the initial gaze position ($P < 0.01$), when it shifted away from the target ($P < 0.01$), and when it shifted away from the initial gaze position ($P < 0.01$). These findings suggest that internal representations of gaze targets are weighted between egocentric and allocentric cues, and this weighting is further modulated by specific gaze parameters.

Title: A model to predict human intention by means of eye movements

Authors: *G. A. ZITO, A. FAISAL;
Dept. of Bioengineering, Imperial Col. London, London, United Kingdom

Abstract: We observe the world through discrete, rapid, focused eye movements acting to align the fovea with an object of interest. Visual information is vital to motor planning and thus monitoring eye movements gives significant insight into our motor intentions. While previous works (Yarbus, Land) focused on demonstrating that eye movement patterns are reflective of specific intentions, we study the inverse problem, to what extent action intention is predictable from eye movements. Thus, we aim to build a computational model that translates highly variable eye-movement patterns into predictions about possible actions. We measure visual exploration behaviour associated with different, well defined, activities of daily living in a table-based scenario. In a first experiment, healthy volunteers are asked to perform a sequence of tasks (e.g. prepare breakfast, eat an apple) while their eye movements are tracked with a head-mounted eye tracker (including scene camera). The various interactions on each object are then associated with a particular pattern of eye movements. Given the high variability of the eye movements, even within restricted task contexts, probabilistic models and pattern recognition algorithms are used for the classification analysis. A Bayesian latent variable model is applied in order to learn the mapping from eye movement features to action. In a second experiment, aiming to validate the developed model, subjects freely perform the same set of tasks in the same scenario. The object they are interacting with is identified based on the analysis of the scene camera. This allows our model to run in a predictive mode, and to label the most likely intention that the subject is going to execute. We report the prediction accuracy of the model against subject actual actions.

Title: Spiking correlations in the frontal eye fields during eye movement planning

Authors: *S. B. KHANNA[1,2], A. C. SNYDER[3], M. A. SMITH[1,2];
[1]Dept. of Ophthalmology, [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Pairs of nearby cortical neurons exhibit correlated spiking activity. There is a strong link between the correlation among neurons and the amount of information that can be represented in a neuronal population. That link is particularly important at the decoding stage, when sensory signals are used to guide motor output, such as eye movements. Very little is known, however, about the correlated activity in areas that bridge the sensory and motor divide. The frontal eye fields (FEF) are considered to be the primary locus of cortical signals controlling eye movements. Because of this and the presence of neurons with both visual and motor responses, they are an ideal candidate for studying the role of correlated activity in planning and executing movements. Of particular interest is the connection between the populations of visual and motor neurons, which might be important for eye movement planning. We used a linear electrode array to record from groups of FEF neurons in alert rhesus macaque monkeys performing a conventional memory guided saccade task. We measured neuronal correlation of spiking activity on both short and long time scales (spike count correlation and synchrony). We found that correlated spiking activity in FEF was similar in a number of ways, such as dependence on distance and tuning similarity, to previous measurements in early visual cortex. When we focused specifically on connections between visual and motor neurons, we found a distinct pattern of results. The overall level of correlation between these groups was lower than visual-visual or motor-motor pairs, but it showed the strongest dependence on the direction of the planned eye movement. These findings suggest that visual and motor populations of neurons in the FEF play a unique role in transforming visual information to motor output.

Title: Palisade endings in extraocular muscles have an exocytosis machinery

Authors: ***R. BLUMER**[1], J. STREICHER[2], P. J. MAY[3], M. A. DAVIS-LÓPEZ DE CARRIZOSA[4], R. R. DE LA CRUZ[4], A. M. PASTOR[4];
[2]Ctr. of Anat. and Cell Biology,, [1]Med. Univ. Vienna, Vienna, Austria; [3]Dept. of Neurobio. & Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [4]Dept. de Fisiología, Univ. de Sevilla, Sevilla, Spain

Abstract: Proprioception from extraocular muscles (EOMs) provides the brain with eye position signals. Surprisingly, classical proprioceptors (muscle spindles and Golgi tendon organs) are absent in the EOMs of most mammals. Palisade endings have been assumed to be an alternative nervous end organ. These structures are formed by axons which extend into the tendon where they make a u-turn and divide into axonal branches that establish nerve terminals around the tip of a single muscle fiber. Palisade endings are exclusively present in EOMs of mammals including man. All frontal-eyed species exhibit palisade endings whereas they are infrequent and less elaborated in lateral-eyed species. For a century, palisade endings have been considered as sensory structures providing eye position information. The debate on the function of palisade endings has been reopened when recent molecular studies and neuronal tracing experiments have shown that they have a cholinergic phenotype and arise from motor nuclei. Despite these clear motor features, the function of palisade endings is unclear and it is still a matter of debate whether they are sensory or motor or eventually both. In motor neurons, neurotransmitter release requires the presence of the so-called SNARE proteins (SNAP25, synaptobrevin, syntaxin, and synaptotagmin) which mediate fusion of synaptic vesicles with the presynaptic membrane. Here, we tested in monkey and cat if palisade endings contain SNARE proteins as well. Palisade endings were doubly immunolabeled with antibodies against choline acetyltransferase (ChAT)/SNAP25, ChAT/synaptotagmin, ChAT/syntaxin, or ChAT/synaptobrevin. Muscle fibers were labeled with phalloidin. Immunolabeled palisade endings were analyzed in the confocal laser scanning microscope. In accordance with previous studies, palisade endings in cat and monkey expressed ChAT. Moreover, all palisade endings were positive for SNAP25, synaptotagmin, syntaxin, and synaptobrevin as well. Our findings that palisade endings, analog to motor neurons, express proteins of the SNARE complex provide further arguments that palisade endings might function as effector organs.

Title: Common motion error correction guides pursuit and fixation

Authors: ***S. N. WATAMANIUK**[1,2], S. J. HEINEN[2];
[1]Psychology, Wright State Univ., Dayton, OH; [2]The Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Smooth pursuit and fixation are generally considered to be controlled by different systems. The pursuit system takes motion information at its input and uses a feedback loop to minimize the retinal image motion of a target. Previously, we found that initial pursuit eye acceleration increased as the number of elements in the stimulus increased, implying that more stimulus elements created a stronger motion signal to drive pursuit (Heinen et al., 2016). The fixation system works to keep the eyes on a target, not only with microsaccades, but also with smooth movements. Therefore it, like the pursuit system, may also operate to minimize retinal motion. Might the fixation system, like the pursuit system, also use motion to control the eyes? We hypothesized that if ocular fixation used a motion signal, then increasing the strength of that motion signal should increase ocular stability. To test this, we used fixation stimuli with different numbers of elements to vary the strength of the retinal motion signal created when the eyes moved smoothly across them. Observers fixated either a small, spot target, the center of a 6° circular array of 8 dots, or the center of a 9-dot conglomerate of these stimuli. Eye movements were measured using an EyeLink 1000 eye tracker at a rate of 1000 Hz. We found that the speed of smooth movements decreased as the number of elements in the stimulus increased, paralleling our previous results on pursuit open-loop acceleration. The results provide evidence that the system controlling smooth movements detects the retinal motion of the fixation object, and uses the motion signal that arises to reduce smooth movement speed and stabilize the eyes. We propose that a feedback loop operates during fixation to minimize retinal motion analogous to the feedback loop that minimizes retinal motion during smooth pursuit.

Title: Interaction between effort and reward in the oculomotor system

Authors: *T. YOON, R. SHADMEHR;
Johns Hopkins Med. Inst., Baltimore, MD

Abstract: It is thought that in selecting between available actions, the brain assigns a utility to each possible action and then selects the action that has the highest utility. This utility depends on the subjective value of reward, and the expected effort. The central question is with regard to how the brain measures effort and how this measure interacts with reward.
We have recently shown that the subjective value of a stimulus affects the vigor with which the brain moves the eyes toward that stimulus: stimuli that are valued more coincide with saccades that have higher velocity (Reppert et al. 2015). Here, we investigated the effect of effort by measuring fixation times that separated voluntary saccades.
It is known that during fixation, the total force produced by the opposing extraocular muscles increases with distance from the center position of the eye, as do the number of spikes need to hold the eyes during fixation. During fixation we estimated the sum of spikes produced by the two abducens motor nuclei as an objective measure of energy spent to maintain fixation, and hypothesized that effort is proportional to this sum. This predicted that the effort associated at fixating a stimulus should increase linearly with distance from center. To test for this, we provided human subjects with two images, constant distance apart, but placed at various locations along the horizontal axis. The images were faces (high value) and shapes (low value). We measured time spent fixating one location as a fraction of total time spent at the two locations. Total time spent was constant for every trial throughout the experiment. We found that the ratio of fixation time on one location by fixation time on the other location with constant distance apart decreased linearly as distance of the image increased from center. That is, as the number of spikes required maintaining fixation increased, the time spent looking at that image decreased. The slope of the line was greater when the stimulus value was smaller. These results suggest that the brain assigns utility as an additive function of reward and effort, not multiplicative, and that effort may be associated with the energetic cost of motoneuronal discharge during the action.

Title: Horizontal and vertical premotor gaze populations within the macaque mesencephalic reticular formation

Authors: M. O. BOHLEN[1], S. WARREN[2], *P. J. MAY[2];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Neurobio. and Anatom. Sci., Univ. Mississippi Med. Ctr., Jackson, MS

Abstract: It has been proposed that the gaze-related portion of the mesencephalic reticular formation (MRF) can be subdivided into two different regions based on physiological features. Stimulation of and recording from the central mesencephalic reticular formation (cMRF), located caudal to the level of the interstitial nucleus of Cajal (InC), suggests this region is related to horizontal gaze. The peri-interstitial nucleus of Cajal portion of the mesencephalic reticular formation (piMRF), located rostrally, at the level of the interstitial nucleus of Cajal, is believed to play a role in vertical gaze. To test whether this dichotomy is supported by the connectivity of the two regions, we have used dual tracer anatomical experiments in macaque monkeys (*M. fascicularis*). Specifically, to examine the premotor connections of the MRF, we placed anterograde tracers in this nucleus and retrograde tracers in the ipsilateral medial and superior rectus muscles. Experiments in which the anterograde tracer was located within the MRF showed extensive close associations between labeled MRF terminals and labeled medial rectus motoneurons located within the ipsilateral oculomotor nucleus and in C-group, and with labeled superior rectus motoneurons located in the contralateral oculomotor nucleus and in S-group. Ultrastructural examination proved the presence of synaptic contacts between these labeled elements. Looking across the cases used in these experiments, we noted that when anterograde tracer was confined to within the cMRF, there was scant anterograde terminal labeling near superior rectus motoneurons. However, with more rostral injection sites that spread into the piMRF, there was a significant increase in terminals associated with superior rectus motoneurons and a decrease in the terminals associated with medial rectus motoneurons. These differences in preferred motoneuron target suggest that there is a difference in the pattern of connectivity between the cMRF and piMRF that is suggestive of differential function in horizontal and vertical gaze, respectively. Whether this finding reflects an absolute difference between these MRF subnuclei or a continuous spectrum of change between the rostral and caudal poles of the MRF remains to be determined.

Title: The postnatal development of palisade endings in extraocular muscles

Authors: R. BLUMER[1], J. STREICHER[1,2], M. A. DAVIS-LOPEZ DE CARRIZOSA[3], R. R. DE LA CRUZ[3], *A. M. PASTOR[4];
[1]Ctr. of Anat. and Cell Biol., Med. Univ. Vienna, Vienna, Austria; [2]Karl Landsteiner Univ. of Hlth. and Sci., Krems a.d. Donau, Austria; [3]Dept. de Fisiología, Univ. de Sevilla, Sevilla, Spain; [4]Dept. de Fisiología, Univ. De Sevilla, Sevilla, Spain

Abstract: Proprioception from extraocular muscles (EOMs) provides the brain with eye position signals. Surprisingly, classical proprioceptors (muscle spindles and Golgi tendon organs) are absent in the EOMs of most mammals. Instead, palisade endings (PE) are found as unique to EOMs of mammals. They are regularly present in frontal-eyed but infrequent in lateral-eyed species. PE are formed by axons which extend into the tendon where axons make a u-turn and divide into axonal branches that establish nerve terminals around the tip of a single muscle fiber. For a century, PE have been considered as sensory structures substituting classical proprioceptors in EOMs. The interest in PE has newly aroused when molecular analysis and recent neuronal tracing experiments have shown that PE are cholinergic and originate from the EOM motor nuclei. Up to date the development of PE is unknown. Here we have analyzed the postnatal development of PE in cats of different ages (P0, P8, P22, and adult) in all four rectus muscles. In cat P0, eyelids are naturally closed and by P8 eyelids start to open. Immunolabeled PE were analyzed in the CLSM. At P0, no PE were found in both vertical and lateral rectus. Only in the medial rectus we observed axons which extended straight into the tendon where they stopped and extensively sprouted. Other axons extended only a very short distance into the tendon where they made u-turns and formed very simple PE on the tip of single muscle fibers. At P8, eyelids start to open in kittens, PE were still absent in the superior and lateral rectus muscles.

In the inferior rectus muscle, simple PE were found whereas those in the medial rectus muscle were more elaborate but still not mature. At P22, PE were still absent in the superior and lateral rectus. In the inferior rectus and medial rectus, PE were still immature but more complex in the medial rectus. In the medial rectus muscle their number resembled that found in adult cats. In the adult cat, PE were found in each rectus muscle. We have recently shown in frontal-eyed animals that the number of PE is much higher in the medial rectus than in the other rectus muscles suggesting that PE play a role in convergence movements. Since the development of PE is faster in the medial rectus muscle, the present findings supports the notion that PE could play a particular role in convergence. Since the development of palisade endings is more accelerated in the medial rectus muscle, the present findings supports the notion that palisade endings could play a particular role in convergence.

Title: Time course for the accumulation of errors in the superior colliculus during memory-guided gaze shift

Authors: *A. SAJAD[1], M. SADEH[2], X. YAN[2], H. WANG[2], J. CRAWFORD[2];
[1]Ctr. for Vision Res., [2]York Univ., Toronto, ON, Canada

Abstract: During a memory-guided gaze shift task, where subjects make delayed gaze shifts towards remembered location of visual stimuli, neurons in the superior colliculus (SC) often show neuronal responses related to visual presentation (visual burst), the evoked gaze shift (motor burst), and the intervening memory delay (delay activity). Previously, we showed that in this task (performed in head-unrestrained conditions), early visual transient response in the SC encodes the accurate location of the visual stimulus (target, T) and the motor burst encodes the final gaze position (G), reflecting the full extent of variability in behavioural errors and this was even observed within single visuomotor (VM) neurons (Sadeh et al., *Eur. J. Neurosci.,* 2015). However, what is unknown is how this T-to-G transition occurs in the SC as activity evolves from vision, to memory delay, to action. In order to investigate this, we analyzed the evolution of

spatial code in 48 visually-responsive neurons from the SC of two monkeys through the entire visual-memory-motor extent of their response. We applied a spatial model-fitting method described previously to identify the spatial code (Keith et al., *J. Neurosci. Methods.,* 2009; Sajad et al., *eNeuro,* 2016): We created a continuum of spatial models (referred to as T-G continuum) that were based on T (target position), G (gaze endpoint), and incremental positions spanning T and G and defined the spatial code as the model that best fits neural data. For each neuron we identified the spatial code during several epochs: early and late visual burst, early and late delay period (obtained by dividing delay period into half), and pre- vs. post-saccadic motor burst. Our individual neuron analysis and population results (30 VM neurons and 18 visual neurons) revealed that the early and late phases of the visual burst both contained a relatively accurate target code, but as activity progressed from the visual burst through memory delay, into the motor burst (in VM cells) there was a progressive transition from T towards G, and this transition was often completed by the time of gaze onset. These results show that the delay activity in the SC does not maintain an accurate representation of the target, but rather maintains a spatial code that is subject to gradual accumulation of errors describing the eventual location of the gaze shifts.

Title: Translating choice to smooth pursuit eye movements in the frontal eye field

Authors: *M. JOSHUA;
The Edmond and Lily Safra Ctr. for Brain Sci., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Action selection and its planning are critical for controlling the environment. We designed this study to characterize the neural dynamics during planning of target selection and link the activity to selection-dependent and selection-independent behavior. We recorded activity in the smooth pursuit area of the frontal eye field (FEF) while monkeys were planning a smooth pursuit eye movement that selected one of two moving targets. The most common preparatory neural activity in the FEF was ramping activity preceding target motion onset, which was linked on a trial-by-trial basis to pursuit eye movement latency rather than to its direction. Pursuit

selection was encoded by the offset of this ramping response, relative to baseline. Planning of selection was commensurate with a winner-take-all representation rather than a representation that matched the specifics of the upcoming movement. These findings characterize the majority of the dynamics in the average activity and show that in planning selection the FEF mainly signals when to move and not where to move.

Title: Representation of Bayesian priors for target speed in the preparatory activity of neurons in the smooth eye movement region of the frontal eye fields

Authors: *T. DARLINGTON, S. LISBERGER;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Many behaviors operate in a Bayesian framework, where actions are guided by a complex interaction between current sensory information and past experience, or “priors”. When current sensory information is weak, it is advantageous to allow the prior to guide behavior. However, the value of prior experience lessens as sensory information strengthens. Despite the generalizability of this phenomenon, it remains unclear how Bayesian estimation is implemented at the level of neural circuits. Smooth pursuit eye movement is an example of a relatively simple sensory-motor behavior that operates in a Bayesian-like manner. We have developed a paradigm that allows for the fast adaptation and probing of Bayesian priors for target speed. Two male rhesus macaque monkeys were trained to track a 100% contrast patch of dots and a 6% contrast sine wave grating with smooth pursuit eye movements. We used a block design to adapt priors for target speed. During the “fast prior” block, targets moved at 20 deg/s for 80% and at 10 deg/s for 20% of the trials. During the “slow prior” block, targets moved at 2 deg/s for 80% and at 10 deg/s for 20% of the trials. During a control block, the targets moved at 10 deg/s for 100% of the trials. Compared to the control block, we find that eye speeds for the 10 deg/s target motion are faster in the fast prior block and slower in the slow prior block. Furthermore, the change in eye speed is greater for the low contrast target (weak motion) compared to the high contrast target (strong motion), consistent with the Bayesian framework. We have used our paradigm for rapid

prior adaptation to ask whether preparatory activity in the smooth eye movement region of the frontal eye field (FEFsem) encodes information about the prior for target speed. Our population of cells in both monkeys exhibited preparatory ramps in firing rate during fixation, prior to visual motion onset. We observed cells with both increasing and decreasing ramps in activity. The magnitude of the ramps was larger during the fast prior block compared to the slow prior block. We conclude that preparatory activity in FEFsem encodes expectation (a.k.a. the prior) for upcoming target speed.

Title: Saccade curvature in sequences of voluntary saccades suggests they are not planned independently

Authors: *R. AZADI, R. M. MCPEEK;
SUNY Col. of Optometry, New York, NY

Abstract: Saccades often have curved trajectories, and previous studies have shown that covert attention and the onset of visual distractors can alter this curvature. Recently we showed that saccadic curvature is modified in systematic ways during sequences of saccades. Specifically, each saccade tends to curve in the direction of the preceding saccade vector and opposite to the direction of the following saccade vector in the sequence. However, these findings are based on studies of reflexive and instructed saccades, rather than free-viewing voluntary (exploratory) saccades. Here we used saccadic curvature as a tool to study planning of sequential saccades in a free-viewing visual search task.
In each trial, eight targets (0.8° diameter rings) appeared in random positions on the screen. A horizontal line (0.15° long) was located at the center of one of the rings, while the other seven contained vertical lines. Subjects were instructed to locate the target containing the horizontal line as quickly as possible. To perform the task, the subjects needed to foveate the targets one by one, while eye position was recorded binocularly.Offline analyses showed that saccadic curvature has a sinusoidal relationship to the angle of the saccadic vector, relatively independent of the saccade amplitude, as shown previously in studies of reflexive saccades (e.g., Smit and

van Gisbergen 1990). This relationship between curvature and saccade angle was binocular and similar in both eyes, implying that the curvature is neural in origin, rather than due to anatomical and muscular properties of the orbit. More importantly, the results showed that saccade curvature is modified by the direction of preceding and following saccades: saccades tended to curve in the direction of the immediately preceding saccade vector, and opposite to the direction of the immediately following saccade vector, consistent with our previous findings. Furthermore, the magnitude of this curvature gradually varied based on the angle of the following or preceding saccades.These findings suggest that voluntary exploratory saccades in this task are not processed independently, since the trajectory of each saccade is influenced by the direction of the preceding and following movements in the sequence.

Title: Insights into sensorimotor transformation in the superior colliculus through current-source density analysis

Authors: *C. MASSOT, U. K. JAGADISAN, N. J. GANDHI;
Eye and Ear Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is crucial for transforming sensory signals that register a target into motor commands that produce an orienting movement to the stimulus. The sensory response is represented as a burst of activity in visual and visuomotor neurons in the superficial and intermediate/deep (collectively, deeper) layers. Saccadic eye movements are produced by yet another burst of activity in the visuomotor and motor neurons in the deeper layers. However, the underlying input signals that produce this pattern of activity are not well understood. We address this gap in knowledge by recording spikes and local field potentials (LFPs) from a 16-channel laminar probe in the SC of a monkey performing randomly interleaved delayed, visually-guided and memory-guided saccades. The electrode penetration was orthogonal to the SC, hence the optimal target locations and/or saccade vectors were comparable across all recording contacts. The target was positioned either close to the center of the response field or at the diametrically opposite location. Here, we quantify LFP information with current-source density (CSD)

analysis to emphasize the location and timing of incoming (source) and outgoing (sink) electrical currents across layers. Preliminary analyses reveal the following observations: 1. The sensory burst is coincident with a robust current source signal in the intermediate layers , with bleeding into the superficial layers. The magnitude of this source decreases gradually during the delay period and then increases modestly at the time of saccade onset. 2. In contrast, a current sink was observed deeper in the SC, at sites of visuomotor spiking activity. This CSD switched to a weak source signal during the delay period, before re-transitioning to a sink at the time of saccade onset to reveal a transient source/sink reversal between intermediate and deep layers. 3. Intriguingly, the CSD trace in the deep layers revealed a potent source signal immediately following the saccade. This cannot be a visual signature since it was also observed for memory-guided saccades. Across all layers, modulations in both LFP and CSD signals during the delay and presaccadic periods were weak compared to the fluctuations observed during sensory and post-saccadic epochs. Taken together these results show key differences between the target and the motoric burst and reveal that each SC layer is involved in different local and global network activity during sensorimotor transformation.

Title: Are catch-up saccades and microsaccades siblings?

Authors: ***S. J. HEINEN**[1], S. N. J. WATAMANIUK[1,2];
[1]Smith-Kettlewell Eye Res. Inst., San Francisco, CA; [2]Wright State Univ., Dayton, OH

Abstract: Catch-up saccades are small saccades that frequently interrupt the smooth component of ocular pursuit. Microsaccades are small saccades that occur frequently during ocular fixation. There is evidence that pursuit and fixation are different neural systems, but are the small saccades that are virtually omnipresent during these ocular behaviors generated by different mechanisms? Here we test this by capitalizing on a curious phenomenon that occurs with microsaccades, notably that before high-acuity tasks, their rate predictably subsides until they are almost completely quieted, and then rebounds. Here we ask if a similar phenomenon occurs for catch-up saccades during pursuit. Observes pursued a linear array of 15 small alphanumeric

characters (0.28° × 0.5°), and performed a character discrimination task on them (Lovejoy et al., 2009). Stimuli appeared stationary for a random fixation duration, then translated either leftward or rightward across the screen at 8°/s, 12°/s, or 16°/s for 1640-2440 ms. At a random time after the fixation period (1040-1440 ms), the character array changed from 8's to 2's and 5's except for a single probe character that changed to a 3 or an E. After 200 ms, all characters changed back to 8's. Observers identified the 3 or E with a keypress. We found that catch-up saccade frequency decreased in prediction of the upcoming discrimination task, and rebounded after the task was completed in a similar fashion to what occurred during fixation. The results provide evidence that the mechanism generating catch-up saccades during pursuit also generates microsaccades during fixation.

Title: Analysis of spiking activity and local field potentials reveals patterned information flow within the superior colliculus

Authors: L. J. DRNACH, *U. K. JAGADISAN, C. MASSOT, N. J. GANDHI;
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is a major hub of sensorimotor integration in the gaze control network, and plays a pivotal role in the generation of saccadic eye movements. The sensory-to-motor transformation is enabled by the intermediate and deep (collectively, deeper) layers of the SC. However, it is unknown whether neurons in these layers constitute a homogeneous network performing similar computations or if there exists finer spatiotemporal patterning therein. To study this in greater detail, we combined linear microelectrode array recordings with multi-channel signal analyses. Linear arrays are especially amenable to recording from a column of neurons to access computations evolving in parallel within the column. We recorded from the SC in two monkeys (Macaca mulatta) performing a delayed saccade task. The electrode contacts (n=16) spanned the dorso-ventral extent of the SC, allowing for the simultaneous recording of spiking activity and local field potentials (LFPs) within the deeper layers.

We performed coherence and Granger causality analyses to assess the flow of information within SC. We found the following:
(1) Following target onset, spike-spike coherence increased between most channel pairs, but only the dorsally located channels exerted a Granger causal influence on the spiking of other channels, suggesting a unidirectional flow of information during sensory processing. In contrast, during the saccade, the middle channels exerted a causal influence on channels located both dorsally and ventrally, indicating bidirectional information flow during peri-saccadic processing.
(2) Spike-LFP coherence revealed stronger coherence between spiking activity recorded from dorsal contacts and LFPs recorded more ventrally, both following stimulus onset and following the saccade. Intriguingly, there was no significant increase in coherence in the lead up to the saccade.
(3) For both epochs, the spike-LFP coherence profile was biphasic, with an early, narrow transient, and a late, broader peak. Granger analyses suggested that both early coherence peaks could be the result of causal dorsal-to-ventral influence of spikes on LFP, whereas the late peaks could be the result of the causal influence of LFP on spikes.
(4) In all cases, coherence and causality decreased as a function of distance between the pair of contacts. Moreover, the strongest influences in all cases were in the sub-beta band (<30 Hz), with a slightly weaker effect in the low-gamma range (30-50 Hz) between dorsal channels.
These results point to distinct communication channels for spikes and LFPs in the SC, and provide evidence for multi-phase processing during sensorimotor integration.

Title: Role of cerebellar nuclei in visual preference for face image and its relevance to autism

Authors: *D. DZIOBEK[1], S. ZHANG[2], J. ASHE[3,5], X. LU[4];
[1]Grad. Program in Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Dept. of Biomed. Engin., [3]Dept. of Neurosci., [4]Dept. of Neurol., Univ. of Minnesota, Minneapolis, MN; [5]Neurol. Service, Veterans Affairs Med. Ctr., Minneapolis, MN

Abstract: The cerebellum has a clear role in the generation of saccadic eye movements. The 'oculomotor vermis', through its projections to the fastigial nucleus, modulates the amplitude of

saccades. The discovery of projections from the medial cerebellar nuclei to cognitive areas in frontal cortex suggests that these nuclei contribute to cognitive functions in unknown ways. Our particular interest was in testing the hypothesis that neural activity in the cerebellum biases the choice of visual targets of saccades toward socially-relevant cues. Healthy human and non-human primate subjects show a strong preference for socially-relevant images, and we recently demonstrated that monkeys, when given a choice in viewing visual images, show an overwhelming preference for facial images of primates. Such behavior is in stark contrast to that of subjects with autism, in whom damage to Purkinje cells is the most common neuropathological finding, who show no bias toward socially-relevant images and in fact may prefer viewing images of inanimate objects. Functional imaging of autistic individuals during eye movement tasks show reduced activation of the Supplementary Eye Fields (SEF), a region associated with cognitive control of eye movements.
Here we trained a monkey on a face image-based oculomotor task in which he had to choose between objects and images of human and non-human faces and unilaterally inactivated different portions of the cerebellar nuclei by injecting a small amount of muscimol. In control experiments before the inactivation studies, the subject had demonstrated a 95% preference for images of faces compared with images of other objects. We found that the preference rate for face image decreased significantly (Z-test, p=0) following inactivation of portions of the ventral cerebellar dentate nucleus (VDN) and the posterior interpositus nucleus (PIN), to 84% after the injection into the VDN, and 75% after injection into the PIN. There was no change in the preference after the injections into dorsal dentate nucleus and anterior interpositus nucleus, and there was no obvious difference in the preference of pairs of non-face images after injection into each portion of the cerebellar nuclei. These results suggest that the cerebellar nuclei, especially the VDN and PIN, contribute to production of saccades to images of primate faces when given a choice of two images to look at. Together with our finding of cerebello-thalamo-SEF pathway, we hypothesize that cerebellum and its projections to the SEF are involved in generation of eye movements towards primate faces, and failure of this circuit may result in the lack of eye movement towards faces associated with autistic behavior.

Title: Pre-existing visual and oculomotor factors that determine the retinal location of a preferred retinal locus (PRL)

Authors: *H. MAZYAR[1], B. S. TJAN[1,2];
[1]Neurosci. Grad. Program, [2]Dept. of Psychology, USC, Los Angeles, CA

Abstract: Diseases such as age-related macular degeneration (AMD) selectively affect foveal and parafoveal vision, leading to central field loss (CFL) and severely impairs functional vision. More than 10 million people in the U.S. suffer from AMD. This number is expected to increase to 21.6 million by 2050[1]. To adjust to CFL, the visual system often adopts an extra-foveal retinal location, called the preferred retinal locus (PRL), to use for fixations. In many patients, saccades are re-referenced to the PRL. The retinal location of a PRL varies across patients. It is not known what visual or oculomotor factors may underlie the development of PRL since measuring these factors before the formation of a PRL had not been feasible. We developed a method that constrains PRL formation to a one-dimensional contour in normally sighted participants. This allows us to comprehensive survey the visual and oculomotor factors prior to PRL formation.

We use the "Contact task" to induce a PRL on a designated one-dimensional contour in normally sighted participants. Participants had to use their gaze to move an opaque and gaze-contingent disc to make contact with a small target. The disc was 6° in radius and centered at the fovea. In each trial, a small target appeared at a random screen location. The participant had to establish contact between the edge of the disc and the target and maintain contact for 0.5 s before the target was dismissed and a new trial began. Before and after performing the Contact task, participants were assessed for their form vision (visual acuity, crowded visual acuity, positional uncertainty) and oculomotor performance (peripherally guided fixation stability and saccade accuracy, number of saccades required to establish peripheral fixation) at 8 evenly spaced locations at 6° eccentricity.

We found that PRL tended to form at a retinal location where it took the participant the least number of saccades to establish peripheral fixation. The retinal location with the least amount of positional uncertainty also facilitated PRL formation. Our results also showed that PRL formation correlated with improvements in visual and oculomotor performance. After PRL formation, the first saccade landing error for establishing peripheral fixation and the number of saccades required were reduced. A slight improvement of crowded acuity was also observed. These findings explain the idiosyncrasy of PRL formation across participants and inform the designs of customized rehabilitation regimens for patients with CFL.

Title: Increased crowding in parafoveal vision in glaucoma

Authors: ***M. KWON**[1], R. LIU[1], C. GIRKIN[2];
[2]Dept. of Ophthalmology, [1]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Crowding, the deleterious influence of nearby items on visual recognition, impairs a person's ability to recognize a target object in clutter (Bouma, 1970; Levi, 2008). A popular explanation of crowding is that features of the target and flankers are integrated inappropriately, as they both fall in the same neural unit due to a large integration field (Pelli et al., 2004). Thus, crowding grows with increasing retinal eccentricity as receptive field size increases (i.e. scale shift) in peripheral vision, while little crowding exists in parafoveal or foveal vision. Glaucoma, a leading cause of irreversible vision loss in the United States, is associated with the loss of retinal ganglion cells. Studies have shown that threshold spatial resolution becomes considerably larger as retinal ganglion cell density decreases (Wall et al., 1991). While this evidence hints that the loss of retinal ganglion cells might bring about a larger integration field, which in turn exacerbates the crowding effect, little is known about visual crowding in glaucoma. Here we report crowding in glaucomatous vision in comparison with age-matched normal vision. Crowding was assessed in 15 individuals with moderate glaucoma (mean Mean Deviation for the worse eye: = −11.58 dB±9.1) and 10 age-matched normal controls. Crowding was quantified as the center-to-center distance (crowding zone) between the target and flankers that yielded a target-identification accuracy of 80%. Measurements were made at 9 different retinal locations (retinal eccentricities: 0°, 2° and 4°). In each trial, a subject was presented with five letters, a target flanked by four tumbling Es, and asked to report the target identity. Our results showed that people with glaucoma had a significantly larger crowding zone, even in parafoveal vision (a decrease by 25%, $p < 0.05$), compared to normal cohorts. However, no significant difference was found in single letter recognition between the two groups ($p > 0.05$), suggesting that reduced acuity cannot account for the increased crowding. Our findings suggest that, contrary to the conventional view that central vision remains intact until the very last stage of glaucoma, the macular region of even moderate glaucoma appears to suffer from unusually large crowding.

Title: From eyes to hands – Inhibition training transfers across motor systems

Authors: *A. VERGHESE;
The Univ. of Queensland, St. Lucia, Australia

Abstract: Inhibition of irrelevant information and motor responses is crucial for goal-directed behaviour. Given the importance of inhibitory processing for adaptive functioning in our daily lives, and its impairment in many psychiatric and neurological conditions, a key question is the extent to which this ability can be enhanced via behavioural training. While studies on training of inhibitory processes have consistently shown improvements on the trained task, it is not clear whether such benefits generalize to distinct (untrained) inhibition tasks. Training-dependent modulations of activity in cortical regions such as the right inferior frontal gyrus, precuneus, inferior parietal lobule and the anterior cingulate cortex have been consistently reported in studies of inhibitory control of eye-movements and manual inhibition measures. Since generalized training benefits for executive functions should be observed when the training and transfer tasks tap a common underlying mechanism, it is conceivable that training the same inhibitory process but using different effector systems – eyes versus hands – could evoke training-induced benefits that generalise. Here we assessed whether training of inhibitory control on an anti-saccade task, in which pre-potent oculomotor responses must be inhibited, transferred to other inhibition tasks in which pre-potent manual responses had to be altered. Specifically, we tested whether the well-known 'Simon effect', characterized by longer manual responses to stimuli in non-corresponding spatial locations, and the 'Stroop effect', characterised by longer responses for stimuli with featural conflict, can be modulated by inhibitory oculomotor training. Importantly, we included two active-control training regimens - fixation training and pro-saccade

training. All three training regimens led to improvements on the trained tasks themselves, as expected, but only anti-saccade training yielded benefits that transferred to the manual response modality. Specifically, anti-saccade training led to reductions in the Simon effect, but did not influence the Stroop effect. Taken together, these findings suggest that training of inhibitory control within the oculomotor system can transfer to the manual motor system, and provide important insights into the boundary conditions necessary for transfer of inhibition training.

Title: A diffusion process underlies action selection in an abstract decision-making task.

Authors: *S. SHUSHRUTH[1,2], M. SHADLEN[1,2,3];
[1]Neurosci., Columbia Univ., New York, NY; [2]HHMI, New York, NY; [3]Zuckerman Mind Brain Behavior Inst., New York, NY

Abstract: When monkeys and humans form perceptual decisions that lead to particular actions, the accumulation of sensory evidence and the planning of motor actions are yoked. If the evidence is acquired before the decision maker is informed of the action required to report a choice, then these two processes are dissociated. In such situations, an abstract representation of the decision is purportedly stored and this representation subsequently used to drive action selection. How such abstract representations can flexibly recruit relevant motor actions has not been explored.
We trained a monkey to decide on the net direction (left or right) of dynamic random dot motion (RDM) and to associate these directions with a color (yellow and blue, respectively). Importantly, the colored choice-targets appeared at random locations in the visual field 0.33s after the offset of the RDM. Although the monkey could report its decision with an eye movement to the blue or yellow target as soon as they appeared, the observed saccadic latencies were prolonged and showed strong inverse correlation with the strength of the evidence

presented earlier in the trial. The dependence of saccadic latency on the motion strength was fit with a bounded drift-diffusion model, and this fit predicted the monkey's choice behavior. Thus, the prolonged latencies are consistent with a deliberative process involving evidence accumulation after the RDM had been shown and extinguished. Consistent with this idea, the rate of rise of the neural activity in area LIP on individual trials during the action selection epoch was correlated with the strength of the perceptual evidence presented earlier in that trial. Further, the evolution of variance and the autocorrelation of the neural activity during this epoch exhibited signatures of a diffusion process. The responses of the same neurons during the RDM viewing epoch displayed none of these features.
Both the behavioral and the neural data suggest that action selection is not a one step conversion of an abstract representation of the decision into an action but is instead a process that evolves over time in a manner that reflects the quality of the evidence received. An intriguing possibility is that the brain stores a representation of the samples of the evidence acquired during the RDM viewing epoch and then accumulates evidence from these samples to reach a decision after the targets are revealed. If so, the decision appears to be postponed until it can be embodied in the framework of the available motor actions.

Title: Temporal change of position representation of a moving object filled with Gabor motion for saccadic eye movements

Authors: *H. UEDA;
NTT, Atsugi-Shi, Japan

Abstract: To interact with a moving object in the environment, it is necessary to know the precise location of the object. However, if a moving object containing internal motion (e.g., rotation) is seen in the visual periphery, the perceived global motion of the moving object is often distorted due to its local motion signals (*motion-induced position shift*). On the other hand, it has been reported (Lisi & Cavanagh, 2015) that eye movements can still correctly localize such a moving object without being affected by the distorted perceived global motion. The study raises two questions: 1) whether the distortion of global motion perception is attributed solely to motion perception or also to position perception, and 2) when target position representation for

eye movements changes from the distorted perceived location to the actual or physical one. In the present study, a well-known curveball illusion, which deviates the actual trajectory of a moving Gabor patch substantially towards the direction of its internal pattern motion, was utilized to examine the temporal change of the position representation of such moving target containing a motion for saccadic eye movements. To this end, we first examined whether this misrepresentation of the global motion trajectory of a moving Gabor patch is attributed to the distortion of its perceived position as well as perceived motion. In the experiment, a moving Gabor target with internal envelope drifts in the orthogonal direction to the global motion appeared at 10 degrees of visual angle to the right of the fixation point and disappeared at random locations on the moving path. Participants localized the final horizontal target position by judging the position was on either the left or right side of a reference line presented shortly afterward (i.e., 2-AFC task). The results confirmed that the moving stimuli containing internal motion induce not only large shifts of perceived motion but also perceived position. In the second experiment, the temporal change of position representation (i.e., motion-induced position shift confirmed in Experiment 1) for saccadic eye movements was examined by varying the elapsed time from target offset to saccade onset. With the same target stimuli as Experiment 1, participants made saccades to the final target position on the motion path after a variety of time-delay. The results showed that, in addition to the previous observation, even when target disappeared 1s before saccade initiation (i.e., memory guided saccade), eye movements could still correctly localize physical target positions. This suggests that a common position representation of a moving object is used for *visually guided* and *memory guided* saccades.

Title: Pre-saccadic mislocalization against saccade direction

Authors: *M. LAPPE[1], T. WATSON[2];
[1]Inst. for Psychology, Muenster, Germany; [2]Sch. of Social Sci. and Psychology, Western Sydney Univ., Penrith, Australia

Abstract: Stimuli flashed within 50 ms before the onset of a saccade appear shifted into the saccade direction and compressed onto the saccade target. The compression could result from an oculomotor feedback of the saccade command that distorts the population activity in visual areas

and appears to shift visual receptive fields. In the present study, we report that stimuli flashed about 100 ms before a saccade are mislocalized in the opposite direction, against the saccade and towards the fixation point. Subjects reported the apparent location of flashes presented on a computer monitor in a dimly lit room while making saccades. Flashes could occur at 5 positions equally spaced between the fixation point and the saccade target and were presented at a random time between 300 ms before saccade onset and well after the saccade. Different sessions tested different paradigms: overlap saccades, step saccades, double step return saccades, and fixation with masking at various ISIs. All saccade conditions showed mislocalization against the saccade direction at around 100 ms before the saccade. This was followed by the familiar pattern of compression towards the target at saccade onset. No mislocalization was observed in the fixation with masking condition. Mislocalization against the saccade direction was strongest for flash positions in the middle between fixation point and target. These findings have important implications for models of peri-saccadic localization and remapping. Since the mislocalization occurs outside the time window of saccadic suppression it is not related to a reduction of visibility. It is also unlikely to be related to an erroneous eye position signal. We propose that the mislocalization towards the fixation point results from enhanced fixation related neural activity during preparation of the saccade motor plan.

Title: Distinct neuronal dynamics of head tilt and translation Purkinje cell signals in the vestibular cerebellar cortex.

Authors: *J. LAURENS, H. MENG, D. E. ANGELAKI;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Brainstem-cerebellar circuits resolve a sensory ambiguity originating from Einstein's equivalence principle, where linear accelerations (A) during translations are physically identical to gravitational accelerations (G).
The underlying computations have been well characterized at a theoretical level. The brain uses an internal model of motion which integrates rotation velocity (Ω) signals into an estimate of tilt

relative to gravity (G), which is used to extract an acceleration estimate (A) from the net otolith signal (F) based on the physical equation F = G+A. This process can be broken down in three equations: (1) dG/dt = GxΩ, (2) G=∫dG and (3) A = F-G. Equation (1) converts a head-referenced rotation velocity signal (Ω) into a gravity-referenced signal dG, i.e. it is a spatial transformation. Equation (2) is an integration that matches the dynamics of the gravity signal with that of F.
We showed previously that the simple spike (SS) responses of one third of Nodulus-Uvula (NU) Purkinje cells (PC) encode G ('tilt' cells), another third encode A ('translation' cells), while the rest ('other') respond to combinations thereof. However, we never investigated the dynamics of tilt and translation signals. Therefore, we couldn't determine if steps (1) and (2) are performed in a single step of neuronal computation or in two distinct neural populations. Furthermore, a subpopulation of otolith afferent carry significant jerk (dF) components, suggesting that equation (3) could be replaced by dA=dF-dG, eliminating the need for equation (2).
Our previous studies were based on sinusoidal stimuli that provide little information about neuronal dynamics. To circumvent this limitation, we recorded the responses of 46 NU PC during combinations of transient tilt and translation stimuli where linear acceleration (A) and tilt (G) followed biphasic profiles while dA/dt and dG/dt followed triphasic profiles. We found that 13 cells responded specifically to tilt and 18 to translation. Strikingly, tilt-selective cells exhibited a triphasic response profile proportional to dG, whereas the response of translation-selective cells was biphasic, proportional to A.
These results suggest that a dG/dt signal (equation 1) is computed by a neuronal population upstream of the Purkinje cells, and that a distinct group of interneurons perform the temporal integration (equation 2). This illustrates how a systematic study of neuronal dynamics through the cerebellar circuitry may allow deciphering the neuronal implementation of a theoretically well understood computation.

Title: Bi-directional modulation of purkinje cell spike activity upon arousal *In vivo*

Authors: *S. HUR, S. J. KIM;
Dept. of Physiol., Seoul Natl. University, Col. of Med., Seoul, Korea, Republic of

Abstract: The cerebellum receives noradrenergic (NA) fibers originating from the locus coeruleus (LC). In the state of arousal, an overflow of this neurotransmitter are diffused and acts on α- and β-adrenergic receptors of neurons modulating the spike activity and synaptic strength. The cerebellum has a well-recognized role in maintaining motor coordination. Many studies regarding cerebellar learning has suggested that by recognizing neural patterns the cerebellum predicts optimal movements thus tuning fine motor movements. The Purkinje cell (PC), the sole output of the cerebellum, receive excitatory and inhibitory inputs from parallel fibers, climbing fibers, and molecular layer interneurons which is summated and relayed to the post-synaptic neuron by simple (SS) and complex spikes (CS) ultimately inducing motor movements. *In vitro* and *in vivo* studies of animals under anesthesia have shown bath and local application of NA excite or depress PC spontaneous spike activity depending on NA concentration. Several reports have introduced change in awake *in vivo* calcium dynamics upon arousal in various cells and regions of the brain. However, how NA effects SS and CS activity of PCs in awake mice upon natural endogenous secretion by arousal has not yet been discussed. Using *in vivo* single-unit electrophysiological recordings in awake C57BL/6J mice, SS and CS activity were recorded from PCs. Recordings began when the mice were in a stable state (low respiration, no locomotion, and stable pupil diameter). To induce arousal, air puff stimulation to the tail evoke a startle response (high respiration, locomotion, and increased pupil diameter). Results show that increase of NA diffused from the LC to the cerebellum show a bi-directional modulation of SS activity upon a startle response but no change in CS activity.

Title: Variable single unit responses in the pontine nuclei during auditory evoked eyelid conditioning

Authors: *E. A. KISH, M. DODLA, E. D. DELORD, H. E. HALVERSON, M. D. MAUK; Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: The cerebellum makes predictions about what the correct movement is in response to the current state of the world. These predictions can be modified by the repeated coincident arrivals of a sensory stimulus and a teaching signal. This can be described as a Pavlovian learning paradigm where the sensory stimulus is the conditioned stimulus (CS) and the teaching signal is the unconditioned stimulus (US). The CS is conveyed to the cerebellum through mossy fibers that originate from the pontine nuclei. In an effort to elucidate what the cerebellum sees in order to learn and make predictions, we performed chronic *in vivo* tetrode recordings in male rabbits across the entire expanse of the right pontine nuclei during 108 trial sessions during presentations of either a pure tone or eyelid conditioning sessions where a tone (CS) was paired with the stimulation of the periocular muscles (US) of the left eye. This allowed us to characterize a variety of response types (e.g. phasic, tonic, and feedback) in the pontine nuclei during the CS period both before and after the rabbits learned to make conditioned responses (CRs), measured as eyelid closure during the CS and preceding the US. While robust phasic responses may convey more information about the onset of the CS, tonic input to the cerebellum may be important for relaying the duration of the CS. Feedback responses, increases or decreases in pontine firing rate that occur after CR onset, have a putative role in chaining together movements or amplifying relevant stimulus inputs. This feedback is potentially driven via direct cerebellar output collaterals to the pontine nuclei or through thalamo-pontine projections receiving cerebellar feedback. These recorded pontine responses were also used as mossy fiber input in a simulation of the cerebellum in order to create a more biologically accurate model of the cerebellum. Since we can manipulate the simulation in ways that are not feasible in live animals, this allows us to ask questions about why certain aspects of the CS input may be important to the cerebellum for both learning and making accurate predictions. These methods allow us to characterize pontine responses during an auditory CS in order to ask questions about what input the cerebellum uses to learn and make predictions.

Title: Selective encoding of unexpected head tilt by the central neurons takes into account the cerebellar computation output

Authors: *I. MACKROUS[1], J. CARRIOT[2], M. JAMALI[3], J. BROOKS[4], K. CULLEN[4]; [1]Physiol., McGill, Montreal, QC, Canada; [2]Physiol. and pharmacology, Univ. of Western Ontario, London, ON, Canada; [3]Harvard, Boston, MA; [4]Physiol., McGill Univ., Montreal, QC, Canada

Abstract: During daily activities, our sensory system is activated by self-generated and external events. We have previously shown that cerebellar output neurons and their targets neurons in the vestibular nuclei robustly encode passively applied motion in the horizontal plane, while they are attenuated during comparable self-generated head motion. However, natural head movements are not restricted to one plane and generate more complex vestibular stimuli because of the presence of the gravity. Specifically, sensory periphery does not provide an accurate representation of the gravity due to Einstein's equivalence. Therefore, we tested whether a neural representation of gravity is included in the internal model used to differentiate between passive and active motion. We first studied neuronal responses of cerebellar output neurons (rostral Fastigial nuclei, rFN) during passive tilts motion and found that neurons could be divided in three groups: translation-selective, tilt-selective and GIA selective cells. Sensitivity of the GiA selective cells was similar to translation and tilt. Tilt selective and translation selective cells showed a higher sensitivity for their respective preferred stimulation. We then recorded the responses of each neuron while monkeys made voluntary changes in head orientation by performing head tilt motion. Relative to their modulation in response to either passive translation or to passive tilt, neuronal responses to comparable self-generated movements were attenuated rFN (78%). This was consistent with prior characterizations for active translation in the horizontal plane showing a ~70% decrease in the neuronal modulation during active movements. Furthermore, because passive and active stimulation are often experienced simultaneously, we also tested whether neurons selectively encode sensory exafference under a condition where the monkeys were passively translated while generating simultaneous voluntary head tilt motion. When submitted to concomitant passive and active stimulation, both translation and GIA-selective cells responses provided a precise estimate of the passive motion. Such modulation was not expected for the tilt-selective cells as they do not encoded passive translation motion. Our findings demonstrated a sophisticated processing, where the internal model integrates not only an exogenous stimulus as shown previously, but also take into account the complex calculation of tilt-translation disambiguation.

Title: Cerebellar complex spiking differentially encodes trial outcome in a voluntary forelimb task

Authors: J. HEFFLEY, A. MCKINNEY, *C. HULL;
Neurobiolgy Dept, Duke Univ., Durham, NC

Abstract: In the mammalian cerebellum, climbing fibers provide a powerful synaptic input to Purkinje cells that evokes regenerative dendritic calcium events called complex spikes. Complex spikes are generally thought to provide instructional signals that drive cerebellar-dependent motor learning. For many simple behaviors such as learned modifications to reflexes, climbing fibers have been shown to provide motor error signals. However, it is unclear whether such a model can explain more flexible behaviors where there are multiple sensory and motor signals necessary to drive learning, which themselves often need to be learned. Therefore, to test the role of complex spiking in motor learning, we have developed a forelimb-based motor learning paradigm for the head-fixed mouse that is amenable to calcium imaging and other recording methods, as well as optogenetic manipulation of neural activity. Here we address the question of what information complex spikes convey prior to learning, and how this information is distributed across large regions of the cerebellum during a motor behavior that can readily be modified by learning. By expressing GCaMP6f in cerebellar Purkinje cells, we studied complex spiking using both widefield imaging to visualize large regions of cerebellar cortex, and resonant scanning two-photon imaging to visualize complex spikes within individual Purkinje cells. Using these approaches, we find robust task-modulated complex spiking localized to lobule simplex, where Purkinje cells can drive ipsilateral arm movements. Contrary to a model where complex spikes signal motor errors, widefield imaging revealed larger amplitude calcium transients in response to successfully timed arm movements as compared with improperly timed movements. To test the underlying source of these differential responses, we imaged individual Purkinje cell dendrites at higher resolution using resonant scanning two-photon microscopy. These experiments revealed that well-timed movements produced both larger responses within individual dendrites, as well as a larger number of responsive dendrites across a local population of Purkinje cells. Thus, we find that task-modulated complex spiking is driven in a temporally specific manner that is linked to trial outcome, properties that are well suited to instruct motor

learning. However, our findings are not consistent with an error-based model of complex spike driven motor learning in our behavioral paradigm. Instead, our results suggest the hypothesis that complex spiking is more closely tied to the specific combination of sensorimotor inputs necessary to drive learning rather than to the valence of the inputs it encodes.

Title: The relationship between local field potentials in the primary motor cortex and the cerebellum during sleep

Authors: *W. XU[1], F. DE CARVALHO[2], A. JACKSON[2];
[1]Fac. of Med. Sci., [2]Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Studies of brain activity during sleep have hitherto largely concentrated on signals from the cerebrum. Despite the fact that both the cerebellum and sleep are heavily implicated in motor learning, very little is known either about cerebellar activity or its relationship to cerebral activity during different sleep stages. Using a wearable device we made recordings of local field potentials (LFPs) from the primary motor cortex (M1) and the cerebellum of the macaque during natural sleep in its home environment. We found that cerebellar and M1 LFP powers generally modulated together in time during sleep. We used modulation of M1 power in the delta band (0-4Hz) as a continuous measure of the periodicity of sleep. We took periods of relatively high delta power to represent slow-wave (stage 3) sleep and periods of relatively low delta power to represent non-slow wave sleep (stage 1, 2 and REM sleep). We find that power in higher frequency bands is modulated out of phase with delta power in both M1 and the cerebellum. Moreover we see a greater degree of coherence between M1 and cerebellar LFPs in these higher frequency bands during periods of relatively low M1 delta power, and vice versa. There is also a greater degree of periodicity in the modulation of powers of frequencies up to the low gamma range during sleep and the coherence between the two brain regions occurs in a different frequency ranges compared to waking. We conclude that the well-known cortical sleep states are associated with distinct patterns of activity in the cerebellum, and that behavioural state influences the interaction between motor cortex and cerebellum.

Title: Amygdala inactivation impairs delay eyeblink conditioning with a visual conditioned stimulus.

Authors: *S. J. FARLEY, J. H. FREEMAN;
Dept of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Amygdala modulation of cerebellar-mediated conditioned responses has recently been demonstrated (Farley et al, 2016, Siegel et al, 2015). A candidate mechanism is that amygdala output may modulate the conditioned stimulus (CS) pathway in delay eyeblink conditioning (dEBC). However, it is unknown if the amygdala modulation is specific to dEBC with an auditory CS. To address this, we trained adults rats in dEBC as previously reported (Farley et al, 2016), but used a white LED as the CS.Adults rats were bilaterally implanted with a cannulae directed at the amygdala central nucleus (CeA). Rats were divided into three groups: MUS (muscimol [GABA-A agonist]), SAL (saline), MUS-EXT (extensive training with muscimol). The MUS and SAL groups received muscimol (2mM, 0.2µl) or saline infusions 30 minutes prior to training during sessions 1-5. Training continued without infusions from session 6 to reaching criterion. Saline and muscimol retention tests were then given to all rats (order counter balanced). The CS was then switched to an auditory CS and rats reacquired dEBC. After reaching criterion, rats were given retention tests again with saline and muscimol infusions. For the MUS-EXT group, rats were trained for 16-sessions with CeA inactivation. Training continued without inactivation from session 17 until reaching criterion, after which they underwent a muscimol retention session.Acquisition of dEBC with a visual CS was severely impaired with CeA inactivation. There were no differences in the rate or magnitude of other eyeblink measures (unconditioned responses, startle responses, etc) during the initial LED training. The number of sessions to reach criterion without inactivation was the same between muscimol and saline animals across CS modalities. After rats in the MUS-EXT group reached criterion, their conditioned responses were impaired with a muscimol retention session and then CRs recovered to pre-retention levels the following session. These results show that CeA inactivation impairs the acquisition and retention of dEBC with either a visual or auditory CS.

Furthermore, despite some learning of the CS-US association with extensive CeA inactivation, amygdala output appears to have a persistent role in the acquisition and retention of dEBC. These results are consistent with previous findings that amygdala output to the pontine nucleus may strongly modulate CS information to the cerebellum.

Title: Amygdala modulates cerebellar learning through the conditioned stimulus pathway

Authors: ***L. J. CEMO**[1], S. J. FARLEY[2], J. H. FREEMAN[2];
[2]Psychological and Brain Sci., [1]Univ. of Iowa, Iowa City, IA

Abstract: Eyeblink conditioning (EBC) is an associative motor learning task requiring the cerebellum. Previous research has shown impaired acquisition and retention of EBC when the central amygdala (CeA) is inactivated with muscimol or bupivacaine in rats (Ng & Freeman, 2014; Farley et al., 2016). The medial CeA has a monosynaptic projection to the basilar pontine nuclei (PN), which relay conditioned stimulus (CS) information to the cerebellum via the middle cerebellar peduncle (MCP). Moreover, there is evidence that the CeA modulates CS-related activity in the PN (Taub & Mintz, 2010). However, the CeA has other projections that could influence the eyeblink conditioning circuitry. In this study, electrical stimulation of the MCP (50 Hz, 100 μA) was given as the CS during eyeblink conditioning in rats in order to bypass the amygdala projection to the CS pathway. The CeA was also pharmacologically inactivated during both acquisition and retention of EBC. If the CeA influences cerebellar learning through projections to the CS pathway, learning with MCP stimulation as the CS should be unaffected by CeA inactivation. On the other hand, if the CeA influences cerebellar learning through projections to the unconditioned stimulus, unconditioned response, or conditioned response pathways, CeA inactivation should at least partially impair EBC when using MCP stimulation as the CS. Acquisition and retention of EBC with MCP stimulation as the CS were completely unimpaired by CeA inactivation. These findings indicate that the amygdala exerts its modulatory effect on cerebellar learning exclusively through the CS pathway, possibly at the level of the PN.

Title: Encoding of voluntary movement by cerebellar interneurons during active whisking

Authors: S. CHEN[1], G. J. AUGUSTINE[2], *P. T. CHADDERTON[1];
[1]Imperial Col. London, London, United Kingdom; [2]Lee Kong Chian Med. Sch., Nanyang Technological Univ., Singapore, Singapore

Abstract: The cerebellum is a major site of sensorimotor integration, but our understanding of how the circuit encodes associated sensory and motor information during behaviour remains limited. Here we use a well-defined model, the mouse vibrissae system, to study how sensorimotor signals are represented by the activity of individual neurons within the cerebellar cortex. We have recently shown that single Purkinje cells linearly encode whisker position via bidirectional firing rate changes (eLife 5: e10509). However, it is unclear how whisker information is processed before reaching Purkinje cells. We examined the contribution of synaptic inputs to this linear encoding scheme by directly recording from two types of upstream neurons, excitatory granule cells and inhibitory interneurons. In vivo patch clamp recordings were made from lobule Crus I in awake, head-restrained mice. Simultaneous high-speed videography and motion tracking allowed us to correlate spontaneous whisking behaviour with single neuron activity. We found that granule cells (n = 5/13 whole cell, 9/15 cell-attached) use high-frequency bursting activity to individually encode sparse and sharply tuned information about whisker set point. Granule cell populations thus provide to downstream neurons an overall linear excitatory drive correlated with set point change. In contrast, putative molecular layer interneurons (MLIs) exhibited bidirectional changes in firing rate during whisking (n = 34/43), with a large fraction displaying linear relationships (n = 19/43) between firing rate and whisker position in the same manner as Purkinje cells. Thus, feed-forward inhibitory signalling via MLIs functionally reverses the sign of whisker-related inputs received by Purkinje cells (and by other interneurons). Our results suggest that sparse and selective granule cell activity is integrated by

downstream neurons to provide a linear representation of volitional movement in MLIs and Purkinje cells.

Title: Temporal prediction signals in the cerebellar dentate nucleus are shaped by GABAergic inputs in behaving monkeys

Authors: ***A. UEMATSU**, M. TANAKA;
Hokkaido Univ. Sch. Med., Sapporo, Japan

Abstract: We previously found that neurons in the cerebellar dentate nucleus (DN) exhibited temporally-specific firing modulation for isochronously repetitive stimuli, which were proportional to the interstimulus interval (Ohmae et al., *J Neurosci,* 2013). To assess the relative contribution of the inputs from Purkinje cells (P-cells) and mossy fibers (MFs) to the firing modulation in the DN, we compared single neuronal activity before and during infusion of either $GABA_A$ receptor antagonist (gabazine, 1–4 mg/mL) or glutamate receptor antagonists (NBQX and CPP for AMPA and NMDA receptors, respectively; 0.5 mg/mL for each). Drugs were pressure-injected (~0.3 μL at 7–15 nL/min) during single neuron recordings using a homemade injectrode and a micropump. Three monkeys performed the "missing oddball" task, in which animals made a saccade in response to a single omission of repetitive visual stimuli that appeared at a fixed interstimulus interval. To accomplish this task, the animals had to predict the timing of each next stimulus in the sequence.
When gabazine was administrated, the magnitude of firing modulation for each repetitive stimulus significantly decreased (paired *t*-test, $n = 12$, $p < 0.05$), while the majority elevated the baseline firing rate ($n = 7/12$, $p < 0.05$). On the other hand, when NBQX+CPP compound was applied, the size of firing modulation remained unchanged ($n = 8$, $p = 0.96$), although most neurons reduced the baseline firing rate ($n = 5/8$, $p < 0.05$). Furthermore, the changes in baseline activity and those in the firing modulation tended to negatively correlate with each other in the gabazine experiments (Spearman's rank correlation, $r_s = –0.50$, $p = 0.10$), whereas they showed a trend of positive correlation in the NBQX+CPP experiments ($r_s = 0.52$, $p = 0.20$). We also found

that only a few neurons showed alteration of saccade-related neuronal activity during either drug infusion in the memory-guided saccade trials. These results suggest that the temporally-specific firing modulation in the DN might be generated by the inputs from the cerebellar cortex, although both the signals from MFs and P-cells may contribute to adjusting the level of baseline activity.

Title: Cerebellar modulation of the prefrontal cortex

Authors: ***A. SCHOTT**, K. KHODAKHAH;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The cerebellum is canonically known for its role in coordinating movement. However, evidence from several anatomical tracing studies suggests that some cerebellar projections terminate in non-motor areas. Recent work in our laboratory has revealed a functional monosynaptic connection between the deep cerebellar nuclei (DCN) and ventral tegmental area (VTA), which influences reward and motivational behaviors through dopamine signaling. The VTA is known to project directly to the prefrontal cortex (PFC), an area that has been implicated in complex cognitive processing. Here, we determined whether VTA cells that receive cerebellar input go on to project to cells in the PFC. For our anatomical tracing experiments, we used GFP-tagged H129, a strain of herpes simplex virus type 1 that trans-synaptically spreads predominantly in an anterograde direction. We found that in mice, injection of H129 into the DCN results in GFP-labeled cells in PFC. In order to assess the functional responses of PFC neurons to cerebellar activation, we performed extracellular *in vivo* recordings in awake, behaving mice. We found that optogenetic stimulation of Channelrhodopsin2-expressing cerebellar axons in VTA robustly modulates firing rates of both VTA and PFC neurons. We observed both excitatory and inhibitory prefrontal responses upon stimulation of cerebellar

fibers. These data suggest that the cerebellum communicates with the prefrontal cortex, and may have a substantial role in influencing cortical processing.

Title: Cerebellar projections to VTA: reward and social roles

Authors: ***I. CARTA**[1], C. H. CHEN[2], S. DORIZAN[3], A. SCHOTT[1], K. KHODAKHAH[1]; [2]Neurosci., [1]Albert Einstein Col. of Med., Bronx, NY; [3]Neurosci., Northwestern Univ., Chicago, IL

Abstract: The cerebellum is an important structure for movement. However, some of its projections terminate in brain areas that are not related to movement. Cerebellar fibers are found throughout the midbrain, including the ventral tegmental area (VTA). The VTA, through dopaminergic signaling, participates in reward, motivation and socially related behaviors. We hypothesized that a cerebellar-VTA connection might be a substrate for cerebellar modulation of non-motor behaviors. To test this, we first examined the functional properties of this connection by expressing Channelrhodopsin2 (ChR2) in the deep cerebellar nuclei (DCN) and recording from the VTA either in vitro or in vivo while stimulating ChR2+ axons from the cerebellum. We found that responses in the VTA were common, and many of these cells were dopaminergic. In order to determine whether the cerebellar input to VTA is important to influence these complex behaviors we expressed either ChR2 or Archaerhodopsin (ArchT) in the DCN of mice, and bilaterally implanted optical fibers above VTA. We then performed behavioral testing to assess reward seeking and sociability. In a simplified self-stimulation test we found that optical stimulation of cerebellar terminals in VTA is sufficient to induce self-stimulation. Moreover, in the three chamber social task, we found that the natural preference of mice for social contexts is lowered if stimulation is offered as an alternative. To further determine whether the cerebellar inputs to VTA play a role in social behavior we silenced them using ArchT and indeed the social preference was decreased during the task. Finally, to test whether the cerebello-VTA pathway is naturally active during social behavior, we injected some mice with GCamp6 in DCN and implanted them with optic fibers in the VTA to detect calcium fluorescence. When we tested them in the three chamber social task, we observed increased calcium fluorescence while the mice were close to the social cue. Our data suggest that cerebellum might be an important

upstream structure that shapes VTA response to salient stimuli thereby influencing reward and social behavior.

Title: A center surround system for movement control in the deep cerebellar nuclei

Authors: ***S. A. HEINEY**[1], J. F. MEDINA[2];
[2]Dept. of Neurosci., [1]Baylor Col. of Med., Houston, TX

Abstract: We previously identified a small region in the anterior interpositus nucleus of the cerebellum that is essential for the expression of learned eyelid movements in mice, and reported that the responses of some neurons located in and around this “hotspot” are positively correlated with the eyelid kinematics on single trials. Here we analyzed how the same neurons respond during locomotion and report an unexpected feature of the response properties. Mice were head-fixed on top of a cylindrical treadmill and trained to blink in response to a light or vibrissal conditioned stimulus (CS) that was repeatedly paired with an airpuff to the eye. We then made single unit recordings in and around the eyeblink hotspot while the mice performed conditioned eyelid movements and walked freely on the treadmill. We found that many of the neurons that had excitatory responses during conditioned eyelid movements were inhibited during locomotion. Furthermore, the firing of nearby neurons was a mirror image: inhibition during conditioned eyelid movements and excitation during locomotion. This antagonistic relationship between neighboring neurons suggests that neurons within the deep cerebellar nuclei contain center surround motor fields analogous to the center surround receptive fields commonly seen in sensory systems.

Title: A hypothesized circuit mechanism underlying motor memory expression in cerebellum

Authors: *A. M. REEVES[1], T. S. OTIS[2];
[2]Neurobio., [1]UCLA, Los Angeles, CA

Abstract: The cerebellum has long been hypothesized to be involved in the storage and expression of motor memories. Recently, our lab showed that optogenetically conditioned motor memories are stored in the cortical and nuclear regions of the cerebellum and expressed via disinhibition-mediated bursts of activity in the cerebellar nuclei. The objective of this study was to determine the impact of preventing disinhibition of the cerebellar nuclei when cueing an optogenetically conditioned forelimb movement. By transiently increasing inhibition of cerebellar nuclei during high-speed video recordings of mice responding to a previously conditioned auditory cue, we demonstrated that preventing disinhibition of cerebellar nuclei prevents the expression of the learned forelimb movements. We conclude that disinhibition-mediated bursting of the cerebellar nuclei is necessary for expressing the motor memory and the subsequent forelimb movement. Furthermore, we suggest this mechanism could be relevant for the expression of other kinds of cerebellum-dependent motor memories.

Title: Spatial updating of saccades: What do the superior colliculus and cerebellum do?

Authors: *R. SOETEDJO;
Physiol. and Biophysics,, Univ. of Washington, Seattle, WA

Abstract: We are constantly moving, and these movements shift the visual representation of the target goal of an impending movement across the retina. The brain must re-compute the programming of the movement toward the goal to take into account the intervening movements so that our goal directed movement is accurate. Spatial updating of movements can be studied using saccades by exposing the subjects to double-step saccade task (DST). In this task, two sequential saccades are made in the dark following two flashes of a small target spot in different locations on a tangent screen. The first saccade disrupts the congruency between the vector of the retinal representation of the second target flash and the desired vector of the second saccade. Because there is no intervening saccade, in targeting saccade task the two vectors are congruent. In DST task, the superior colliculus (SC) is thought to send the desired saccade vector signal to brainstem burst generator to produce the second saccade. However, our data showed that the saccade-related bursts of neurons in the intermediate layer of the SC appeared to encode the initial vector of the retinal representation of the second target flash (retinotopic goal). The incongruity between the signal from the SC and the vector of the impending saccade requires a correction. For example, in a DST task in which the two target flashes appears at 8 and 16 degree eccentricities, the monkey must make two 8 degree saccades in the same direction. Saccade-related burst neurons located at 8 degree site burst for the first 8 degree saccade. They do not burst for the second 8 degree saccade, but neurons located at 16 degree site do. Therefore, the drive signal from the SC would be too large for producing 8 degree second saccade, and other neuronal structures must compensate for it. One candidate is the cerebellar caudal fastigial nucleus (cFN) because it projects directly to the burst generator. Neurons in cFN exhibit earlier burst for contraversive saccades and later burst for ipsiversive saccades. It is thought that the early burst is accelerating the contraversive saccades, and the late burst is decelerating ipsiversive saccades. Our recording from cFN neurons using DST task indicated that their burst timing and magnitude seem appropriate to compensate for the retinotopic goal signal from the SC during the execution of the second saccade. Taken together, these data argue that the oculomotor cerebellum may involve in computing the spatial updating of saccades.

Title: Comparing visuovestibular modulation of floccular interneurons and Purkinje cells; or, Where does the diversity go?

Authors: R. A. HENSBROEK, J. MARUTA, B. J. VAN BEUGEN, *J. I. SIMPSON; PHYSIOLOGY & NEUROSCIENCE, New York Univ. Sch. of Med., New York, NY

Abstract: "Neuronal machine" is a metaphor for the cerebellum, although knowledge of how the parts of the machine work together to provide an appropriate output is quite limited. This situation reflects the difficulty in identifying the activity of the various parts of the "machine", especially during an awake animal's behavior. Recently, we developed a decision tree using spontaneous firing patterns to identify classes of interneurons. The ability to distinguish among mossy fiber inputs, interneuron classes, and Purkinje cell outputs provides opportunities to study integration in cerebellar signal processing. We report here on the modulation of identified floccular Purkinje cells and interneurons in the awake rabbit responding to visuovestibular stimulation. Single-cell recordings were made in the flocculus of two awake rabbits that were sigmoidally oscillated about a vertical axis in the light. This stimulation allows determination of sensitivity to rotation direction and to the underlying movement kinematics. Earlier work in our laboratory showed that the vast majority of those rabbit floccular Purkinje cells whose complex spikes (CSs) were best modulated by visual image slip about the vertical axis responded in the dark with an increase in simple spike (SS) activity during contralateral head rotation and/or a decrease in SS activity during ipsilateral head rotation. (Responses with such a directional polarity are called type II. Responses with the opposite polarity are type I). Interestingly, floccular mossy fibers have been reported to be type I or type II in roughly equal numbers. In the present study, each interneuron class - unipolar brush cell, granule cell, Golgi cell, and basket/stellate cell - had both type I and type II members. Unipolar brush cells and granule cells had more type II than type I responsive cells (8 vs 4 and 12 vs 8, respectively), Golgi cells had more type I responsive cells (10 vs 3), while basket/stellate cells had nearly equal numbers of type I and type II responsive cells (6 vs 5). In marked contrast, in the present study the 16 Purkinje cells with CSs best responsive to visual slip about the vertical axis all had type II SS modulation. Taken together, the findings reveal that the roughly balanced presence of type I and type II input modulations is maintained on the interneurons, but is absent on the output Purkinje cells. The extent to which this loss of diversity was divided between moment-to-moment

computational processes and longer-term plastic processes is not yet known. In situations other than the one reported here, other SS modulation patterns may arise, drawing from the wide range of available interneuron diversity.

Title: Intrinsic movement representation in the cerebrocerebellum

Authors: *T. ISHIKAWA[1], D. S. HOFFMAN[2,3], S. KAKEI[1];
[1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Dept. of Neurobio., [3]Cent. for the Neural Basis of Cognition, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: In primates, the hemispheric part of the cerebellum is termed the cerebrocerebellum because it receives its primary input from the cerebral cortex via pontine nuclei. The ponto-cerebellar projection terminates as mossy fibers (MFs) in the granular layer of the cerebellar cortex. The MFs projecting to lobules IV-VI of the cerebrocerebellum receive predominant inputs from the primary motor cortex (M1) and premotor cortex (PM) in the frontal lobe (Kelly and Strick 2003). The output of this part of the cerebrocerebellum is generated in the dentate nucleus (DN) and sent back to M1 or PM via thalamus. Because of this anatomical structure, examination of activity patterns of the MFs and DN cells during a movement should provide important clues for understanding the functional role of the cerebrocerebellum in control of voluntary movement.
We recorded unit activity of MFs and DN cells in 2 monkeys during step-tracking movements of the wrist joint in two forearm postures: full pronation (Pro) and full supination (Sup). We found 52 MFs and 51 DN cells with significant task-related activity in both forearm postures. Most of these (n=49 MFs and n=48 DN cells) had clear somatosensory receptive fields in the distal part of the ipsilateral arm. For each cell, we calculated a task-related preferred direction (PD) before movement onset and determined the change in PD from Pro to Sup postures. More than half of the MFs (n=27) and DN cells (n=27) showed directional tuning in both forearm postures and had a significant change in PD (40-120 deg) between postures. This change in PD was comparable to

that of EMG activity of task-related forearm muscles (average 65 and 100 deg in the two monkeys) and also matched that of "intrinsic-like" M1 cells reported in a previous study (Kakei et al. 1999). Furthermore, the timing of the modulations in MFs and DN cells preceded movement onset (average of 83 and 77 msec, respectively). Taken together, our results are consistent with the view that MFs projecting to lobules IV-VI of the cerebrocerebellum transmit an efference copy of motor cortical activity prior to movement onset. The timing of DN output to M1 and PM is early enough to provide a prediction of the sensory outcome of the planned movement prior to any sensory feedback from the actual movement. Thus, our results indicate that the cerebrocerebellum contains a forward model directed to frontal lobe motor areas to improve the precision of motor control.

Title: Firing of Purkinje cells and neurons of the cerebellar nuclei during free and optogenetically perturbed locomotion in awake mice

Authors: *R. SARNAIK, I. M. RAMAN;
Dept. of Neurobio., Northwestern Univ., Evanston, IL

Abstract: Purkinje (Pkj) cells change their firing rates during movements and modulate the activity of target cells in the cerebellar nuclei (CbN) via convergent, GABAergic projections. Large CbN cells generate cerebellar output that can facilitate coordinated movements or correct errors. To test how the firing rates of Pkj and CbN cells change during rest and locomotion, and to examine how Pkj firing patterns affect CbN cells, we made loose cell-attached recordings in head-fixed mice running ad lib on a cylindrical treadmill. The position of the ipsilateral hindpaw was monitored so that firing could be examined relative to the step cycle. Mice expressed channelrhodopsin (ChR2) in Purkinje cells (L7-cre x Ai27D), and illumination was applied through an optical fiber in the patch pipette. Optogenetic stimulation of Pkj cells near the recording pipette was used (1) to activate Pkj or inhibit CbN cells and so confirm the identities of neurons, (2) to evoke light-induced discontinuities in ipsilateral hindlimb movement and so verify that cells were in an ipsilateral hindpaw-specific region in lobule VI (Pkj) and in the

anterior interpositus (CbN), and (3) to manipulate Pkj cell firing patterns. When mice were stationary, the firing rates of both Pkj and CbN cells were similar, and, when mice ran, the mean rates of both groups increased (Pkj: rest 69 ± 7, run 109 ± 9, n = 26; CbN: rest 71 ± 5, run 92 ± 6 sp/s, n = 27). During running, most Pkj and CbN cells modulated their firing consistently at distinct phases of the step cycle, usually regardless of the stride length. Plots of instantaneous spike rates relative to the step cycle showed that firing could be (I) in phase, (II) 90 degrees shifted, with rates rising on the stance, (III) out of phase, (IV) 270 degrees shifted, with rates rising on the swing, (V) doubly peaked, with rises on the stance and swing, (VI) doubly peaked, with decreases on the stance and swing, or (VII) unmodulated. Pkj and CbN cells were found in all categories, with the largest groups of Pkj cells in classes II (n = 6/26) and V (n = 11/26) and the largest groups of CbN cells in classes I (n = 9/32) and II (n = 9/32). Optical stimulation of Pkj cells could perturb ipsilateral hindpaw movement in running mice or initiate running in stationary mice. In each cell, the light stimulus was varied, including steps (1-2 s) of different intensities and trains at several rates (1-ms pulses, 20-225 Hz). Even when mean firing rates of Pkj cells were matched, movement was more likely to be altered by light steps than by light trains, especially with Pkj firing rates <100 Hz. These data suggest that cerebellar output can vary with temporal patterns of Pkj cell activity.

Title: The ghost in the machine: long range cerebellar signals

Authors: *L. S. POPA, Mr, M. L. STRENG, T. J. EBNER;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The cerebellum is essential for precise and skillful motor behaviors. The time frame for expression of cerebellar function in motor control is generally assumed to be relatively short, close to real time. However, increasing evidence for cerebellar involvement in sequencing and working memory argues that cerebellar function manifests over extended time periods in both motor and cognitive domains.
In this study we examine the time frame of the cerebellar cortex signaling. Inter-temporal regression analysis of simple spikes (SS) firing recorded from 183 Purkinje cells during pseudo-random tracking reveals that modulation with kinematics (position, velocity and speed) and performance errors (position and radial errors) persists up to 2 s before and after behavior. The significance of the SS modulation for each behavioral parameter was assessed against regressions obtained with trial shuffled data that decoupled SS firing from behavior while preserving data statistics. Importantly, the long range signals in the SS firing were abolished in the trial shuffled data. For each behavioral parameter we divided the ± 2000 msec window of interest into eight epochs of 500 msec. The presence of signals was based on the largest significant local maxima of the R^2 temporal profile in each epoch. Position, velocity and position errors have the most frequent and strongest long-range predictive and feedback modulations, with less common, weaker long-term correlations for speed and radial error. Autocorrelations of the behavioral parameters show no secondary peaks that could explain the long range correlations. Furthermore, cross-correlations between behavioral parameters reveal only a few pairs with strong interactions that cannot fully explain the SS encoding of those parameters. Position, velocity and position errors can be decoded from the population SS firing with remarkable accuracy for even the longest predictive (-2000 to -1500 msec) and feedback epochs (1500 to 2000 msec). In the -500 to 0 and 0 to 500 msec epochs, decoding for all behavioral parameters is almost perfect.
We conclude that Purkinje cells SS discharge includes not only short-range predictive and feedback signals but also long-range activity over ± 2 s related to working memory and expectations of future behavior. Such long-range signals could provide the neural substrate underlying cerebellar involvement in working memory and sequencing. These results suggest the cerebellum evaluates the consequences of motor commands over a time frame consistent with the widespread 3-4 sec integration window characterizing motor, sensory and cognitive processes, considered to represent the "subjective present".

Title: The fine temporal structure of neural spike trains impacts motor behavior

Authors: *H. L. PAYNE[1], R. LI[1], C. C. GUO[2], J. L. RAYMOND[1];
[1]Stanford Univ., Stanford, CA; [2]QIMR Berghofer, Brisbane, Australia

Abstract: Neural spike trains can be characterized by both their overall firing rate and precise temporal patterning. Whereas firing rate is widely assumed to affect the activity of downstream neurons, the functional significance of the fine temporal structure of neural spike trains has been more difficult to test. An understanding of this functional impact may be especially relevant in designing and interpreting stimulation experiments, which typically use perfectly regular stimulus trains, although neural activity *in vivo* is often highly irregular.
We leveraged the experimental advantages of the oculomotor cerebellum to test the effects of the fine temporal structure of spike trains in intact animals. Optogenetic stimulation of Purkinje cells, the output neurons of the cerebellar flocculus, drove smooth eye movements time-locked to the stimulus. We investigated the interaction between two parameters: the irregularity and mean rate of Purkinje cell stimulation. Irregular activation patterns drove significantly smaller mean eye movements than the corresponding regular pattern at the same underlying rate. A biophysical model of the Purkinje cells' target neurons, modified from Luthman et al. (2011), was used to investigate how the irregularity of stimulus-driven, inhibitory synaptic input from Purkinje cells interacts with ongoing spontaneous input to control downstream pre-motor targets.
Finally, we assessed the impact of firing rate irregularity in the more natural context of eye movements driven by sensory stimuli. Recordings from Purkinje cells during oculomotor behaviors in both mice and monkeys revealed that the irregularity of spiking, as well as the spike rate, varied rapidly during behavior. Naturalistic sequences of concurrent changes in firing rate and irregularity were then played back optogenetically to Purkinje cells *in vivo.* The results provide causal evidence that the changes in spiking irregularity driven by sensory stimuli can serve to amplify the impact of firing rate changes on motor output.

Title: Cross correlation and coherence study of cerebellar and cerebral cortical responses to tDCS using an *In vivo* approach

Authors: S. GEEVARUGHESE, J. H. YOO, *H. LU;
PCOM - Georgia Campus, Suwanee, GA

Abstract: The use of transcranial direct current stimulation (tDCS) as a potential therapeutic treatment for movement disorders associated with cerebellum has shown promise according to early studies. Our previous studies on the effects of tDCS to the cerebellum using rats suggested there were changes in Purkinje cell firing rate and local field potentials (LFPs). In our current investigation, dual recordings from the cerebellar and motor cortices were conducted on six Sprague-Dawley rats. A total of 16 Purkinje cells were isolated *in vivo* along with LFP recordings in both cerebellar and cerebral cortices with anodal tDCS at two different intensities: 100 μA and 200 μA. Both types of stimulation generated an overall decrease in Purkinje cell firing rate by 13%, which is in contrast to previous studies showing an increase. This indicates that the change in firing rate of the Purkinje cells is variable. Power spectrum analysis of LFPs in the motor cortex by tDCS revealed frequency changes in 13 out of 16 recordings. These changes are associated with an activity peaked at a frequency ranged from 85-100 Hz. In 3 cases, there is an immediate increase in amplitude for low frequencies following stimulation. The results support previous studies that electrophysiological changes in the motor cortex are associated with the activity changes in cerebellar cortex. We further studied the tDCS effects on cerebello-cerebral cortical relationship using cross correlation and coherence methods. Analysis shows a cross correlation ranging from 0.2-0.5 after normalization in 15 of 16 recordings. Further analysis on cross correlation lags indicates that the signal from the motor cortex precedes that of the cerebellar cortex although a variable change by tDCS is observed. Coherence analysis using magnitude squared coherence estimation shows correlation in two frequency ranges: 5-25 Hz and 85-100 Hz. The higher frequency range appeared in the power spectrum analysis for LFPs in both cortical regions. Future studies will include a computational modeling method to study the tDCS effects on a single Purkinje cell to help explain the bidirectional changes in firing rate and its involvement in the changes of cerebello-cerebral correlation.

Title: A cerebellar commissure carries projections of the vestibular ganglia and the vestibular nuclear complex

Authors: D. T. DALY[1], *M. ARIEL[2];
[1]Ctr. for Anatom. Sci. and Educ., [2]Pharmacol. & Physiol., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: At SfN '15, we described a transverse cerebellar commissure of thick myelinated axons within the Purkinje Cell Layer (PCL) in the pond turtle *Trachemys Scripta*. This commissure connects the lateral edge of the cerebellar cortex (Cb) on one side to that on the other. Electrical stimulation of one eighth cranial nerve (cnVIII) evokes a rapid response in the contralateral edge of the Cb (Brown et al, J Neurophysiol 2011). The present work confirms the vestibular role of this commissure in mediating connections to vestibular afferents of the vestibular ganglia (VG) and to neurons of the vestibular nuclear complex (VNC). Intact brains of anesthetized turtles, with attached temporal bones, were prepared for pathway tracing from fluorescent dextrans (in vitro) placed in lateral Cb or carbocyanine dyes (fixed tissue) placed in cnVIII. Following fixation (4% para), decalcification (0.1M EDTA), and embedding in 3% gelatin, 30-μm sections were visualized with confocal microscopy. Commissural fibers were again seen in the PCL. Dextran filled somata were observed in both the ipsilateral and contralateral VG. This finding supports the lateral Cb's common name 'vestibulocerebellum', providing direct evidence of a vestibular input rather than only a general nVIII input. Somata observed bilaterally within the VG have bipolar morphology, measuring up to 18 μm wide and 29 μm long. Neurons were also observed bilaterally in VNC with multipolar soma diameters up to 20 μm. Additional experiments left the neural structures intact in fixed tissue except for a midsagittal cut through the brainstem below the Cb, from the obex to the midbrain. Then, one cnVIII was severed and DiI crystals were placed into that proximal nerve stump. That preparation was incubated for 5 weeks at 35°C before analysis. DiI-labeled cell bodies were observed bilaterally in each VNC at the same level as those labeled with dextrans and had similar morphology. The presence of labeled VNC somata contralateral to the dye placement, in a brainstem severed along the midline, indicates that the Cb provides a commissural path that is distinct from commissural fibers within the ventral brainstem. When observed in tangential sections, this commissure is located in the middle third of the Cb's rostral-caudal axis. Both DiI transport from cnVIII to the contralateral VNC after severing the brainstem mid-line, and the filling of contralateral VG cells from the lateral Cb, further elucidate the nature of the cerebellar

commissure and its anatomical relationship to the vestibular system. This thick, myelinated vestibular commissure traveling within the PCL may be integral in the bilateral processing of head movements.

Title: Cerebellar learning deficits in a mouse model of premature birth injury

Authors: *A. SATHYANESAN, V. GALLO;
Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington, DC

Abstract: Premature births constitute a rapidly rising percentage of live births in the US. Annually ~65,000 preterm infants are born ‘very low birth weight’ or ‘VLBW’ (<1500 g; 32 weeks gestation), making them 40-100 times more likely to develop disruptive motor disorders compared to regular birth weight infants. Biomedical studies have established perinatal hypoxia as a major cause of grey and white matter abnormalities in the CNS of VLBW infants, with the cerebellum being particularly vulnerable to hypoxic injury. Previous work from our laboratory has shown that GABAergic signaling is significantly reduced in the white matter of the cerebellum in an established mouse model of perinatal hypoxic injury [Zonouzi, M. et al. GABAergic regulation of cerebellar NG2 cell development is altered in perinatal white matter injury. *Nature Neuroscience*, 2015]. Quite strikingly, the cerebellar cortex is also affected post-hypoxic injury (Hx). Hx results in a drastic reduction in number of molecular layer interneurons, and dramatically altered Purkinje cell arborization compared to normoxic controls (Nx). However, whether this cellular alteration in the cerebellar cortex due to hypoxic insult results in a difference in motor behavior remains unexplored. Using an automated behavioral apparatus - the Erasmus Ladder - to monitor motor performance and learning we have studied cerebellar behavior in Hx mice. This horizontally-oriented computerized ladder allows us to measure stepping patterns using pressure-sensitive rungs. Our results show that compared to normoxic controls, P25 Hx mice display profound deficits in both motor performance - measured as

percentage of missteps on the ladder, as well as conditioned motor learning - measured as adaptability to adjust stepping patterns to avoid a computer-controlled obstacle preceded by a warning tone. This deficit in motor performance and learning is present even in naïve P45 Hx mice, albeit to a lesser extent than P25 Hx deficits. Further, stepping pattern data indicate alterations in locomotor strategy in Hx mice. Finally, misstep percentage is partially rescued after pharmacological intervention with a GABA reuptake inhibitor in P25 Hx animals. Thus, our data indicates a long-term miscoordination phenotype characterized by motor malperformance, as well as adaptive cerebellar-learning deficits in a mouse model of premature birth injury.

Title: A novel mouse model of cerebellar stroke

Authors: M. MORENO, R. EMS, J. YONCHEK, *N. QUILLINAN;
Anesthesiol., Univ. of Colorado, Aurora, CO

Abstract: Objectives: Patients who have suffered cerebellar stroke present with neurological impairments such as motor coordination, motor learning deficits, vertigo and acute hearing loss. Cognitive-affective impairments have also been reported in these patients, suggesting an important role for the cerebellum in non-motor function. There are no animal models of cerebellar stroke currently available to investigate mechanisms of injury and repair. Therefore we have developed a mouse photo-thrombotic model of cerebellar stroke.
Methods: Adult male mice (C57Blk6, 8-12 week) were subjected to an intraperitoneal administration of Rose Bengal (150 ug/g), a light-sensitive dye that reacts with light and generates thrombosis by causing platelet aggregation. The injection was followed by a 15 minute exposure to a cold white light source. Sham controls were exposed to the light but were not injected with Rose Bengal. Stereological analysis of hematoxylin and eosin (H&E) staining was performed at 1 and 7 days after cerebellar stroke. Evans blue extravasation was used to interrogate blood brain barrier (BBB) integrity and immunohistochemistry was used to assess glial responses and formation of glial scar in the infarcted area. Neurobehavioral testing

including cylinder task, footprint analysis and contextual fear conditioning, were performed 7 days after cerebellar stroke.
Results: A cerebellar infarct and histological injury to cerebellar cortex was visible at both 24 hours and 7 day time-points after stroke onset. Infarct was localized to the intermediate zone of cerebellar cortex and a glial scar was present 7 days after stroke. Evans Blue dye was present in cerebellar stroke mice compared to controls, suggesting BBB disruption. Stroked animals showed changes in paw preference in the cylinder task suggesting a limb impairment. Footprint analysis showed reduced stride length and increased displacement between paws, indicating gait abnormality. Surprisingly, contextual fear conditioning testing showed impaired memory acquisition in cerebellar stroke animals compared to controls.
Conclusions: We have developed a reproducible model for cerebellar stroke that causes motor deficits. These outcomes are consistent with injury in the intermediate and lateral zones of the cerebellum. Also, we have been able to observe non-motor deficits that correlate with clinical studies of patients who have suffered a cerebellar stroke. This novel model will allow us to test neuroprotective and neuro-restorative strategies to improve functional outcome after cerebellar stroke.

Title: Purkinje cell heterogeneity in the anterior and posterior cerebellar lobule

Authors: *H. NEDELESCU[1], M. ABDELHACK[2], A. T. PRITCHARD[3];
[1]Dept. of Systems Physiol., Tokyo Med. and Dent. Univ., Tokyo, Japan; [2]Grad. Sch. of Informatics, Kyoto Univ., Kyoto, Japan; [3]Independent Scholar, Manchester, United Kingdom

Abstract: In the cerebellum, regional differences in cytoarchitecture could affect local connectivity and physiology, with possible consequences for neuronal computation. Analyses of Purkinje cells - which are functionally critical as they provide the sole output - have suggested that the cerebellar cortex is not uniform in structure as traditionally assumed. However, there have been insufficient numbers of reconstructed cells to resolve systematic differences in morphology between different cerebellar regions. To address this question, we compared Purkinje cell architecture in an anterior and a posterior lobule of the cerebellar cortex. Using Neurolucida 360 with confocal stacks from mice expressing green fluorescent protein selectively

in Purkinje cells, we reconstructed dendritic arbors of Purkinje cells residing in the bank of their respective lobules, then analyzed their structure and organization. We observed that in the posterior lobule, half of the reconstructed Purkinje cells had two primary dendrites emanating from their soma, in both young and adult mice. By contrast, only 9 out of 38 young and 5 out of 44 adult Purkinje cells showed this characteristic in the anterior lobule. Furthermore, our analysis revealed that Purkinje cells in the anterior lobule exhibited slanted dendritic arbors, oriented more towards the apex of the lobule than those found in the posterior lobule. This difference only appeared in the mature cerebellum, after the dendritic arbors had attained their definitive morphologies. These differences in Purkinje cell morphology support a microenvironment which could facilitate differential patterns of afferent input, and will need to be considered in future studies of cerebellar neural computation.

Title: Changes induced by hypoxic preconditioning in $GFAP^+$ cells from the roof of the fourth ventricle

Authors: M. BECERRA-GONZÁLEZ, R. DURAIRAJ VARMAN, *A. MARTINEZ-TORRES;
INB-UNAM, Queretaro, Mexico

Abstract: Introduction. Cerebellum is known for its role in motor control. It harbors a uniform cytoarchitecture composed of neuronal (molecular, granular and Purkinje neurons) and glial (astrocytes and Bergmann glia) lineage. We recently reported the presence of a cellular niche composed of diverse cell phenotypes located on the roof of the fourth ventricle that spans lobes I and X. The niche includes glial fibrillary acidic protein ($GFAP^+$), and $nestin^+$ cells distributed along the antero-posterior axis. Niches of $GFAP^+$ and $nestin^+$ cells in the lateral ventricles are well known neuronal or glial precursors that have the ability to respond upon hypoxic

preconditioning (HP). Yet, little cell proliferation has been demonstrated in cerebellum.
Aims. To evaluate the distribution of $GFAP^+$ cells on the roof of the fourth ventricle, and to determine whether they respond to hypoxic preconditioning (HP), a condition that promotes cell proliferation.
Methods. 25 days-old transgenic male mice expressing the enhanced green fluorescent protein under the GFAP promoter (GFAP-eGFP) underwent a three-cycle session of oxygen deprivation. Brains were collected at days 1 to 7 after HP. Distribution of the glial component was assessed by standard histological techniques and confocal microscopy, and western blot analyses evaluated changes in the levels of GFAP expression after HP.
Results. The organization of Bergmann glia cells was altered, somas were displaced and processes disorganized. Within the array of $GFAP^+$ cells of the roof of the fourth ventricle the expression of eGFP decreased after HP, but rebounded by day 7. This was confirmed by means of Western blot using antibodies against GFAP.
Conclusions. HP induces morphological changes in the Bergmann glial cells. The changes are minimal after seven days. HP reduces the expression levels of eGFP, which returns to normal levels after seven days. Consistently, expression of GFAP is also reduced by HP and returns to normal levels within the same period of time. In general, HP induces changes in the glial cells from cerebellum that induces a response to low levels of oxygen due to HP. Whether the $GFAP^+$ cells proliferate and differentiate as well as the molecular mechanisms of the cellular response under HP conditioning remain to be elucidated.

Title: Synaptic excitation by climbing fiber collaterals in the deep cerebellar nuclei of juvenile and adult mice

Authors: M. NAJAC, *I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Neurons in the inferior olive (IO) give rise to climbing fibers (CFs) that excite Purkinje cells and send collaterals (CFCs) to the cerebellar nuclei (CbN). Because *in vivo* and *in vitro* data suggest that CFC-CbN excitation is weak in adult mice, we examined CFC input to large CbN cells over development. We expressed channelrhodopsin in CFs with viral injections to the IO of P1 or P21 mice and recorded from large CbN cells in acute cerebellar slices from P12-P22 (juvenile, "*juv*") and P44-P50 ("*adult*") mice. CFCs were activated by 1- or 2-ms blue light pulses. CFC stimulation transiently increased CbN cell instantaneous firing rate (*juv*: from 46 ± 12 to 241 ± 66 Hz, n=4; *adult*: from 88 ± 8 to 109 ± 14 Hz, n=5; cell attached mode). In 6/9 cells (*juv*: 3/4, *adult*: 3/5), responses were well-timed, with a 0.8 ± 0.1 spike probability in a 2-ms window after the pulse. EPSC amplitude at -70 mV was -685 ± 118 pA in juveniles (n=38), but only -166 ± 20 pA in adults (n=16), suggesting that synaptic strength decreases with age. EPSCs had short but variable latencies (*juv*: 2.2 ± 0.1 ms, jitter 0.2 ± 0.03 ms; *adult*: 2.4 ± 0.1 ms, jitter 0.3 ± 0.06 ms). 5-Hz trains of EPSCs depressed strongly, indicating a high release probability (*juv*: $EPSC_{2/1}$ 0.50 ± 0.03, $EPSC_{5/1}$ 0.36 ± 0.03, n=30; *adult*: $EPSC_{2/1}$ 0.32 ± 0.07, $EPSC_{5/1}$ 0.22 ± 0.04, n=10). Most cells (*juv*: n=30/33, *adult*: 13/16) showed composite EPSCs on most trials with 2-6 detectable peaks within 1-6 ms. We tested whether peakiness arose from burst firing in CFCs, polysynaptic activation, firing in multiple convergent CFCs, or asynchronous release from one axon. In loose-cell-attached recordings from IO axons, light evoked a variable-latency spike (0.9 ± 0.2 ms, jitter 0.07 ± 0.02 ms, n=26), but only 5/26 of axons fired bursts (2-4 spikes). Consistent with monosynaptic connections, NMDAR EPSCs were evident in CbN cells at positive voltages even with AMPARs and $GABA_A$Rs blocked (n=4/4). Peakiness remained with reduced activation of feed-forward pathways (low [Ca]out, n=5; low DNQX, n=5), making a polysynaptic origin unlikely. In juveniles, raising Ca from 1.5 to 3 mM affected neither the amplitude, charge, shape, nor depression of EPSCs, suggesting that release from CFCs was already maximal (n=7). Conversely, reducing Ca to 0.5 mM decreased EPSC amplitude and charge to 43 ± 5 % and modestly reduced depression ($EPSC_{2/1}$ 0.73 ± 0.06, $EPSC_{5/1}$ 0.43 ± 0.08, n=5) while leaving EPSC shape, i.e., the temporal structure of release, unaffected. Thus, the excitatory strength of CFCs onto large CbN cells decreases with age, but throughout development, CFCs evoke peaky EPSCs, likely resulting from innervation by multiple fibers and/or release asynchrony in individual afferents.

Abstract: Genetic-targeting strategies have proven useful in understanding the role of individual neuron types in circuit function and behavior. In the cerebellum, Purkinje cells (PCs) are the sole output neuron type and receive inhibition from molecular layer interneurons (MLIs). Using fate mapping to distinguish MLIs from PCs has been challenging because both cell types are GABAergic. Without the means to target MLIs, the role of molecular layer inhibition in motor control and adaptive learning is enigmatic. To address this challenge, we made a knock-in mouse to express Cre recombinase (c-kit-IRES-Cre) in cerebellar MLIs under control of the c-kit oncogene allele. In mature mice, we achieved high-level transduction of MLIs using adeno-associated viruses (AAV) with Cre-dependent fluorescent proteins and, notably, had no PC labeling. We functionally validated this result by virally expressing either optogenetic or chemogenetic actuators in c-kit-cre mice. We observed a high-degree of specificity in manipulating MLI activity. In conclusion, the c-kit-IRES-Cre mouse line proved to be a flexible and reliable tool to target MLIs and will allow the interrogation of molecular layer inhibition in cerebellar circuits using genetically-encoded effectors and reporters of activity.

Title: The basal interstitial nucleus provides inhibitory afferent input to the cerebellar flocculus

Authors: *D. JAARSMA[1], F. BLOT[2], M. SCHONEWILLE[2], Z. GAO[2], T. J. H. RUIGROK[3], C. I. DE ZEEUW[2,4];

Abstract: *BIN neurons (arrows) and Golgi cells (arrow heads) in the flocculus of a GlyT2-EGFP mouse.*
The cerebellar cortex is known for its simple and well characterized neuronal circuitry, consisting of two main excitatory afferent systems, the climbing fibers and mossy fibers that converge on a single output neuron, the Purkinje cells. In addition, the cerebello-cortical circuitry contains granule cells that transfer mossy fiber input to Purkinje cells, and at least 4 classes of inhibitory interneurons and one class of excitatory interneuron. Here we show that the flocculus, a part of the vestibulocerebellum, receives a unique additional afferent input: We show that neurons of the basal interstitial nucleus (BIN), a hitherto neglected cerebellar nucleus originally identified by Langer in macaque cerebellum (J Comp Neurol. 1985, 235:26), provides widespread GABAergic/glycinergic afferents to the glomeruli of the floccular granule cell layer. We mapped the BIN in macaque, man, rabbit and rodent cerebellum using retrograde tracing (rabbit, rat, mouse), by immunostaining for ChAT (macaque and man), Gad65/67 (all species) and the muscarinic M2 receptor (all species), and by using a GlyT2-EGFP reporter mouse line. In macacque, man and rabbit BIN neurons are mainly distributed in the white matter between the lateral cerebellar nucleus and the flocculus, while in rodent they are concentrated in the floccular white matter. Retrograde tracing and analysis of neurobiotin-filled BIN neurons showed that each BIN neuron has widespread projections throughout the flocculus. In addition, using anterograde and retrograde tracing we identified afferents that make multiple VGluT2+ synaptic contacts on the soma and proximal dendrites of BIN neurons, and that arise bilaterally from neurons in the antero-medial medullary reticular formation. In summary, our data show that the BIN represents a unique novel inhibitory afferent system to the flocculus that complements inhibition by Golgi cells. We propose that the BIN cells play a unique role in the integration of vestibular and visuo-motor mossy fiber input, and may be a specific adaptation to appropriately modulate Purkinje cell activity during compensatory eye movements and compensatory eye movement adaptation.

Title: Characterization of Purkinje cell axonal torpedoes during postnatal development in mice

Authors: *D. LANG-OUELLETTE, L. LJUNGBERG, A. YANG, A. J. WATT;
Dept. of Biol., McGill Univ., Montreal, QC, Canada

Abstract: Information is carried from the cerebellar cortical microcircuit via action potentials propagated along Purkinje cell axons. In several human neurodegenerative diseases, as well as animal models, focal swellings in the axons of Purkinje cells − torpedoes − have been observed, often during disease progression when Purkinje cell loss occurs. How axonal torpedoes affect cerebellar function is poorly understood: both neurodegenerative and neuroprotective roles have been suggested. Interestingly, torpedo-like axonal swellings have also been transiently observed in the developing cerebellum. The role of developmental torpedoes in cerebellar information processing is even less understood than those in disease.

To elucidate the role of developmental Purkinje cell axonal torpedoes in the maturing cerebellum, we studied postnatal L7-*tau*-eGFP transgenic mice which label Purkinje cell axons. We found a transient increase in the number of torpedoes during the second postnatal week of development: peaking at P11 when up to ~40% of Purkinje cells had axonal torpedoes. Since Purkinje cell apoptosis occurs during development, we wondered whether torpedoes could be precursors of dying Purkinje cells. However, since we found that the majority of Purkinje cell death occurs prior to P9, when torpedo numbers were low, we conclude that developmental torpedoes are predominantly observed on the axons of Purkinje cells that survive into adulthood. Next, we wondered whether torpedoes were associated with axonal reorganisation, since developing axons undergo dramatic pruning during postnatal development. However, only a fraction of developmental torpedoes were found at branch points (~7% at P11). Furthermore, microglia were not enriched around torpedoes, as might be expected if they were associated with axonal pruning or cell death, and most torpedoes were myelinated. The accumulation of disorganized neurofilaments is a hallmark feature of disease-related axonal torpedoes. We observed enriched neurofilament in developmental torpedoes, which suggests that they may be structurally similar to torpedoes found on Purkinje cell axons in disease states.

Our findings show that Purkinje cell axonal torpedoes exist transiently in the developing mouse cerebellum, but are unlikely to be associated with cell death or axonal pruning. Furthermore, we find that developmental axonal torpedoes share common structural features with disease-related torpedoes, which may indicate that they serve a similar function in these different states of the cerebellar circuit.

Title: Nucleo-cortical neurons of the parvocellular interpositus target the Purkinje cell layer of the paraflocculus.

Authors: *G. J. WOJACZYNSKI[1], J. P. CARD[2];
[2]Neurosci., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A central tenet of cerebellar processing has been the existence of a universal circuit motif that extends throughout the cerebellar cortex. However, differences in cytoarchitectural organization and afferent innervation observed across the deep cerebellar nuclei (DCN) imply that not all of the deep nuclei display identical synaptic relationships with the cortex, as has been previously thought. One aspect in which the DCN could differ is their recurrent projections to the cortex. For example, recent studies have shown that there exists a glycinergic nucleo-cortical projection stemming from the dentate nucleus which has not been observed thus far in other subdivisions of the DCN. We therefore tested the uniformity of nucleo-cortical projections by injecting an anterograde tracer, BDA, into a cytoarchitecturally and connectionally unique subnucleus of the DCN, the parvocellular interpositus nucleus (pcIP), and analyzing the terminal morphology and neurotransmitter content of nucleo-cortical projections in adult male rats. We demonstrate here the existence of a novel nucleo-cortical projection that originates from the pcIP and targets the paraflocculus. This projection arborizes immediately subjacent to the Purkinje cell (PC) layer, parallel to the orientation of PC dendrites, and does not match any previous descriptions of nucleo-cortical fibers. Though the majority of synaptic swellings were in the immediate vicinity of the PC layer, occasional swellings were also found within the deeper granular layer and the molecular layer. Immunocytochemical and ultrastructural analyses revealed that these fibers are excitatory, similar to recurrent nucleo-cortical projections from principal projection neurons in other subdivisions of the DCN. This projection was not seen when BDA injections were made outside of the pcIP, indicating that this projection is unique to the pcIP/paraflocculus. This unique connection suggests that the entirety of the cerebellar cortex may not function identically and that regions of the cortex and DCN are anatomically specialized to support different cerebellar functions.

Title: Purkinje cell collaterals enable output signals from the cerebellar cortex to feed back to Purkinje cells and interneurons

Authors: *S. RUDOLPH[1], L. WITTER[1], R. T. PRESSLER[2], S. LAHLAF[1], W. G. REGEHR[1]; [1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Dept. of Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: Purkinje cells (PCs) provide the sole output from the cerebellar cortex. Although PCs are well characterized on many levels, surprisingly little is known about their axon collaterals and their target neurons within the cerebellar cortex. It has been proposed that PC collaterals play an important role in early development, where they transiently control circuit assembly. However, after development functional PC to PC connections are thought to be pruned. Here, we find that all PCs have collaterals well into adulthood in mice. PC collaterals are restricted to the parasagittal plane, and most synapses are located in close proximity to PCs, although some are present also in the molecular layer. Using optogenetics and electrophysiology we find that in juveniles and adults PCs make synapses onto other PCs, as well as onto some other types of interneurons. These findings establish that PC output can feed back and regulate numerous circuit elements within the cerebellar cortex. Notably, collaterals are well suited to contribute to processing in parasagittal zones by suppressing firing of diverse neuron types within the cerebellar cortex.

Title: High dimensional neuroanatomical and behavioral analysis for probing cerebellar involvement in nonmotor function

Authors: T. D. PEREIRA[1], J. W. METZGER[1,2], B. DEVERETT[1,2,3], T. J. PISANO[1,2,3], A. BADURA[1,4], *S. S.-H. WANG[1,2];

Abstract: Genetically encodable Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) allow reversible inactivation of identified cell types in freely-moving animals on a time scale of hours. To understand the role of specific cerebellar regions in guiding behavior during development and adulthood, we have developed detailed quantitative approaches for analyzing the extent of DREADD inactivation and the consequent pattern of behavioral perturbation.
In both juvenile and adult mice, we performed cerebellar lobule-specific injections of AAV8-hSyn-hM4D(Gi)-mCherry to co-express an inhibitory DREADD (hM4D) and a fluorescent reporter (mCherry). After administration of DREADD agonist clozapine-N-oxide (CNO), mice were tested sequentially in five behavioral paradigms commonly used to model autism in mice: an elevated-plus maze, reversal in a swimming Y-maze, self-grooming, three-chamber social preference, and a virtual reality-based working memory task. In each case, direct monitoring and video recording were used to acquire subsecond-resolution measurements of animal trajectory for offline analysis. To define different dimensions of autism-like phenotypes, we used principal components analysis to identify patterns of animal-to-animal covariation encompassing multiple behavioral measurements. In this way we created a basis set of "eigenbehaviors" constructed from performance in unperturbed mice, which we used to quantify lobule-specific inactivation.

These behaviors constitute a multidimensional autism-like phenotype.
We next sought to associate behavioral phenotypes with spatial patterns of DREADD expression. We used serial two photon (STP) reconstruction to render anatomical volumes complete with precisely mapped regions of expression. Our developed image processing pipeline builds aligned volumes from these STP stacks and registers the volumes to a standard mouse brain coordinate system (Allen CCFv2). Comparison of anatomical representations to behavioral phenotypes will test the hypothesis that lobule-specific perturbation of cerebellar regions leads to multi-dimensional effects on behavior. Our experimental and analytical framework enables quantitative linkage of neuroanatomy to behavior.

Abstract: Cerebellar lobules VI/VII and crus I/II form reciprocal loops with neocortical regions associated with executive functions (Wang et al, 2014). To test the functional significance of those connections we used DREADDs to disrupt neural activity of these cerebellar regions during adulthood or postnatal development, and measured the consequences in two major domains: (1) social choice and behavioral inhibition; and (2) cognitive flexibility.
We made lobule-specific injections of AAV8-hSyn-hM4D(Gi)-mCherry to achieve expression in molecular layer interneurons (MLIs), a major source of inhibition to Purkinje cells, which themselves send inhibitory projections to thalamus and neocortex in an organized map. For developmental inactivation, mice were injected with the virus at postnatal day 21 (P21), and received DREADD agonist clozapine-N-oxide (CNO) from P30 through P56. For acute inactivation, mice were injected at P42, followed by testing at P56 with CNO administered through i.p. on the day of testing. The inhibitory action of CNO on DREADD-expressing MLIs was confirmed in acute cerebellar brain slices, as well as through indirect effects on Purkinje cell firing in vivo in awake mice. To analyze behavioral data, we used principal component analysis (see abstract by Pereira, Metzger et al.).
In lobule VI, CNO administration in adult mice led to increased perseveration. The mice also showed reduced performance and bias in a virtual reality-based working memory task. Tasks were not affected by juvenile administration of CNO. These results suggest that lobule VI is an active part of brainwide circuitry for cognitive flexibility.
Developmental effects were seen from perturbations of crus I, crus II, and lobule VII. After unilateral AAV injections of crus I, CNO administration during development led to reduced social interaction in a three-chamber test and impaired reversal learning in a Y-maze, consistent with a role for crus I in social and cognitive maturation. Unilateral crus II perturbation led to reductions in movement in the elevated-plus maze and three-chamber task, as well as reduced social preference in the three-chamber test. None of these effects were seen with adult CNO treatment. In lobule VII, juvenile treatment with CNO decreased exploratory activity in the elevated-plus maze and increased social behavior in the three-chamber test. Opposite effects were seen in acute adult treatment with CNO, suggesting that lobule VII contributes to maturation and acute function of exploratory behavior.
These experiments provide direct evidence for the developmental diaschisis hypothesis of cerebellar contributions to autism-like phenotypes.

Title: Whole-brain mapping of cerebellar output pathways using transsynaptic viruses and light-sheet microscopy

Authors: *T. J. PISANO[1,2,3], S. DEIVASIGAMANI[1,2], J. C. LEE[1,2], B. DEVERETT[1,2,3], E. ENGEL[1], L. ENQUIST[2], S. S.-H. WANG[1,2];
[1]Princeton Neurosci. Inst., [2]Mol. Biol., Princeton Univ., Princeton, NJ; [3]Rutgers-Robert Wood Johnson Med. School-Princeton Univ. MD/PhD Program, Rutgers Univ., New Brunswick, NJ

Abstract: The cerebellum and neocortex exchange information in a region-specific manner via closed, bidirectional loops. In the ascending direction, cerebellar projections pass from Purkinje cells of the cerebellar cortex to the deep cerebellar nuclei (DCN) to thalamic and other midbrain areas before finally reaching the neocortex. To date, these pathways have been mapped largely using classical tracers that do not reveal polysynaptic connectivity. We are using a combination transsynaptic tracing viruses, iDISCO tissue clearing (Renier et al. 2014, Cell 159:896), and light-sheet fluorescence microscopy (LaVision Biotec., Bielefeld, Germany) to reconstruct and quantify cerebello-thalamo-neocortical projection patterns on a whole-brain scale without need for tissue sectioning.
We injected the anterogradely-transported herpes simplex virus 1 H129 CMV-EGFP (HSV1-H129, $2.7x10^4$ to $8.0x10^4$ PFUs, Wojaczynski et al. 2015 Brain Struct. Func. 220:3) into cerebellar lobule VI. Coinjection with Cholera Toxin B revealed that injection sites were 300 - 1200 micrometers wide. We detected viral antigen immunohistochemically (DAKO B0114) in the DCN at 37 hours post-injection, in the thalamus at 41 and 49 hours, and in the neocortex after 54 hours, consistent with the expected cerebello-thalamo-neocortical path. Corresponding with specific injection sites, we found expression in thalamic areas with nonmotor associations (lateral dorsal, medial dorsal, and parafascicular nuclei) and ventral tegmental area, nucleus accumbens, amygdala, and hypothalamus.
We also investigated the origins of pathways to specific neocortical targets by injecting a retrogradely-moving pseudorabies virus (PRV) strain of herpesvirus (PRV-Bartha CMV-EGFP, $2.4x10^4$ PFUs, Smith et al. 2000 PNAS 97:16) into specific neocortical regions. After 53 hours

we detected PRV antigen via immunofluorescence (Rb 134, Card et al. 1990, J. Neurosci. 10:1974) in Purkinje cells of multiple lobules, demonstrating the existence of spatially diverse cerebellar locations that converge upon a specific neocortical target. We are now using PRV to trace cerebellar pathways leading to mediodorsal nucleus of the thalamus, anterior cingulate cortex, and other forebrain regions thought to contribute to executive function.

Title: Effects of disrupted cerebellar activity on dendritic development at distal neocortical sites.

Authors: *J. VERPEUT[1,2], A. TAO[1,2], C. HILDRETH[1], E. C. COPE[1,3], B. A. BRIONES[1,3], E. GOULD[1,3], S. S.-H. WANG[1,2];
[1]Princeton Neurosci. Inst., [2]Mol. Biol., [3]Psychology, Princeton Univ., Princeton, NJ

Abstract: Major sources of within-brain communication originate in the cerebellum, the most frequently observed site of structural abnormality in human autism-spectrum disorder. The cerebellum projects via thalamus in an organized manner to a wide variety of neocortical targets, including regions that contribute to cognitive and affective processing. In rodent frontal cortex, ascending axons from the thalamus synapse onto basal but not apical dendrites of pyramidal cells in layer 2/3 (Shigematsu et al., Cerebral Cortex 2015:1-16). To test whether cerebellar activity shapes neocortical dendritic arborization and spine formation through cellular plasticity mechanisms, we examined spine density in basal and apical dendrites in layer 2/3 pyramidal neurons of prelimbic (corresponding to medial prefrontal cortex) cortex in heterozygous L7-tuberous sclerosis 1 (L7-Tsc1) mice, which have alterations in Purkinje cell firing activity, abnormal social interactions, and repetitive behaviors (Tsai et al. 2012, Nature 488:647). We assessed neocortical dendritic and spine morphology using small-molecule lipophilic (DiI) labeling. Adult male L7-Tsc1 heterozygous mice had an increased density of total spines on basal dendrites compared to wild-type (WT) mice (20 neurons in 4 L7-Tsc1 mice, 25 neurons in

5 WT mice). However, the density of spines on apical dendrites was not different between heterozygotes and wild-type (20 neurons in 4 L7-Tsc1 mice, 25 neurons in 5 WT mice). These results are consistent with the hypothesis that cerebellar activity is necessary for normal pruning of spines at distal neocortical sites, potentially accounting for the ability of early-life cerebellar injury to cause autism-like pathologies. To test whether local perturbation can also influence dendritic structure in specific neocortical targets, we are now using adeno-associated viral vectors to express Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to alter cerebellar activity in specific cerebellar lobules. These experiments will test the hypothesis that input from specific lobules of the cerebellum during sensitive periods of development can influence the growth and maturation of specific distal forebrain circuitry.

Title: Purkinje cell to granule cell synapse provide feedback to the input layer of the cerebellar cortex

Authors: ***C. GUO**, L. WITTER, S. RUDOLPH, H. ELLIOTT, K. ENNIS, W. REGEHR; Neurobio., Harvard Univ., Boston, MA

Abstract: The flow of information through the cerebellar cortex is primarily feed-forward: mossy fiber inputs activate granule cells, which in turn drive Purkinje cells, the sole output neurons of the cerebellar cortex. Inhibition onto granule cells is thought to play a key role in gating the flow of signals into the cerebellum, and it is thought that Golgi cells are the only interneurons that inhibit granule cells. Here we show that Purkinje cells synapse onto granule cells via axon collaterals, thus providing a route for direct output to input layer feedback in the cerebellar cortex. We propose that this non-canonical feedback could regulate excitability of the input layer, maintain sparse coding and mediate temporal integration.

Title: A novel cerebellar molecular layer interneuron inhibited by Purkinje cell feedback

Authors: *J. KIM, G. J. AUGUSTINE;
LKC Med. School-NTU, Singapore, Singapore

Abstract: Although the organization of cerebellar cortical circuits is relatively well known in comparison to other brain areas, some potentially important synaptic connections remain unexplored. Here we have examined the function of a novel inhibitory synaptic circuit between Purkinje cells (PC) and molecular layer interneurons (MLIs). High-speed optogenetic circuit mapping (PNAS 104: 8143), using brain slices from transgenic mice selectively expressing channelrhodopsin-2 in PCs (Front. Neural Circuits 7:160), revealed the presence of a subset of MLIs (~16%) located in the inner third of the molecular layer that receive strong, fast and monosynaptic inhibitory inputs from PCs. These MLIs receiving PC feedback had several electrical characteristics – including larger hyperpolarization-activated current (Ih), larger membrane capacitance, and more hyperpolarized resting membrane potential – different from those of MLIs not receiving PC input. MLIs receiving PC input also had high input resistance, suggesting the absence of electrical coupling with neighboring MLIs. Consistent with this interpretation, the gap junction blocker mefloquine (Cell Rep. 7: 1601) selectively increased the input resistance of basket cells but not MLIs with PC input. Further, dye coupling measured with neurobiotin was present in basket cells but absent in MLIs receiving PC feedback. Thus, we conclude that MLIs with PC input do not participate in the gap junction network of MLIs. Further, the morphology of MLIs with PC input is clearly different from other MLIs: although they were located in the inner third of the molecular layer, they formed neither baskets around PCs nor had horizontal processes characteristic of basket cells. These results indicate that MLIs that receive PC feedback inhibition represent a novel type of MLI. The unique circuit formed between PCs and these MLIs may play an important role in cerebellar information processing by synchronizing neighboring PCs via disinhibition.

Title: Calcium imaging reveals coordinated simple spike pauses in populations of Cerebellar Purkinje cells

Authors: J. E. RAMIREZ[1], *B. M. STELL[1,2];
[1]Univ. Paris Descartes, Paris, France; [2]CNRS, Paris, France

Abstract: The cerebellum is thought to coordinate movement by processing sensorimotor information in the cerebellar cortex before relaying its output to other brain structures. Since all information processed by the cerebellar cortex converges on Purkinje cells (PCs), the ability to record spiking from identified populations of these cells presents new possibilities for understanding cerebellar processing. Here we show that somatic calcium imaging can be used in slices and in vivo to easily distinguish calcium fluctuations generated by complex spikes from those generated by trains of simple-spikes (SS). Moreover, the estimated calcium influx from a single SS is shown to be remarkably consistent between PCs ($\Delta F/F_0$ of 0.1 +/- 0.03%, n = 6) and therefore permits monitoring the relative changes in SS firing frequency. We report that transitions into and out of pauses in SS activity (lasting longer than three median inter-spike intervals) are correlated between PCs in the sagittal plane. The source of this organization is shown to be presynaptic GABAergic network and blocking $GABA_A$Rs with gabazine abolishes the synchrony (permutation tests, $p < 0.05$ in control; $p > 0.05$ in treatment; n = 7 pairs). Also, paired cell-attached recordings of adjacent PCs in sagittal slices (n = 72 pairs) showed that this synchrony decays abruptly after a distance of ~200 um between PCs, consistent with the mean length of GABAergic interneuron axons in the cerebellar molecular layer (de San Martin et al. 2015). Thus, this method reveals that simple-spike pauses are organized in groups of neighboring PCs by presynaptic interneurons to maximize the effect of PC inhibitory synapses on their common downstream targets.

Title: Exploring molecular layer interneuron network activity in the cerebellar cortex *In vivo* using the calcium indicator protein GCaMP6f

Authors: *M. GRAUPNER, A. JALIL, I. LLANO;
Univ. Paris Descartes, Brain Physiol. Lab, CNRS, Paris Cedex 06, France

Abstract: Networks of inhibitory neurons coupled through chemical and/or electrical synapses are abundant in the brain and have been shown to exhibit synchronous, oscillatory activity. Such oscillations have been proposed to provide a reference signal for temporal encoding, sensory binding of features, and storage and recall of information. Molecular layer interneurons (MLIs) of the cerebellum are interconnected by GABAergic chemical synapses and by electrical synapses. These connections have been shown to promote synchrony and shape the temporal precision of action potentials. However, the activity patterns and the role of the MLI network in the intact animal remain unknown. While fluorescent calcium sensors such as GCamMP6f provide a means to track the activity of neuronal populations *in vivo*, the interpretation of such signals from tonically firing inhibitory neurons with potent calcium-binding proteins, such as parvalbumin remains challenging.

In order to shed light on the activity patterns occurring in and the functional role of the interneuron network *in vivo*, we perform calcium imaging experiments from ensembles of MLIs in lobule V of the cerebellar vermis of ketamine/xylazine-anethetized mice (P30-50). The *PV-Cre* driver line was crossed with the *Ai93 GCaMp6F-TIGRE* promoter line which led to ubiquitous GCaMP6f expression in MLIs accompanied by sparse expression in granule and Purkinje cells. To study the link between the calcium signal and spiking activity in cerebellar MLIs we conducted simultaneous cell-attached recordings from single interneurons using patch-clamp pipettes. Sensorimotor-driven synaptic inputs to MLIs were simulated using parallel fiber stimulation with theta-glass pipettes inserted in the molecular layer.

We characterize the information carried by the calcium signal about the underlying spiking activity for the tonically firing MLIs in the anesthetized animal. Analysis of spontaneous activity epochs and activity evoked by parallel fiber stimulation allows us to extract the minimum change in firing that can be faithfully detected by GCaMP6f. Our measurements allow us to discern the calcium signal component generated by MLI spikes from the part of the signal due to synaptic

inputs. We furthermore characterize the magnitude and spatial extend of correlated activity changes across neighboring MLIs conveyed by the fluorescent signal. Our results provide a key step to measure and interpret activity patterns and synchronization regimes of the MLI network. Deciphering MLI activity is required to advance our understanding of this interconnected microcircuit and its involvement in generating coordinated movement in mammals.

Title: Alternation of transcription factor gene expression in cerebellar Purkinje cells disrupts the synchrony of simple and complex spike in deep cerebellar nuclei

Authors: ***G. KUMAR**[1], W. Y. TAM[1], K. M. KWAN[2,3], C. H. E. MA[1,4];
[1]City Univ. of Hong Kong, Kowloon, Hong Kong; [2]Sch. of Life Sciences,The Chinese Univ. of Hong Kong, Shatin, Hong Kong; [3]State Key Lab. of Agrobiotechnology (CUHK), The Chinese University of Hong Kong, Hong Kong; [4]Ctr. for Biosystems, Neuroscience, and Nanotechnology, City Univ. of Hong Kong, Kowloon, Hong Kong

Abstract: The cerebellar Purkinje cell is inimitable and complex neuron acts as a computation center in the brain. It receives convergent projections from all other cortical neurons and providing the sole output signal to deep cerebellar nuclei (DCN). DCN acts as relay center to receive all the information from Purkinje cells (PCs) and convey to premotor nuclei. These DCN neurons integrate synaptic inputs with their own spontaneous activity to generate motor signals for locomotion and fine-tuning of movement. The impairment of Purkinje cells may modify excitatory synaptic transmission electrophysiology i.e. spontaneous simple and complex spike firing rate, duration of spike, and the duration of the simple spike pause after the complex spike. Intrinsic dynamics of neurons is a critical step in the process of network behavior, synaptic integration, and information processing in the brain. Previous studies have reported that partial loss of PC was associated with ataxia-like phenotype in mice due to reduced Purkinje neuron activity and increased DCN intrinsic excitability. Hence, electrophysiological study of DCN will give insight into dissecting the motor neurocircuitry pathway of output signal from the central

nervous system to the peripheral nervous system. We therefore hypothesized that ablation of a transcription factor in PC cells affects the DCN neurons spike firing and modulating the motor output signal. In the present study, conditional mutant mice with ablation of a transcription factor in cerebellar PCs exhibited lack of motor coordination assessed by rotarod. Neurocircuitry pathway of motor output was further confirmed by recordings the DCN neurons activity in mutant mice. The results of present study showed that mutant mice exhibited significant decrease in retention time on rotarod as compared with control ($p<0.05$). Recording of DCN neurons exhibited significant changes in simple and complex spike frequency, since a subset of neurons displayed bursts of action potentials in the mutant mice which required further confirmation. These ongoing studies suggest that ablation of transcription factor alter motor signal by modulating the DCN intrinsic excitability. Further studies will focus on elucidating the cerebellum neurocircuitry in mutant mice.

Title: Principles of excitatory and inhibitory connectivity in the cerebellar molecular layer *In vivo*

Authors: ***C. ARLT**[1], C. D. WILMS[2], M. HAUSSER[1];
[1]Wolfson Inst. For Biomed. Res., Univ. Col. London, London, United Kingdom; [2]Scientifica, Uckfield, United Kingdom

Abstract: Molecular layer interneurons (INs) and Purkinje cells (PCs) in the cerebellar cortex receive common excitatory granule cell input, resulting in feed-forward inhibition (FFI) of PCs by INs. Climbing fibers (CFs) are thought to instruct cerebellar learning at the parallel fiber synapse onto PCs, but also influence INs: *in vitro* experiments have shown that CF input excites INs via glutamate spillover, but can also cause IN inhibition, by recruiting GABAergic interactions among INs. However, the spatiotemporal patterns of activity emerging from CF, IN and PC interactions remain poorly understood. Using simultaneous patch-clamp recordings from

INs and PCs guided by two-photon microscopy in anesthetised mice, we studied higher-order functional connectivity of CFs, INs, and PCs using cross-correlation analysis of PC complex spikes, simple spikes, and IN spikes.
We find that single spontaneous IN spikes can correlate with PC spike rate decreases (PC rate z-score of <-3 0-10 ms after IN spike, n = 24 of 56 pairs), and that induced spikes in a single IN can cause PC inhibition to a similar degree. IN-PC functional connectivity depends on vertical distance: INs with inhibitory effects on PCs are closer to the PC layer than INs without an effect (mean distance from PC layer: 106 ± 43 versus 135 ± 30 μm, p = 0.006). In a subset of functionally connected IN-PC pairs (n = 6), PC inhibition after the IN spike is preceded by a narrow increase in spike rate (PC rate z-score of >3 -10-0ms from IN spike), indicative of the IN and PC receiving common granule cell input and the IN delivering FFI to the PC.
CF input assessed by measuring complex spikes (CSs) in PCs results in a variety of IN rate changes, with INs either exhibiting rate increases (IN rate z-score of >3 0-20ms after CS, n = 13), delayed decreases (z-score of <-3 10-30ms after CS, n = 8), or increases followed by decreases (n = 3). IN responses to CF input also depend on vertical distance: Excited INs are closer to the pia, whereas inhibited INs are closer to the PC layer (mean IN distance to PC layer: 126 ± 39 versus 78 ± 33 μm, p = 0.03). This organisation is in line with a preference for INs higher up to inhibit INs lower in the molecular layer, which we have assessed directly by dual recordings from IN-IN pairs.
Finally, we analyse the overlap of functional CF-IN and IN-PC connectivity, and find that there is no preference for connected IN-PC pairs to receive common excitatory CF input, but rather for INs inhibiting a PC to be inhibited upon CF input. This motif is especially prevalent in IN-PC pairs with common granule cell input, which may help to maintain FFI during plasticity, controlling the ratio of weights of granule cell inputs to INs and PCs.

Title: Large-scale realistic modeling reveals spatiotemporal dynamics of cerebellar granular layer responses to mossy fiber bursts

Authors: *S. CASALI[1], M. TOGNOLINA[1], E. D'ANGELO[1,2];
[1]Brain and Behavioral Sci., Univ. of Pavia, Pavia, Italy; [2]Brain Connectivity Center, C. Mondino Natl. Neurolog. Inst., Pavia, Italy

Abstract: The investigation of the internal algorithm of the cerebellar microcircuit is proving extremely challenging from an experimental perspective largely due to the difficulty of recording from multiple individual neurons simultaneously. Detailed computational modelling can provide insight into the structure of network computation. The NEURON-Python platform has been used to develop a large scale realistic model of cerebellar granular layer (GL), including connectivity and representations of its main neuronal types, Granule cells (GrCs) and Golgi cells (GoCs), and of their synapses (D'Angelo *et al.*, 2001; Nieus *et al.*, 2006, 2014; Diwakar *et al.*, 2009, 2011; Solinas *et al.*, 2007*a*,*b*, 2010). The model has been validated against observations at the mesoscopic scale (including VSD/MEA recordings and two-photon Ca^{2+} imaging *in vitro* and LFP recordings *in vivo*). The main goal of the present work is to demonstrate that spatiotemporal dynamics taking place in the GL at a mesoscopic scale can be understood as emergent phenomena, caused by the complex interaction occuring among microscopic variables including the topology of intercellular connectivity and the neurophysiological properties of neurons and synapses. Our results show that (1) the center-sorround profile describing the ratio between excitation and inhibition observed in cerebellar slices depends on the spatial arrangement of GrC - GoC connectivity; (2) the interaction between different spots of activation generates antithetical response patterns, combined excitation and inhibition (logical operators AND and XOR); (3) transverse and parasagittal connectivity can be differentially modulated by the GrC-GoC ascending axon (AA) and parallel fibers (PF), by GoC-GoC gap-junctions, and by GoC-GoC inhibitory interneurons. Interestingly, the AA confines feedback inhibition to local GL clusters, while PFs have weak effect on GoC activity. Conversely, relevant local effects are generated by GoC-GoC connections. (4) The GL as a whole can generate coherent oscillations in response to random background when two conditions are met: the MF input conveyed to GoCs is weak and GoCs do not inhibit each other; (5) different frequency patterns of random MF background can tune the response properties of the GL toward a wide range of inputs, making the cerebellar input-stage adaptive to various forms of incoming informations. In conclusion, our results show that reconstructing the biophysical and structural network features can predict the emergence of the spatiotemporal properties that let the GL to be defined as a reconfigurable dynamical system.

Title: Processing of individual body parts by direct (drd1) and indirect (drd2) pathway neurons on the dorsal striatum

Authors: *K. COFFEY[1], M. WEST[2];
[1]Rutgers Univ., New York, NY; [2]Rutgers Univ., Piscataway, NJ

Abstract: The dorsolateral or sensorimotor striatum (DLS) is a prominent target of research on control of voluntary movement, sensorimotor integration. The DLS is comprised mainly (95%) of type IIb, medium spiny projection neurons. These neurons receive direct monosynaptic projections from primary somatosensory (S1) and motor (M1) cortices in a similar manner across species. Clusters of medium spiny neurons (MSNs) show firing rate (FR) increases related to sensorimotor activity of individual body parts in monkeys and rats. To this date, this work has yet to have been extended to mice. These striatal MSNs are thought to output through the "direct and indirect pathways". According to this model, "direct pathway" MSNs project gabba to the substantia nigra pars reticulata (SNr) and the globus pallidus internal segment (GPi). The inhibition of GPi and SNr leads to disinhibition of the thalamic glutamatergic neurons, which project to the cortex and is thought to facilitate movement. Conversely the "indirect pathway" MSNs inhibits the GABAergic neurons of the GPe, leading to a disinhibition of the glutamatergic neurons of the STN. This is hypothesized to result in the reduction of locomotor activity and movement. In addition to their distinct projections, MSNs of the direct and indirect pathway are characterized by the differential expression of dopamine (DA) receptors. D1 dopamine receptors (Drd1) are hypothesized to be expressed by direct pathway MSNs, whereas D2 dopamine receptors (Drd2) are expressed by indirect pathway MSNs. No one has yet attempted to reconcile the very well classified single body part (SBP) neurons with the primary functional tenet of the direct/indirect pathway hypothesis: that Drd1 neurons are active during movement, while Drd2 neurons are active during non-movement. Based on the theory alone, one might predict that single body part neurons are all Drd1 expressing MSNs witch reside in the direct pathway. However, the recent evidence showing Drd2 MSN activation during movement suggests that it is possible that both Drd1 and Drd2 MSNs could be single body part neurons. The present study first seeks to confirm that dorsolateral striatum in the mouse brain has an analogous sensorimotor function to that of primates and rats. We then seek to confirm that Drd1 MSNs primarily project to GPi, while Drd2 MSNs primarily project to GPe, and we also seek to determine for the first time if body part sensitivity of striatal MSNs can be discriminated unambiguously in the mouse. Finally, we seek to determine for the first time if these single body part neurons express Drd1 or Drd2 and reside in the direct and/or indirect pathways.

Title: Functionally dissecting the cortical control of direct versus indirect pathways in the striatum

Authors: *J. R. KLUG[1,2], H. A. HOFFMAN[1,2], F. OSAKADA[4], E. M. CALLAWAY[1,3], X. JIN[1,2];
[2]Mol. Neurobio. Lab., [3]Systems Neurobio. Lab., [1]Salk Inst. for Biol. Studies, La Jolla, CA; [4]Nagoya Univ., Nagoya, Japan

Abstract: The dorsal striatum and its excitatory inputs are involved in decision-making, especially action selection, initiation and learning. These abilities are compromised in human patients with neurological disorders, such as Parkinson's and Huntington's disease, affecting the striatum and its afferents. Spiny projection neurons (SPNs), the principal GABAergic projection neurons of the striatum, receive dense glutamatergic inputs from various cortical regions as well as thalamic nuclei. There are two intermixed subpopulations of SPNs: dopamine receptor 1 - containing (D1-SPNs, direct pathway) and dopamine receptor 2 - containing (D2-SPNs, indirect pathway). While the two major neural pathways constitute the core components of the classic model of the basal ganglia, very little is known about the connectivity and specificity of their excitatory inputs and role in behavior. In order to address these fundamental questions, we have used AAV-Cre-dependent helper viruses along with an EnvA-pseudotyped, glycoprotein (RG) - deleted recombinant rabies virus (SAD delta G-Rabies) expressing channelrhodopsin-2 (ChR2) to selectively activate monosynaptic inputs to D1- or D2-SPNs. The input pathway specific functional expression of ChR2 allowed for the determination of shared, overlapping excitatory populations to direct or indirect neurons in whole-cell brain slice electrophysiological recordings. Optic fiber based optogenetic stimulation in the freely moving mouse was utilized to examine the contribution of different cortical and thalamic regions to locomotor behavior, intracranial self-stimulation and operant sequence execution. These results provide new insight to how excitatory inputs connect to D1- and D2-SPNs, and determine the contribution of region- and pathway-specific corticostriatal subcircuits to behavior.

Title: Feed-forward inhibition of nigrostriatal dopamine release by goal-directed action

Authors: *N. G. HOLLON, J. R. KLUG, H. LI, C. D. HOWARD, X. JIN;
Mol. Neurobio. Lab. J, Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Nigrostriatal dopamine is critically involved in voluntary movement, motivation, and reinforcement learning, but its precise role in instrumental action remains poorly understood. In the current work, we examined how self-initiated goal-directed action influences nigrostriatal dopamine transmission in the absence of any overt changes in an animal's external environment. Mice expressing channelrhodopsin in their dopamine neurons learned to press a lever on a continuous reinforcement schedule to deliver blue-light stimulation into their substantia nigra pars compacta. Performance of this free-operant optogenetic intracranial self-stimulation (opto-ICSS) was sensitive to changes in the action-outcome contingency, indicating that animals' behavior was goal-directed. Using fast-scan cyclic voltammetry, we monitored changes in dorsal striatal dopamine concentration during both opto-ICSS performance and subsequent playback of stimulations delivered in the same temporal sequence but not contingent upon any action. Stimulation-evoked dopamine release during opto-ICSS performance was markedly lower than that during non-contingent playback, indicating that self-initiated action causes a robust suppression of striatal dopamine release, even when driven by direct optogenetic stimulation of dopamine neurons. Omission probe trials revealed transient dips below baseline dopamine levels after non-reinforced lever presses, consistent with the idea of a feedforward inhibition triggered by the goal-directed action, likely through an efference copy. Probe trials with delayed stimulation or varied magnitude revealed that the action-induced suppression is precisely timed and well balanced to counteract the expected consequence of that action. Collectively, these findings demonstrate that nigrostriatal dopamine could signal prediction errors in action-outcome associations, and have fundamental implications in instrumental behavior and movement control.

Title: Basal ganglia circuits for reinforcement and learning

Authors: *A. LALIVE, A. KREITZER;
Neurolog. Disorders, Gladstone Inst., San Francisco, CA

Abstract: Dopamine D1 receptor-expressing medium spiny neurons (D1-MSNs) in the dorsal striatum project to and inhibit the Substantia Nigra reticulata (SNr), forming the direct pathway of the Basal Ganglia (BG). Activation of this projection is sufficient to increase movement and drive locomotion. Interestingly, direct pathway activation can also drive real-time place preference, and mice readily learn to self-stimulate D1-MSNs, demonstrating their role in reinforcement. However, little is known about the locus or underlying mechanisms of reinforcement, which could include plasticity in the striatum or downstream targets. Here we designed a five-day training paradigm where mice could self-stimulate D1-MSNs. To determine if reinforcement occurred in striatum or downstream, we tested whether mimicking direct pathway stimulation effects on SNr could also drive reinforcement. Because inhibition of the SNr leads to disinhibition of target regions, including Substantia Nigra compacta (SNc), dorsal raphe, thalamus, and brainstem, we asked whether direct activation of SNr-recipient nuclei would be sufficient to drive reinforcement. Our results have delineated several potential targets of the direct pathway that are sufficient to drive reinforcement. We are now in the process of determining which of these circuits are necessary for direct pathway-mediated reinforcement, and finally testing the role of these circuits in learning to natural reinforcers.

Title: Optogenetic stimulation of the dorsolateral striatum increases performance automaticity in cue-driven and response-driven tasks

Authors: *F. ŠTOCEK, A. C. G. CREGO, A. G. MARCHUK, K. S. SMITH;
Psychology and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Within the basal ganglia, the dorsolateral striatum (DLS) is known to play an important role in action selection and behavioral automatization. For example, in maze tasks, the DLS is involved in shaping "response" strategies in which choices are dictated by learned action routes. Response strategies can be achieved in principle by action selection at the outset of performance. Consistent with this notion, recording studies have identified a phasic burst of DLS activity at the onset of action sequences, which correlates with how fluid and fast the action sequence will be. To study the causality of this signal, rats were trained to execute a response strategy (run, turn, stop) for a sucrose reward on a plus-maze task. Optogenetic stimulations (channelrhodopsin) or inhibitions (halorhopsin) were applied at the start of runs and compared to manipulations during the middle of the run or during the full run. DLS stimulation at the start and for the full duration led to increased run speed and reduced deliberative head movements at the choice point. DLS inhibitions produced the opposite effects. This suggested that DLS activity at the start of a behavior carries influence over how automatic the behavior is. It remained unclear if this DLS activity promoted the selection of a learned action sequence, as though it were "chosen" from the start, or if it promoted the most optimal action routine on the task, in this case to execute a certain run-turn routine. To address this, we have begun to similarly evaluate the DLS on a task requiring animals to navigate towards visual cues that could only be identified at the choice point in the maze, after the run had been initiated. Preliminary, we find that DLS stimulation at the start of such runs increases the efficiency of runs on this task as well. In addition, DLS stimulation in the middle of the run, when the navigation choice must be made, also increased performance efficiency. The same was not true in the "response" task, in which optimal actions could be selected from the start of the run; mid-run stimulation in that condition had no effect on behavioral measures. Across both tasks, run accuracy was not altered. These findings highlight a preferential role for on-line DLS activity in shaping how optimal and/or fluid

a reinforced behavior is, whether that behavior involves active cognitive processing (i.e., locating and navigating towards a cue) or whether it might not (i.e., executing a response routine).

Title: Exploring a causal role for the dorsolateral striatum in action-reward contingency shifts

Authors: *A. C. CREGO, K. S. SMITH;
Dartmouth Col., Hanover, NH

Abstract: In the basal ganglia, phasic bursts of activity at the onset of action sequences arise as those sequences are learned and become automatic. This pattern is particularly prevalent in the dorsolateral striatum (DLS) and is linked to the fluidity with which actions are performed. The relationship between increased DLS activity and fluid action performance can occur early in learning, suggesting a role for the DLS in the formation and maintenance of automatic actions. DLS loss-of-function studies show that it is necessary for the expression of automatic action sequences and habits once they have been acquired. However, it is unknown if on-line DLS activity is sufficient to strengthen action sequences; nor is it known, when new action patterns must be learned in place of old ones, whether engagement of DLS activity strengthens the previously learned (cached) behavior or instead promotes the formation of the newer, more optimal behavior? To address this issue, we leveraged the spatiotemporal precision of optogenetics to manipulate DLS activity at precise time points during an operant task, in which rats were exposed to a series of contingency shifts. Rats first learned an FR1 contingency, which was then suddenly shifted to an FR3 (upshift). After training on the FR3 schedule, rats were then suddenly returned to an FR1 (downshift). DLS was optogenetically stimulated using channelrhodopsin at the first lever press for both the (1) surprise upshift and (2) surprise downshift. Compared to controls, during the upshift, DLS stimulation resulted in fewer 1-press bouts versus 3-press bouts. Similarly, DLS stimulation during the downshift led to an increase in

1-press bouts, with fewer 3-press bouts. Though preliminary, this finding suggests that DLS stimulation at the start of an action tends to result in behavior that favors the more optimal action strategy for reward, in this case either a 1-press or a 3-press bout, rather than simply strengthening the most recently learned lever-press pattern or promoting perseverative pressing in general. In other words, DLS stimulation appeared to aid on-line behavioral flexibility and performance optimization. Finally, persistence in lever pressing was evaluated through a shift to a VI30 contingency protocol, in which reward was delivered independent of pressing. DLS stimulation resulted in animals showing less pressing than controls. This finding again suggests that DLS stimulation aided animals' sensitivity to the new contingency, resulting in a more optimal response strategy. Additional performance measures are being assessed.

Title: Precisely timed optogenetic inhibition of dopaminergic neurons during fine motor skill acquisition in rats

Authors: D. J. ELLENS[1], M. GAIDICA[2], A. R. HURST[1], *D. K. LEVENTHAL[1,4,3]; [1]Neurol., Univ. of Michigan, Ann Arbor, Ann Arbor, MI; [2]Neurosci. Grad. Program, [3]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI; [4]Neurol., VA Ann Arbor Hlth. Syst., Ann Arbor, MI

Abstract: Striatal dopamine loss is the most prominent neurochemical finding in Parkinson Disease (PD), and dopamine replacement dramatically improves motor function in PD patients. Standard models of the basal ganglia, as well as the short duration response to levodopa, suggest that striatal dopamine acutely influences motor function. It is also clear, however, that striatal dopamine influences implicit learning processes. How these dual functions of dopamine are related to clinical parkinsonism is unclear, and difficult to tease out with interventions that

operate on timescales of hours (e.g., pharmacology) to days or years (e.g., lesions). Precisely timed optogenetic inhibition of midbrain dopaminergic neurons during acquisition and performance of a fine motor skill allows us to separate potential “learning” and “performance” roles of striatal dopamine. We employed a rat skilled reaching task with real-time computer vision to detect reach onset and initiate optogenetic suppression of dopamine neurons. Our preliminary results suggest that dopamine neuron suppression at reach onset does not influence reach trajectory, but reduces the likelihood that rats will perform future reaches. Our ongoing studies aim to distinguish motor from motivational effects of dopamine neuron suppression, define functional subpopulations of midbrain dopamine neurons with respect to skilled reaching, and examine how the timing of dopaminergic neuron activity influences motor skills.

Title: Distributed by asymmetric encoding of time in cortical and striatal networks

Authors: ***K. BAKHURIN**, V. GOUDAR, J. L. SHOBE, L. D. CLAAR, K. LEE, D. V. BUONOMANO, S. C. MASMANIDIS;

Abstract: Telling time is fundamental to many forms of learning and behavior, including the anticipation of rewarding events. While the neural mechanisms underlying timing remain unknown, theoretical work has led to the hypothesis that the representation of time is an emergent property of the dynamic activity of neural networks. Computational models have largely focused on the representation of time in simulated networks that mimic cortical microcircuitry. However, motor timing deficits in Parkinson’s disease, experimental evidence from animals, and imaging studies in humans have pointed to a role for the striatum in temporal processing. Recent electrophysiological studies have demonstrated that the striatum may also encode time through moment-to-moment changes in spiking activity across its neural networks.

Despite these gains, a comparison of the extent to which cortical and striatal networks can represent time has not yet been performed. In this study, we made extracellular recordings of large neuron populations (55-120 simultaneously recorded units) in the striatum or prefrontal cortex (PFC) of awake, behaving mice that were trained to learn a fixed temporal relationship between odor cue presentations and the delivery of a reward. We used a machine-learning algorithm to quantify how well networks in each of these brain areas encoded the passage of absolute time along the cue-reward interval. While both cortical and striatal datasets were capable of encoding time, the striatum outperformed the PFC. In addition to decoding the elapsed time during the interval, we were able to use the population activity to predict, up to a second in advance, movement onset in the task. Again, this function was more robust in the striatum. Lastly, prediction of absolute time and movement onset time was dependent on the number of single units included in the analysis. These findings were recapitulated by repeating the same analyses in networks recorded simultaneously in both the PFC and striatum. This study reveals that time may be represented in a distributed manner, both within networks and across different regions of the brain. It also highlights the privileged role of the striatum in telling time, which is perhaps a result of its unique role as an integrator of activity from a diverse set of inputs.

Title: Behavioral changes and voltage imaging of cortical activity in a forced choice licking task using optogenetic inhibition of basal ganglia output in mice

Authors: *A. MORRISSETTE[1], P.-H. CHEN[1], P. Y. BORDEN[2], G. B. STANLEY[2], D. JAEGER[1];
[1]Biol., Emory Univ., Atlanta, GA; [2]Biomed. Engin., Georgia Tech., Atlanta, GA

Abstract: The modulation of cortical activity by basal ganglia output in behaving animals remains poorly understood. The substantia nigra pars reticulata (SNr) is the major source of inhibitory basal ganglia (BG) output in the mouse. It receives input from the direct and indirect basal ganglia pathways and transmits this activity via ascending projections (to the thalamus) and descending projections (to the superior colliculus and brainstem). Previous studies inactivating or ablating basal ganglia output in primates showed slowing of movement and little to no change in reaction time, however, these studies lack temporal specificity during animal behavior. In order to examine the effects of transient changes in basal ganglia output on cortical activity we expressed archaerhodopsin (eARCH3.0) or a novel inhibitory chloride channel (iC++) in the SNr for output inhibition with light stimulation. Behavioral impact of stimulation was assessed during open field spontaneous behavior and in a forced choice licking task. Further, we imaged cortical activity using the genetically encoded voltage indicator (GEVI) VSFP-Butterfly (VSFPB 1.2). Preliminary data suggest that unilateral optogenetic stimulation starting before or at the onset of go sensory cue in a left/right licking task leads to decreased reaction times and an increased number of licks to both left and right lick ports during the behavioral task. In open field behavior, contralateral rotations significantly increased during extended periods (5 min) of unilateral optogenetic inhibition, though mean velocity remained unchanged. Voltage imaging showed reliable cortical activation during licking behavior in motor cortex. Transient cortical activation was also seen following silencing of basal ganglia output, even in the absence of motor behavior. We will further examine cortical activity and behavior changes due to SNr stimulation during specific segments of the left/right licking task to determine effects of SNr silencing on movement initiation and suppression.

Title: The role of corticostriatal circuits in transition of behavior

Authors: *J. SJÖBOM, M. TAMTÈ, P. HALJE, I. BRYS, P. PETERSSON;
Integrative Neurophysiol. and Neurotechnology, Lund Univ., Lund, Sweden

Abstract: In natural behavior, we smoothly change from one type of motor activity to another in a sequence of motor patterns that can be flexibly combined depending on behavioral context or the specific functional goal of the motor act. How such action sequences are constructed by neuronal circuits is largely unknown but corticostriatal circuits have long been thought to have a particularly important role in this type of organization of motor behavior.
To clarify the role of corticostriatal circuits in behavioral transitions we have investigated neuronal activity patterns in primary and secondary motor cortical areas, as well as in the lateral and medial volumes of the dorsal striatum receiving input from these areas. The rodent grooming behavior is organized into a number of discrete behavioral phases, each characterized by the execution of a very stereotypic motor program, which are combined into longer action sequences. As such, it is a good candidate for studying transitions in behavior.
Recordings of single neuron firing patterns in female Sprague Dawley rats revealed a strong engagement of these circuits in the on- and offset of grooming but also in the transitions between individual grooming phases. Based on our data we suggest a mechanistic model where corticostriatal circuits are controlling behavioral transitions through a population-gating mechanism involving both projection neurons and interneurons in cortex and striatum.
These results provide the first description of corticostriatal control mechanisms underlying behavioral transitions in a natural, complex and spontaneous behavior. The way these circuits control behavioral transitions may give important clues to the pathophysiological mechanisms underlying motor dysfunction in diseases involving cortico-basal ganglia circuits.

Title: Population coding of kinematic features in the striatum during motor learning

Authors: *W. TAOUALI[1], P. E. RUEDA-OROZCO[2], D. ROBBE[1];
[1]INSERM-INMED UMR901, Marseille Cedex 09, France; [2]Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Well-learned actions are typically executed with very little variability to comply with action-specific constraints. The neuronal mechanisms that contribute to constraining the trajectory and timing of learned movements are unclear. Recently a role of the dorsal striatum in controlling the kinematics of actions has been proposed and is supported by monotonic correlations between firing rate of individual neurons and movements kinematics. These correlations may indeed underlie neuronal encoding, defined here as the capacity to predict specific kinematic features from neuronal activity. However, monotonic regression analyses impose a very specific type of relationship between neuronal activity and the kinematics features to be decoded. In other brain regions such as the hippocampus strong encoding has been observed despite non-linear relationships between neuronal activity and the decoded feature. Moreover, how monotonic correlations between movements kinematics and neuronal firing rates translate into predictive power both at the single cell and populations level is not known. To address these issues, we applied a Bayesian decoder to spiking activity recorded in the dorsal striatum of rats running on a motorized treadmill. Two groups of rats were compared: well-trained animals performing a stereotyped running sequence and naive animals hand-guided to perform a similar running sequence. We first measured the accuracy of decoding the animals running speed, acceleration, position on the treadmill and time passing during the sequence. Decoding accuracy using single neurons was very low in both groups but increased with the number of neurons included in the decoder. Importantly, population decoding accuracy was higher in well-trained rats compared to naive rats. Notably acceleration and time, despite weak monotonic correlations with firing rates, were well decoded at the population level in the Bayesian framework. Finally, we report that the gain in decoding could be partially accounted for by a reduction of neuronal intertrial variability, but also by less expected changes in single cell tuning properties such as firing rate range. The contribution of these changes to the decoding depends on the decoded feature and the population size. These results suggest that the encoding accuracy of task-relevant kinematic features by single striatal neurons is generally weak and does not change after motor learning, despite a gain in monotonic correlations after learning. However, at the population level there is a better encoding of task-relevant kinematic features which can not be solely explained by a reduction of neuronal variability.

Title: Thalamic intralaminar nuclei control of striatal microcircuits

Authors: *U. GYAWALI, K. K. COVER, M. H. PATTON, B. M. ROBERTS, M. G. WHITE, B. N. MATHUR;
Pharmacol., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Successful reward acquisition in a dynamic environment requires attention to salient sensory stimuli that instruct striatally-encoded actions. While striatally-projecting intralaminar nuclei of the thalamus encode salient information, how the different thalamic intralaminar nuclei govern striatal activity requires further investigation. To probe this, we employ optogenetics, electrophysiology and fast-scan cyclic voltammetry in mouse brain slices. Our preliminary data suggest that individual intralaminar nuclei form unique striatal microcircuits to differentially control striatal dopamine release. These results shed new light on the role of the thalamus in action control.

Title: Cell-type- and projection-specific study of the external globus pallidus circuit organization

Authors: *V. LILASCHAROEN, S. SHIN, D. A. KNOWLAND, B. LIM;
Biol. Sci., UCSD, La Jolla, CA

Abstract: Recent advances in circuit tracing have provided powerful tools that reveal extensive information about the neural circuitry. However, thus far, no viral tracer has been proven potent enough to allow a robust, long-lasting retrograde expression of transgenes without inducing cytotoxicity. Because even neighboring neurons of the same cell-type differ in their connectivity and functions, a new method is required to achieve both cell-type- and projection-specific delivery of transgene via retrograde transduction. Here we present a new viral-genetic strategy that allows long-term expression of transgenes including fluorescent proteins, optogenetic tools and genetically encoded calcium indicators in a cell-type- and projection-specific manner. We have developed a novel viral vector based on the rabies-glycoprotein-pseudotyped equine infectious anemia virus (RG-EIAV), which has been proven successful to infect neurons retrogradely. We genetically engineered the RG-EIAV vector to express site-specific recombinases including Flp and Dre in a Cre-dependent manner. Together with recombinant adeno-associated virus (AAV) expressing transgenes of interest in a Flp- or Dre-dependent manner, we are able to induce robust expression of transgenes in distinct neuronal populations of the same cell-type based on their projection targets. We demonstrate the application of this strategy by studying the circuit architecture of the parvalbumin-expressing neurons in the mouse external globus pallidus (GPe), one of the major nuclei of the basal ganglia that is thought to contribute prominently to basal ganglia dysfunction in movement disorders such as Parkinson's disease. The characterization of the GPe neuronal population including cell-types, circuit organization, and functional roles in pathological symptoms have not been fully addressed. By applying our novel strategy with transgenic mice expressing Cre recombinase in specific neuronal cell-types, we were able to identify two distinct populations of parvalbumin-expressing neurons in the GPe based on different projection patterns. This strategy will allow us to further our understanding of the GPe circuitry by elucidating efferent and afferent connections, electrophysiological properties and transcriptional profile of each specific neuronal population.

Title: Theta and gamma rhythm generation in a model network of fast-spiking striatal interneurons

Authors: *J. A. CHARTOVE, M. MCCARTHY, B. PITTMAN-POLLETTA, N. KOPELL; Boston Univ., Boston, MA

Abstract: Theta (4-10 Hz) and gamma (40-90 Hz) oscillations in the striatum manifest during behaviorally relevant times in movement, reward, and decision making tasks, as does their cross-frequency coupling. Fast-spiking interneurons (FSIs) in striatum strongly inhibit the medium spiny neurons (MSNs), the output cells that make up 95% of striatum; therefore, they have a powerful influence in patterning striatal activity. These FSIs communicate with one another using both GABA-mediated synapses and dendro-dendritic gap junctions, and therefore comprise a coupled network potentially involved in producing behaviorally relevant rhythms within the striatum.
To explore rhythm generation by FSIs, we simulated a network of 100 fast-spiking interneurons, each of which was a two-compartment Hodgkin-Huxley neuron with a D-type slowly-inactivating potassium current (D-current). In isolation, these model neurons burst at 5 Hz when stimulated tonically, with spikes within a burst occurring at 75 Hz. These frequencies are determined by the time constants of the potassium currents within the cell. A network of these FSIs can produce either a theta frequency, a gamma frequency, or both, depending on the conductances of the gap junctions and inhibitory synapses between the individual cells. We simulated increased dopaminergic tone by increasing gap junction conductance as well as excitability of the FSIs, and decreasing D-current conductance. The rhythmic regime of the network was altered by changes in dopaminergic tone; our findings suggest that dopamine may induce the theta and high gamma (80 Hz) rhythms seen in vivo and carried by striatal FSI networks. Thus, theta and gamma rhythms in striatum and cortex may reflect dopaminergic tone, and may play a role in processing related to reward and motivation during decision making.

Title: Distinct firing patterns of GPe Arkypallidal and Prototypical neurons in a reinforcement learning task

Authors: *M. A. FARRIES[1,2], J. D. BERKE[1,2];
[1]Dept Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: The basal ganglia (BG) are a set of subcortical structures involved in the modulation and control of adaptive behaviors. The GPe lies at the center of the BG network, receiving projections from input stations of the BG (striatum and subthalamic nucleus) and making GABAergic projections to all major BG nuclei. The GPe is best known for its projections downstream to BG output nuclei, but Mallet et al. (*Neuron* 2012) identified a distinct class of GPe cells, dubbed "Arkypallidal" (Arkys), that project exclusively to the striatum. Arkys can be distinguished from "Prototypical" (Proto) GPe cells by their firing rates and variability during natural waking and sleep states, and are especially responsive to Stop cues (Mallet et al. *Neuron 2016)*. To gain further insight into their distinct functions, we recorded presumed Arkys and Protos in rats engaged in a trial-and-error decision-making task (Hamid et al. *Nat Neurosci 2015).* On each trial, rats hold their nose in a central port until a Go cue prompts a left- or rightwards movement, with each option rewarded probabilistically. Unlike Protos, Arkys were generally more active during the intertrial interval (ITI), reducing their firing just before trial initiation and elevating it after trial completion. Both Arkys and Protos were more active, on average, when preparing contralateral movements compared to ipsilateral movements, but for Protos (only) this choice-related activity appeared even before the Go cue prompted movement. Both Arkys and Protos increased firing, on average, following reward delivery compared to unrewarded trials. However, this reward response was stronger and more consistent in Arkys, and the Arky population sustained reward-related changes in activity throughout the ITI, including an elevation in firing rate just before the onset of the next trial when the previous trial had been rewarded. We suggest that Protos are more concerned with choice preparation and execution, while Arkys are more concerned with trial outcomes, providing value information to the striatum during the ITI that may influence decisions to work.

Title: Synaptic responses and plasticity properties in corticostriatal circuits *In vivo*

Authors: *K. JUCZEWSKI[1,2], D. A. KUPFERSCHMIDT[1], D. M. LOVINGER[1];
[1]Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [2]Dept. of Neurosci., Karolinska Inst., Stockholm, Sweden

Abstract: Corticostriatal circuits are involved in action control and action learning. The prefrontal cortex (PFC) projects strongly to the dorso-medial striatum (DMS) while the primary motor cortex (M1) projects mainly to the dorso-lateral striatum (DLS). It is believed that goal-directed actions are mostly controlled by DMS whereas habitual behaviors are controlled by the DLS. To understand specific dynamics of these circuits we used a classical physiological technique, local field potential (LFP) recording in urethane anaesthetized mice. In our studies we focused on several aspects of synaptic responses and plasticity evoked by cortical stimulation with a tungsten electrode and recorded by a glass pipette. Because little is known about origin and significance of the corticostriatal LFPs, we characterized these responses. We changed depth of the recording electrode, intensity of the stimulating current and stimulation parameters. We observed systematic changes in the waveforms of evoked LFPs that depended on all the mentioned parameters. Next, we combined electrical stimulation and optogenetics to take advantage of unique precision of this latter technique for pathway-specific interrogation. We determined that field potentials can be evoked with ChR2 expression and light stimulation. Mice expressing ChR2 in cortex were generated by breeding Emx1-Cre mice with AiCOP4 conditional ChR2-expressing mice. We performed in vivo recordings in DLS and DMS to compare electrically- and optically-evoked field potentials. We examined effects of stimulus duration and light power on the response characteristics. Additionally, light-evoked responses were compared in M1 and at different depths of the striatum showing topographical organization of this region. Control experiments indicated no light-evoked responses in C57Bl6/J mice that did not express ChR2. In ongoing experiments we are examining mechanisms of synaptic modulation and plasticity using various electrical- and light-stimulation patterns and intracerebroventricular drug application. Moreover, we are combining in vivo fiber photometry with our LFP-recording system that will give us a new insight into real-time plasticity changes observed in the corticostriatal circuits.

Title: Motor cortex: a tutor for the basal ganglia?

Authors: *S. B. WOLFF, A. K. DHAWALE, R. KO, B. P. OLVECZKY;
Harvard Univ., Cambridge, MA

Abstract: The remarkable capacity of the brain to acquire and execute motor skills depends on a distributed motor network. While many components have been identified, the intricate interplay between the distinct brain areas involved, their specific roles, and the implementation of the learning process in neuronal circuitry remain elusive. To dissect how the motor system underlies the acquisition and execution of complex motor skills, we train rats in a lever-pressing task which results in spatiotemporally precise movement patterns. Previously, we addressed the role of motor cortex (MC), showing that the learned skills we train survive chronic lesions of MC, while transient optogenetic manipulations of MC acutely degrade their execution. Thus, while activity in MC has the capacity to modulate the learned skills, it seemingly does not exercise this function once the behavior has been consolidated. This is consistent with our previous finding that MC is necessary for the initial acquisition of the skills we train. Based on these results we hypothesize that MC acts as a 'tutor' during skill learning, with its input to downstream motor areas serving as a teaching signal that guides the acquisition and refinement of subcortically generated motor sequences. Here we show that the striatum, in particular the part that receives input from MC, is necessary for both acquiring and executing the motor skills we train, thus identifying striatum as a possible subcortical target of MC's tutoring function. To address the role of MC-striatum interactions directly, we use viral and molecular strategies to selectively access distinct MC projection pathways. In line with our hypothesis, transient optogenetic manipulations of corticostriatal projections acutely degrade the execution of the learned skills. Moreover, chronic and selective silencing of corticostriatal projections prevents animals from acquiring those skills in the first place. Together with our previous findings, this supports the idea of MC acting as a tutor of subcortical circuits through its modulation of striatal activity. To further dissect MC's tutoring role, we are using chronic long-term electrophysiological recordings and optogenetic identification of projection neurons during skill acquisition to study the activity of corticostriatal projections and the changes in cortical and striatal networks over the course of learning.

Title: Efficient cortical control of basal ganglia recipient motor thalamus.

Authors: *H. BOKOR, N. HADINGER, L. ACSADY;
Inst. of Exptl. Medicine, Hungarian Acad. of Sci., Budapest, Hungary

Abstract: The motor thalamic nuclei are key players in the circuit that control motor planning and execution. The thalamocortical neurons which receive GABAergic afferents from the output nuclei of basal ganglia (BG) project to frontal, motor cortical areas (M1, M2). Conversely layer 5 (L5) neurons of these regions innervate the first station of the BG circuit, the striatum, as well as its last station, the BG recipient thalamic nuclei. In the present study we aimed to elucidate the physiological and anatomical features of the L5 corticothalamic (CT) pathway to the motor thalamic nucleus ventromedialis (VM) and compare it to L5 input to sensory thalamus (nucleus posterior, Po) as well as to layer 6 (L6) projection to VM. We investigated the L5 CT pathway using Thy1-Chr2-EYFP and Rbp4- and the L6 CT pathway by the ntsr1-cre mice lines. Selective labeling of L5 axons revealed only small diameter (1-2 μm) terminals in the VM compared to the giant L5 driver terminals in the somatosensory Po (4-8 μm). The size range of L5 boutons in VM was close to that of the L6 inputs (0.5-1μm). At the ultrastructural level, however, L5 and L6 terminals displayed significant differences in VM. L5 boutons established much larger, often multiple perforated or branching synapses, always contained mitochondria and had significantly larger volume. L5 terminals mostly innervated specialized large headed (>300nm) dendritic spines. In contrast, L6 terminals established simple and smaller synapses, targeted thin (≤0,5 μm) dendritic shafts and contained mitochondria only in 10% of the cases. Photoactivation of L5 input from M1 and M2 motor cortex could reliably evoke action potentials in VM cells under ketamine/xylazine anesthesia. Repetitive activation of L5 was able to entrain VM neurons firing. Several VM cells could be reliably driven with up to 20 Hz stimulation. In contrast, photoactivation of Po cells via the large S1, L5 terminals led to significant depression in response probability above 4 Hz. Unexpectedly, we found that VM cells can be driven by L5 input arising from the contralateral cortex as well. At the electron microscopic level L5 terminals from the contralateral cortex had larger volume and postsynaptic density area compared to the L5 terminals from the ipsilateral cortex. Axonal labeling and photoactivation of L5 neurons in different frontal cortical regions revealed that L5 afferents are organized according to horizontal sectors within VM.

Our results demonstrate that neocortex can exert strong, top-down influence on the information transfer at the last, thalamic stage of the basal ganglia circuit via morphologically specialized synaptic connections.

Title: Communication between subthalamic structures and pontine nuclei

Authors: ***K. B. RAMAKRISHNAN**, K. KHODAKHAH;
Albert Einstein Col. of Med., Bronx, NY

Abstract: The subthalamic nucleus (STN), zona incerta (ZI), and pontine nuclei (PN) are subcortical brain regions that contribute to motor and non-motor related activity. The STN is part of the basal ganglia structure with primarily glutamatergic projection neurons. Although the projection of the STN within the BG circuit is well studied, its projection outside the BG is not well understood. The ZI, located dorsal to the STN, is known to send both excitatory and inhibitory projections to PN, which is part of brainstem. The PN, which also receives extensive cerebral inputs, targets the granular layer of the cerebellum as glutamatergic mossy fibers. These structures are all known to be involved in motor related activity, and their dysfunction may contribute to movement disorders.We examined whether STN or ZI affect the activity of the PN neurons by combining optogenetics with single unit recordings in awake mice. Channelrhodopsin was injected in either the STN or the ZI, and their axonal projections were optically activated in PN while recording the single cell activity of neurons using an optrode. We find that in STN-targeted mice, about 50% of recorded cells responded to the stimuli, whereas in ZI-targeted mice more than 75% of the recorded cells were responsive to optical excitation of the fibers. In both STN- and ZI- ChR2 mice, optical activation of the opsin carrying axons increased the firing rate in the PN neurons with a short latency of approximately 2-4 milliseconds. The stimuli also inhibited the spontaneous firing in about 20% of neurons. Our data suggest that both STN and ZI are capable of modulating the activity of the PN.

Title: The basal ganglia and cerebellum contribute to the control of the adrenal medulla

Authors: *R. P. DUM[1], M. E. MARCELLE[2], D. J. LEVINTHAL[3], P. L. STRICK, 15261[2]; [1]Neurobiology, Ctr. for Neural Basis of Cognition, Systems Neurosci. Inst., [2]Neurobiology, Ctr. for Neural Basis of Cogn., Systems Neurosci. Inst., Univ. of Pittsburgh Brain Inst., Univ. Pittsburgh, Pittsburgh, PA; [3]Medicine, Div. Gastroenterology, Hepatology, and Nutr, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We used retrograde transneuronal transport of rabies virus to determine if the adrenal medulla is the target of output from the basal ganglia and cerebellum. We injected rabies virus (N2c strain) into the adrenal medulla of 5 cebus monkeys. The animals were allowed to survive long enough to label second-order (n=1), third-order (n=1) or fourth-order neurons (n=3). We first observed substantial numbers of labeled neurons in the basal ganglia and cerebellum in animals with fourth-order labeling. This is the same survival time in which substantial numbers of labeled neurons were first present in the cerebral cortex. These observations indicate that the basal ganglia and cerebellar labeling was mediated by connections to efferent systems in the hypothalamus, midbrain or brainstem, rather than through the classical basal ganglia-thalamo-cortical or cerebello-thalamo-cortical circuits. The labeled neurons in the basal ganglia and cerebellum were consistently observed in the substantia nigra pars reticulata (SNpr), the internal segment of the globus pallidus (GPi) and each of the three deep cerebellar nuclei. Overall, we observed about four times as many labeled neurons in the basal ganglia as in the cerebellum. Within the basal ganglia, most labeled neurons (80%) were located in the SNpr and were concentrated in a subregion that is interconnected with area 9 in the prefrontal cortex. The remainder of basal ganglia labeling was scattered throughout the motor and non-motor regions of the GPi. Within the cerebellum, more than half of the labeled neurons were located within the ipsilateral (30%) and contralateral (21%) fastigial nucleus. These results indicate that the basal ganglia and cerebellum can influence at least one element of the sympathetic nervous system- the

adrenal medulla. This influence appears arise more prominently from the basal ganglia than from the cerebellum. Moreover, this basal ganglia output originates primarily from its non-motor region. Our results suggest that the cerebellum, and especially the basal ganglia, are involved in the neural regulation of internal organ function. Thus, our anatomical results may provide a neural substrate for autonomic dysfunction that is associated with basal ganglia and cerebellar disorders.

Title: Glycinergic neurons are implicated in basal ganglia dependent functions

Authors: *Y. P. HUIZAR[1], R. ORTEGA[2], R. A. PEREZ[2], E. CASTANEDA[3], M. MIRANDA[2]; [1]Biochem., Univ. of Texas At El Paso, El Paso, TX; [2]Biochem., [3]Psychology, Univ. of Texas at El Paso, El Paso, TX

Abstract: The basal ganglia is responsible for somatosensory discrimination and both voluntary and involuntary movement. The functions regulated by the basal ganglia involve the release of dopamine from dopaminergic nerve terminals in the striatum. Activation of post-synaptic dopamine receptors leads to activation of the direct and indirect pathways to regulate motor function. Although the contribution of GABAergic fibers to basal ganglia function is well documented, glycinergic neurotransmission is completely unknown. We are currently analyzing glycine transporter 1 (GlyT1) immunoreactivity in the globus pallidus and our findings suggest the presence of GlyT1 in neurons. To investigate the functions regulated by these glycinergic neurons, sprague dawley rats were subjected to intracranial injections of saline or the glycine receptor antagonist strychnine followed by motor assessment, sensorimotor evaluation, testing

postural reflexes, and analyzing open-field behavior. The results suggested a potential contribution of glycinergic transmission in the regulating voluntary motor activity. Current and future research will elucidate the role of nigropallidal glycinergic fibers in the control of motor functions.

Title: Optogenetic interrogration of distinct and complementary nigral sub-circuts that shape movement.

Authors: *G. I. RIZZI[1], K. R. TAN[2];
[1]Biozentrum, [2]Univ. of Basel, Basel, Switzerland

Abstract: Motor behavior stands at the core of every mammalian organism's survival and evolvement within its environment. The Substantia Nigra Pars Reticulata (SNr) has long been identified as the prime output nucleus of the Basal Ganglia, an ensemble of brain structures that governs motor behavior. The SNr is commonly regarded as GABAergic and homogenous. Its activity patterns have been correlated with different aspects of locomotion such as sensory input, movement planning, execution and interruption. Such versatile function suggests a more complex organization of the SNr than has been thought so far. Using a combination of anatomical and functional techniques we identified two marginally overlapping sub-populations of GABAergic neurons that are embedded within separate circuits, execute different functions, and act complementarily to warrant locomotion. More specifically, we used optogenetic-targeting techniques to dissect the function of each nigral sub-population and verify the effect of their combined interaction. While VGAT-positive neurons encode the execution of movement, PV-expressing cells alone do not alter locomotion. Interestingly when activated synchronously, the two populations drastically increase the robustness of locomotion.
We provide fundamental understanding of basic SNr circuitry and function with a cell-type specific resolution. This represents a critical step in refining our knowledge in the cellular, synaptic and circuit bases of motor-related behaviors.

Title: The motor cortex to substantia nigra: a novel pathway

Authors: *M. LODGE, G. RIZZI, K. R. TAN;
Biozentrum, Basel, Switzerland

Abstract: The basal ganglia, a complex network of interconnected nuclei, have been linked to the formation and execution of voluntary movement. The principal model of movement control involves two distinct pathways originating from direct spiny projection neurons (dSPNs) and indirect projection neurons (iSPNs) of the striatum. Through different projection targets the dSPNs and iSPNs are able to initiate and stop movement respectively, via the substantia nigra pars reticulata (SNr). Here, we describe a novel pathway from the motor cortex directly onto the SNr, and we aim to elucidate the role of this pathway in locomotion.
Using retrograde and anterograde mapping tools we show an anatomical connection between the M1/M2 motor cortex and the SN. Functional connectivity is investigated using *in vitro* electrophysiology, providing confirmation of a glutamatergic projection onto two cell populations- IH positive (putative dopamine neurons) and IH negative (putative GABA neurons)- with a preferential connection to IH positive neurons. To expand on this we will use optogenetics in combination with a motor task to investigate its role in motor behaviour output. Thus, we hope to understand what this novel pathway does in relation to the currently accepted roles of the direct and indirect pathways- and more importantly how this opens the door to more complex locomotor circuitry.

Title: Reward based motor adaptation mediated by basal ganglia

Authors: *T. KIM[1], K. C. HAMADE[1], W. TEKA[2], W. H. BARNETT[2], S. N. MARKIN[1], I. A. RYBAK[1], Y. I. MOLKOV[2];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Georgia State Univ., Atlanta, GA

Abstract: The basal ganglia (BG) are involved in a broad range of motor and cognitive behaviors. It is widely accepted that the BG play a key role in action selection and reinforcement learning facilitated by the activity of dopaminergic neurons that encode the prediction error when the reward outcome is higher or lower than expected. The BG are thought to select proper motor actions by gating appropriate commands and suppressing inappropriate ones from a repertoire of cortical signals arriving at the striatum. This process of action selection is mediated by the direct striato-nigral (GO), and the indirect stiato-pallidal (NOGO) pathways. Previous models confirmed the plausibility of the above concept, but in an abstract way only, lacking the details about formation of neuronal activity patterns actuating the muscular-skeletal apparatus, and hence did not allow studying BG involvement in motor adaptation. We have developed a more complete and detailed model of BG interacting with a movement execution system in the context of goal directed reaching tasks. The model included sensory and motor cortices, the BG, the spinal cord circuitry, and a virtual mechanical arm allowing for simulation of 2D reaching movements. The arm was composed of 2 joints (shoulder and elbow) controlled by 6 muscles (4 mono-articular and 2 bi-articular). The spinal cord network contained motoneurons to control 6 muscles and sensory interneurons receiving afferent feedbacks and providing basic reflexes. The cortical neural activity corresponding to possible movements was determined by solving an inverse problem based on the initial arm position, reaching distance and direction. Reaching movements were performed in response to a sensory cue associated with the target arm position. Target positions located in an arbitrary number of different directions were used as a set of possible actions. The function of BG was to associate the cue with a proper reaching movement by adjusting weights of cortico-striatal inputs through reinforcement learning. The BG had an intrinsic exploratory mechanism allowing for seeking better cue-action responses delivering larger rewards. Reinforcement learning relied on the dopaminergic signal measuring trial-to-trial changes in the reward. The model was used to simulate reward based adjustment of reaching movements to verify that such a system is capable of quick (10-100 trials) motor adaptation

observed in experiments. Our analysis shows that (1) potentiation of cue-NOGO inputs is crucial for quick dropping of pre-existing cue-action associations; (2) quick learning occurs at the expense of relatively poor accuracy and high variability of the movements.

Title: The control of action selection by cell-type specific circuits of the striatum in auditory-guided decision task

Authors: ***L. CUI**[1,2], N. XU[1];
[1]Inst. of Neuroscience,CAS, Shanghai City, China; [2]Univ. of Chinese Acad. of Sci., Shanghai, China

Abstract: The transformation from sensory information to motor actions is a fundamental process in decision making. Although the striatum has been implicated in movement control and decision making, its critical role in the sensory-motor decision is still elusive. This can be due to the lack of proper quantitative behavioral measurement with correspondence to precise manipulation of specific striatal circuits, where different sub-regions and different output (direct and indirect) pathways of the striatum could play distinct roles. Here we combined quantitative psychophysics task in mice with specific circuit manipulations to address this problem. We trained head-fixed mice to perform an auditory-guided two-alternative forced choice (2AFC) task, in which mice distinguished sounds with different frequencies and licked left or right water port to report their choice. This behavior paradigm provided precise time control and accurate behavioral readout, allowing for probing the striatal circuits in different aspects of sensory-based action selection. First, we examined the regional specific roles of striatum in the auditory-guided action selection. Unilateral optogenetic silencing of a posterior sub-region of the dorsal striatum, where it receives input from auditory cortex, impaired mice's contralateral choice but not the ipsilateral choice, whereas silencing of an anterior region of dorsal striatum, where it mainly receives input from motor cortex, showed no significant effect on behavioral performance, suggesting a region and modality specific functional role of the striatum in action selection.

Second, we specifically manipulated subtypes of striatal projection neurons associated with direct or indirect output pathways. Unilateral activation of D2 receptor expressing neurons (using floxed-ChR2 in D2-cre mice) suppressed contralateral behavioral choice, suggesting a suppressive role of the indirect pathway in action selection. In contrast, activation of D1 receptor expressing neurons (using floxed-ChR2 in D1-cre mice) drove the contralateral choice, supporting sufficiency of the direct pathway in driving contralateral choices. Taken together, our results provide direct evidence for the control of action selection in perceptual decision-making by sub-region and cell-type specific circuits in the striatum. Prospectively, our behavior paradigm, when combined with optogenetics and in vivo imaging techniques, will provide a unique window to gain mechanistic understanding of the operation principles of basal ganglia circuits in sensory-motor decision making.

Title: An Influence of motor costs in human reinforcement learning

Authors: *K. SATO, J. IZAWA;
Empowerment Infromatics, Univ. of Tsukuba, Tsukuba, Japan

Abstract: The principle of the motor learning is forming an association between sensory observation and motor actions: a motor policy of how the brain select optimal actions at the certain state of the body and the environment. There is ample evidence to suggest that the brain employs optimal feedback control in computing motor commands that maximize reward and minimizes effort (i.e. motor costs) [Izawa 2008, 2011]. Yet, how exactly the brain optimizes the motor policy is still unclear. On the other hand, the reinforcement learning that fits well with the behavioral data of decision making tasks has uncovered the roles of the basal ganglia in maximizing future rewards with exploration and exploitation of actions, which is mathematically identical to an optimization algorithm of forming the state-action map whereas its role in human motor control has not been well examined. To seek a contribution of reinforcement learning mechanism of the human brain to optimization of motor commands, we focused on the motor costs in a human reinforcement learning task and investigated the property of the brain in

forming motor policy over the visual state space which was also influenced by the physical effort of actions.
We extended the 'grid sailing task' developed by Doya and his colleagues [Fermin 2010] where the subjects were asked to explore an optimal route of the agent's (i.e. visual cursor) navigation from the start cell to the goal cell by deciding the agent's action with pushing the keys: This is similar to learning for controlling a new tool with finding a series of the finger tapping although a computational problem behind this task is forming the state-action pairs rather than memorizing a tapping sequence. Based on this paradigm, we simplified the state space and implemented the motor cost: The subjects pushed the two force sensors with the index and the middle fingers instead of a keyboard, where we manipulated the amount of the force that the subjects were requested to produce to select agent's actions which brought the cursor to the next state.
We observed a route selection difference between the cost situation and no-cost one: The selected action at each state is biased to one with the lower motor cost while maintaining the low number of actions. Also, we observed that subjects generalized the previously learned state-action memory among two situations with different motor costs. This result suggests that the human brain has the capacity to learn state-action pairs by taking account of the physical efforts to achieve the goal. The further analysis with Q-leaning model may reveal the structures of the action-value memories for the reward-based and the effort-based motor optimization.

Title: Distinct roles of subthalamic nucleus alpha and beta oscillations in stopping and delaying manual and verbal actions

Authors: *A. GHAHREMANI[1,2], K. UDUPA[3], J. WESSEL[4], U. SAHA[3], T. HOQUE[3], A. LOZANO[3], M. HODAIE[3], S. KALIA[3], A. ARON[5], R. CHEN[3];

Abstract: Inhibitory control over the motor system is thought to be implemented by a frontal-basal ganglia network to either delay or entirely stop actions. The subthalamic nucleus (STN) of the basal ganglia is considered a key node in this network. Several studies of manual stop tasks have reported increased power of STN beta band [13-30Hz] oscillations when actions are successfully stopped. Studies with other response control tasks reported increased STN power in lower frequencies such as alpha [8-12Hz] and theta [4-8Hz] bands in relation to delaying responses. Here we recorded oscillations from the STN in two groups of Parkinson's disease patients undergoing deep brain stimulation surgeries. We ran a standard manual stop signal task (n=8) and a speech stop signal task (n=10). Our objectives were to compare manual and verbal versions with respect to STN signatures for a) stopping (i.e. successful vs. failed stop trials) and b) delaying movement (i.e. going slow vs. fast on Go trials). Consistent with several studies, we found increased beta activity in the STN for successfully stopping manual actions ($F(1,7)=12.27$, $p=0.01$). For the comparison of slow "go" trials compared to fast "go" trials, alpha activity was commonly increased in the STN in both manual and speech tasks (manual: $t(7)=5.66$, $p=0.002$; speech: $t(9)=4.51$, $p=0.003$). Thus, increased oscillatory power was detected in the STN for inhibitory control of both manual and verbal actions. The findings also show that different signatures (beta vs. alpha) relate to stopping vs. delaying actions, possibly related to different frontal-STN hyperdirect pathways.

Title: The basal ganglia control the urgency of a reach choice, but not the choice itself

Authors: *D. THURA, P. CISEK;
Dept Neurosci., Univ. Montreal, Montreal, QC, Canada

Abstract: The basal ganglia (BG) have long been implicated in many aspects of cognition and motor control. One prominent theory suggests that they play a key role in selecting desired actions and suppressing competing actions on the basis of decision-variables learned through reinforcement. However, choice selective signals in the GPi often lag behind cortical regions and are largely simultaneous with muscle contraction. Furthermore, GPi inactivation has no effect on which movements are selected in decision tasks, but instead reduces the velocity and extent of movements, consistent with the proposal that the BG regulate motivation and response vigor. It therefore remains unclear whether the BG play a causal role in decision-making and if so, precisely what that role may be. To investigate this question, we recorded cortical and pallidal activity in two monkeys trained to perform a reach selection task that allows us to dissociate the process of deliberation from the moment of commitment. In different blocks, the temporal properties of the task were varied to induce adjustments of monkeys' speed-accuracy trade-off (SAT). We found that while animals deliberate between two reach targets, neurons in dorsal premotor (PMd) and primary motor cortex (M1) continuously reflect the evolving sensory evidence guiding the decision. By contrast, BG output via the globus pallidus internus (GPi) remains untuned until the commitment time is signaled in PMd/M1, possibly confirming the cortical decision and movement initiation. We also observed that the SAT context in which the task was executed strongly modulated a large proportion of GPe (50%) and GPi (63%) cells. Crucially, this modulation was congruent with the cells' variation of activity during deliberation within each block: "build-up" cells tended to be *more* active during fast than slow blocks, especially in GPe; while "decreasing" cells were *less* active in fast than slow blocks, suggesting that the BG provides a time-varying signal reflecting the growing "urgency" to commit, which is adjusted to control speed/accuracy tradeoffs. Our results are consistent with the proposal that cortical activity reflects a dynamic, biased competition between candidate actions, which is gradually amplified by an urgency signal from the BG that effectively controls the amount of evidence needed before the animal commits to the currently favored reach choice. Eventually, the cortical bias in favor of one of the targets becomes strong enough to engage tuning in the GPi, at which point the BG "gate" is opened leading to a positive feedback that constitutes commitment to the action choice.

Abstract: Dynamic changes in cortico-basal ganglia circuit function underlie action learning. How functional changes in discrete, connectivity-specified circuits manifest in vivo during such learning remains unknown. Using in vivo fiber photometry, we assessed real-time activity and plasticity of distinct cortical inputs to the striatum during motor skill learning. The genetically encoded calcium indicator, GCaMP6s, was virally expressed in excitatory cortical neurons in medial prefrontal cortex (mPFC) or motor cortex (M1) of mice. An optical fiber was implanted into dorsomedial striatum (DMS) of mPFC-injected mice to target associative inputs, and dorsolateral striatum (DLS) of M1-injected mice to target sensorimotor inputs. Activity-dependent fluorescent calcium dynamics were assessed in presynaptic elements of these inputs as a proxy for projection activity as mice were trained on the accelerating rotarod. Engagement of associative inputs was modest during initial trials on the rotarod, peaked during early training, and rapidly diminished as performance was automatized. In contrast, sensorimotor inputs were robustly engaged during initial trials, and showed a progressive decrease in activity with training. Somatic photometric recordings of DMS-projecting mPFC neurons and DLS-projecting M1 neurons revealed unique engagement patterns, suggesting differential learning-related plasticity at somatic and presynaptic elements of corticostriatal inputs. Our work describes novel approaches to observe real-time activity dynamics in discrete corticostriatal inputs, and provides new insight into how cortico-basal ganglia circuits encode action learning.

Title: A role for dynorphin in the basal ganglia

Authors: *R. LALCHANDANI, J. B. DING;
Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: The human brain has evolved to reward specific behaviors that increase the probability of propagating of one's genetic material. Drugs of abuse— such as cocaine, prescription painkillers and heroin— hijack these built-in systems to change the way different areas of the brain communicate. This shortcut to reward is especially problematic when drug experiences are linked to the memory of the circumstances in which drug use occurred, which often leads to relapse after periods of abstinence. Much remains unknown about how changes in reward circuits lead to addiction and how the brain creates memories that increase susceptibility to relapse. The basal ganglia are highly implicated in conscious cognitive processes, including learning, memory and addiction. The largest nucleus of the basal ganglia, the striatum, utilizes endogenous opioids to modulate information integration. Dynorphin is a potent opioid that is synthesized in striatonigral pathway neurons and is understood to fine-tune basal ganglia transmission at the synaptic level. Dynorphins act primarily on kappa-opioid receptors, which occur in high densities in the basal ganglia at both pre-synaptic and post-synaptic sites, and action of dynorphin at kappa-opioid receptors reduces the release of dopamine. Drugs of abuse cause increases in dynorphin expression in the basal ganglia, and the opiate antagonist, naltrexone, acts primarily at mu and kappa opioid receptors as a treatment against relapse in certain addictions. Despite the prevalence of the dynorphin in the basal ganglia and its link to addiction, its role in the basal ganglia is not well understood. As dynorphin is expressed widely throughout the brain, we have developed a system in which dynorphin can be removed in a cell-type specific manner and have subsequently assessed behavioral changes in response to selective dynorphin deletion.

Title: Exogenous and endogenous auditory prediction in speech

Authors: *D. SHILLER[1], M. SATO[2];
[1]Ecole d'orthophonie et d'audiologie, Univ. of Montreal, Montreal, QC, Canada; [2]Lab. Parole et Langage, Aix-Marseille Univ. & CNRS, Aix-en-Provence, France

Abstract: Auditory sensory prediction plays a central role in speech motor planning and control. One approach to investigating this predictive process is through the comparison of auditory cortical responses to auditory feedback during active speech vs. passive listening to the same acoustic speech signals. Neural responses during active speech production are typically suppressed, which is presumed to reflect a subtraction of the motor-sensory prediction from auditory feedback. In the present EEG study, we further explored the link between online (feedback) and offline (passive listening) speech processing by measuring auditory evoked responses in combination with two different manipulations that alter a talker's ability to accurately predict the sensory consequences of speech actions: one involving a real-time change in auditory feedback during vowel production, and the other involving the presenting a stable auditory vowel target before each production.
Methods: Participants carried out two pairs of tasks, each consisting of matched speech production and passive listening phases. In each task pair, subjects first produced 240 vowel-consonant syllables during a portion of which vowel F1 frequency was altered in real-time (35% increase). Following production, subjects passively listened to the recorded speech sequence (identical in timing and amplitude to the preceding speech auditory feedback). Two such pairs of production/listening tasks were carried out, one involving a visual cue to speak and the other involving an auditory presentation of the speech target. During all tasks, averaged EEG auditory-evoked potentials (N1/P2) were computed for each task, feedback condition and target cueing condition.
Results: Behaviorally, subjects compensated for the auditory feedback manipulation under both visual and auditory-cueing conditions. EEG analyses showed a significant speech-induced suppression (SIS) of the auditory evoked N1/P2, with a difference in amplitude between the auditory and visually cued productions. Interestingly, this difference in SIS magnitude resulted from a differential effect of cueing modality on the evoked responses during the listening task,

with a reduction in auditory evoked N1/P2 between the auditory target and the subject's speech production (auditory habituation) occurring during offline listening, but not during online production.
In demonstrating distinct exogenous and endogenous predictive processes during speaking and listening, the results suggest that online auditory processing of speech feedback is functionally decoupled from offline processing of speech originating from outside the speaker.

Title: Cortical control of postural responses on swallowing movement: A fNIRS study

Authors: *M. YAMAWAKI, S. SHIBANO, G. MATSUDA;
Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: (Backgrounds) The swallowing center in the medulla is the key integrator of swallowing performance. In addition, there are subcortical and cortical centers above the brainstem that induced swallowing movement, however, their specific role and connections are not well understood. There are technical limitations of conventional neuroimaging techniques that require subjects to be in a supine position and/or restrict head movements. Such limitations narrow the range of experimental task options for swallowing. To challenge these issues, we applied functional near-infrared spectroscopy (fNIRS), an optical method that noninvasively measure cortical hemodynamics, for brain mapping in swallowing.
(Methods) Eighteen of right-handed healthy male were analysed. Subjects, on the chair or in supine position were put 34-channel holder of OMM-2000 Optical Multichannel Monitor (Shimadzu, Kyoto, Japan). An increase in oxyHb is used as an indicator for brain activation. Sensorimotor cortex and frontal lobe were set as the region of the interest. Data analysis was performed according to our previous study. Optode positions were measured using a 3D magnetic space digitizer (FASTRAK-Polhemus, Colchester, VT). Probabilistic method was used to register NIRS data to MNI (Montreal Neurological Institute) standard brain space. The statistical method used was a general linear model employing a two-level summary statistics approach for random effects analysis with a one-tailed t test.

(Results) Activation areas in each task were detected separately in SMI ($p < o.o5$ by Student t, one-tailed, FDR controlled). During swallowingin supine, activation was detected in tongue SMI and BA 40 ($p < o.o5$, one-tailed, FDR controlled). The haemodynamic pattern observed during swallowing was different in sitting versus supine position in BA 6 and BA 40 ($p < o.o5$, one-tailed, FDR controlled).
(Conclusions) The haemodynamic pattern during swallowing appeared different in sitting versus in supine position in BA 6 and BA 40. Our findings suggest that the sensory input is more important in supine than in sitting posture. Since fNIRS measurements are limited to the cortical surface, determining cortical connections to insula and basal ganglia in swallowing requires continued research.

Title: Volitional vocal responses to unexpected perturbations in voice pitch auditory feedback

Authors: *C. R. LARSON[1], J. H. KIM[1], D. ROBIN[2];
[1]Communication Sci. and Disorders, Northwestern Univ., Evanston, IL; [2]Communication Sci. and Disorders, Univ. of New Hampshire, Durham, NH

Abstract: When monitoring voice pitch auditory feedback and controlling voice fundamental frequency (F0), speakers may adjust F0 to follow the change in feedback (feedforward) or to counter the change (feedback) for a correction. The present study measured neural responses (ERPs) from EEG electrodes as subjects vocalized and changed their F0 to either mimic the direction of positive or negative changes in the pitch feedback (follow up or down) or to oppose the directional change in feedback. The follow condition is similar to a feedforward control system, and the oppose condition is similar to a negative feedback control system. ERPs were obtained from a 32 channel EEG cap (BrainVision) as subjects vocalized into a microphone. Voice auditory feedback was presented to the subjects over earphones. Voice pitch feedback was altered at random times during the vocal tasks. In the feedforward condition, subjects were instructed to change their F0 in the same direction (up or down) as a change in voice pitch auditory feedback. In the feedback condition, subjects changed their voice F0 in the opposite direction to the change in voice pitch feedback. That is, if the feedback pitch increased, subjects decreased their F0. The N1 ERPs in the posterior electrodes (parietal areas) had significantly

(RM ANOVA, p< .000) shorter latencies for both feedforward (86 ms vs. 103 ms) and feedback (87.8 vs. 101 ms) responses than the the frontal electrodes. The P2 electrodes had significantly (p<.009) larger response magnitudes in the posterior electrodes for both the feedforward (2.25 vs. 1.05 uV) and feedback (2.15 vs. 0.86 uV)responses. The P2 ERPs also had significantly (p < .04) larger magnitudes in the left hemisphere compared to the right (2.25 vs. 1.48uV). Results of this study indicate left posterior regions of the brain, such as the left posterior temporal and parietal lobes may play important roles in volitional vocal responses to changes in voice auditory feedback.

Title: The role of the insula in speech motor control: structural connectivity profiles in healthy volunteers and spasmodic dysphonia patients

Authors: *G. BATTISTELLA[1], V. KUMAR[1], K. SIMONYAN[2];
[1]Dept. of Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept. of Neurol. and Otolaryngology, Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: The importance of the insula in speech control is acknowledged but poorly understood, partly due to a variety of clinical symptoms resulting from insults to its different regions. We conducted detailed examination of insular structural connectivity related to speech control in 12 healthy subjects (55±7 years, 7F/5M) and 12 patients with spasmodic dysphonia (SD, 54.1±11, 7F/5M), which is an isolated focal dystonia that selectively affects speech production. We used probabilistic diffusion tractography to parcellate the insula based on its structural connections with the Broca's area, Wernicke's area, and laryngeal motor cortex (LMC) and compared the anatomical distributions of the resulting partitions in HV and SD groups. We further used a 112-region whole-brain parcellation, including the parcellated insular regions identified above, to assess the insular large-scale structural network in HV and SD groups.
In HV, insula-Broca connections were localized to the dysgranular portion of the anterior insula; insula-LMC connections were found in the dysgranular insula more centrally and closer to its

posterior portion, and insula-Wernicke connections were distributed in the granular posterior insula. Insula-LMC and insula-Wernicke connections showed left-hemispheric lateralization. Larger-scale insular connectivity patterns were characterized by the representation of the strongest connections in the hippocampus, superior orbital, middle occipital, and middle frontal gyri. Conversely, SD patients showed abnormal overlap of the insular connection partitions and a larger representation of the insula-LMC connections, especially in the right hemisphere. The left-hemispheric distribution of insular connections seen in HV was diminished with a more bilateral representation of insular fiber tracts. Subsequently, the larger-scale insular connectivity was also different from that in HV and included SD-specific nodes in the sensorimotor, middle cingulate, inferior temporal, and inferior parietal cortices.
We demonstrated anatomical segregation of the large-scale insular network, specifically involving the cortical regions responsible for different aspects of speech processing and production. This organization appears to be altered and skewed towards motor overrepresentations in a neurological disorder affecting speech production. Such differences in insular (dis)organization may underlie distinct symptomatology due to the insular insult affecting its different divisions.

Title: Prosodic influence in face emotion perception: evidence from functional near-infrared spectroscopy

Authors: *K. M. BECKER, D. C. ROJAS;
Psychology, Colorado State Univ., Fort Collins, CO

Abstract: The ability to make inferences about the emotional state of another individual is facilitated by the seemingly automatic integration of concurrently presented vocal and facial information. Humans possess a special neural network dedicated to the recognition of facial expressions, which is distinct from brain regions devoted to face detection and prosody recognition. This study aims to examine the neural correlates of these responses by measuring changes in oxygenated hemoglobin (HbO) using functional near-infrared spectroscopy. Prosodic stimuli consisted of affective vocalizations of the sound “ah” produced in neutral, angry, and happy tones. Face stimuli were made by morphing the images of an actor making a happy and an

angry face to create a continuum of faces that varied from 100% happy to 100% angry. These stimuli were used to create six conditions, allowing for the presentation of bimodal (face and voice) and voice only in all three prosodies. An additional face only condition was added to further contrast bimodal and prosodic influences in emotion perception. One-hundred and five channels of fNIRS data were acquired using a NIRx Medical Systems NIRScout Extended system. Data were processed in the SPM_fNIRS software package. Bimodal happy stimuli exhibited greater concentrations of HbO bilaterally in the temporal-parietal junction (TPJ) region when compared to the bimodal neutral condition, whereas bimodal angry stimuli were shown to have decreased HbO concentrations when compared to the neutral stimuli. Additionally, across conditions, bimodal stimuli showed decreased HbO in the posterior superior temporal sulcus (pSTS) of the right hemisphere when contrasted with the voice only condition. When compared to the face only condition, the voice only conditions exhibited greater activation in the supramarginal gyrus bilaterally, greater HbO concentrations in the somatosensory cortex of the left hemisphere, and increased HbO concentrations in the supplementary motor cortex of the right hemisphere. These findings indicate that a constellation of brain areas contribute to emotion perception, with TPJ and pSTS areas playing a key role in multisensory integration of emotion perception.

Title: Characterization of a song locus in the right posterior superior temporal gyrus via electrical stimulation and focal cooling during awake neurosurgery

Authors: *K. KATLOWITZ[1], H. OYA[2], M. A. HOWARD[2], J. D. W. GREENLEE[2], M. A. LONG[1];
[1]New York Univ., New York, NY; [2]Dept. of Neurosurg., Univ. of Iowa, Iowa City, IA

Abstract: While the right hemisphere has been shown to be preferentially involved in music, the precise roles of the individual cortical loci that underlie this lateralization are still being

characterized. In a case study during an awake craniotomy, we found that electrical stimulation to a single locus in the right posterior superior temporal gyrus selectively interrupted singing but not speaking. We further characterized the role of this region with focal cooling during the production of simple sequences of either speech or singing. We found no noticeable defects in vocal quality or timing in either task. Unexpectedly, consistent pitch shifts were detected for spoken words but not singing. Identifiable changes in formants were detected in both vocal tasks. These results highlight the specialized processing of higher order vocal parameters in the right posterior superior temporal gyrus and suggest that a multi-modal approach is necessary for characterizing these factors.

Title: Pre-speech auditory modulation in a picture naming task

Authors: A. HANS[1], A. DALIRI[2], *L. MAX[1,3];
[1]Univ. Washington, Seattle, WA; [2]Boston Univ., Boston, MA; [3]Haskins Labs., New Haven, CT

Abstract: Sensorimotor integration for voluntary movements involves predictions that are used to optimize motor commands and to respond appropriately to sensory inputs. It is well documented, for example, that the central nervous system (CNS) modulates its response to self-generated vs. externally-generated afferent inputs. In the speech domain, cortical responses to self-generated vocalizations are reduced in comparison with responses to a played-back version of the same vocalizations. Current theoretical models suggest that such sensory modulation during movement execution occurs when the CNS detects a match between predicted and actual sensory consequences. Using EEG recordings and probe stimuli delivered prior to speech onset, our own lab has repeatedly demonstrated that motor-to-sensory signals already start to modulate auditory processing during the planning phase that preceeds movement execution. In our basic

paradigm, written words were presented on a screen, and we recorded long latency auditory evoked potentials (LLAEPs) in response to probe tones presented while the participant was planning to say the word out loud vs. a control condition with only silent reading. With a view to studying the phenomenon of pre-speech auditory modulation also in children, we have now developed a modified protocol that involves picture naming rather than word reading. In this new protocol, a probe tone is played after a picture is shown on a screen but before a green border appears around the picture. In 'speaking' blocks of trials, each picture is named when the green border appears, and in 'no-speaking' blocks of trials, each picture is viewed silently. LLAEPs are recorded to measure the auditory system's responses to the probe tones. In a first experiment, we validated the new paradigm with a group of adult participants to ensure that the results could be directly compared with those from our prior studies. Findings confirmed that pre-speech auditory modulation during the picture naming task is indeed comparable to that previously observed during our word reading task. In a second experiment, we have started investigating whether the duration of a data collection session can be reduced - without negative effects on the ability to detect pre-speech auditory modulation - by presenting more than one auditory stimulus per trial. Again we are initially testing adult participants to avoid confounding age effects and protocol effects. Overall findings from these experiments with the novel picture naming task confirm its sensitivity for detecting pre-speech auditory modulation, and, thus, support its application in future studies with children as participants.

Title: Multisensory perturbation effects on speech timing and sequencing

Authors: *F.-X. BRAJOT[1], J. LEE[2];
[1]Communication Sci. and Disorders, [2]Ohio Univ., Athens, OH

Abstract: The purpose of this pilot study was to evaluate the impact of vibration at the neck on healthy adults' responses to a temporal perturbation of auditory feedback in order to further delimit the integrated role of somatosensory and auditory feedback on the on-going coordination of speech gestures. Monolingual, native speakers of English read sentences in four

sensory feedback conditions: normal feedback, delayed auditory feedback, vibration at the neck, and delayed auditory feedback plus vibration. Vibrotactile stimulation resulted in a decrease in speaking rate, but speakers were otherwise fluent relative to the baseline condition. Delayed auditory feedback alone lead to a decrease in speaking rate, as well as an increase in overall number of speech errors, including sound, syllable and word-level repetitions. Combining vibration to the neck with delayed auditory feedback further decreased speaking rate and increased the number of speech errors, beyond what was observed for delayed auditory feedback alone. Results support previous research demonstrating phonatory/articulatory interactions and further establish a role for the perilaryngeal somatosensory system in the temporal coordination of speech.

Title: Orofacial somatosensory inputs enhance the change of speech perception induced by speech motor learning

Authors: ***H. OHASHI**[1], T. ITO[1,2,3];
[1]Haskins Labs. Inc, New Haven, CT; [2]Gipsa-lab, CNRS, Saint Martin D'heres Cedex, France; [3]Univ. Grenoble-Alpes, Grenoble, France

Abstract: Somatosensory input alters speech perception (Ito et al., 2009; Gick & Derrick 2009) even when listening to speech. One possible explanation is that during development, perceptual representations for speech are encoded from the integration of motor action and their auditory and somatosensory consequences. The resulting representations are sensorimotor in nature. As a result, somatosensory stimulation during speech perceptual discrimination is decoded as a change in motor action. To test this hypothesis, we focused on the change of speech perception induced by speech motor learning and examined whether a change in speech perception can be modified by additional somatosensory inputs associated with facial skin deformation. We tested native speakers of American English for the production and perception of /s/ and /sh/ consonants. For the speech training, subjects were asked to repeat the utterance ‘a shed’ under conditions of

altered auditory feedback. The produced consonant sound /sh/ was feedback to the subjects with modulation of the spectral centroid frequency (Shiller et al., 2009). The spectral centroid was increased resulting in acoustic signal properties closer to those of /s/. During adaptation, somatosensory stimulation associated with facial skin stretch was synchronized with the articulatory motion for the production of /sh/. The direction of skin stretch was opposite to the primary direction of skin deformation for the production of the target consonant, /sh/. Perceptual discrimination testing using an /s/-/sh/ acoustic continuum was carried out prior to and immediately after speech training. In a control group of participants, skin stretch was not presented during a training session. The degree of the speech motor adaptation was quantified as a change in spectral centroid frequency of the target consonant /sh/. Perceptual discrimination was evaluated as a change in the detection threshold for the /s/ and /sh/ consonants. Both groups showed significant adaptation to the altered auditory feedback and change in the perceptual boundary between /s/ and /sh/ consonants. Most notably, we found that the perceptual shift in the skin-stretched group was greater than that in the control group indicating additional somatosensory input during training enhanced the perceptual shift induced by speech motor learning. The result suggests that speech production is linked to the perceptual processing of speech through somatosensation during learning. Moreover, the data provide support for speech perception as a sensorimotor process.

Title: Paralyzed recurrent laryngeal nerves demonstrate significant differences in morphometric parameters compared with non-paralyzed nerve

Authors: *M. B. CHRISTENSEN[1], A. HELLER[2], M. R. CHAO[1], K. A. HOWE[3], J. L. PIERCE[2], M. E. SMITH[4];
[1]Bioengineering, [2]Communication Sci. and Disorders, [3]Biol., [4]Otolaryngology/Head and Neck Surgery, Univ. of Utah, Salt Lake City, UT

Abstract: Vocal fold paralysis can be treated by surgically connecting the paralyzed recurrent laryngeal nerve (RLN) to a branch of the ansa cervicalis. This procedure has a good success record in restoring voice, although results vary from patient to patient. This may be due to a variety of factors that have not been well studied. One of these may be the degenerative state of

the paralyzed nerve, which can be investigated by histological studies. Morphometric measurements can be taken from these specimens which yield quantitative information about the nerve, including myelinated fiber counts, densities, packing, and g-ratio and fiber diameter distributions. This study describes the morphometric characteristics of paralyzed laryngeal nerve specimens and compares those to non-paralyzed nerves. RLN specimens from patients with unilateral RLN paralysis who underwent a laryngeal reinnervation procedure were processed using plastic embedding, sectioning, and staining techniques. High-power montage images were collected from each fascicle in the nerves and processed through custom LabVIEW-based programs to identify individual fibers. Morphometric parameters from each fiber were then collected using ImagePro Plus. Control data from RLN samples collected from laryngectomy specimens were also collected. Paralyzed nerves show varying degrees of degeneration. Overall, paralyzed nerves have significantly lower fiber counts, densities, and packing (percent of fascicle area occupied by fibers) than control nerves. Mean g-ratio values for paralyzed nerves were significantly higher than non-paralyzed nerves, indicating thinner myelination. Fiber diameter distributions were also significantly shifted towards smaller diameter fibers. It is unclear if this is due to a preferential loss of large diameter fibers, or a general loss of fibers followed by collateral sprouting during limited regeneration. Further analysis will compare the state of degeneration in the nerve to the amount of time between onset of paralysis and tissue collection. Morphometric data can also be compared with clinical data such as age, gender, cause of injury, laryngeal EMG, and voice outcome from reinnervation. This may provide insights into patient selection to improve the outcomes of laryngeal reinnervation for vocal fold paralysis.

Title: Unilateral molar tooth extraction induces changes in the number and morphological features of astroglial cells within mouse orofacial motor cortex

Authors: T. WATASE[1], D. TANG[2], P. CHERKAS[2], D. K. LAM[2], S. BEGGS[3], M. SALTER[3], Z. SELTZER[2], B. J. SESSLE[2], *L. AVIVI-ARBER[4];
[1]Nihon Univ., Tokyo, Japan; [2]Univ. of Toronto, Toronto, ON, Canada; [3]Sick Kids Hosp., Toronto, ON, Canada; [4]Univ. of Toronto Dent., Toronto, ON, Canada

Abstract: **Background**: We have shown in rodents that orofacial injury, including tooth extraction, is associated with functional plasticity in the orofacial primary motor cortex (oM) and trigeminal medullary dorsal horn neurons, and that the latter changes are associated with changes in the number and volume of medullary astroglial cells. **Objective**: To determine if changes occur in the number and 3D morphological features of astroglia in the oM following extraction of right maxillary molar teeth in mice. **Methods**: Under Isoflurane general anaesthesia, young female BXA-24 mice had either extraction of the right maxillary molar teeth or sham operation, and naïve mice had no treatment (n=5/group). Mice were fixation-perfused on day 21 following extraction or sham operation. Coronal cryosections (40μm) of the oM region were immunolabeled with anti-GFAP (an astroglial marker). Whole slides were scanned with an Aperio Scanscope at 20x magnification. CaseViewer and Panoramic software were used to select regions of interests (ROI) within layers 1-2 (600 x 75 μm^2) and 5 (300 x 300 μm^2) within the left oM of 5 slices/mouse, and the numbers of astroglial cells were counted manually. In addition, 3D Z-stack images were collected using a spinning disk confocal microscope equipped with 63x/1.3 (water) objective lens, and Bitplane Imaris software was used to quantify the volume and morphological features of astroglial processes within ROIs in layers 1-2 (155 x 75 x 15 μm^3) and 5 (155 x 155 x 15 μm^3) of the left oM. Statistical analysis used ANOVA followed by *post-hoc* Bonferroni, $p<0.05$ was considered statistically significant. **Results**: In comparison with naïve and sham mice, tooth extraction was associated with a significantly increased number of astroglia in layers 1-2 and 5 of oM ($p<0.05$), as well as increased surface area and volume of astroglial processes ($p<0.01$). **Conclusions**: Together with our previous published data, these novel findings suggest that astroglial cells are involved in the mechanisms underlying oM changes following tooth loss, and that oM astroglia may represent a potential novel target for modulating orofacial sensorimotor functions following orofacial injury.

Title: Neural mechanisms underlying temporal organization in mouse courtship vocalizations

Authors: *G. A. CASTELLUCCI[1], E. W. ZAGHA[2], D. A. MCCORMICK[2];
[1]Neuroscience, Linguistics, [2]Neurosci., Yale Univ., New Haven, CT

Abstract: Vocalizations produced by a wide variety of organisms - including pinnipeds, songbirds, and humans - display a high degree of temporal regularity. We have recently demonstrated that the ultrasonic courtship vocalizations ("song") of male mice also exhibit a characteristic rhythmic structure composed of stereotyped alternations between two temporally distinct call ("syllable") types and three silent interval ("boundary") classes (Castellucci et al. 2016, *Sci. Rep.*, 23305). In the present study, we demonstrate that this rhythmic structure is an archetypal characteristic of wildtype (C57Bl/6J) song, and the temporal features of syllables as well as bouts of syllables are extremely stable across mice. We also observed distinct temporal signatures in syllables adjacent to boundaries and transitions between syllables types, indicating that this vocal rhythmic structure may be planned to some extent by the motor system. We have also begun examining motor coordination during vocalization production using freely moving plethysmography and vocal tract electromyography to better understand the articulatory strategies used in syllable and boundary production. For example, we have determined that different boundary types are articulated with distinct patterns of respiratory activity. Finally, despite the high degree of stability in the temporal organization of vocalizations across mice, we found that disruptions in *Foxp2* expression and lesions to the cerebellum result in temporal defects in song production. Interestingly, the speech of humans with mutations in the *FOXP2* gene or damage to the cerebellum also displays timing and prosodic irregularities, suggesting that the study of the murine vocalization production system may prove to be a valuable model in which to study the biological basis of temporal organization in speech and diseases that affect it.

Title: A model comparison guide of DNA double-strand breaks in the brain and tongue

Authors: *G. TORRES[1], J. R. LEHESTE[2];
[1]NYIT COM, Old Westbury, NY; [2]Biomed. Sci., NYIT-COM, Old Westbury, NY

Abstract: DNA damage occurs throughout the entire lifetime of neurons due in part to their high rates of oxygen metabolism, post-mitotic state and relatively long life span. Some damage may have an evolutionary function; however, the majority of the damage occurs spontaneously and can alter key cellular function contributing to pathology. DNA double-strand breaks are a type of molecular lesion in which the double helix structure is physically broken at specific genomic loci. While DNA double-strand breaks are widespread in developing and mature nervous system landscapes, deficiencies in repair of nuclear and mitochondrial DNA damage have been linked to several neurodegenerative disorders, including Parkinson's disease (PD). The objective of the present study is to use the animal model of PD, the PIT3X mouse, to address the issue of DNA double-strand breaks in the brain. In addition, we address the extent of DNA double-strand breaks in the tongue as structural and nuclear changes are widespread in PD, including cell pathways involved with energy sensing and metabolic control. It should be noted that the tongue is heavily involved in the physiology of perception, with emphasis on gustation and chemesthesis. In addition, electrical signals from the tongue yield sustained activation within the medial orbito-frontal cortex and hippocampus, indicating a reward response. In this context, PD patients often present with deficits in olfactory and gustatory sensing along with core motor features of the disease, including tremor, bradykinesia and muscle rigidity. These findings suggest that the ability of the tongue to probe calorie content and taste signaling may be diminished in PD as a result of excessive DNA double-strand breaks. Indeed, our preliminary results indicate that the hippocampus and tongue of PIT3X mice appear to differ in their relative load of DNA double-strand breaks from that of healthy control C57BL/6J mice. Further insight on the relative contribution and potential synergies of the brain and tongue to PD pathology is needed to refine applicable programs of therapy for this particular neurodegenerative disease.

Title: Ankle impedance modulation evoked by imposed inversion/eversion stiffness during locomotion

Authors: C. ARNET[1], J. OCHOA[1], D. STERNAD[2], *N. HOGAN[1];
[1]MIT, Cambridge, MA; [2]Northeastern Univ., Boston, MA

Abstract: As a distal joint, the ankle is responsible for mechanical interaction between the human body and the ground. Previous research showed that humans modulate ankle mechanical impedance during walking: for most of the swing phase, ankle impedance is low, but it increases towards the end of the swing phase prior to heel-strike, when its action resembles a 'shock absorber'. However, previous research also showed that the human ankle is especially weak and compliant in inversion, consistent with the prevalent direction of ankle sprains. In this study we examined the effect of externally-applied inversion/eversion (IE) stiffness, both stabilizing (positive) and de-stabilizing (negative), with applications to the treatment of chronic ankle instability. The experiments studied healthy subjects walking on both a treadmill and overground while a wearable ankle robot imposed a programmable IE stiffness. During locomotion, the robot recorded the knee angle profile and ankle excursions in the IE and DP (dorsi/plantarflexion) directions. Muscle activity was recorded from Tibialis Anterior, Peroneus Longus, Gastrocnemius, and Soleus using surface electromyography (EMG). Pressure sensors under the heel and toes identified the heel-strike and toe-off phases of the gait cycle. Trials were divided into four five-minute epochs, administering neutral, positive, and negative stiffness in the IE direction only; no external stiffness was applied in the DP direction. Each epoch allowed for sufficient time to assess immediate response and possible adaptation to the imposed stiffness. First, zero stiffness was applied to establish a baseline. Subsequently, positive stiffness (40 Nm/rad)—analogous to walking with an IE brace—was applied. IE stiffness was then returned to zero to assess the persistence of any adaptation. Next, IE stiffness was decreased to a negative value (-10 Nm/rad)—analogous to walking on a thin pipe. Lastly, the imposed stiffness returned to zero to assess the persistence of any adaptation induced by the negative stiffness. As expected, imposing positive IE stiffness evoked a decreased range of IE motion but did not affect range of DP motion. Imposing negative IE stiffness evoked an increased range of IE motion. Remarkably, it also evoked a reduced range of DP motion, consistent with increased neuromechanical stiffness in both DP and IE. The latter may be due to restoring the stability margin reduced by the negative external stiffness, the former due to coupling between degrees of freedom. These results suggest that maintaining adequate ankle stiffness is an important aspect of human locomotion and may have implications for robot-aided locomotion therapy.

Title: The effect of optic flow direction on orthogonality of balance control during walking

Authors: *J. NIELSEN;
Biomechanics, Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Background: A healthy sensorimotor system maintains spatial parameters (step-length and step-width) within a range of variability during walking. It has been seen that the influence on spatial variability is direction-dependent such as when walking in the anterior-posterior plane (forwards), step-length is consistent while the orthogonal, step-width, is significantly more variable. Consequently, when walking in the sagittal plane (sideways) there is a reversal of this variability. This has led to the inference that orthogonality of balance control, indicated by the characteristic orthogonality of movement variability during walking, is governed by the direction of progression. However, it is not clear how visual flow information affects this orthogonality. **Methods:** Participants walked on a treadmill while wearing a virtual reality (VR) headset. Once a preferred walking speed was established (PWS) for both anterior-posterior (AP) and medial-lateral (ML) walking, familiarization trials with the headset were performed in the AP and ML directions. Subsequently, participants randomly performed 8 trials - 4 VR conditions in each of the two directions. The VR conditions consisted of walking in a VR corridor that provided: AP optic flow (OF), ML OF, diagonal OF, and an Oscillating OF. Coefficient of variation was calculated for step-length and step-width. **Results:** The effect of walking direction led to a ten-fold increase in variability in the orthogonal direction. The effect of VR was the following: In comparison to the congruent OF conditions (i.e., OF in AP for AP walking and ML for ML walking), walking trials with the orthogonal OF showed a 6.6% increase, the diagonal OF, a 0.6% increase, and the oscillating OF, an 8.6% increase in COV. **Discussion:** During trials with conflicting locomotor and OF directions there was an increase in variability between steps. This shows the importance of reliable visual perception of self-motion for maintaining balance control during dynamic tasks such as walking.

Title: Effects of hand posture on corticospinal excitability to trunk muscles

Authors: *J. K. WONG, S. CHIDAMBARAM, S.-Y. CHIOU, P. H. STRUTTON;
Dept. of Surgery and Cancer, Fac. of Med., Imperial Col. London, London, United Kingdom

Abstract: Trunk muscles are critical for the successful performance of many daily tasks. They maintain postural equilibrium in response to external and internal perturbations, such as upper limb movements. We have shown that corticospinal excitability to the trunk muscles is increased during dynamic shoulder flexion indicating interactions between the neural pathways controlling upper limb and trunk muscles in a postural task. Further, we have shown that increases in trunk corticospinal excitability also occur during static contractions of certain upper limb muscles. Whether cortical input to trunk muscles can also be facilitated during functional hand movements, in which the postural disturbance is less, is unclear and was the purpose of this study.

Twenty healthy subjects (mean [SD] age 22.1 [1.1] years; 12 male, 8 female) performed static hand tasks with varying grips (power, precision) and postures (neutral, pronated, supinated) with the dominant hand. Transcranial magnetic stimulation at an intensity of 120% of active motor threshold was delivered to the primary motor cortex targeting the hotspot for the contralateral erector spinae (ES) during the tasks. The resulting motor evoked potentials (MEPs) in ES were recorded using electromyography (EMG). ES MEP amplitudes during different tasks were normalised to a control task to allow inter-subject comparisons. Pre-stimulus EMG recorded from the ES was matched across all tasks to ensure consistent levels of motoneuron excitability. The normalised ES MEP amplitudes were higher for the neutral hand posture (112.61±9.06%), than the supinated posture (97.77±9.23%) during a power grip ($p<0.01$). There were no differences in MEP amplitudes between postures for the precision grip. Further, there were no differences for a given posture between grip types ($p>0.05$). These findings suggest that crossed facilitation exists between hand and trunk muscles and grasping with different hand postures may have distinct effects on trunk corticospinal excitability. The clinical implications of the current findings include rehabilitation, where improvements in trunk control in people with deficits in trunk control such as stroke and spinal cord injury, using repetition of hand movements, might be possible.

Title: Effect of co-contraction on cortical excitability of lower limb musculature

Authors: ***T. M. KESAR**[1], M. R. BORICH[1], S. EICHOLTZ[2], S. L. WOLF[1];
[1]Physical Therapy, 1441 Clifton Rd NE, Room 205, Atlanta, GA; [2]Emory Univ., Atlanta, GA

Abstract: INTRODUCTION: Transcranial magnetic stimulation (TMS) has been extensively used to evaluate corticospinal circuitry, but the majority of studies have investigated upper extremity musculature. There is a paucity of investigations on lower limb muscles, and on how methodological aspects such as agonist or antagonist activation influence TMS-evoked responses. Here, our objective was to evaluate the effect of agonist-antagonist co-contraction on TMS-evoked motor evoked potentials (MEPs) recorded from the tibialis anterior (TA) muscle.
METHODS: 13 young, neurologically-unimpaired adults (3 male, 10 female, ages 23-35 years) participated in this study. TMS pulses were delivered at 120% resting motor threshold over the TA hotspot, and TMS-evoked MEPs were recorded from the TA muscle using surface electromyography (EMG). Three conditions were tested: TA and soleus at rest (Rest), TA activated at 10% maximum EMG activation (Agonist-on), and both TA and soleus activated at 10% of maximal activation (Co-contraction). Paired t-tests were performed to compare TA MEPs as well as pre-stimulus background EMG amplitude during the rest and co-contraction conditions with the Agonist-on condition.
RESULTS: Comparison of background EMG amplitudes confirmed that the TA background activation was greater during Agonist-on and Co-contraction versus Rest. There were no differences in TA background EMG during the Agonist-on versus Co-contraction conditions. Compared to the Rest and the Agonist-on conditions, TA MEP amplitudes were significantly greater during the TA-soleus Co-contraction condition ($p<0.05$). Ongoing analysis is exploring whether cortical excitability of proximal lower limb muscles (e.g. quadriceps) are influenced by co-contraction at the ankle joint.

DISCUSSION: Our results suggest that during the measurement of TMS-evoked MEPs, agonist-antagonist co-contraction may have potential as a testing condition that provides enhanced cortical excitability and more controlled muscle activation states. Greater cortical excitability observed during the Co-activation condition may be caused by several factors. Co-activation may require greater cognitive effort and cortical activation. Additionally, previous studies suggest that TA and soleus may have overlapping cortical representations. Furthermore, due to the location of the lower extremity M1 deep within the inter-hemispheric fissure, both the TA and soleus corticomotor-neurons may be activated by suprathreshold TMS. Future studies will determine to what extent aging, neurologic impairment, and gait training influence the effects of muscle activation on cortical excitability.

Abstract: Objective:Clinical observations that supratentorial lesions often impair postural balance suggested an important role of the cerebral cortex in human bipedal postural control. Accordingly, concurrent cognitive task (dual-task) often leads to impaired performance of postural or gait task in elderly people. However, several studies have shown that postural stability is improved under dual-task condition in younger people. These paradoxical findings raise a question about the cortical role for the human postural control. To investigate the cortical mechanisms for this paradoxical finding, we directly assess the postural task related cortical activation using functional Near infrared spectroscopy (fNIRS) system. Methods:We recruited 15 healthy young subjects. For the postural task, we applied brisk forward and backward translations of a platform as a perturbation. Fourteen perturbations were delivered with randomized intervals of 10-18 s. For the cognitive task, we asked the subjects to perform flanker

task in the upright position. For the dual task, they performed flanker task between perturbations. As a measure of balance ability, the cumulative displacement of the position of the center of pressure (COP) during three seconds around the perturbation. To detect task-related cortical activation, statistical analysis using general-linear model were performed with Oxy-Hb based signal. Results:Multi-subject's analysis of Oxy-Hb signals showed that prefrontal cortical areas in both hemispheres as well as the left supplementaly motor area significantly activated in simple postural task than dual-task . On the other hand, there was no area more activated in dual-task than simple postural task. In behavioral analysis, mean COP sway by perturbations was smaller in dual-task than simple postural task. Conclusions:Our findings suggested the better postural control in dual-task condition would associate with the smaller cortical activation, But there would be several possible interpretation including less cortical demand lead to more automatic, reflexive postural control resulting in better postural control, or predictive recruitment of the cortical resource for upcoming perturbation would reduce task-related cortical activation in dual-task condition.

Title: Effects of dynamic arm cycling on crossed-corticospinal facilitation to trunk muscles

Authors: *D. CHRISTMAS, S. DAVE, S.-Y. CHIOU, P. H. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: Voluntary use of the upper limb muscles in a static isometric contraction has previously been shown to increase corticospinal excitability to the trunk muscles, known as crossed-corticospinal facilitation. These interactions may underlie the postural adjustments associated with upper limb movements. Evidence exists that an alternating dynamic task significantly increases the corticospinal excitability of upper limb muscles over an EMG matched static equivalent. Whether an alternating dynamic task produces similar increases in crossed-corticospinal facilitation in muscles of the trunk has not been studied. The aim of this

study was to determine whether the corticospinal excitability of the trunk muscles during a continuous unimanual cycling task differs to the excitability seen in a static upper limb task. 20 healthy subjects (mean [SD] age 23.6 [5.8] years) performed a dynamic task (forward arm cycling at 60 revolutions per minute), a static task (exerting force on the locked pedal) and a control task (hands resting on the thighs). EMG activity was recorded from the contralateral erector spinae (ES) at the T12 vertebral level and rectus abdominis (RA) and from biceps brachii (BB) and the triceps brachii (TB) of the cycling arm. Transcranial magnetic stimulation was applied to the hotspot for ES over the primary motor cortex at the pedal position corresponding to maximal BB EMG (6 o'clock position) and maximal TB EMG (12 o'clock position). Prestimulus EMG in ES was matched within the 3 tasks for the different pedal positions. The study demonstrated that the size of MEPs for ES in dynamic and static tasks were significantly larger than the control in the 6 o'clock pedal position, but there were no significant differences in ES MEPs in the 12 o'clock pedal position. This is in-keeping with a recent study suggesting that crossed corticospinal facilitation between the upper limb and the trunk is increased in a static isometric BB contraction but not in a static TB contraction. Our results suggest that for a task with minimal postural requirement, the corticospinal excitability of the trunk muscles is independent of contraction type of the upper limb muscle. This could have implications for development of rehabilitation programmes in subjects with impaired trunk control, such as spinal cord injury or low back pain.

Title: Definition of cerebral networks involved in straight walking and steering of gait in normal young human subjects using ^{18}F-FDG PET imaging

Authors: *J.-P. SOUCY[1,2], F. STARRS[3], C. PAQUETTE[4];
[1]Montreal Neurolog. Inst., Montreal, QC, Canada; [2]PERFORM Ctr., Concordia Univ., Montreal, QC, Canada; [3]Kinesiology and Physical Educ., [4]McGill Univ., Montreal, QC, Canada

Abstract: Introduction: Steering of gait is an essential element of goal-directed locomotion involving a high degree of sensorimotor integration. Gait steering and directional changes while

walking are complex tasks which place a significant burden on the CNS, especially as individuals age and are affected by a variety of neurological diseases. Current concepts on control of ambulation propose that steering of gait and straight walking are supervised by distinct neuronal networks. fMRI studies in subjects imagining they are walking found that volitional goals (steering) originate from SMA which then modulates more automatic brain stem structures controlling straight walking via basal ganglia loops. Of course, such protocols do not involve actual walking and cannot account for sensory-motor integration. Therefore, the **aim** of this study is to identify the neuronal networks involved in the control of gait (straight walking versus upright standing) and steering of gait (steering of gait versus straight walking) in young healthy subjects using ^{18}F-fluorodeoxy-glucose (^{18}F-FDG) Positron Emission Tomography (PET). It is **hypothesized** that superior parietal and sensorimotor regions will be activated during steering of gait and that occipital areas and supraspinal structures will be activated during straight walking. **Methodology**: ^{18}F-FDG-PET was used to assess rCMGIc in 7 healthy subjects (mean age= 25). On testing days, subjects performed 1 of 3 motor tasks for 40 minutes immediately after tracer injection (approx. 150 MBq of ^{18}F-FDG): 1) steering of gait, 2) straight walking and 3) upright standing. Image acquisition started ~15 minutes after task completion. Straight walking images were subtracted from steering of gait images and upright condition images were subtracted from straight walking images. Regions showing significant increases or decreases in glucose metabolism were thresholded at $p < .05$, and corrected for multiple comparisons. **Results & Conclusions**: During steering of gait, our subjects showed consistent activation of the intraparietal sulcus, sensorimotor cortex and cerebellar vermis. The straight walking network for its part showed recruitment of the visual areas of the occipital lobe, sensorimotor cortex and the cerebellar vermis.
^{18}F-FDG-PET allowed for measurement of whole-brain activations during complex locomotor tasks and showed consistent steering of gait and straight walking neural networks. Information on the integration of sensory information with motor controls in controls is crucial for developing rehabilitation therapies for pathological populations and understanding the compensatory mechanisms of normal aging.

Abstract: Humans share locomotion with all vertebrates, a capacity relying on a phylogenetically conversed neuronal network able to autonomously organize the locomotor pattern in relationship with internal and external constraints. It involves the central pattern generators at the spinal level, the mesencephalic locomotor region (MLR), that includes the pedunculopontine (PPN) and the cuneiform nuclei, at the brainstem level, the basal ganglia, the cerebellum and various, mainly fronto-parietal, cortical areas. In cats, electrical or chemical modulation of the neuronal activity of the MLR, the subthalamic nucleus area and the cerebellum provokes locomotor activity and postural tone changes. In humans, imaginary of gait triggered gait-specific activity in the PPN neurons, but no or few changes in the subthalamic nucleus (STN). To further decipher the role of the PPN and the STN in the human locomotion and postural control, we recorded the neuronal activity of these structures during real bipedal gait in patients with deep brain stimulation (DBS) electrodes. We recorded local field potentials (LFP) during gait initiation in 26 patients with Parkinson's disease (PD) implanted bilaterally for STN (n=22) or PPN (n=4) DBS, and 2 patients with obsessive compulsive disorders (OCD) implanted bilaterally for STN-DBS. Gait initiation, that comprises a preparatory postural phase and an execution phase, was quantified by coupling kinetic, kinematic and electromyographic acquisitions. In both PD and OCD patients, we observed STN neuronal activity modulations during the gait initiation with i) a synchronization in the theta-alpha band during the preparatory phase, ii) a desynchronization in the beta band that started at the preparatory phase , iii) an increased theta-band and gamma synchronization for the first and following steps preparations. In PD patients, the gait initiation process differently affected PPN neuronal activity with an increased synchronization in the alpha and gamma bands that started at the time of the first step execution, and the following steps, with no significant changes during the preparatory phase. These results may suggest that, in human, the STN is mainly involved in the preparatory phases and the PPN in the rhythmic stepping activity during locomotion.

Title: Neural correlates of dual-task walking: influence of priority on attentional demands

Authors: S. SANGANI[1], T. KURAYAMA[2], *J. FUNG[3,1];
[1]Feil/Oberfeld/CRIR Res. Ctr., Jewish Rehabil. Hosp., Laval, QC, Canada; [2]Physical Therapy, Uekusa Gakuen Univ., Chiba, Japan; [3]McGill Univ., Montreal, QC, Canada

Abstract: Walking while simultaneously performing another task requires divided attention, eg. holding a cup without spilling. Stability control during gait alone requires attention, which may be compromised as the cognitive demand increases. Our primary goal was to investigate neural correlates associated with increased attentional demands when holding a hot coffee/tea cup versus a cup of room-temperature water while walking using functional near-infrared spectroscopy (fNIRS). Healthy young adults (n=11) and a stroke participant walked on a 3m long force-sensing treadmill (CMill, Motek-Forcelink). Cortical activation was acquired with a NIRScout system (NIRx) using a custom-built cap covering the frontal cortex. The protocol included repeated block trials consisting of four alternating blocks of standing (20s) and walking (25s) at a comfortable speed determined prior to the experiment. Five walking trials were performed, each consisting of four randomized conditions including holding a Styrofoam cup that was empty or filled with water, jelly or hot liquid. Participants held the cup in the dominant or non-paretic hand. The cortical hemodynamic response was quantified by concentration changes of oxygenated hemoglobin (oxyHb) in the frontal cortex. Cortical response maps were determined based on the general linear model using SPM (nirsLAB) by dividing the walking trial in three different time segments, acceleration, steady-state walking and deceleration. In healthy controls, walking while holding a hot beverage was associated with an increased activation of the dorsolateral prefrontal cortex (DLPFC) only during the acceleration and deceleration phase. In

addition, the comparison of walking with a liquid medium (water/coffee/tea) vs a semi-liquid medium (jello) resulted in activation of SMA and DLPFC during acceleration and steady-state walking phase. On the other hand, comparison of walking with water vs jello in stroke participant results in cortical activation of lesioned as well as contralesional hemispheres. During acceleration, DLPFC of the lesioned hemisphere showed increased activation while steady-state walking was associated with increased activation of the contralesional DLPFC. The deceleration phase showed bilateral activation of the prefrontal cortex. The results of the study suggest that walking with a hot beverage increases priority on attentional demands which are associated with activation of the prefrontal cortex during different phases of dual-task locomotion.

Title: EEG brain functional connectivity during static and dynamic reactive balance control

Authors: *J. PAROKARAN VARGHESE[1], W. E. MCILROY[2];
[2]Kinesiology, [1]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Human bipedal balance control is importantly dependent on rapid reactions to internal or external perturbations to stability. It is now believed that a distributed network is involved in such reactive balance control with a potential role for the cerebral cortex. Our potential understanding of the role of cortical regions during balance control will benefit from identification of both functional segregation and neural integration/connectivity. Previous EEG studies have shown that a whole body balance perturbation results in a negative potential (N1) that peaks around 100 ms after the perturbation onset and is widely distributed across fronto-central-parietal areas. In addition, an evoked N1 potential also exists during automatic balance reactions that occur continuously when one is standing still and is widely distributed across fronto-central-parietal areas. The widespread distribution of N1 during static and dynamic reactive balance control leads to speculation that an integrated activity of different neuronal assemblies might generate N1 rather than a single dipole. Hence, this study aims to explore the EEG functional connectivity linked to the N1 by examining the event-related phase coherence between pairs of 30 EEG electrodes recorded during reactions to external balance perturbations

and internal perturbations during standing still. Twelve young healthy adults performed 30 sec of quiet standing (Tandem Romberg stance) on a force plate. Another twelve young healthy adults performed feet-in-place balance reactions to temporally unpredictable whole body perturbations evoked by releasing the cable of a lean and release system. The grand average connectivity matrix revealed that a robust functional connectivity exists between fronto-central-parietal areas in theta (4-6 Hz), alpha (8-12 Hz), and beta (14-30 Hz) frequency bands during perturbation-evoked N1 and natural instability-evoked N1. These results are compatible with the idea that integrated activity of different neuronal assemblies segregated in frontal, central, and parietal cortical areas might be involved in generating complex reactive balance control strategies.

Title: Proprioception under dual task conditions in older adults. Does physical activity matter?

Authors: I. BRAGINA, *C. VOELCKER-REHAGE;
Inst. of Human Movement Sci. and Hlth., Technische Univ. Chemnitz, Chemnitz, Germany

Abstract: Aging is associated with declines in sensorimotor and cognitive functioning. Further, older adults often recruit additional cognitive resources to perform a sensorimotor task and/or to reach youth-like motor performance levels. This becomes especially apparent in situations when a person has to perform more than one task simultaneously (so-called dual- (DT) or multi-task situations). In this line, proprioceptive acuity, especially in lower limbs, has been shown to decline with increasing age and to require more cognitive resources. Proprioceptive information from the mechanoreceptors is necessary for the performance of successful movements. Changes in proprioceptive acuity may contribute to an enhanced risk of falling and lead to restrictions in everyday life.
Lifestyle factors, like regular physical activity are proven to benefit motor and cognitive performance in older adults. Also lower limb proprioceptive acuity seems to be higher in persons who are physically active (Ribeiro and Oliveira, 2010). Whether this finding applies to older adults under DT conditions as well is unclear.
We investigate proprioceptive acuity under single-task (ST) and DT conditions in a sample of 50

older adults between 65 and 75 years of age. Further, we analyze whether baseline activity level has an influence on proprioceptive acuity. Physical activity is measured with an adapted version of the IPAQ (international physical activity questionnaire). Proprioceptive acuity is assessed by an ankle position-matching task under ST and DT conditions. Under DT conditions, the matching task is performed simultaneously with a Random Number Generation Task (Albinet et al., 2006) in order to determine the attentional costs of proprioceptive acuity.
We expect that persons who are regularly physically active, reach better performance in the proprioceptive and cognitive tasks under ST conditions and further exhibit less DT costs during the motor and cognitive tasks under DT conditions. The early recognition of declines in proprioception may contribute to prevent falls in the future. Further, insights into the relationship between physical activity and processing of proprioceptive acuity may provide important insights for exercise recommendations for older adults.

Title: The role of stride frequency for transition from walk to run in humans

Authors: *E. A. HANSEN, A. M. NIELSEN, L. A. R. KRISTENSEN, M. VOIGT, P. MADELEINE;
Ctr. For Sensory-Motor Interaction (SMI), Aalborg Univ., Aalborg, Denmark

Abstract: A better understanding of the control of bipedal locomotion can contribute to the development of programs for enhancement of human function and performance. Researchers within e.g. neuroscience, physiology, and psychology have investigated an intriguing long-standing question: Why do humans spontaneously shift from walk to run, at a certain point during gradually increasing velocity? (1, 2). To investigate this, we recruited 26 healthy individuals (19 men and 7 women of age, height, and body mass of 26.3±5.4 years, 1.78±0.08 m, and 75.2±10 kg, respectively) for treadmill walking and running. We showed that calculated stride frequency at walk-to-run transition (70.6±3.2 strides per min) agreed with transition stride frequency (70.8±3.1 strides per min) predicted from stride frequencies occurring during behaviourally natural conditions of walking and running at freely chosen velocities and stride frequencies. The two stride frequencies used for prediction were considered attractors. And the prediction was that gait is shifted to running at the point where the walking stride frequency

starts to get closer to the running attractor than it is to the walking attractor. Agreement was based on Bland & Altman's statistics for assessing agreement between two methods (3). Previous research has focussed on transition velocity (1, 2) and optimisation theories based on minimisation of e.g. rate of energy turnover (4) or biomechanical loadings of the legs (5). The previously reported coincidence between energetically optimal and freely chosen stride frequencies in locomotion could reflect evolutionary development rather than deliberate motor control prioritising minimisation of energy turnover. We propose the central phenomenon of walk-to-run transition to be attributed to the following. Based on a dynamical systems approach, attractors in form of stride frequencies during behaviourally natural gait conditions (here, walking and running at freely chosen velocities and stride frequencies) occur. The attractors possibly reflect outputs from a non-hierarchical tripartite system consisting of spinal central pattern generators, their supraspinal input, and their sensory feedback. During walking at increasing velocity, gait is shifted to running at the point where the walking stride frequency starts to get closer to the running attractor than it is to the walking attractor. Title: Adjacent motor cortical areas have distinct brain functional connectivity

Authors: *A. M. ALBISHI[1], J. SMITH[2], B. FISHER[2], J. KUTCH[2];
[1]USC, Los Angeles, CA; [2]USC, LOS ANGELOS, CA

Abstract: Background: Postural control studies suggest that primary motor area (M1) is responsible for volitional movement execution while supplementary motor area (SMA) plays a role in postural preparation. Support for the role of SMA in postural control would be provided by determining functional connectivity and establishing greater connection of SMA to critical postural control areas compared to M1. Both M1 and SMA have direct projections to the spinal cord, thus muscle representational maps can be obtained using transcranial magnetic stimulation (TMS). However, motor representational maps do not identify what brain areas are connected to

M1 and SMA. Resting-state functional magnetic resonance imaging (rs-fMRI) can be used to identify muscle-specific neural circuitries.This study will compare whole-brain functional connectivity (FC) of SMA and M1 representational areas of external oblique (EO) to gain insight into the differential function of SMA and M1 in the control of this muscle. **Purpose:** Determine the location of EO cortical representation and explore resting state (rs) FC in SMA and M1 among healthy adults. **Methods:** 13 adults participated. TMS mapping of M1 and SMA was conducted. MEP amplitudes for EO determined the Center of Gravity (CoG) in both M1 and SMA. The MNI coordinates of EO CoG in SMA and M1 were used to explore FC of these areas utilizing rs-fMRI. **Results:** MEPs were elicited consistently in M1 and SMA. MNI coordinates for EO CoG were determined for M1 and SMA. FC analysis demonstrate that anterior cingulate, basal ganglia and cerebellum are more connected to SMA; Prefrontal, precuneus, and parietal cortex are more connected to M1. **Conclusion:** While EO is represented in both SMA and M1, these representations are not functionally equivalent in their interaction with the rest of the brain. Therefore, SMA and M1 may play distinct roles in the control of this postural muscle. Greater connectivity of SMA to basal ganglia and cerebellum compared to M1 can support the distinct role of SMA in postural control.

Title: Unilateral learning in a bilateral walking task

Authors: *G. BORIN, J. T. CHOI;
Kinesiology, Univ. of Massachusetts, Amherst, MA

Abstract: Complex motor skills, such as those involving sequencing, must be learned through repeated practice. In piano training, it is common to practice the left and right finger sequence separately before playing with both hands. Footwork sequence (e.g., for dancing) is usually practiced with both legs instead. Here we tested whether a learned bilateral step length sequences could be decomposed into individual leg components. If the sequence components were stored separately (unilaterally), then the two could be flexibly combined to produce new (untrained) bilateral walking patterns. In addition, we hypothesize that inter-limb transfer will occur if

learned sequences were stored as high-level task variables that could be implemented with either leg. **Methods:** Walking was challenged by presenting visual stepping targets displayed on a screen in the front of the treadmill. Subjects had to take different step lengths (i.e., short, medium or long) to hit the targets. Training consisted of both random blocks (with no repeating sequence) and sequence blocks (Figure 1a). Three groups of subjects were tested. The training sequence (A) was the same for all groups, while the transfer sequence (B) was different between groups (Figure 1 b). The difference in block performance was interpreted as sequence-specific learning (A3 - R3 and B3 - R4) and sequence-specific transfer (B1 - R3 and A4 - R4). **Results:** There was complete transfer of learning when the left and right sequences were shifted to create a new bilateral sequence (Group 1). There also complete transfer of learning when the left and right sequences were switched between legs (Group 2). There was incomplete transfer when the left and right sequences were changed (Group 3). In conclusion, the results observed in the present study suggested that unilaterally sequence components were learned and stored, and that inter-limb transfer learning is mediated at a higher level allowing the task to be executed with either leg.

Abstract: Background: Control of walking involves a balance between “automatic” (primarily sub-cerebral) and “executive” (cerebral) control strategies. Executive control has a major role in real-time gait adaptations and may also serve an additional compensatory role for control of basic walking if automaticity is impaired. This compensation could compromise the safety of walking because executive control is attention demanding, slow, and susceptible to interference. New insights into the executive control of walking are possible with the use of functional near infrared spectroscopy (fNIRS), which allows for cortical neuroimaging during natural movements. We hypothesize that individuals with mobility deficits will exhibit greater reliance on executive control during walking, as measured by prefrontal cortex activation. Methods: Participants included 14 adults post-stroke with moderate/severe mobility deficits, 15 elderly adults with mild mobility deficits, and 9 young healthy adults. fNIRS was used to measure prefrontal cortex activation during four walking tasks: typical walking, walking over obstacles, walking in dim lighting, and a dual-task condition of walking plus a verbal fluency task. Participants with stroke were also assessed with the Activities Specific Balance Confidence

Scale and the Fugl-Meyer Assessment of lower extremity function. Results: Prefrontal activity during walking showed a main effect of group ($p<0.001$) and task ($p<0.001$), with stroke > elderly > young. Furthermore, lower functioning stroke participants exhibited greater prefrontal activity than higher functioning stroke participants when subgroups were defined by either the Fugl-Meyer score ($p=0.011$) or the balance confidence score ($p=0.006$). Prefrontal/executive reserve capacity, as quantified by the difference in prefrontal activity between dual-tasking and typical walking, was lower in the elderly and post-stroke participants ($p=0.003$). Conclusions: Executive control of typical and complex walking tasks is increased in individuals with mobility deficits, as indicated by greater prefrontal cortical activity. Increased use of executive control is likely a compensation for impairment in neural circuits of locomotor automaticity. Assessing locomotor control strategies with fNIRS is a promising direction for objective assessment of impairment and recovery in humans with mobility deficits.

Title: Motor cortical modulation of trunk muscles during anticipatory postural adjustments.

Authors: J. QUEK, S.-Y. CHIOU, T. A. CONSTANTIN, *P. H. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: The increase in trunk muscle activity prior to rapid movement of the upper limbs is termed anticipatory postural adjustments (APAs). Since APAs occur within a time window considered too fast to be a result of afferent feedback, it has been suggested that they are controlled in part by cortical mechanisms. This is substantiated by our previous work showing increases in corticospinal excitability of trunk muscles at time points closer to the initiation of rapid arm movements. However, the neural mechanisms modulating these increases in corticospinal excitability of the trunk muscles remain unclear, and were therefore investigated in the present study. Twenty healthy subjects performed rapid shoulder flexion in response to a visual cue while standing. Electromyographic (EMG) activity was recorded from the anterior

deltoid (AD) and erector spinae (ES) at the T12 vertebral level. Non-invasive cortical and cervicomedullary stimulation were used to examine motor evoked potentials (MEPs) and the activity of intracortical inhibitory circuits (short-interval intracortical inhibition, SICI) measured from the ES. Stimuli were given at rest, and at two time points (75ms and 25ms) prior to the expected increase in EMG activity of the AD; this was calculated using a recognition reaction time task prior to experimentation. Compared to those at rest, MEPs in the ES were similar at 75ms prior to the increase in AD EMG but were larger at 25ms prior to the increase in AD EMG. In addition, at 75ms, SICI was comparable to that at rest, but at 25ms, was significantly reduced. In contrast, cervicomedullary MEPs in the ES remained unchanged across time points. Our results suggest that the increase in corticospinal excitability of the ES during the APAs are modulated at a cortical level. These findings not only provide insight into the neural mechanisms of APAs in the trunk muscles, but also highlight the importance of using functional task training in subjects with deficits of postural control such as lower back pain and stroke. This may be relevant in the development of rehabilitative strategies for such conditions.

Title: Localization of cortical and subcortical activity related to reactive balance control with or without performing a visual-working-memory task

Authors: M. D. BOGOST[1], P. I. BURGOS[2], C. E. LITTLE[3], M. WOOLLACOTT[1], *B. H. DALTON[1];
[1]Dept. of Human Physiol., Univ. of Oregon, Eugene, OR; [2]Dept. of Kinesiology, Univ. de Chile, Santiago, Chile; [3]Fac. of Kinesiology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Upright balance equilibrium relies on complex processing and integration of information arising from visual, somatosensory and vestibular cues. However, little is known about the subcortical and cortical structures that are active with respect to reactive postural control. The purpose of this study was to elucidate the active brain areas related to whole-body surface translations and to determine whether the activity of these localized cortical and subcortical areas is depressed during a dual task compared to a single task paradigm. This study utilized high-density electroencephalography in conjunction with independent component analysis, dipole location, and measure projection analysis from event-related potentials (ERPs)

time-locked to backwards surface translation onsets to determine which cortical or subcortical structures were active when performing reactive postural control. Participants (n = 15) either reacted to whole-body surface translations while performing a visual working memory task (dual task) or standing quietly (single task). During the single task, activity was localized to the following sources: somatosensory, motor, spatial processing, conflict and error detecting areas. Interestingly, activity related to the perturbation onset shifted to more somatosensory association, spatial, navigation and memory processing and visual and auditory processing areas and less error detecting areas during the dual task. Further, mean absolute N1 ERP amplitudes from brain areas active during both tasks were significantly attenuated during the dual-task compared to the single-task paradigm. Overall, our results indicate additional frontoparietal area activity, related to spatial attention and memory, and less activation within areas related to error-detection for the dual compared with single task. These results provide evidence of resource re-allocation within the cortical and subcortical structures in the presence of a dual task compared with a single task. Thus, we emphasize here that reactive postural control activity displays distinct patterns within the cortical or subcortical structures depending on the task (i.e., single versus dual) suggesting an attenuation of ERP activity and a re-allocation of neural resources during a dual task when compared to a single task.

Title: The coupling of gaze and gait when walking over real-world rough terrain

Authors: *J. S. MATTHIS;
Ctr. for Perceptual Systems, Res. Univ., Austin, TX

Abstract: When walking over rough terrain, walkers gather information about the upcoming path to support stable and efficient locomotion. In this context, the biomechanics of human gait define the task constraints that organize eye movements when traversing difficult terrain.

Specifically, humans must perform a rapid visual search to identify stable footholds in upcoming terrain in a manner that is temporal coupled to the ongoing gait cycle. In this way, walkers adapt their energetically optimized, biomechanically preferred gait cycle to account for the complexity of the terrain being traversed. We developed a novel experimental apparatus to record eye movements and full-body kinematics of subjects walking over real-world terrain. For the first time, we can precisely record gaze and body movement data during natural behavior in unconstrained outdoor environments. Subjects walked over terrain of three increasing difficulties: flat packed-earth paths, moderately rocky trails, and extremely rough dry creekbeds. In flat terrain, the absence of environmental impediments allows subjects to adopt their preferred gait cycle that exhibits highly regular stride length and timing. In this condition, ground fixations were infrequent and not directed towards footholds, consistent with the minimal visual information needed to guide stepping in flat terrain. When walking over the moderate and extremely rough terrain displayed strong spatiotemporal coupling between gaze patterns on upcoming terrain and their ongoing gait cycle. In difficult terrain, subjects performed rapid visual search on regions around 2-4 steps ahead, often fixating precisely on locations of upcoming footholds. In all types of terrain, both visual and locomotor aspects of subject behavior shows a highly regular phase timing, while the spatial components were more variable. These results highlight the essential inseparability of gaze and gait during locomotion over rough terrain, and indicate that the visual control of locomotion over rough terrain is primarily organized around the phasic timing of the bipedal gait cycle.

Title: Effects of initial standing position on postural control associated with arm movement and contingent negative variation

Authors: *K. MAEDA[1], K. FUJIWARA[2];
[1]Morinomiya Univ. of Med. Sci., Osaka, Japan; [2]Dept. of Sports and Hlth., Kanazawa Gakuin Univ., Kanazawa, Japan

Abstract: [Purpose] We investigated the effects of difference of initial standing position on postural control associated with bilateral arm movement and contingent negative variation (CNV). [Methods] Thirteen healthy adults (age: 20-42) standing on a force platform rapidly flexed their shoulder bilaterally from the sides of the body to the horizontal level in response to a response signal (S2) in warning signal (S1) - S2 paradigm (inter-stimulus interval (ISI): 2 sec). The standing positions the subjects maintained until S2 presentation (initial positions (IPs)), calculated as the percentage distance of COP from the heel in relation to foot length (%FL), were as follows: quiet standing position, 20%FL, 30%FL, 40%FL, 50%FL, 60%FL, 70%FL and 80%FL. After ten trials of arm movement were performed at any position next ten trials were performed at another position. The order of the position was randomized for each subject. After 10 trials were performed at each position another 10-15 trials were performed for each position. Electromyography (EMG) were recorded from anterior deltoid (AD), erector spinae (ES), biceps femoris (BF), the medial head of the gastrocnemius (GcM), soleus (Sol) and abductor hallucis (AH). Electroencephalography (EEG) recorded from Cz during ISI was averaged for each IP with mean amplitude in the 500 ms period before S1 was used as the baseline. The mean waveforms shifted negatively during ISI were defined as CNV. [Results] Preceding activation with respect to activation of AD was found at all IP in ES, 40%FL and more anterior in BF, 50%FL and more anterior in GcM and 70%FL and 80%FL in AH. Continuous significant increase in CNV from baseline ($p < 0.05$) was found considerably earlier at 70%FL and 80%FL than another position. IP at which significantly larger CNV amplitude with respect to the mean amplitude in the period of 1000-1100 ms before S2 ($p < 0.05$) were found at 50%FL, 60%FL and 80%FL. [Discussion] It was suggested that the onset timing of brain activity related to attention and motor preparation become relatively earlier as the initial standing position shifts near an

extreme forward position and that the preceding activation of the triceps surae was effective in postural control since the activation was found at more anterior position than quiet standing.

Title: Effects of hand posture on corticospinal excitability of the trunk muscles in dynamic tasks.

Authors: ***S. CHIDAMBARAM**, J. K. L. WONG, S.-Y. CHIOU, P. H. STRUTTON; Imperial Col. London, London, United Kingdom

Abstract: Trunk muscles play an important role in the maintenance of posture and execution of voluntary movements. It is well established that movements of the upper limbs induce activity in muscles that are related to, but not directly involved in the task. These postural adjustments serve to stabilise the body against the impending perturbation, but the neural mechanisms underlying them are unclear. We have shown that contractions of the upper limb muscles, including those of the hand, increase the corticospinal excitability of trunk muscles. This cross-facilitation effect has been characterised in hand muscles. However, the link between such fine control of the hand muscles and trunk muscles has not been studied. Thus, the present study investigates the effects of hand posture on the corticospinal excitability to trunk muscles using tasks involving power and precision grip.

Twenty healthy subjects [mean (SD) age 22.2 (0.89) years] participated in the study. Subjects were seated and instructed to reach, with the dominant hand, for a wooden ball and a plastic peg, then lift up the object using a power grip or a precision grip, respectively. Electromyographic activity was recorded from the contralateral erector spinae (ES) at vertebral level T12 and rectus abdominis (RA). Transcranial magnetic stimulation (TMS) was delivered over the motor cortex, to the hotspot for ES, at 120% active motor threshold. During the tasks, TMS was delivered while reaching, just prior to the object being picked up, or after it had been picked up. The sizes of the motor evoked potentials (MEPs) were normalised to a control condition (subjects seated with arms extended in front). The amplitudes were calculated to assess the corticospinal excitability of the trunk muscles. Background activity in ES was matched across tasks to minimise the effects of ongoing EMG on the MEP size.

The results showed normalised MEPs were greater in ES when executing the power grip than the precision grip while reaching for the object (141.52±12.2% power vs 106.7±8.87% precision) and upon lifting the object up (156.4±16.7% power vs 122.0±10.3% precision). There was no difference between the precision grip tasks and control tasks or between the "pre" and "post" pickup tasks. The results suggest that there is a task specificity in the corticospinal control of trunk muscles, even during hand movements, which likely induces far less of a postural disturbance than rapid movements of the entire upper limb. Further, the clinical implications of these results include rehabilitation, where improvements in trunk control in subjects with incomplete spinal cord injury, using repetition of simple hand movements, might be possible.

Title: Effects of light touch and visual search on the rambling and trembling components of postural sway

Authors: *D. G. SANTOS[1,2], R. GARBUS[3], S. FREITAS[3];
[1]Lab. do Movimento (LAM), Univ. Cidade De Sao Paulo (UNICID), Sao Paulo, Brazil; [2]Physiotherapy, Hosp. Israelita Albert Einstein, São Paulo, Brazil; [3]Laboratório do Movimento (LAM), Univ. Cidade de São Paulo (UNICID), São Paulo, Brazil

Abstract: The light touch of the index fingertip on a fixed surface provides additional somatosensory information that is used to reduce postural sway during quiet standing. Individuals also reduce their postural sway when performing a cognitive, visual search task while standing. However, it is still unknown which components of the postural sway (i.e., rambling and trembling) are affected by the light touch and visual search task. Therefore, the aim of the present study was to examine the effects of the light touch and visual search task on the components of the postural sway. Thirteen right-handed adults stood, as quiet as possible, on an AMTI force plate during 70 seconds. Participants performed three trials for each touch (with and without the right index fingertip touching a fixed bar composed by a force sensor ATI) and visual (with or without visual search task) conditions. For the visual search condition,

participants were instructed to search and count the letters in a text displayed one meter ahead and to say the number of letters counted to the evaluator after each trial. Different letters were used for each trial. For touch condition, participants maintained the elbow in extension while lightly touched (applied force less than 1 N) a rigid surface using their right index fingertip. The center of pressure (COP) at anterior-posterior direction was computed using the forces and moments of the force plate and decomposed in two components: rambling, representing the migration of the reference point on the supporting surface, and trembling, representing the deviation of the COP from its equilibrium position. The amplitude of COP and its components, the mean force applied on the bar during the trials with touch and the error in the cognitive task were assessed. The COP and rambling amplitude reduced when participants performed the visual search task or touched the bar. However, the trembling reduced only in the touch condition with or without the visual search task being performed simultaneously. For all conditions, the reduction of the rambling was greater compared to the trembling. The force applied on the bar increased when the search task was performed with the touch but the performance on the cognitive task was not affected by the touch. The visual search task affects only the rambling trajectory that reflects the supraspinal process. Conversely, the light touch reduces, in addition to the rambling, the trembling trajectories that reflect the action of spinal reflexes and the mechanical properties of the muscles and joints. Overall, the findings suggest that the reduction on postural sway is mainly due to the need of postural stabilization to perform the visual search task or the touch.

Title: Dynamic entrainment of human walking to ankle dorsi-flexion perturbations

Authors: *J. OCHOA[1], D. STERNAD[2], N. HOGAN[3];
[1]Mechanical Engin., Massachusetts Inst. of Technol. Dept. of Mechanical Engin., Cambridge, MA; [2]Biology, Electrical and Computer Engineering, and Physics, Northeastern Univ., Boston, MA; [3]Mechanical Engineering, and Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The concept of a central pattern generator as a rhythmic movement primitive has been well established in animal locomotion. Our recent research on human locomotion demonstrated dynamic entrainment to periodic perturbations in ankle plantar-flexion, evidence of an underlying limit-cycle oscillator. *Entrainment* of subjects' gaits with *phase-locking* at ankle 'push-off' suggested that the torque pulses provided mechanical assistance with forward propulsion. To further explore the mechanical and neural origin of that oscillator, this study tested the effect of torque pulses in dorsi-flexion given that 'toe-up' torque does not assist propulsion. As before, perturbations were delivered periodically to both treadmill and overground locomotion.

Fourteen healthy subjects walked overground (OG) and on a treadmill (TM) while wearing an exoskeletal robot that was programmed to exert short square torque pulses in dorsi-flexion at a period 50 ms different from subjects' preferred stride period. Entrainment was observed during both OG and TM walking, evidenced by a near-constant phase of maximum knee flexion with respect to the torque pulse. Entrainment during TM trials took longer in comparison to OG trials, occurring after an average of 15 vs. 26 perturbation cycles, respectively. Entrainment was always accompanied by phase-locking: the pulses converged to 'initial swing' (71.92% ± 4.28% of the gait cycle), suggesting that subjects assumed a phase relation such that the perturbation assisted ankle dorsi-flexion to facilitate foot-ground clearance and limb advancement.

These observations support the presence of a limit-cycle attractor underlying human locomotion. However, these results cannot be attributed to mechanics alone since phase-locking occurred while the foot was in the air, when the imposed torque pulses did not influence mechanical work. Overall, the observed behavior seems to require a neural adaptation that cannot easily be ascribed to biomechanics, suggesting a hierarchical organization between the supra-spinal nervous system and the spinal neuro-mechanical periphery: *episodic supervisory control*. In this scenario, the supra-spinal nervous system may behave as a *tele-operator* of the *semi-autonomous* spinal neuro-mechanical periphery to reduce the burden on higher centers of the brain, especially given the delays in neural conduction and limited speed of muscle response. Taken together, these results indicate that a limit-cycle oscillator exists in the semi-autonomous lower-levels, which is capable of stable rhythmic walking with little high-level intervention.

Title: Estimation of optimal stimulus amplitude for balance training using electrical stimulation of the vestibular system

Authors: *R. GOEL[1], M. J. ROSENBERG[2], Y. E. DEDIOS[3], H. S. COHEN[2], J. J. BLOOMBERG[4], A. P. MULAVARA[5];
[1]Univ. of Houston, Houston, TX; [2]Baylor Col. of Med., Houston, TX; [3]Wyle Science, Technol. and Engin. Group, Houston, TX; [4]NASA Johnson Space Ctr., Houston, TX; [5]Universities Space Res. Assn., Houston, TX

Abstract: Sensorimotor changes such as postural and gait instabilities can affect the functional performance of astronauts following gravitational transitions. By training astronauts preflight with supra-threshold noisy stochastic vestibular stimulation (SVS), the central nervous system can be trained to reweight sensory information by utilizing veridical information from other sensory inputs, such as vision and proprioception, for postural and gait control. This, in turn, can enhance functional performance in novel gravitational environments. The optimal maximum amplitude of stimulation to simulate the effect of deterioration in vestibular inputs for preflight training or for evaluating vestibular contribution in functional tests in general, however, has not yet been identified. Most studies have used arbitrary but fixed maximum current amplitudes from 3 to 5 mA in the medio-lateral (ML) direction to disrupt balance function in both ML and anterior-posterior (AP) directions in healthy adults. The goal of this study was to determine the minimum SVS level that yields an equivalently degraded balance performance. Fourteen subjects stood on a compliant surface with their eyes closed and were instructed to maintain a stable upright stance. Measures of stability of the head, trunk, and whole body were quantified in the ML direction. Objective perceptual motion thresholds, were estimated ahead of time by having subjects sit on a chair with their eyes closed and giving 1 Hz bipolar binaural sinusoidal electrical stimulation at various current amplitudes. Results from the balance task suggest that using stimulation amplitudes of 280% of motion-perceptual threshold (~2.2 mA on average) significantly degraded balance performance and increasing the stimulation amplitude did not lead to further degradation. We anticipate that preflight training using supra-threshold SVS stimulation will be a component of preflight sensorimotor adaptability (SA) training designed to improve adaptability to novel gravitational environments. This combination may help to

significantly reduce the time to recover functional performance after long-duration spaceflight or after landing in a novel gravitational environment (e.g. Moon or Mars). Another application of using electrical stimulation of the vestibular system is in the evaluation of tests for vestibular function by simulating acute deterioration of vestibular sensory inputs.

Title: A comparison of spinal and motor cortical neurophysiology in highly trained martial artists versus untrained controls

Authors: *Y. LIU[1,2], W. OGLE[1], A. M. PHIPPS[1,2], M. R. ENYART[1,2], A. RECTOR[1], D. M. KOCEJA[1,2], H. J. BLOCK[1,2];
[1]Dept. of Kinesiolgoy, [2]Program in Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: The practice of martial arts requires an exceptional level of control in order to execute motor skills such as overhead kicks with both speed and accuracy while maintaining balance and postural control. Motor skill training has been shown to induce changes in both spinal and cortical neurophysiology. For example, athletes in sports with high postural demands show reduction in spinal Hoffmann reflex (H-Reflex) excitability (Nielsen et al. 1993). In addition, professional musicians show evidence of greater recruitment of neurons in the hand area of motor cortex for a given stimulus intensity (Rosenkranz et al. 2007). These and other studies suggest that expert motor skill can be associated with changes in both spinal and motor cortical circuitry. However, because these sites have not been compared directly in a single highly skilled population, the degree to which each contributes is unknown. Here we asked whether highly trained martial artists would show differences from untrained controls in spinal reflexes, motor cortical responses, or both. To quantify spinal neurophysiology, the H-reflex for the right soleus muscle was measured at varying stimulus intensities to construct a recruitment curve. To quantify motor cortical neurophysiology, motor evoked potentials (MEPs) were elicited with transcranial magnetic stimulation (TMS) applied over the soleus area of the motor cortex; stimulation intensity was varied to construct a recruitment curve for motor cortex. In each case,

the subject was seated and muscle twitch amplitude was measured with electromyography using surface electrodes. Linear regression was used to determine the slope of each recruitment curve. Five right-footed subjects have participated to date: 2 untrained controls and 3 martial artists with 7-15 years of intensive martial art training experience. In these subjects, recruitment curve slope is lower in martial artists than untrained controls for both H-reflex and motor cortex. This could indicate that martial arts training is associated with recruitment of fewer neurons for a given stimulus intensity, at both the cortical and spinal level. Data collection is ongoing, but differences in both cortical and spinal neurophysiology would be consistent with the literature that has found, separately, changes at each level related to highly trained motor skill.

Title: Effects of contralateral common peroneal nerve conditioning on ipsilateral soleus H-reflex during walking

Authors: *M. R. ENYART[1,2], K. KITANO[3], A. M. PHIPPS[2,3], D. M. KOCEJA[3,2];
[2]Program in Neurosci., [3]Kinesiology, [1]Indiana Univ., Bloomington, IN

Abstract: The soleus spinal stretch reflex is implicated in maintaining posture and balance during bipedal human locomotion. Furthermore, previous studies have demonstrated that the neural circuitry from the contralateral antagonist has crossed-spinal modulatory influences on this reflex while standing and lying prone. The influence of the contralateral antagonist has not, however, been investigated during walking. The purpose of this study was to assess the modulatory effect of the contralateral tibialis anterior on the ipsilateral soleus H-reflex. The four subjects who participated were asked to walk at a speed of 4km/hr while receiving tibial nerve stimulations at 7 different interstimulus intervals that represent different times during single leg stance (0, 2.5, 5, 7.5, 10, 12.5, and 15%). These stimulations were delivered at specific intervals following heel strike that corresponded to the desired timing of the stance phase. The conditioning stimuli consisted of trains of 4 stimulations to the common peroneal nerve of the contralateral tibialis anterior spaced 5ms apart, for a total of 20ms. The timing of the conditioning stimuli were fixed to 30% of the gait cycle following ipsilateral heel strike, and the intensity was set to 1.5x motor threshold. Intensity for the control soleus H-reflex was set to 15%

of M-max for each subject, which was obtained during walking. The conditioning protocol resulted in facilitation of the ipsilateral soleus H-reflex at the 7.5% interstimulus interval, which was significantly different from the control value ($t(3) = 3.780$, $p = .032$). The results demonstrate that at an interstimulus interval of 7.5% of single leg stance (~80ms following conditioning stimulus), the modulatory effect of the contralateral tibialis anterior on the ipsilateral soleus is facilitation. This is consistent with the literature that exists on standing subjects, which shows a facilitatory effect of the contralateral tibialis anterior at an interstimulus interval of 75ms. Further research is needed to elucidate the effects of the contralateral agonist muscle on the ipsilateral agonist (i.e. soleus-soleus interaction).

Title: Response of spinal cord interneurones to finger perturbations.

Authors: *D. S. SOTEROPOULOS, S. BAKER;
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: For hand and wrist muscles there is strong evidence demonstrating that the primary motor cortex is a major contributor to the long latency response seen in muscles following a mechanical perturbation. There are also other areas that are likely to contribute, but the contribution (if any) from spinal cord (SC) circuits has so far been rarely considered. Two adult awake behaving monkeys were trained to perform a precision flexion finger movement with the index finger. At the end of each trial, the motor controlled lever returned the finger to starting position rapidly, with peak velocities in excess of 200^{o} per second. This produced a response in muscles controlling the finger, recorded through intramuscular wire electrodes. During performance of this task we recorded the extracellular activity of neurones firstly from the contralateral M1 (n=211) and subsequently from the ipsilateral intermediate zone SC (n=119). The perturbation produced a response in over 60% of neurones in both M1 (149/211) and SC (76/119). Comparable fractions of identified neurones responded in each area - 73% of corticospinal cells (n=73) in M1, and 62 of premotor spinal interneurons (n=21) responded to the perturbation. In M1, of the cells responding to the perturbation, 67% did so with an increase in

firing rate, while in the spinal cord this fraction was significantly ($p<0.01$, X^2 test) much higher at 82%. The onset latency of the neural responses however were comparable between the two areas (M1 mean: 20.6ms, SC mean: 20.2ms, $p>0.2$, unpaired t-test). The amplitude of the response to the perturbation relative to the baseline was also comparable between the two areas (M1 mean: 1.6, SC mean: 1.6, $p>0.4$, unpaired t-test). Our results support the well-established involvement of M1 in long latency reflexes, but also support a contribution from spinal cord interneurons to both short and long latency components of the stretch response.

Title: Changes in fusimotor parameters suffice to explain position thresholds, velocity thresholds, and gains of the stretch reflex; but produce strong interactions among them

Authors: *K. JALALEDDINI[1], A. MARJANINEJAD[2], S. CHAKRAVARTHI RAJA[3], F. J. VALERO-CUEVAS[1,2];
[1]Div. of Biokinesiology and Physical Therapy, [2]Dept. of Biomed. Engin., [3]Ming Hsieh Dept. of Electrical Engin., USC, Los Angeles, CA

Abstract: Position threshold, velocity threshold, and gain are the preferred kinematic and EMG metrics to assess the strength of the stretch reflex. The thresholds describe how soon the reflex is evoked and the gain describes the sensitivity of the response. But how do these metrics arise from changes in physiological parameters of the monosynaptic stretch reflex such as of dynamic and static fusimotor drives? We used a neuromorphic system to answer this question. The system was a faithful implementation of the spinal stretch reflex circuitry with a population of spiking neurons, including 128 muscle spindles with tunable dynamic and static fusimotor drives and 768 motor neurons with rate coding and size principle. They controlled the input of a Hill-type

model of skeletal muscle to emulate the muscle force. An electric motor converted the emulated muscle force to tension in a tendon. Finally, two independent systems emulated the forces of a pair of antagonistic tendons, acting to the flexion-extension of the joint. We performed ramp-and-hold perturbations to the joint (replicating those performed in the assessment of the stretch reflex) using a stiff servo motor with a wide range of velocities while systematically and differentially changing the static and dynamic fusimotor drives. For each set of fusimotor parameters, we quantified the minimum amplitude and velocity of perturbation required to evoke a reflex as well as the gain of the response.
We find that 1) changes in fusimotor drive resulted in a wide range of thresholds and gain within the reported range for normal and pathological populations, and 2) these metrics were correlated to each other and depended on the values of the static and dynamic fusimotor drives. This demonstrates that our neuromorphic system sufficed to emulate healthy and pathologic behaviors. We conclude that measurement of the thresholds together with gain is necessary to fully explain the strength of the stretch reflex response. Moreover, our results inform new approaches to use simple reflex tests to interrogate the underlying mechanisms of fusimotor control.

Title: Stretch reflexes in shoulder muscles are described best by heteronymous pathways

Authors: *M. H. SOHN[1,2], E. M. BAILLARGEON[1,2], D. B. LIPPS[3], E. J. PERREAULT[1,2]; [1]Northwestern Univ., Chicago, IL; [2]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [3]Univ. of Michigan, Ann Arbor, MI

Abstract: Healthy shoulder function requires the humeral head to remain secure in the glenoid cavity. Stretch-sensitive feedback may be critical for glenohumeral stability, since it is known that pathologies impairing feedback (e.g. stroke or spinal cord injury) often lead to shoulder instability. However, little is known about stretch reflexes at the shoulder due to experimental limitations. This study investigated the coordination of stretch reflexes elicited by rotations of the glenohumeral joint using a manuipulandum developed by our lab to study 3D shoulder mechanics and neural control. We hypothesized that stretch reflexes would be described more accurately by a heteronymous model linking muscles of the shoulder than by a homonymous model considering only the state of an individual muscle. Subjects (n=10) were seated with the right arm fixed to a rotary motor. Electromyograms (EMGs) were recorded from 8 shoulder muscles in response to pseudo-random binary perturbations as subjects exerted voluntary isometric torques (±10 and ±20% max contraction) about 3 measurement axes. Reflexes were quantified by average rectified EMG in short- (20~50 ms), medium- (50~75 ms), and long-latency windows (75~100 ms) after perturbation onset. Background activity was computed 100 ms before each perturbation. The volitional torques created rich patterns of background activity, providing a means to test our hypothesis using a linear mixed-effects model between background activity and stretch reflexes. Separate models (n=144) were constructed for reflexes in each muscle, perturbation direction, and response window. A simulated log-likelihood ratio was used to determine if models considering background activity in all muscles (heteronymous) were significantly better than those considering only background activity in the muscle in which the reflex was measured (homonymous). The heteronymous model was significantly better than the homonymous model in all tested conditions. The heteronymous models had an average $R^2 = 0.68 \pm 0.19$, and explained 28.6 ± 22.5% (mean ± std) more of the total measured variance than the homonymous models, demonstrating a wide range of improvements. The improvement differed across response windows ($p = 0.025$; 1-way ANOVA): greater ($p = 0.013$; Tukey's correction) in the long-latency (34.5 ± 3.45%, mean ± se) than the short-latency (22.1 ± 3.10%) window. Our results demonstrate that stretch reflexes in the shoulder are sensitive to changes in the background activity of multiple muscles, not simply that from which the reflex is measured. This suggests that shoulder reflexes consider the state of the entire joint to coordinate a response to perturbations.

Title: Implementation of a multilayer perceptron neural network for classifying a hemiplegic and healthy reflex pair using an iPod wireless gyroscope platform

Authors: *R. C. LEMOYNE[1], T. MASTROIANNI[2];
[1]Independent, Running Springs, CA; [2]Independent, Pittsburgh, PA

Abstract: The features of the patellar tendon reflex response provide significant perspective for the standard neurological examination. The iPod is a ubiquitous portable media device that has successfully quantified the patellar tendon reflex response. The iPod is equipped with inertial sensors, such as a gyroscope, which enable a convenient representation of the patellar tendon reflex response. The iPod can function as a wireless gyroscope platform by the incorporation of a software application. The integration of a multilayer perceptron neural network to distinguish a feature set of the patellar tendon reflex response provides expanded capability of the system incorporating the iPod as a wireless gyroscope platform for reflex quantification. Machine learning platforms, such as the multilayer perceptron neural network, offer considerable utility relative to the standard neurological examination. A hemiplegic and healthy patellar tendon reflex pair demonstrates visibly distinguishable characteristics, which can be consolidated into a quantified feature set from a gyroscope signal recording. The iPod utilizes a software application to record the gyroscope signal and wirelessly transmit the trial as an email attachment for post-processing amenable to machine learning. The iPod wireless gyroscope platform implementing a multilayer perceptron neural network successfully classifies a hemiplegic and healthy reflex pair.

Title: Static and dynamic soleus stretch reflex responses in standing humans are independently modulated by postural threat.

Authors: *B. C. HORSLEN[1], M. ZABACK[1], T. INGLIS[1,3,4], J.-S. BLOUIN[1,4,2], M. G. CARPENTER[1,3,4];
[1]Sch. of Kinesiology, [2]The Inst. for Computing, Information and Cognitive Systems, Univ. of British Columbia, Vancouver, BC, Canada; [3]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada; [4]Djavad Mawafaghian Ctr. for Brain Hlth., Vancouver, BC, Canada

Abstract: Threats to standing balance have been shown to increase tendon-tap stretch (T-) reflexes, likely due to increased muscle spindle sensitivity [1]. Spindle static and dynamic sensitivity are thought to change differently with task novelty or threat in cats [2], yet T-reflexes are primarily subject to dynamic sensitivity, and involve only a select number of receptors. As such, it is unknown if threat independently modulates static and dynamic aspects of spindle-based reflex responses to large muscle stretches in humans. This study examined velocity- and amplitude-dependent changes to spindle-based ramp-and-hold short- (SLR) and medium-latency stretch reflexes (MLR) with a height-induced postural threat.
Sixteen young healthy adults stood with their right foot on a servo-controlled tilting platform and left foot on a stable surface level with the tilting platform; the platform was positioned at the edge of a hydraulic lift. Participants stood at a low threat condition (1.1m high; away from edge) followed by a high threat condition (3.5m high; at edge). Toe-up ramp-and-hold stretches were delivered at 3 angular velocities (Vel) of 60, 100 and 170°/s (all to 5°), and 3 amplitudes (Amp) of 2, 5 and 7° (all at 170°/s); Soleus T-reflexes were evoked by taps to the Achilles tendon with a linear motor. Surface EMG was recorded from Soleus and Tibialis Anterior, and platform Amp and Vel were calculated from a potentiometer. Individual slopes were calculated between SLR and platform Vel (dynamic) and MLR and platform Amp (static) and compared across heights. Main effects of height were also calculated for SLR and MLR amplitudes.
T-reflexes were on average 14% larger at height ($p=0.06$), replicating prior work [1]. SLR and MLR amplitudes were correlated to platform Vel and Amp, respectively (SLR low: $r=0.49$; SLR high: $r=0.57$; MLR LOW: $r=0.80$; MLR HIGH: $r=0.79$). SLR/Vel slopes tended to be steeper at height (44% steeper, $p=0.067$), yet MLR/Amp slopes were not affected by height (7% steeper, $p=0.5$). There were no main effects of height on either SLR (5% larger, $p=0.52$) or MLR amplitudes (3.5% larger, $p=0.34$).
Observations of increased velocity-dependent scaling of human lower-limb SLR slopes and T-reflex amplitudes suggest spindle dynamic sensitivity may be increased with postural threat. The lack of amplitude-dependent MLR slope changes suggests no change in static sensitivity with threat. These results together may be explained by selective fusimotor control, which has been inferred from other human studies using non-balance lower-limb attention tasks [3].

Title: A neuromorphic implementation of spinal alpha-gamma circuity suffices to produce simple voluntary movements in cadaveric hands

Authors: ***S. CHAKRAVARTHI RAJA**[1], K. JALALEDDINI[2], N. LIGHTDALE-MIRIC[4], F. VALERO-CUEVAS[2,3];
[1]Dept. of Electrical Engin., [2]Dept. of Biokinesiology and Physical Therapy, [3]Dept. of Biomed. Engin., USC, Los Angeles, CA; [4]Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: The roles of fusimotor drive and α-γ coactivation in the control of voluntary movement have been debated since the time of Sherrington. We have taken a synthetic analysis approach to build a custom, real-time neuromorphic system which features a physiologically faithful representation of the stretch reflex loop including muscle spindles with tunable fusimotor drives and populations of motor neurons with recruitment and rate-coding [1,2]. This multiscale system allows the recording and adjustment of time-varying physiological variables which are otherwise inaccessible in intact subjects and specimens. The neuromorphic system has recently been used by us to explore the role of fusimotor activity in closed loop monosynaptic stretch reflex responses.
In this work, we demonstrate how the settings of the fusimotor system affect the kinematics that arise from a same sinusoidal alpha command. As a first step, we applied half-wave rectified cortical voluntary drives (i.e., alpha signal) to a pair of antagonist muscles. A 180° phase shift ensured that the drives to the antagonist pair were out of phase and never countered each other, ensuring smooth sinusoidal movement. Upon systematically varying the tonic gains of the fusimotor drives, we found that they affected the amplitude, velocity and mean position of voluntary finger oscillation. To our knowledge, this is the first neuromorphic implementation of voluntary finger movement in cadaver specimens. While these results are not unexpected, they are a critical first step in the simulation and understanding of healthy and pathological

movement, tremor, dystonia, and spasticity. Moreover, this provides a mechanistic platform to explore the role of α-γ coactivation from physiological and anatomical first principles.

Title: Soleus H-reflex modulation by the contralateral common peroneal nerve stimulation during the late stance phase of human gait

Authors: *K. KITANO[1], A. PHIPPS[1,2], M. ENYART[1,2], D. KOCEJA[1,2];
[1]Dept. of Kinesiology, [2]Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: H-reflex methodology and related techniques have been employed in order to study spinal mechanisms. However, neural mechanisms which control bilateral coordination of the extremities are still unclear. Previous studies from our group have demonstrated a possible neural connection between motor pools in the ipsilateral soleus and the contralateral tibialis anterior, which may contribute to the generation of stereotypical bilateral coordination. However, neural mechanisms which embody bilateral coordination is yet to be determined. It is known that human soleus H-reflex is modulated during gait and this modulation is known to be dependent on a phase of the gait cycle. Therefore, the purpose of this study was to explore soleus H-reflex modulation using contralateral tibialis anterior conditioning. Four subjects participated, each with no history of neuromuscular disease and with normal fitness levels. Subjects walked on a

treadmill at 4km/h. An EMG signal was collected from the right soleus and stimulating electrodes were prepared at the right popliteal fossa and the left head of fibula in order to delivery electrical stimulation to the right tibial nerve and the left common peroneal nerve. Control H-reflex amplitudes were set at 15% of M-max and inter-stimulus intervals (ISI) were selected at 0%, 2.5%, 5%, 7.5%, 10%, 12.5%, and 15% of gait cycle. Conditioning stimulation to the left common peroneal nerve was delivered prior to the test stimulation. Conditioning stimuli were a train of 4 pulses during 20 msec and intensity was set at 1.5 motor threshold in the tibialis anterior. Test H-reflex was evoked at two different gait cycle points: single support and double support during the late stance phase. Soleus H-reflex during double support phase was significantly inhibited at 2.5% ISI conditioning (-57%) and significantly facilitated at 10% ISI conditioning (+96%), compared with unconditioned H-reflex. This modulation observed in double support phase was different from that in single support in the late phase. Results suggest that the status at the spinal neural network in the late phase of gait may differ between double support and single support. Sensory inputs attributable to the conditioning stimulation had greater impact on the contralateral soleus H-reflex in double support phase than in single support phase. It is implied that neural inputs from the contralateral side are controlled with other sensory information and/or a phase of gait cycle.

Title: Interlimb reflexes between the forelimbs and hindlimbs are asymmetrically organized during locomotion in intact adult cats.

Authors: ***M.-F. HURTEAU**, E. DESROCHERS, Y. THIBAUDIER, C. DAMBREVILLE, A. TELONIO, A. FRIGON;
pharmacologie-physiologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Locomotion requires precise coordination between the four limbs, which is thought to be mediated by pathways coupling the fore- and hindlimbs, such as interlimb reflexes. Miller et al. (1977) showed that homolateral interlimb reflexes in decerebrate cats were modulated with phase and were stronger for descending (forelimb to hindlimb) than ascending (hindlimb to

forelimb) ones. Here, we characterized interlimb reflexes in intact cats during treadmill locomotion and extended the analysis to diagonal limbs. Three cats were implanted with electrodes for electromyography and to stimulate the superficial peroneal (SP) and superficial radial (SR) nerves. Reflexes were evoked during treadmill locomotion at 0.4 m/s with a train of three 0.2 ms pulses at 300 Hz. For each nerve, ~120 stimuli were given at 1.2 times the motor threshold throughout the cycle. Stimulating the SP nerve evoked ascending interlimb reflexes in the homolateral triceps brachii (TriB) in 3/3 cats, with short-latency inhibitory responses (N1) during forelimb stance starting at ~25 ms, followed by small excitatory responses (P2) at ~50 ms. Similar responses were observed in the diagonal TriB of 2/3 cats, with N1 responses during forelimb stance starting at ~20 ms followed by P2 responses at ~45 ms. Ascending interlimb reflexes in the homolateral and diagonal biceps brachii were only observed in 1/3 cats for both limbs, with P1 responses starting at ~20-25 ms during forelimb swing. Therefore, ascending interlimb reflexes appear more frequent in elbow extensors compared to elbow flexors. With SR nerve stimulation, descending interlimb reflexes were evoked in an homolateral hindlimb extensor muscle, vastus lateralis or lateral gastrocnemius, in 2/3 cats, with N1 responses starting at ~30 ms during hindlimb stance. One cat also showed P1 responses starting at ~20 ms during hindlimb swing. Diagonal responses in hindlimb extensors were observed in 3/3 cats, with N1 responses during hindlimb stance starting at ~30 ms. Descending interlimb reflexes were found in the homolateral and diagonal semitendinosus in 3/3 cats, with P1 responses starting at 20-30 ms during hindlimb swing. Therefore, both ascending and descending interlimb reflexes are present during treadmill locomotion in the intact cat, with projections to homolateral and diagonal limbs. Consistent with previous findings, the strength of descending interlimb reflexes appears stronger than ascending ones. Interlimb reflexes could be a mechanism to rapidly reduce the excitability of extensor muscles, thus lowering the center of gravity, and/or to prolong or delay phase transitions to optimize dynamic stability.

Title: The roles of contralateral conditioning and ipsilateral control stimulus timing on the soleus H-reflex during human gait

Authors: *A. M. PHIPPS[1,2], K. KATANO[1], M. ENYART[1,2], D. M. KOCEJA[1,2];
[1]Kinesiology, [2]Program in Neurosceince, Indiana Univ. Bloomington, Bloomington, IN

Abstract: Past studies have demonstrated the modulatory effects of crossed-spinal conditioning on the soleus H-reflex. These studies have only explored crossed-spinal conditioning during static positions. However, given the critical role for coordination between the ipsilateral and contralateral muscles of the lower extremities play in movement control, the purpose of this study was to assess crossed-spinal conditioning of the soleus H-reflex during gait. Four young, healthy subjects were tested while walking on a treadmill at 4 km/h. Control H-reflexes, set to 50% Hmax, were elicited from the ipsilateral soleus muscle at two points in the gait cycle: (1) mid stance and (2) late stance. Mid stance was determined to be 30% of the gait cycle, while late stance was determined to be approximately 43% of the gait cycle post-ipsilateral heel strike. Conditioning stimuli, a train of four for 20 ms, was applied to the contralateral common peroneal nerve at the fibular head preceding the ipsilateral test stimulation to the tibial nerve popliteal fossa. Conditioning stimuli were set to 1.5 x motor threshold and delivered at interstimulus intervals (ISIs) set at 0%, 2.5%, 5%, 7.5%, 10%, 12.5%, and 15% of the gait cycle. Contralateral conditioning delivered at 2.5% ISI of the gait cycle resulted in modulation of the soleus H-reflex during late stance phase by -38% (inhibition). A one sample t-test showed this inhibition to be significantly different from the control H-reflex. However, there was no significant inhibition/facilitation of the soleus H-reflex during mid stance phase. These results show contralateral conditioning at 2.5% of the gait cycle has differential modulation on the ipsilateral soleus H-reflex. This modulation was dependent on when the test stimulus to the ipsilateral soleus was delivered during the gait cycle (mid vs. late stance phase), suggesting that contralateral antagonist sensory information is regulated by the phase of gait cycle. Overall, more investigations into this complex reflex response in humans will be required to make advancements in the understanding of crossed-spinal communication during human gait.

Title: Built for fighting: neuroendocrine and transcriptomic regulation of aggression in a fighter strain of the siamese fighting fish Betta splendens

Authors: *D. GONÇALVES[1], A. RAMOS[1], C. HUANG[2], S. M. Y. LEE[2];
[1]Univ. of St. Joseph, Macau, Macao; [2]Univ. of Macau, Macao, Macao

Abstract: Across southern Asia, breeders have been selecting males of the Siamese fighting fish *Betta splendens* for fighting contests for a period of over 200 years. This strong directional selection has produced a variety of *B. splendens* morphologically different and more aggressive than wildtypes. Because wildtypes are still available in remote regions of southern Asia, the comparison with fighter strains provides an excellent opportunity to identify the genetic and neuroendocrine mechanisms underlying the expression of aggression in fish. In this study we compared the behavior, endocrine response and brain transcriptome profile of a strain of fighters with wildtypes when exposed to an aggressive challenge. As predicted, males fighters displayed more aggressive behavior both towards their mirror image and towards an opponent than wildtypes. Interestingly, female fighters were also more aggressive than female wildtypes, in spite of only males being the target of selection. In control animals (not displaying aggression), plasma androgen levels of 11-ketotestosterone (11KT), but not of testosterone (T), were more elevated in fighter males. Both fighter and wildtype males increased very significantly the secretion of both androgens in response to a 1h aggressive challenge. Whole brain gene expression profiling of wildtype and fighter males generated 74.7Gb of sequencing data that was assembled with Trinity, with 77% of unigenes annotated into known proteins. The analysis revealed significant differences in the brain transcriptome between wildtypes and fighters, both in the control and aggression-elicited treatment, with over 12,000 transcripts being differentially expressed, suggesting that selection for aggression has resulted in a highly divergent brain transcriptome profile. Exposure to the mirror treatment induced a similar number of differentially expressed genes in the two strains (443 in fighters and 312 in wildtypes), and enrichments detected by pathway analysis included steroid hormone biosynthesis, estrogen signaling and AVP/AVT pathways. In addition to providing the first annotated transcriptome for Betta splendens and identifying potential genomic pathways relevant for the expression of aggressive behavior, the study shows that selection for aggression produced a significantly altered brain transcriptome in males and co-selected high aggression levels also in females. The results also suggest that 11KT may be a key hormone modulating the high levels of aggression observed in males of the fighting strain.

Title: Investigating the role of serotonin receptor subtypes mediating aggressive behavior in a novel species

Authors: *A. BUBAK[1], M. J. WATT[2], K. J. RENNER[3], J. G. SWALLOW[4];
[1]Biol., Univ. of Colorado-Denver Anschutz Med. Campus, Denver, CO; [2]Ctr. for Brain and Behavior Research, Basic Biomed. Sci., [3]Biol., Univ. of South Dakota, Vermillion, SD;
[4]Integrative Biol., Univ. of Colorado-Denver, Denver, CO

Abstract: Aggression is a complex and nearly universal behavior, documented in animal species ranging from humans to flies. Based on comparative research investigating the proximate mechanisms responsible for the appropriate perception and execution of aggressive behaviors, it is clear that genes and neurochemicals (i.e., biogenic amines, hormones, neuropeptides) that mediate this suite of behaviors are conserved across a wide range of taxa. The serotonergic (5-HT) system, in particular, shares deep evolutionary origins between vertebrates and invertebrates and has been largely implicated in aggressive behavior. However, most of our understanding with respect to the mechanisms of the serotonergic system derive from manipulations that result in global 5-HT changes. To better understand the system and the role of 5-HT we need to target individual genes such as receptor subtypes. Additionally, a large majority of this work has focused on a few model organisms, predominantly rodents and fruit flies, with the primary focus on males. This has led to significant gaps in our understanding of the conserved mechanisms that govern aggressive behavior as well as the substantial differences between sexes. We use a novel species, the stalk-eyed fly *Teleopsis dalmanni*, to explore the conserved underlying genetic and neurochemical mechanisms that mediate aggression. Members of this species are sexually dimorphic; males have exaggerated eyestalks that protrude laterally from their head, which they use as aggressive signals and weapons against conspecifics. Females are relatively docile compared to males, rarely engaging in aggressive conflicts with other females. Using next generation sequencing (RNA-seq) and RNA interference (siRNA), we are able to uncover the serotonergic-mediated mechanisms responsible for the sexually dimorphic aggressive behavioral response in a novel species.

Title: 5HT3 receptor blockade during AAS withdrawal reduces AAS-enhanced anxiety without altering aggression

Authors: *T. R. MORRISON, L. RICCI, R. H. MELLONI, Jr;
Psychology, Northeastern Univ., Boston, MA

Abstract: Despite legal prohibitions against anabolic/androgenic steroids (AAS) in the US, usage rates amongst high school aged males are steadily rising and range between 2-5%, with some states reporting abuse rates as high as 8%. The AAS use during adolescence is associated with a host of risk factors and traits that include increased violence and aggressive behavior. Alongside aggression, AAS exposure during adolescence is also linked to an increased incidence of anxiety disorder diagnoses during adulthood that occur after the cessation of AAS abuse. Relatedly, adolescent males with *low* circulating testosterone report higher levels of anxiety, while those with *high* testosterone show no changes in anxiety, but exhibit *high* levels of aggression. Together, these data suggest that androgen fluctuations inversely affect aggression and anxiety, perhaps indicating that substrates of these behaviors are linked. Data generated in our lab support this hypothesis and show that AAS exposure during adolescence increases aggression and reduces anxiety. During withdrawal from AAS, anxiety levels rise significantly in the presence of normalized aggression. The effects of AAS on aggression and anxiety are likely regulated by 5HT and AVP signaling interactions in the lateral anterior hypothalamus (LAH) since, for example, AAS-aggression levels positively correlate with AVP fiber density in the presence of lower anxiety and reduced 5HT afferents in the LAH. Conversely, during withdrawal when anxiety levels are high, 5HT signaling remains reduced while AVP fibers and aggressive behavior return to control levels. Recently we showed that 5HT agonist injection in the LAH increases anxiety during AAS exposure. Along with previous reports showing that 5HT3 agonists increase aggressive behavior, 5HT3-activated anxiety suggests that this receptor is an important modulator of the relationship between aggression and anxiety after AAS exposure. To build on this notion, we measured aggression and anxiety during AAS withdrawal after injection of 5HT3 antagonists in the LAH. Blockade of 5HT3 receptors reduced AAS-withdrawal induced anxiety without affecting aggression. These data suggest that 5HT3 receptors regulate the anxiety component of the LAH circuit, and may indicate that the LAH modulates both

aggression and anxiety through a single upstream AVP pathway that diverges into parallel downstream mechanisms regulated by different populations of 5HT receptors.

Title: Acute manipulation of Avpr1b CA2 neurons regulates expression of maternal aggression in mice.

Authors: ***S. WILLIAMS**[1], H.-J. LEE[2], J. SONG[3], W. YOUNG[3];
[1]Section on Neural Gene Expression, NIMH, Bethesda, MD; [2]Kyungpook Natl. Univ. Sch. of Dent., Daegu,, Korea, Republic of; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Avp activation of the Avpr1b subtype is necessary for social recognition and aggression in both males and females. Avpr1b expression in the central nervous system is strictly limited to hippocampal CA2 neurons. We've shown that replacement of Avpr1b into the CA2 of Avpr1b knockout (KO) males via viral (pan-neuronal) expression rescued the behavioral deficits in aggression. This study indicated that activity of Avpr1b in the CA2 during adulthood, but not development, was important for regulating resident-intruder aggression. We are now interested in determining the causal role of Avpr1b neuronal activity in aggressive behavior. The use of designer receptor exclusively activated by designer drugs (DREADDs) allows for non-invasive acute manipulation of neuronal excitability in a cre-dependent manner. We created a transgenic mouse line that 'knocked-in' Cre-recombinase under the control of the Avpr1b promotor (Avpr1b-Cre), such that the Avpr1b was replaced by the Cre gene. Double in situ hybridization confirmed Cre expression in Avpr1b CA2 neurons in heterozygous adult mice. This line of mice was used to test two hypotheses: 1) Acute enhanced excitability will rescue deficits observed in Avpr1b KO female mice; and 2) acute inhibition will reduce female aggression. Experiment 1: Avpr1b-Cre heterozygous and Avpr1b-Cre KO female mice were injected with a Cre-dependent virus expressing either DREADD-Gq or control fluorescent marker. Experiment 2: Avpr1b-Cre heterozygous females were injected with a Cre-dependent DREADD-Gi or control fluorescent marker. Females were then paired with males until pregnancy was confirmed, and the male was removed. Females were administered CNO (ligand for DREADD) prior to resident-intruder

aggression testing. Tests were repeated several times across the mid-lactational period. Behavior was scored for latency and duration of aggression. Pup retrieval was recorded following aggression tests. Preliminary results suggest that Avpr1b-Cre KO mice injected with DREADD-Gq are more likely to attack and show a shorter latency to attack compared to KOs injected with GFP. Furthermore, Avpr1b-Cre mice injected with DREADD-Gi show increased latency to attack ($p < 0.05$) and decreased duration of aggression ($p < 0.05$) compared to Avpr1b-Cre mice injected with GFP. Manipulation of CA2 neuronal activity does not appear to affect maternal care.These data suggest that the acute activity of CA2 neurons is important for the expression of typical maternal aggression. These data add to our understanding the precise temporal time course of CA2 neuronal activity in regulation aggressive behaviors and indicates that effects are not sex-specific.

Title: The role of the ventromedial hypothalamus during confrontation against conspecific aggressors

Authors: *L. WANG, D. LIN;
New York Univ. Sch. of Med., New York, NY

Abstract: In the wild, male animals fight for limited resources like food, mates, and territory. When they fight, they chase, lunge, and bite other males. After several rounds of confrontations, the more aggressive animals win the fight, and the losers hold up front paws in front of their chest to protect their core and actively defend themselves. These attack and defense scenarios can also be observed in the laboratory by using mice as an animal model. Previous studies in mice, rats, and hamsters have shown that c-fos, an immediate early gene, was elevated in the ventromedial hypothalamus (VMH) in males that were defeated by other conspecific aggressors (Kollack-Walker et al., 1997; Motta et al., 2009; Silva et al., 2013). The aim of our study is to understand the role of the VMH during confrontation against aggressive males. We first examined the expression patterns of c-fos after the residents animals were attacked by an aggressor introduced into their home cages. Consistent with previous findings, we observed elevated c-fos in the VMH, suggesting the involvement of the cells during confrontation against aggressors (Kollack-Walker et al., 1997; Motta et al., 2009; Silva et al., 2013). To further

understand the behavioral events, during which the VMH cells are activated, we performed electrophysiological recordings in VMH in freely moving animals. We observed acute increase of the VMH cell activity as the animal got attacked by the aggressor but not during his social investigation of the aggressor, indicating that the role of cells may be related to the physical defensive action of the animals. To test this hypothesis, we then optogenetically activated the VMH cells and observed light-bounded defensive behaviors, such as immobility, upright postures, and dashing. Taken together, our results suggest that the VMH cells may play an essential role in conspecific defense.

Title: TRPA1 is indispensable to escaping from predator

Authors: R. AKAHOSHI[1], Y. KATAYAMA[1], R. YAMAGUCHI[2], T. YONEMITSU[3], J. L. PAULI[2], H. KASHIWADANI[2], *T. KUWAKI[2];
[1]Dept. of Physiol., Kagoshima Univ. Sch. of Med., Kagoshima, Japan; [2]Kagoshima Univ-Grad Sch. Med., Kagoshima, Japan; [3]Anesthesiol., Fujimoto Gen. Hosp., Miyakonojo, Japan

Abstract: Transient receptor potential ankyrin 1 (TRPA1), a member of the TRP superfamily, is expressed in a subset of sensory neurons and mediates nociception evoked by pungent chemicals. We have reported that TRPA1 knockout mice (KO) failed to avoid entering a chamber filled

with vapor of formalin, allyl isothiocyanate, and acrolein and proposed that TRPA1 serves as a frontline sensor to avoid environmental chemical threats (Sci Rep 3: 3100, 2013). In this study, we tested our hypothesis that TRPA1 also play a role in escaping from predator. As expected, TRPA1-KO failed to avoid fox feces and 2,4,5-trimethylthiazoline (TMT), a synthetic predator odor isolated from fox anal secretions. TRPA1-KO also failed to increase blood ACTH when exposed to TMT, but normally found buried food pellet indicating normal olfaction at least to smell of food. Nasal administration of AP-18, a specific blocker to TRPA1, in the wild-type mice reproduced the defect in TRPA1-KO. Finally, immunohistochemical examination revealed that TRPA1 is expressed in the nerve bundles in the respiratory turbinates of the nasal cavity. Taken together, we conclude that TRPA1 is indispensable to escaping from predator and that pungency of TMT, in addition to its smell, is important factor as a threatening cue.

Title: Oxytocin decreases aggression during courtship and increases investigation of intruders in the California mouse

Authors: *C. D. GUOYNES, C. MARLER;
Psychology, UW Madison, Madison, WI

Abstract: The neuropeptide hormone oxytocin (OT) plays a significant role in social bonding, social recognition, and anxiolytic behavior in both human and animal models. We examined the acute effects of intranasal OT (0.8 IU/kg) in male California mouse (*Peromyscus californicus*), a monogamous rodent that forms reliable pair bonds for mates and exhibits aggression towards territorial intruders. Previous research in prairie voles has shown that an acute dose of OT can decrease latency to form a partner preference; however, it is also important to ask how oxytocin influences behavioral interactions both before and after pair bond formation has occurred. Our goal was to determine the role of OT in males during critical social periods: pair bond formation, intrasexual aggression after pair bonding, pup retrievals with first litter, and partner preference after weaning of first litter. Males were treated with 25 uL of OT or saline 5 minutes before each

behavioral test, receiving a total of four treatments of either OT or saline (N=12 per group). In the first 10 minutes of pairing, the OT group engaged in significantly fewer aggressive interactions than the saline group (t=2.19, p=0.04). During a same-sex intruder encounter in their home territory, males given oxytocin showed significantly greater anogenital sniffing (t=2.3, p=0.03) with no change in number of aggressive attacks. Results from other behavioral tests will be reported. Based on the hypotheses that OT increases aggression towards the out-group, but increases affiliation towards the in-group, we hypothesize that OT will increase a number of behavioral traits: responsiveness to pup calls and pup licking and grooming during pup retrievals, allogrooming towards partner and aggression towards stranger in the partner preference tests. In summary, OT administered to males has different behavioral effects depending on the social context and appears to influence a variety of aggressive and affiliative behaviors, including during pair bond initiation in male California mice. These results are similar to the effects seen in male prairie voles with the exception that vasopressin—not oxytocin—is implicated in pair bond initiation for male voles.

Title: Aggressive interactions between mantis shrimp (Neogonodactylus oerstedii) are mediated by brain monoamine levels and recognition of previous opponents

Authors: A. D. KOCH[1], J. D. W. YAEGER[1], M. W. BUCHANAN[1], M. L. PORTER[2], M. J. WATT[3], *K. J. RENNER[1];
[1]Biol., Univ. of South Dakota, Vermillion, SD; [2]Biol., Univ. of Hawaii at Manoa, Honolulu, HI; [3]Basic Biomed. Sci., Sanford Sch. of Med., Vermillion, SD

Abstract: The mantis shrimp *Neogonodactylus oerstedii* is a solitary marine crustacean that actively defends territory from conspecifics. Serotonin (5-HT) has been linked with aggression in several crustacean species based on exogenous 5-HT application. However, whether endogenous monoamines in the crustacean brain mediate aggression and contest outcome is relatively

unknown. In other species, contest outcome is also influenced by recognition of previously-fought opponents, as it can prevent further costly disputes when the likely outcome is already known. Some species of mantis shrimp exhibit brief memory of previous opponents as indicated by olfactory-based avoidance, but is not known if this alters subsequent aggression. Here, we first staged fights between size- and sex-matched pairs of *N. oerstedii* and measured brain octopamine, dopamine (DA) and 5-HT immediately afterwards, and show that contest losers have higher levels of 5-HT and DA relative to winners. Next, we determined if opponent recognition would reduce the duration and intensity of aggressive interactions between previously-fought individuals. Size and sex matched *N. oerstedii* engaged in two interactions with the same opponent but separated by a 24 h period, with control groups comprising winners and losers from the first fight paired with size-matched novel opponents of unknown status in the second contest. Shrimp paired with familiar opponents exhibited decreases in interaction length, number of strikes and threat displays in the second fight, with winning and losing status remaining consistent across contests. In contrast, individuals confronted with an unfamiliar opponent maintained their previous level of aggression, and 23% of subjects were able to reverse prior contest outcome. Our results suggest endogenous brain DA and 5-HT mediate initial expression of aggression in *N. oerstedii*, and that contest outcome is also heavily influenced by memory of previous opponents for at least 24 h after social status has been established. We are now testing if pretreatment with exogenous 5HT or DA can reverse the outcome of the second fight in familiar *N. oerstedii* opponents, which will provide insight into proximate mechanisms underlying formation and maintenance of social hierarchies.

Title: Stereological analysis of intact ventromedial hypothalamus morphology and synaptic organization: new tools for understanding juvenile social behaviour plasticity

Authors: *A. CICCARELLI, R. PAOLICELLI, D. WEIJERS, F. ZONFRILLO, E. PERLAS, G. BOLASCO, C. GROSS;
Mouse Biol. Unit, EMBL, Monterotondo, Italy

Abstract: Changes in social behaviour induced by juvenile conspecific interactions is a critical and pro-survival form of behavioral plasticity conserved across species. This form of neuroadaptation is supposed to depend on the high degree of brain plasticity present during development; however it is still unclear if a critical period for shaping social behaviour exists and from which brain region it is regulated. Ventromedial hypothalamus (VMH) has a pivotal role in regulating many types of social behaviours, such as defensive behaviour, aggression and sexual receptivity. We hypothesize that in mice structural plasticity occurring in this hypothalamic brain region could underlie behavioural changes induced by stressful social experiences during development. In this study we developed a behavioural protocol aimed to study the effect of repetitive social defeat on juvenile mice (from p22 to p31). Preliminary data show that juvenile-defeated mice display an increase in adult aggressive behaviour and social avoidance indicating a long-lasting form of behavioural plasticity. To study structural plasticity in VMH we first performed a detailed characterization of VMH synaptic network in control mice. We used a transgenic mouse line (*Nr5a1::*Cre; *Rosa-CAG::*LSL-Synaptophysin-GFP; *Rosa-CAG*::LSL-Tomato) that allows us to visualize: a) the majority of VMH neurons and their axonal/dendritic morphology; 2) the VMH excitatory synapses (presynaptic terminals) within the VMH (excitatory collaterals) and in VMH target regions (e.g., PAG). Quantitative analysis using confocal microscopy and immunofluorescence revealed that VMH collateral synapses represent approximately 30% of total VMH inputs and are denser in the rostral part of VMH. Double staining with presynaptic markers revealed that VMH collaterals express mainly Vglut2 and this region is enriched as well in synaptic inputs arising from extra-VMH excitatory neurons (Vglut1-positive). Next, in order to systematically describe the entire VMH morphology and collateral synapses, we clarified the whole VMH of adult transgenic mice using a modified CLARITY protocol. With lightsheet microscopy we visualized the intact VMH and analysed the full population of VMH Nr5a1-positive neurons and the excitatory collateral synapses. Automatic quantification revealed that the VMH total number of neurons is approximately 32000 and 3D rendering showed new morphological properties of this region. In conclusion, here we describe a new form of juvenile-induced social behavioural plasticity and provide new tools for systematic analysis of intact VMH and its structural plasticity in mice.

Abstract: The physiological response in rats to traumatic stress can be acutely and chronically measured using a multitude of neuroendocrine and behavioral markers. Responses of these interrelated neuroendocrine and behavioral markers may vary from molecule to molecule and behavior to behavior, and outside factors like the type of stressor or the phase in circadian cycle may also influence observed changes. While rodent models of traumatic stress have provided a glimpse into the physiological response to acute and chronic stressors, few studies have examined a more comprehensive interrelated molecular and behavioral approach. The aim of the present study is to provide a more complete examination to describe the subacute effects of traumatic stress exposure and recovery to a panel of neuroendocrine markers, and to compare those alongside acute and long lasting behavioral responses such as exploratory behavior and acoustic startle response, over the circadian cycle. Rats were exposed to either underwater trauma (UWT) or predator exposure (PRED). Then repeated behavioral tests (exploratory behavior on the elevated plus maze, acoustic startle) were conducted across 5 individual time points over a 7 day period. Additionally, blood samples were simultaneously collected over 10 time points across the circadian cycle in yoked stress-exposed cohorts. Neuroendocrine markers were quantified from serum using LC-MS or ELISA, analyzed over time, and compared against behavioral responses at corresponding time points. Preliminary data show differential responses for UWT and PRED across the experimental timeline, and distinct response timelines for the different measures collected. Title: Seasonal variations in the dorsolateral and medial cortex, the reptilian homologue of the hippocampus

Authors: A. D. ABDILAHI[1], A. B. DAY[1], *R. E. COHEN[2];
[1]Minnesota State University, Mankato, Mankato, MN; [2]Biol. Sci., Minnesota State Univ. Mankato Dept. of Biol. Sci., Mankato, MN

Abstract: The hippocampus is a region of the brain involved in spatial learning and memory and is a site of neural plasticity in the adult brain. Specifically, this region has been shown to add new neurons in adulthood in a variety of animals, as well as have altered morphology (volume) under different seasonal conditions in some bird species. In the seasonally breeding green anole lizard, *Anolis carolinensis*, breeding season (BS) lizards exhibit territorial and aggressive behaviors to vigorously compete for large territories, with a decrease in these behaviors and territory sizes during the non-breeding season (NBS). Previous work has shown that morphology of brain areas involved in reproduction is altered seasonally and this is likely due to seasonal changes in steroid hormones, specifically testosterone (T) and its metabolites, estradiol (E2) and 5α-dihydrotestosterone (DHT). It is currently unknown whether there are seasonal changes to the anole hippocampus. To investigate potential seasonal effects in the lizard homologue of the hippocampus, the dorsolateral cortex (DC) and medial cortex (MC), we examined 1) morphology in BS and NBS males and 2) neuron addition in BS males treated with various hormones. In experiment 1, we obtained males during the BS and NBS, collected brains, and examined volumes in Nissl stained sections. In experiment 2, we gonadectomized BS males and implanted subcutaneous capsules containing T, E2, DHT, or left empty (blank). After hormone implantation, animals were injected with bromodeoxyuridine (BrdU; 50mg/kg) once per day for three days and brains collected after 25 days. Immunohistochemistry for BrdU and HuC/D (a neuronal marker) was performed to determine the number of new neurons present in the DC after treatment. Preliminary results for experiment 1 have shown no significant difference in DC and MC volume between BS and NBS lizards ($t < 1.10$, $p > 0.385$, $n = 2$). Additionally, experiment 2 preliminary results suggest that there may be a decrease in new neuron survival with T ($n = 5$) compared to blank ($n = 3$; $t = 2.35$, $p = 0.057$). These preliminary results suggest that DC and MC volume does not change seasonally, but steroid hormones may promote increased turnover of new neurons. Data collection for both experiment 1 and 2 is in progress and we will also examine new neuron numbers in animals treated with E2 and DHT.

Title: Gene x environment interactions in pathological aggression modify the expression and function of CB1 receptors: relevance to the comorbidity between antisocial behavior and cannabis use

Authors: *K. M. MCFARLIN[1,2], M. BORTOLATO[2];
[1]Univ. of Kansas, Lawrence, KS; [2]Dept. of Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT

Abstract: Antisocial behavior (AB) is a neuropsychiatric disorder characterized by inappropriate and often exaggerated aggressive and violent responses. Ample evidence has shown that the pathogenesis of aggression reflects the synergism of genetic and environmental vulnerability factors; in particular, the best-characterized gene x environment (GxE) interaction in AB concerns: 1) a low-activity variant of the *MAOA* gene, encoding the enzyme monoamine oxidase A; and 2) child neglect and/or abuse. Our lab has recently developed the first mouse model of this GxE interaction, based on exposing hypomorphic MAOA mutants ($MAOA^{Neo}$) to early stress (ES) during the first week of postnatal life. In line with clinical evidence, adult male $MAOA^{Neo}$ mice subjected to this manipulation exhibit a marked increase in aggression, as compared to their non-stressed (NS) or wild-type (WT) controls. One of the major problems in AB management lies in its association with abuse of psychoactive substances, and, most notably, cannabis. This comorbidity may reflect a self-therapeutic attempt; indeed, low doses of the main psychoactive ingredient of cannabis, Δ^9-tetrahydrocannabinol (THC), have been shown to reduce aggression. The antiaggressive effects of cannabis are posited to be mediated by cannabinoid 1 receptors (CB1Rs) in key brain regions that orchestrate the emotional response to threat, such as amygdala and hypothalamus. Nevertheless, the neurobiological bases of the comorbidity between cannabis abuse and aggression remain unclear. To address this issue, we hypothesized that the aggression in ES-exposed $MAOA^{Neo}$ mice may be underpinned by brain-regional changes in CB1Rs. In line with this idea, we found that adult male ES-$MAOA^{Neo}$ mice displayed

increased levels of hypothalamic CB1Rs. Furthermore, low-dose THC (0.03 mg/kg, IP) selectively ablated aggressive responses in adolescent ES-exposed $MAOA^{Neo}$ mice, without affecting their locomotor behavior. Notably, these effects were dissociated from changes in anxiety-related changes and prevented by a selective CB1R antagonist, AM251 (1 mg/kg, IP). These results collectively suggest that CB1Rs are directly and selectively implicated in the regulation of GxE interactions in AB. Ongoing studies in our lab are currently assessing the temporal trajectory of the alterations in the endocannabinoid system with respect to the ontogeny of aggression, as well as the anti-aggressive mechanisms of THC.

Title: The 5α-reductase inhibitor Finasteride increases suicide-related aggressive behaviors in a schizophrenia-like phenotype

Authors: *C. MAURICE-GÉLINAS[1], C. MONPAYS[1], J. DESLAURIERS[2], P. SARRET[1], S. GRIGNON[1,3];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. of California, San Diego, CA; [3]Dept. of Psychiatry, Ctr. Hospitalier Universitaire de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Death by suicide is 4 to 10 times higher among schizophrenia patients than in the general population. At odds with the general population, there is now compelling evidence suggesting that the pathophysiology of suicide in schizophrenia does not involve serotonergic neurotransmission. We recently described and characterized a murine Two-Hit Model of Suicide-related behaviors in a schizophrenia-like context (THMS) involving gestational inflammation followed by adolescent social isolation (SI). In this model, pregnant C57BL/6 mice are injected with polyinosinic/polycytidylic acid (PolyI:C) 20 mg/kg at gestational day 12 and their offspring are submitted to SI from postnatal (PN) days 21 to 53. In this THMS, clozapine normalized prepulse inhibition, aggressiveness, impulsivity and anxiety-like behaviours (1). While the basis of clozapine superior effectiveness on suicidal behaviors in schizophrenic patients is not well understood, previous works has revealed that clozapine alters central neurosteroid (NS) levels, such as allopregnanolone.
Methods. As a preliminary step to ascertain a potential NS involvement, we submitted control and THMS mice to daily intraperitoneal administration (from PN43 to PN53) of 5-alpha-

reductase inhibitor finasteride (50 mg/kg) before clozapine (3 mg/kg) or vehicle injection. Clozapine and finasteride were administered 30 min and 20 h before behavioural testing, respectively. Prepulse inhibition (PN50), elevated plus maze (PN51), resident intruder test (PN52) and forced swim test (PN53) were then performed to assess the sensorimotor gating, anxiety-like behaviours, aggressiveness, and depressive-like responses, respectively. Mice were then sacrificed for biochemical analyses.
Results. As previously reported, male THMS mice were more aggressive and impulsive than controls. In the THMS only, finasteride treatment further increased aggressiveness (# attacks +123 % ($p<0.01$); time spent attacking +70% ($p<0.05$)) and impulsiveness (55 % decrease in the latency before the first attack, $p<0.05$). Clozapine essentially normalized these parameters under both conditions (THMS or THMS + finasteride), without any evidence of a specific interaction with finasteride.
Conclusion. These results thus suggest that neurosteroids may intervene in the control of aggression in the THMS model, but do not specifically underlie the beneficial effects of clozapine.

Title: Evaluation of aggressive behavior in an animal model of perimenopause

Authors: *L. C. DALPOGETO[1], N. PESTANA-OLIVEIRA[2], J. A. ANSELMO-FRANCI[3], C. M. LEITE[3];
[1]Univ. De Sao Paulo, Ribeirao Preto, Brazil; [2]Dept. de Fisiologia, FMRP-USP, [3]Dept. de Morfologia, Fisiologia e Patologia Básica, FORP-USP, Univ. de São Paulo, Ribeirao Preto, Brazil

Abstract: During the perimenopause - a transition period that precedes menopause - women experience mood disorders like anxiety, depression as well as episodes of irritability and aggressiveness, which can be related to the hormonal changes like low levels of progesterone and testosterone as well as elevated or normal concentrations of estrogens. In rodents, 4-vinylcyclohexene diepoxide (VCD) induces a gradual depletion of ovarian follicles, modeling the transition to menopause in women. We aimed here at investigating if aggressive behavior is also expressed in this animal model. Female Wistar rats (28 days old) were treated with VCD (160mg/Kg s.c) or oil for 15 consecutive days. Sixty five days after the onset of VCD treatment, rats were placed in individual cages, and the estrous cycle was verified daily. Around 10 days after, rats with regular cycles in the diestrus phase were submitted to social instigation for 5 min followed by the Resident-Intruder test for 10 min. The recorded behavior was analyzed for offensive aggression (lateral threat, clinch attack, keep down, bites, upright posture, chase and move towards) and defensive aggression (move away, defensive upright and submissive posture). VCD-treated rats exhibited higher frequency of offensive aggression, lower frequency of defensive aggression and lower attack latency ($p<0,05$). There was a significant increase in the offensive behaviors clinch attack and bites and a decrease in the defensive behavior move towards ($p<0,05$). There was no difference among non-aggressive behaviors like social and non-social exploration, rearing and grooming, suggesting that locomotor activity was not impaired by the VCD-treatment. The higher aggressive behaviors displayed by rats in periestropause are similar to those exhibited by women, indicating that this animal model is suitable for the studies of perimenopause. These results incite new researches about the impact of the perimenopausal hormonal changes in the neural mechanisms that regulate aggressiveness.

Title: Developmental gating of aggressive behaviors in *Drosophila*

Authors: *E. H. MOSCATO, B. MAINWARING, M. S. KAYSER;
Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: A critical challenge in neuroscience is determining how complex behaviors arise from rapidly changing circuitry in the brain. Early in life, animals initiate a broad repertoire of behaviors essential for survival, such as feeding, sleeping, and aggression. Somehow, young animals know how to engage in these activities, and for this reason, such innate behaviors are often referred to as "hard-wired". However, innate behaviors can arise from immature underlying neural processes, show dramatic ontogenetic change, and be altered by experience, indicating that these circuits are highly dynamic and modifiable. Aberrant emergence of social behaviors in early life is a hallmark of human neurodevelopmental disorders, emphasizing the importance in gaining a mechanistic understanding of behavioral ontogeny. We are using the model system *Drosophila* to dissect the neural, molecular, and genetic logic underpinning the gating of aggression in early life.
We have found that newly eclosed male flies do not exhibit aggressive behaviors for the first 24 hours of adult life; this finding does not reflect a generalized inability to enact complex behaviors, as male flies begin courting females as early as 4 hours post eclosion. As flies age, aggression becomes increasingly robust: older flies display a greater number of aggressive behaviors, a decreased latency to initiate aggression upon encountering another male fly, and increased tendency to establish dominance over a fighting partner. To discover novel regulators of aggression ontogeny, we have undertaken a thermogenetic screen to identify neurons and circuits that can drive aggression in juvenile flies. Activation of neurons defined by two Gal4 lines, YF1 and YF2, strongly promotes aggressive behaviors on the first day of adult life, when flies are normally non-aggressive. On-going work aims to determine how these neuronal populations interact with each other and with previously characterized regulators of mature aggression to modulate the developmental gating of aggressive behaviors in *Drosophila*. These studies will provide fundamental insights into the neurobiological mechanisms that regulate the maturation of essential behaviors.

Title: mGluR2 mediates the interaction between low MAO A activity and early stress model of aggression

Authors: *S. C. GODAR[1,2], L. J. MOSHER[1,2], C. M. JONES[1], H. STRATHMAN[1], S. SCHEGGI[3], C. GAMBARANA[3], M. DE MONTIS[3], M. BORTOLATO[2];

Abstract: Pathological reactive aggression is a neurodevelopmental condition with devastating socioeconomic ramifications. The pathogenesis of this disorder is largely governed by the interplay between gene x environmental (GxE) factors. One of the best characterized genes for aggression is monoamine oxidase A (MAOA), the primary metabolic enzyme for serotonin (5-HT) and norepinephrine degradation. A host of evidence has shown that individuals with low MAOA activity allelic variants, who have been subjected to early life neglect and/or abuse, are predisposed to aggression and antisocial behaviors.
Based on these clinical findings, we developed a novel animal model of this GxE interaction by subjecting non-aggressive MAOA hypomorphic mutant mice ($MAOA^{Neo}$) to daily early stress (ES, maternal separation and saline injection) from postnatal day 1 through postnatal day 7 (PND1-7). Adult ES-$MAOA^{Neo}$ mice exhibit high levels of aggression compared to the wild-type littermates and non-stressed $MAOA^{Neo}$ counterparts. These behaviors were accompanied by a gradual reduction in N-methyl-D-aspartate receptor (NMDAR) expression and function in the prefrontal cortex in adulthood, likely contributing to a prefrontal disinhibition over subcortical circuits.
Previous studies revealed that ES-$MAOA^{Neo}$ pups displayed elevated levels of 5-HT, as well as the 5-HT receptor 2A (5-HT_{2A}) in the prefrontal cortex at PND7. Selective pharmacological 5-HT_{2A} blockade during the first postnatal week attenuated the aggressive behaviors and NMDAR deficits in ES-$MAOA^{Neo}$ mice, suggesting that 5-HT_{2A} hyperstimulation in early stages mediates aggression. However, it is unclear how NMDAR function in adulthood is affected by early 5-HT_{2A} receptor alterations.
Building on these premises, recent evidence has indicated that 5-HT_{2A} receptors inversely mediate the properties of metabotropic glutamate receptor 2 (mGluR2), a modulator of NMDAR function, through the formation of heteromeric complexes. Here we found that ES-$MAOA^{Neo}$ mice display reduced mGluR2 expression in the prefrontal cortex at PND 7. Pharmacological treatment with the mGluR2 positive allosteric modulator biphenylindanone A (BINA, 30 mg/kg, IP) during the first postnatal week elicited a robust reduction in aggression in ES-$MAOA^{Neo}$ animals. These findings suggest that the interaction between low MAOA activity and early stress in aggression is likely contributed by 5-HT_{2A} receptor-mediated disruption of mGluR2 during early stages.

Title: CORT 118335 and imipramine affect endocrine stress responses through different central mechanisms in male and female rats

Authors: *E. T. NGUYEN[1,3], J. L. CALDWELL[1], J. STREICHER[1], S. BERMAN[1], V. GHISAYS[1,2], C. M. ESTRADA[1,2], M. B. SOLOMON[1];

Abstract: Glucocorticoid dyshomeostasis is implicated in the pathophysiology of stress-related disorders (i.e., depression and anxiety). Glucocorticoids exert their biological effects by acting on Type I (mineralocorticoid MR) and Type II (glucocorticoid GR) receptors. Accordingly, compounds targeting both MR and GR are being pursued as putative antidepressants and anxiolytics. Women are twice as likely to suffer from stress-related disorders which may be due to sex differences in glucocorticoid production. For example, female rodents display heightened hypothalamic-pituitary-adrenal (HPA) axis activity (increased basal and stress-induced glucocorticoid concentrations) relative to male rodents. Previous data from our laboratory indicate that in most cases, compounds targeting GR dampen central (c-Fos), endocrine, and behavioral stress responses in males. Because of the dynamic interplay between MR and GR in regulating HPA axis tone, compounds targeting both receptor subtypes are of interest for stress-related pathology. In this vein, we have determined that CORT 118335, a dual selective GR modulator/MR antagonist, attenuates endocrine and metabolic stress responses in males. Given the female biased increase in endocrine and behavioral stress responses, this study sought to assess potential sex differences in the efficacy of CORT 118335 to modulate central (c-Fos), endocrine, and behavioral stress responses. To accomplish this goal, adult male and female rats were treated for 5 days with either vehicle, CORT 118335, or imipramine (tricyclic antidepressant) and exposed to restraint (Experiment 1) or forced swim test (FST) (Experiment 2) stress. CORT 118335 significantly dampened corticosterone stress responses in both sexes. Notably, imipramine dampened corticosterone stress responses in males, but increased corticosterone responses in females. The neuroendocrine stress dampening properties of CORT 118335 did not impact behavioral responses in the FST in either sex. CORT 118335 did not affect c-Fos expression in response to FST exposure in the hippocampus in males, but increased c-Fos expression in the CA1 in females. Interestingly, imipramine dampened c-Fos expression in

the hippocampus (CA1 and CA3) in males, but had no effect in these areas in females. Imipramine decreased c-Fos expression in the basolateral amygdala in both sexes, but increased c-Fos expression in the central amygdala in females only. These data indicate sex differences in the efficacy of these compounds to modulate central and endocrine stress responses and suggest differential recruitment of neural circuits during stress exposure in males and females.

Title: Corticosterone interferes with the response of TRHergic hypophysiotropic neurons to neural stimulation by attenuation of CREB phosphorylation. Mechanism involves GR interaction with catalytic subunit of PKA.

Authors: *I. SOTELO RIVERA, R. M. URIBE, A. COTE-VÉLEZ, J.-L. CHARLI, P. JOSEPH-BRAVO;
Inst. de Biotecnologia, UNAM, Cuernavaca, Mexico

Abstract: Cold exposure activates the hypothalamic-pituitary-thyroid (HPT) axis, increasing the expression of thyrotrophin releasing hormone (TRH) in hypophysiotropic neurons of the paraventricular nuclei of the hypothalamus (PVN), TRH release into the portal blood, thyrotrophin (TSH) and thyroid hormone concentrations in serum. Stress inhibits the activity of the HPT axis and we have recently shown that a previous stress exposure as well as a corticosterone injection interferes with the response of the HPT axis to acute cold (1). We have characterized the response elements of the TRH gene promoter that bind phosphorylated CREB (CRE), and the dexamethasone activated glucocorticoid receptor (GR) GRE, and demonstrated,

in primary cultures of hypothalamic cells that the combined treatment of PKA activators and dexamethasone interfere with the stimulatory effect of cAMP on TRH mRNA levels, on TRH transcription and on pCREB binding to CRE or GR binding to GRE (2); the latter process does not involve chromatin compaction (I. Sotelo-Rivera in preparation). We now evaluated the degree of CREB phosphorylation in PVN-TRH neurons of rats injected with corticosterone and exposed 1h to cold, measuring the total amount of cells expressing proTRH mRNA (detected by in situ hybridization) and pCREB, measured by immunocytochemistry. pCREB and TRHergic/pCREB neurons were increased by cold exposure but this was attenuated by corticosterone treatment. We confirmed in neuroblastoma cell line SH-SY5Y the results previously obtained in hypothalamic primary cell culture providing clear evidence for diminished pCREB in cells coincubated with forskolin and dexamethasone compared to forskolin alone. This combined treatment attenuated the proper translocation of GR or PKAc to the nucleus, compared to that observed with cells incubated only with forskolin or dexamethasone. Coimmunoprecipitation analyses confirmed protein-protein interaction between GR:PKAc. These results strongly support that the interaction of GR with PKAc might be responsible for the diminished CREB phosphorylation induced by cAMP or neuronal activation.

Title: Membrane-initiated nuclear translocation of the glucocorticoid receptor in hypothalamic neurons

Authors: *J. R. RAINVILLE, N. VASUDEVAN, J. G. TASKER;
Cell & Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Classical glucocorticoid receptor (GR) signaling as a transcription factor begins with ligand binding to the intracellular GR, release of the GR from chaperone proteins and dimerization, and translocation of the GR dimer to the nucleus, where the GR binds to the glucocorticoid response element (GRE) to regulate GRE-dependent transcription. We studied GR nuclear translocation via activation of a putative membrane GR in a murine hypothalamic cell line, mHypoE-N42, which expresses endogenous GR. We found that the GR synthetic agonist dexamethasone (Dex) conjugated to bovine serum albumin (Dex-BSA), which is membrane limited, is able to rapidly induce nuclear translocation of the GR. Using a GR antibody and intensity analysis of the nuclear-to-cytoplasmic ratio of GR-immunoreactivity, we found that nuclear translocation of GR was increased equally by Dex and Dex-BSA within 20 minutes. We confirmed the Dex- and Dex-BSA-induced GR translocation to the nucleus in primary hypothalamic neurons cultured from male P1 C57/BL6 mice. The Dex-BSA-induced nuclear translocation suggests the mobilization of an unliganded GR by signaling from the membrane. Akt activation blocked Dex-BSA-, but not Dex-mediated GR nuclear translocation, suggesting an alternative nuclear localization pathway may be initiated by membrane signaling. COS7 cells, which have no endogenous GR, were transfected with GR-GFP, and responded to both Dex and Dex-BSA treatment with GR nuclear translocation, suggesting that GR is sufficient for membrane-initiated nuclear translocation of GR. Dex treatment resulted in an increase in GRE-mediated transcription, detected with a GRE-luciferase assay, but Dex-BSA treatment for up to an hour did not result in an increase in GRE-luciferase activity. This suggests that the mobilization of the unliganded GR by Dex-BSA does not produce a transcriptionally active GR at the GRE, and serves as a control for the restriction of the Dex-BSA actions to the membrane. Thus, signaling from an unidentified membrane-associated receptor stimulates nuclear trafficking of GR, which is not transcriptionally active at the GRE. However, the unliganded GR may act on other transcriptional regulators to mediate some of the genomic effects of glucocorticoids.

Title: Intracellular signaling pathway of the membrane glucocorticoid receptor responsible for endocannabinoid modulation of excitatory synaptic inputs to hypothalamic neuroendocrine cells

Authors: *G. L. WEISS, C. HARRIS, S. DI, J. G. TASKER;
Tulane Univ., New Orleans, LA

Abstract: The hypothalamus controls homeostatic functions and acts as a site for crosstalk between brain circuits controlling fluid regulation, reproduction and the stress response. Glucocorticoids (GCs) secreted into the blood during stress activation of the hypothalamic-pituitary-adrenal (HPA) axis feed back on the hypothalamus to inhibit HPA activation and curtail the stress response. GCs have rapid inhibitory actions on neuroendocrine cells in the supraoptic and paraventricular nuclei (SON/PVN) by activation of a putative membrane glucocorticoid receptor and downstream synthesis of the endocannabinoid 2-arachidonoylglycerol (2-AG) and retrograde suppression of glutamate release at excitatory synapses. Here, we used whole-cell patch-clamp recordings and pharmacological manipulations in hypothalamic slices to further explore the intracellular signaling pathway responsible for 2-AG synthesis by activation of the membrane glucocorticoid receptor. Using the synthetic glucocorticoid dexamethasone (Dex), we found that the rapid glucocorticoid-induced 2-AG suppression of excitatory synaptic inputs to magnocellular neurons is dependent on the activation of PKA, PKC, ERK, and SRC signaling pathways, as well as on inositol triphosphate receptor-mediated calcium release. PKA was found to be upstream of PKC and ERK in the signaling pathway. Interestingly, while PKC inhibition blocked the glucocorticoid-induced endocannabinoid suppression of excitatory synaptic inputs, PKC activation alone was not sufficient to activate endocannabinoid release, which suggested a bifurcation in the intracellular signaling pathway. In support of this, phospholipase C activation stimulated the endocannabinoid-mediated suppression of excitatory inputs, suggesting that both phospholipase C-induced intracellular calcium release and PKC activation may be necessary for the endocannabinoid suppression of glutamate release. Preliminary findings and other published studies suggest that SRC is a potential link between PKA and phospholipase C. These results suggest a model of the signaling by the membrane glucocorticoid receptor in hypothalamic neuroendocrine cells that includes PKA activation, which in turn activates SRC and phospholipase C, which leads to intracellular calcium release and PKC activation, which causes ERK activation. ERK then stimulates 2-AG synthesis, which is released retrogradely at excitatory synapses to suppress glutamate release.

Title: Corticotropin-releasing hormone (CRH) regulation by acute glucocorticoid receptor activation and restraint stress

Authors: *A. TURNIDGE[1], R. J. HANDA[1,2];
[1]Dept. of Biomed. Sci., Colorado State Univ., Fort Collins, CO; [2]Dept. of Basic Med. Sci., Univ. of Arizona Col. of Med., Phoenix, AZ

Abstract: Activation of the hypothalamic pituitary adrenal (HPA) axis enables homeostatic responses to environmental changes by increasing glucocorticoid (GC) production. Yet, chronic HPA activation alters behaviors in rodents and increases risk for neuropsychiatric disorders in humans, emphasizing the importance of understanding its regulation. The principle regulator of the HPA axis is CRH, a glucocorticoid regulated neuropeptide synthesized and secreted by neurons of the hypothalamic paraventricular nucleus (PVN). Largely through binding to the glucocorticoid receptor (GR), GCs directly down-regulate PVN CRH expression to maintain basal and stress-induced HPA activity within homeostatic limits. Despite its significance, the molecular mechanisms underlying GC negative regulation of CRH remain poorly understood. To inhibit PVN *Crh* expression, GCs can influence *Crh* transcription either through direct DNA binding mechanisms or indirect interactions with other signal transduction pathways. Initially, using immunohistochemistry on CRH-cre:tdTomato (Ai14) mice in which CRH neurons are permanently tagged with a tdTomato fluorphore, we demonstrated expression of GR in virtually all CRH neurons of the PVN. To then determine if GRs are involved in the effects of acute glucocorticoid treatment on HPA activity and *Crh* expression we utilized digital droplet PCR (ddPCR) to allow us to measure, with a high degree of sensitivity and accuracy, absolute levels of CRH mRNA and primary transcript (heterologous nuclear RNA; hnRNA) in micropunched PVN. 48 hrs after adrenalectomy (ADX), male C57bl5/J mice were injected with RU28362 (0.4 mg/kg BW; a selective GR agonist) or Vehicle and then challenged with a 20-minute restraint stress. Mice were sacrificed immediately at the end of restraint (stressed mice) or after removal from their homecage (unstressed mice). Brains were frozen, thick coronal sections were taken, and the paraventricular nuclei were micropunched. Absolute levels of CRH mRNA and CRH hnRNA were measured using ddPCR. Results show that RU282362 treatment decreases CRH hnRNA compared to vehicle treated controls in unstressed animals ($P<0.05$). Following the 20'

restraint stress we also observed a significant decrease in CRH mRNA ($P<0.01$) and hnRNA ($P<0.01$), which was potentiated by RU28362. These data indicate that GCs can act through GR to rapidly suppress HPA activity and, moreover, restraint stress can also rapidly reduce CRH transcription. Our results ultimately suggest that GR plays a role in down-regulating PVN CRH in a context dependent manner.

Abstract: Anxiety disorders constitute a major disease and social burden worldwide, however many questions concerning the underlying molecular mechanisms still remain open. Besides the involvement of the major excitatory (glutamate) and inhibitory (GABA) neurotransmitter circuits in anxiety disorders, the stress system has been directly implicated in the pathophysiology of these complex mental illnesses. The glucocorticoid receptor (GR) is the major receptor for the stress hormone cortisol (corticosterone in rodents) and is widely expressed in excitatory and inhibitory neurons, as well as in glial cells. However, currently it is unknown which of these cell populations mediate GR-actions that eventually regulate fear and anxiety-related behaviors. In order to address this question, we generated mice lacking the receptor specifically in forebrain glutamatergic or GABAergic neurons by breeding $GR^{flox/flox}$ mice to *Nex-Cre*-mice or *Dlx5/6-Cre* mice, respectively. GR deletion specifically in glutamatergic, but not in GABAergic neurons induced hypothalamic-pituitary-adrenal axis hyperactivity, and reduced fear and anxiety-related behavior. This was paralleled by reduced GR-dependent electrophysiological responses in the basolateral amygdala. Importantly, viral-mediated GR deletion additionally showed that fear expression, but not anxiety, is regulated by GRs in glutamatergic neurons of the BLA. This

suggests that pathological anxiety likely results from altered GR signaling in glutamatergic circuits of several forebrain regions, while modulation of fear-related behavior can largely be ascribed to GR signaling in glutamatergic neurons of the BLA. Collectively, our results reveal a major contribution of GRs in the brain's key excitatory, but not inhibitory neurotransmitter system in the regulation of fear and anxiety behaviors, which is crucial to our understanding of the molecular mechanisms underlying anxiety disorders.

Title: Hippocampal neurons of dystrophic mdx mice respond differently to acute corticosterone treatment, both *In vitro* and *In vivo*, compared to wild type

Authors: *M. DE STEFANO[1,2], F. COSMI[1], I. BOZZONI[1], P. FRAGAPANE[3];
[1]Dept. of Biol. and Biotech. Charles Darwin, Sapienza Univ. of Roma, Roma, Italy; [2]Inst. Pasteur-Fondazione Cenci Bolognetti, Roma, Italy; [3]Consiglio Nazionale delle Ricerche, Inst. di Biologia e Patologia Molecolari, Roma, Italy

Abstract: Stress induces hypothalamus-pituitary-adrenal axis activation and increase in circulating glucocorticoids (GCs). Major brain target of GC is the hippocampus, in which acute and chronic stressful stimuli induce changes in neuronal activity and synaptic functions, relying on circuit remodelling largely mediated by gene expression modifications. GCs are anti-inflammatory, used as treatment in a variety of pathologies, including the Duchenne Muscular Dystrophy (DMD), a lethal, X-linked disease characterized by progressive muscular wasting consequent to lack of dystrophin (Dp427). Dp427 is a cytoskeletal protein highly represented in muscles, but also expressed by several brain regions, including hippocampus. As a consequence, DMD patients also experience various neurological disorders. In this study, we analysed whether GC treatment affected hippocampal neuron physiology, both *in vitro* and *in vivo*, focusing on the modulation of GC receptor (GR) expression and activation. GR mRNA and protein levels were

analysed in hippocampal neuron cultures from E18 wild type (WT) and dystrophic *mdx* mice, following acute incubation with either 1 μM or 10 μM corticosterone (CORT). In WT mouse neurons, GR mRNA levels significantly increased (1.5 folds) after both treatments, compared to control (vehicle alone). Differently, in *mdx* mouse neurons, mRNA levels increased slightly only after 1μM CORT incubation. Protein levels (Western blot) and intensity of immunolabeling for GR and active *p*GR (phosphorylated) changed accordingly to mRNA results. These first data suggest that the GC-GR intracellular signalling in *mdx* mouse neurons could be less effective compared to WT, negatively affecting GR mRNA synthesis and consequent post-transcriptional modifications. Alternatively, *mdx* mouse neurons could be "pre-sensitized" during gestation by blood-derived GCs of pregnant mothers, which are afflicted by mild myodegeneration and inflammation. This might induce a sort of negative feedback, as described *in vivo*. Acute *in vivo* treatment, gave different results. One hour after CORT injection, levels of *p*GR increased significantly in both WT and *mdx* mouse hippocampi. GR protein levels, instead, significantly decreased in WT mice (negative feedback response), but remained similar to control in *mdx* mice. This result reinforces the idea that GC-GR intracellular signaling, and/or stress modulation by other factors (i.e. sympathetic neuron activity), could be affected in dystrophic mice.

Title: Increased serotonin transporter expression by chronic stress in adrenal glands: a glucocorticoid-dependent effect

Authors: ***S. SHANKER**[1], N. SAROJ[2], M. NOYOLA-DIAZ[2], J. A. TERRÓN[2];
[1]FARMACOLOGIA, [2]Pharmacol., CINVESTAV-IPN, Ciudad DE Mexico, Mexico

Abstract: Chronic restraint stress (CRS) has been shown to increase acute stress-induced corticosterone (CORT) secretion in rats through a mechanism involving increased serotonin (5-HT) levels in the adrenal cortex. Similarly, chronic stress increases expression of 5-HT transporter (5-HTT) in the central nervous system. The purpose of the present study was to investigate whether 5-HTT-like immunoreactivity (5-HTT-LI) and expression may also be increased in the adrenal glands as a result of CRS exposure. In addition, we asked the question

whether potential CRS-induced changes in adrenal 5-HTT might be glucocorticoid-dependent. We examined the effect of CRS (20 min/day) as compared to control (CTRL) home cage conditions for 14 days on 5-HTT-LI in adrenal gland sections and 5-HTT protein levels in whole adrenal glands. On the other hand, the effect of a chronic 14-day treatment with CORT (20 mg/kg, s.c. per day for 14 days) as compared to vehicle (VEH; 1 mL/kg, s.c.) was also evaluated on 5-HTT-LI and 5-HTT protein in adrenal glands. 5-HTT-LI and 5-HTT protein levels in adrenal glands were determined, respectively, by immunohistochemistry and Western blot experiments using specific antibodies. CRS decreased body weight gain and relative thymus weight while increasing relative adrenal weight. Furthermore, CRS markedly increased 5-HTT-LI in the adrenal cortex as compared to CTRL treatment; this change involved an increased expression of 5-HTT as an increased amount of protein was detected in adrenals from CRS animals. Interestingly, whereas chronic CORT treatment induced a significant decrease of body weight gain and relative thymus weight, it evoked a significant involution of adrenal glands with respect to VEH treatment. Similar to CRS, chronic CORT treatment induced an increase of 5-HTT-LI in the adrenal cortex as compared to VEH as well as an increased amount of 5-HTT protein in whole adrenal glands. Together, these results suggest that CRS-induced up-regulation of 5-HTT in the adrenal glands is a glucocorticoid-dependent effect that might be associated with the mechanism of endocrine dysregulation leading to increased stress-induced CORT secretion in rats. Whether the adrenocortical 5-HTT could be a target of antidepressant 5-HT reuptake inhibitors remains to be investigated. CRS-induced adrenal gland hypertrophy seems to be a glucocorticoid-independent phenomenon.

Title: Opioid alterations of the reward circuit transcriptome involve glucocorticoid pathways within astrocytes

Authors: *R. A. PRZEWLOCKI, S. GOLDA, M. PIECHOTA, U. SKUPIO, M. KOROSTYNSKI, J. BARUT, M. TERTIL;
Mol. Neuropharm., Inst. Pharmacol PAS, Krakow, Poland

Abstract: Our previous study suggested that various drugs of abuse causing alterations of brain gene expression may involve glucocorticoid mechanisms. The aim of the study was to identify using next-generation sequencing the specific transcriptional alterations in the nucleus accumbens (Nac) in opioid-dependent mice and protracted withdrawal mice. We used C57Bl/6J mice injected acutely with morphine, or injected chronically with increasing dose of the drug twice a day. The transcriptome analyses were accompanied by the estimation of corticosterone level in the blood. Acute morphine (20 mg/kg 4h after injection) activated expression of several genes (Fkbp5, Zbtb16, Tsc22d3, Slc2a1, Plin4; FDR<0.1) regulated by GR-receptor, as well as activity-dependent genes (Fos,Fosl2) and group of genes such as Camk1g, Trim2 or Gpr83, which are suggested to be involved in neuronal plasticity. Prolonged treatment with morphine led to significant increase in GR-regulated genes and circadian clock genes (Per1, Per2, Per3) in the Nac of opioid-dependent mice. These changes were positively correlated with the peak of corticosterone in the blood. All the alterations in the transcriptome were transient and absent in protracted withdrawal mice that displayed a depressive–like behavior. In order to identify transcriptional changes in the specific striatal cell types of mice treated with a single dose of morphine or dexamethasone (a GR ligand) we isolated primary neurons and astrocytes utilizing MACS sorting technology. The study revealed that the vast majority of the GR genes are altered in astrocytes but not in neurons. The study indicates that stress and circadian systems in the Nac may affect the reward circuit using GR-dependent molecular pathways within astrocytes. The mechanism may be essential for development of opioid tolerance, dependence and addiction, and predict molecular targets for future therapies.

Title: Characterizing HPI axis response to acute stress using mutant zebrafish strains in the HPI axis receptors

Authors: *H. LEE[1], T. L. SCHWAB[2], R. G. KRUG, II[3], M. R. SERRES[2], A. N. SIGAFOOS[2], B. N. SUNDBERG[2], C. E. BULLARD[2], B. C. BERRY[2], K. J. CLARK[3,2];
[1]Mayo Grad. Sch. - Neurobio. of Dis., Rochester, MN; [2]Biochem. and Mol. Biol., Mayo Clin., Rochester, MN; [3]Neurobio. of Dis., Mayo Grad. Sch., Rochester, MN

Abstract: A hallmark pathophysiological change in neuropsychiatric disorders is alterations in the hypothalamic-pituitary-adrenal (HPA) axis activity. The HPA axis mediates vertebrate-specific systemic stress response (SR) through biphasic glucocorticoid receptor (GR) signaling comprising rapid non-genomic and slower genomic responses. It is largely unknown how changes in non-genomic GR response lead to lasting alterations in genomic response. Leveraging that the HPI (interrenal cells) axis in zebrafish is a functional homologue to the HPA axis, we hypothesized that zebrafish locomotor response to hyperosmotic stimulation (100 mM NaCl) is dependent on the HPI axis and rapid non-genomic GR signaling. This larval zebrafish locomotor assay provides a versatile platform that can dissect molecular components of non-genomic glucocorticoid signaling independently from any genomic response. By measuring locomotor response, genomic GR activation, cortisol levels, and drug response to selected antagonists using zebrafish mutants in the HPI axis, we have demonstrated that the locomotor response is dependent on *mc2r* (adrenocorticotropic hormone receptor). Both GR somatic mutants injected with TALENs and GR germline mutants have significantly decreased genomic response shown by the level of GR transcripts and glucocorticoid response element activation. However, rapid locomotor response to hyperosmotic stress is not decreased in GR germline mutants whereas significantly decreased in GR-targeting TALEN-injected fish. We are investigating translational GR isoforms potentially responsible for non-genomic response in germline mutants by targeting alternative loci in GR with different TALENs and TALEN-mediated precision knock-in strategies. Dissecting non-genomic and genomic GR response with genetic perturbation may lead to an establishment of a versatile assay system to investigate vertebrate SR and identification of components in non-genomic GR response.

Title: Effect of chronic corticosterone treatment on the amount and distribution of serotonin 5-HT7 receptors in rat adrenal glands

Authors: *N. SAROJ, S. A. MENDOZA-CONTRERAS, S. SHANKER, M. NOYOLA-DIAZ, J. A. TERRÓN;
Pharmacol., CINVESTAV-IPN, Ciudad de Mexico, Mexico

Abstract: Chronic restraint stress (CRS) increases acute stress-induced corticosterone (CORT) secretion in rats apparently through an ACTH-independent mechanism involving 5-HT7 receptors, and also increases the amount of 5-HT7 receptors in the adrenal cortex. Furthermore, ectopic expression of adrenocortical 5-HT7 receptors has been reported in human ACTH-independent glucocorticoid-producing adrenal tumors. In this study we asked the question whether CRS-induced changes in adrenocortical 5-HT7 receptors are glucocorticoid-dependent. The effect of a chronic 14-day treatment with CORT (50 mg/kg, s.c., per day) as compared to that of vehicle (VEH; 1 mL/kg, s.c., per day) was evaluated on: 1) 5-HT7 receptor-like immunoreactivity (5-HT7-RLI) in adrenal gland sections; 2) 5-HT7 receptor protein in whole adrenal glands; and 3) baseline (0 min) and restraint (10 and 30 min)-induced ACTH and CORT secretion. One day after completion of treatments (on day 15), one group of animals of both treatments were anesthetized and perfused with fixative via the ascending aorta; another group of VEH- and CORT-treated animals were decapitated and trunk blood, adrenal glands and thymus were collected. 5-HT7-RLI and 5-HT7 receptor protein levels in adrenal glands were determined by immunohistochemistry and Western blot assays, respectively, using specific antibodies; hormone levels were measured using commercially available Elisa kits. Chronic CORT treatment significantly decreased body weight gain and thymus weight; in contrast to observations in chronically stressed animals however, chronic CORT evoked a significant involution of adrenal glands with respect to VEH treatment. Chronic CORT treatment induced a modest but noticeable increase of 5-HT7-RLI in the adrenal cortex as compared to VEH with the signal predominantly located in adrenocortical *zona fasciculata* cells. In addition, a significant increase in the amount of adrenal 5-HT7 receptor protein was detected in CORT- as compared to VEH-treated animals. Finally, chronic CORT treatment evoked a significant decrease of stress-induced secretion of ACTH at 10 min of restraint along with a trend towards a decrease of ACTH levels at 0 min (baseline) and 30 min of restraint; also, significantly higher CORT levels were detected at 0 min, but not at 10 and 30 min of restraint in CORT-treated animals. Results support the notion that CRS-induced increase of adrenocortical 5-HT7 receptors is partly dependent on glucocorticoids; the development of hypercorticolemia during chronic stress however may involve additional mechanisms further to increased 5-HT7 receptor expression in adrenocortical steroidogenic cells.

Title: Early life trauma has life-long consequences for sleep

Authors: *M. P. LEWIN[1,3,4], R. M. SULLIVAN[3,2], D. A. WILSON[3,2];
[1]NYU, New York City, NY; [2]NYU, New York, NY; [3]Emotional Brain Inst., Nathan Kline Inst., Orangeburg, NY; [4]Sackler, NYU Sch. of Med., New York, NY

Abstract: Early life adversity is linked increased the incidence of later life psychiatric diseases related to anxiety, depression, anger, and antisocial behaviors. Individuals who have experienced trauma in early life are also reliably found to have a higher incidence of sleep problems, however, these human data generally rely on self-report and actigraphy, thus they provide limited insight into potential specific sleep mechanisms affected, and it remains unclear whether sleep disturbance is a consequence of psychiatric outcomes, or rather, a cause. Here, we used a naturalistic model of early life trauma in the rat where mothers are supplied insufficient wood shavings for nest building during specific postnatal periods of pup development (from 8-12 days old). The dearth of resources produces aberrant maternal behavior and harsh, mistreatment of the pups. Though they do not suffer from abnormal postnatal weight gain, pups in this low shavings (LS) condition exhibit robust behavioral and neurological disturbances across the lifespan, including depressive-like behavior, disordered social behavior, impaired emotional learning (fear conditioning), as well as altered neural function. We monitored sleep-wake function and circadian rhythms at 3 different points across the lifespan, recording from 7 age-matched LS-CON pairs in each age group: adolescence (PN 21-30), young adulthood (2-4 months old), and older adulthood (6-10 months old), using telemetry cortical local field potential recordings and EMG. Data were collected continuously for each pair for up to 72 hrs. Our initial results demonstrate not only a difference in sleep physiology after early life trauma, but a trajectory of sleep dysfunction that changes across the lifespan. Postnatally abused animals show abnormally consolidated NREM sleep in early life (longer bouts of NREM sleep, greater NREM delta power) which shifts to NREM deficiency (NREM fragmentation, reduced NREM delta) in older adulthood. Future experiments will examine whether this sleep pathology may be bidirectionally

related to the neurobehavioral deficits associated with early life trauma, and specifically whether sleep repair can ameliorate its lasting cognitive/emotional consequences.

Title: Effects of maternal maltreatment on parvalbumin cells in the basolateral amygdala

Authors: ***A. N. SANTIAGO**[1,2], K. LIM[1], M. OPENDAK[1,2], C. AOKI[1], R. SULLIVAN[1,2]; [1]New York Univ., New York, NY; [2]Nathan Kline Inst., Orangeburg, NY

Abstract: Early life trauma, particularly during the developmental sensitive period for infant attachment, is a major risk factor for later-life vulnerability to psychiatric disorders characterized by heightened fearfulness. The basolateral amygdala (BLA), long known for its integral role in threat response, has recently been shown to be hyper-responsive following early life abuse from the caregiver. However, the anatomical substrates that mediate increased responsiveness of the BLA at a synaptic level are unknown. Here, we use a rodent model of maternally-induced trauma to investigate the hypothesis that abuse during critical periods of neurodevelopment directly alters the inhibitory neurocircuitry for disinhibition of the BLA. Fast-spiking parvalbumin positive (PV+) inhibitory interneurons are known to play a major role in defining critical periods of neurodevelopment and have recently been shown to play a critical role in BLA fear response. A class of extracellular molecules referred to as perineuronal nets (PNNs), have been shown to end critical periods of neurodevelopment by locking axo-somatic synapses onto PV+ somata, thus preventing synaptic rearrangement onto these cells. Dissolution of PNNs has been shown to reopen critical windows for plasticity, allowing synaptic rearrangement onto PV+ cells to restore healthy function following deprivation. We hypothesize that early life abuse induces increased inhibitory synaptic input onto PV+ cells in the BLA, thus facilitating disinhibiton, which becomes locked by PNN development. Here, we report the effects of 5 days of maternally-induced trauma on amygdala hyperactivity in the BLA of rats at 3 specific ages: post-trauma (PN14), during post-trauma recovery (PN18) and at weaning (PN23). We then used light

microscopy to measure PNN formation over PV+ cells, as well as electron microscopy to quantify axo-somatic input onto PV+ neurons. Group differences are reported.

Title: Chronic early life stress reduces cognitive flexibility and orbitofrontal cortex axonal integrity in mid-aged mice.

Authors: ***C. A. OOMEN**[1,2], H. AMIRI[2], H. J. KRUGERS[1], J. C. GLENNON[2];
[1]SILS - Ctr. for Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands; [2]Cognitive Neurosci., Donders Institute, Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Adversity early in life has been found to increase the risk for developing stress-related disorders in adulthood, such as depression and anxiety disorders. One of the major moderators in this is the quality of parental care. In rodents, disrupting maternal care can result in a stress-sensitive phenotype and learning and memory deficits, often studied at the level of the hippocampus. However, less is known about how early life stress impacts the prefrontal cortex and executive functions such as cognitive flexibility, especially in older animals.
In order to address this, we studied the effects of chronic early life stress (ELS) on reversal learning and orbitofrontal cortex structure in mice. ELS was induced by limiting the availability of nesting and bedding material from postnatal day (PND) 2-9 which results in fragmented maternal care and a stress sensitive phenotype in the offspring later in life. Between 11 and 15 months of age, ELS and control mice were tested on instrumental conditioning, reward-based visual discrimination learning and subsequent reversal learning using a touchscreen-equipped operant chamber. After testing behaviour, mice were scanned using an 11.2T MRI scanner. Single voxel ^{1}H magnetic resonance spectroscopy (MRS) and diffusion tensor imaging (DTI) experiments were performed to assess potential metabolic and structural changes in the orbitofrontal cortex and dorsomedial striatum. Finally, detailed morphological analysis of these

areas was performed post-mortem, by 3D reconstruction and analysis of dendritic complexity of individual (Golgi-stained) neurons.
We found that ELS does not impair acquisition of a visual discrimination paradigm. However, ELS reduces cognitive flexibility as reflected by increased correction errors during reversal learning of the acquired contingencies. This was paralleled by a decrease in the fractional anisotropy (FA) in the orbitofrontal cortex, indicative of changes in axonal architecture, while no differences in dendritic morphology were found. We conclude that ELS has long-term effects on executive function, which are present at mid-age, possibly mediated by differences in axonal projections.

Title: Effects of early postnatal undernutrition on affective behavior and conditioned fear in male and female Sprague Dawley rats

Authors: *R. M. DE GUZMAN, L. M. COLON, A. M. POULOS, J. L. WORKMAN; Psychology, Univ. at Albany, State Univ. of New York, Albany, NY

Abstract: Undernourishment during critical periods of brain development has long-term consequences for brain and behavior. In humans, early childhood malnutrition increases depression and suicidal thoughts in adolescents, as well as externalizing behaviors compared with well-nourished children. In rats, early-life undernutrition restricts growth and impairs spatial navigation. The hippocampus, which is involved in memory, stress, and affect, is particularly affected. For instance, early-life undernutrition decreases the total number of granule cells and cell proliferation in the dentate gyrus. However, rodent studies investigating hippocampal plasticity following early-life undernutrition have mainly investigated males. This study aimed to determine the behavioral and neural changes that occur following early postnatal undernutrition in male and female Sprague Dawley rats during adolescence and adulthood. Many rodent models of early-life undernutrition restrict food or nutrient availability to dams, which can alter maternal care. In this study, dams underwent either thelectomy (surgical removal of teats to inhibit milk letdown), sham surgery, or no surgery (control). During the postnatal period,

offspring born to thelectomized and sham rats were rotated every 12 h to restrict feeding and offspring from control dams were not rotated and had unrestricted feeding. All dams had ad libitum access to food. Maternal care did not significantly differ between groups. We tested whether early postnatal undernutrition affected fear acquisition and extinction in fear conditioning and affective behaviors in the forced swim test and open field. Early postnatal undernutrition reduced body mass throughout lifespan and reduced distance traveled in the open field. When distance traveled was controlled for, early postnatal undernutrition increased entries into and time spent in the center of the open field in adolescents only, which suggests early postnatal undernutrition reduces anxiety-like behavior. Data on fear conditioning, forced swim test, and hippocampal neurogenesis will be presented. This research will reveal how early-life undernutrition influences behavior and brain plasticity in males and females and has implications for humans who experienced early life undernourishment.

Title: Relation between maternal separation during breastfeeding in rats and giardia infection

Authors: M. F. GERENA-CRUZ[1], D. G. GARCÍA LAGUNA[3], *Z. DUENAS[2]; [1]Ciencias Fisiológicas, [2]Univ. Nacional De Colombia, Bogota DC, Colombia; [3]Ciencias Fisiológicas, Univ. Nacional de Colombia, Bogotá D.C., Colombia

Abstract: It has been reported in studies with rodents that maternal separation during breastfeeding (MSDB) generates changes at behavioral and physiological levels of the offspring. The breastfeeding, it has been shown that it provides benefits as a protective factor on gastrointestinal parasitic infections. Currently there are no reports correlating the disruption of breastfeeding caused by maternal separation and the development of intestinal infection for Giardia. The aim of this study was to establish the effect of maternal separation during breastfeeding on the Giardia infection in Wistar rats. MSDB protocol was performed from postnatal day 1 to postnatal day 21 for 360 minutes a day (180 in the morning and 180 in afternoon) with reverse light cycle. On postnatal day 22, the pups were distributed by sex and

treatment; Group 1 (MSDB with infection), Group 2 (MSDB without infection), Group 3: (No MSDB with infection) and Group 4 (No MSDB without infection). Infection induction at postnatal day 25 was performed through oral ingestion of Giardia Lambia cysts isolated. The course of infection was analyzed by direct quantification of cysts in the feces, which were collected during the days 5, 10, 15 and 20 post-infection. Intestine samples were taken for future analysis. The results show that rats with MSDB have more infection compared with non MSDB rats ($p < 0.05$). The analysis for sex of the release of cysts indicates that MSDB males have more infections than control males ($p<0.05$). Additionally, was found statistically significant differences for sex, among the four study groups with their respective controls, between group 1 Vs. group 2 and group 3 Vs. group 4 ($P <0.05$). The analysis of intestinal tissue of rats is currently under study in order to analyze possible histological changes in the small intestinal mucosa based on the infection. Preliminary results suggest that maternal separation with the interruption of breastfeeding predisposes to develop a Giardia infection, increasing the risk of disease in the intestinal tissue. These data supports that breastfeeding as a protective factor in the development of intestinal infections by this parasite.

Title: Early-life obesity increases susceptibility to post traumatic stress and disrupts hippocampal structure

Authors: *J. D. VEGA-TORRES[1], P. KALYAN-MASIH[2], C. MILES[2], E. HADDAD[2], S. RAINSBURY[2], M. BAGHCHECHI[2], A. OBENAUS[2], J. D. FIGUEROA[2];
[1]Basic Sci., [2]Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract: Early-life traumatic stress and obesity co-occur frequently and have been identified as major risk factors for anxiety disorders. Surprisingly, preclinical studies examining how obesity disrupts the ability of the brain to cope with traumatic stress are lacking. The objective of this study was to determine whether an obesogenic Western-like high-fat diet (WD) predisposes rats to posttraumatic stress. Adolescent Lewis rats (postnatal day, PND, 28) were fed *ad libitum* during eight weeks with either the experimental WD diet (41.4% kcal from fat) or the control diet (CD; 16.5 % kcal from fat). Posttraumatic stress responses were evaluated at one week following exposure to a predator odor threat by using standard behavioral paradigms. The

elevated plus maze and the open field test revealed increased anxiety-like behaviors in the rats consuming the WD when compared to control animals at one-week posttraumatic stress ($p < 0.05$). Magnetic resonance imaging (MRI) showed a significant 20% reduction in the total hippocampal volume of animals fed the WD when compared to controls. The reduced hippocampal formation was associated with increased behavioral indices of anxiety, neuroinflammation, and FKBP51 protein levels. Notably, we found asymmetric hippocampal vulnerabilities to the WD and stress, particularly in the ventral and left hippocampus. This study shows how WD intake during early life impacts key substrates implicated in posttraumatic stress disorder (PTSD). Understanding how trauma and obesity affect the developmental trajectories of the stress neurocircuitry is critical, as stress susceptibility imposes a marked vulnerability to neuropsychiatric disorders.

Title: Consequences of neonatal maternal separation on the efficacy of the oxytocinergic control of pain

Authors: ***M. MELCHIOR**, P.-E. JUIF, N. PETIT-DEMOULIÈRE, V. CHAVANT, Y. GOUMON, V. LELIÈVRE, A. CHARLET, P. POISBEAU;
INCI, Strasbourg, France

Abstract: Prematurity is a huge public health issue, since it concerns as many as 1/10 birth in the world. Most of the time, an integration in intensive care units is required for these preterm newborns, where they are submitted to repeated painful procedures and to maternal separation (MS) possibly altering the mother-infant link. In both human and animal studies, these perinatal events are known to have detrimental effects on the development of the newborn, especially on brain maturation. Clinical data strongly suggests that preterm babies are indeed at high risk of developing, at adulthood, neuropathologies affecting cognitive functions, chronic anxiety, depressive states, chronic pain and visceral dysfunctions. Hypothalamic changes, among other mechanisms, may explain the high prevalence of anxiety, stress disorders, visceral hypersensitivity, cognitive and social impairment seen after MS. We hence chose to study the consequences of MS on hypothalamic functions, with a particular interest in oxytocin (OT), a

neurohormone modulating pain responses as well as regulating social and maternal behavior. MS is performed by separating Wistar rat pups from their mother 3 hours per day, between postnatal day 2 and 12 (P2-P12), mimicking some developmental and environmental components of preterm birth. Combining behavioral, electrophysiological and molecular studies, we identified a strong hypersensitivity to mechanical and thermal hot stimulation and a clear dysfunction of hypothalamic descending controls of pain after MS. In vivo electrophysiological recordings of wide dynamic range neurons in the spinal cord of MS rats revealed that OT failed to exert an efficient inhibitory control on nociceptive processing. This result was further confirmed on freely-moving animals since stress-induced analgesia mediated by OT receptors could not be observed. In carrageenan-induced inflammatory pain, OT inhibitory controls were also inefficient since MS animals displayed more intense pain symptoms and had a longer-lasting expression of them.
Altogether, behavioral and electrophysiological results strongly suggest that the descending inhibitory control of pain is impaired in adult rats previously submitted to MS. Lack of efficacy of OT in non-painful and painful stress conditions may easily explain several maladaptive behaviors observed after MS in these animals. The spinal mechanisms underlying these alterations are currently under investigation but may also affect supraspinal structures expressing OT receptors.

Title: Early-life predictors of the effects of repeated maternal deprivation on the development of 129Sv mice

Authors: *O. V. BURENKOVA, E. A. ALEKSANDROVA, I. Y. ZARAYSKAYA;
P.K. Anokhin Res. Inst. of Normal Physiol., Moskva, Russian Federation

Abstract: Maternal care during early life influences physiology and behavior of adult animals via epigenetic mechanisms. In particular, maternal deprivation of neonatal mice and rats has long-term dramatic impact on offspring development. Previously we revealed immediate and

long-lasting adverse effects of repeated maternal deprivation (45 min daily on postnatal days (PND) 3-6) on physiology and behavior of 129Sv mice. In the present work, we investigated hormonal and behavioral factors which could cause these changes.
We analyzed two early-life stress markers: pup ultrasonic vocalizations (USVs) rates on PND 3 & 6, and the levels of corticosterone in pups on PND 7. In addition, we examined maternal behavior in the home cage for 30 min before deprivation and for 30 min immediately after the reunion with the pups on PND 3 and 6. This allowed us to reveal the correspondence between distinct acoustic properties of different signal types and the types of maternal behavior.
Maternal deprivation for 45 min/day from PND 3 to PND 6 resulted in changes in maternal behavior, which was accompanied by hormonal and behavioral stress response in 129Sv pups. Specifically, we found an increase in corticosterone levels and USV rates during deprivation in comparison with baseline levels and with non-deprived pups. It is important to emphasize that the elevation of corticosterone levels and USV rates showed no recovery to the baseline levels for 30 min after the reunion. In addition, the increase in USV rates from PND 3 to PND 6 was revealed in deprived pups, but not in non-deprived pups.
Our results suggest that hormonal and behavioral responses described above might be the early-life predictors of the long-term adverse effects of repeated 45-min maternal deprivation on the development of 129Sv mice.

Title: Increased corticostreone response on postnatal day 11 does not alter emotional or hormonal stress responses of adult male rats: role of maternal care

Authors: *D. SUCHECKI, A. CONSOLI, R. CABBIA;
Univ. Federal de Sao Paulo, Sao Paulo, Brazil

Abstract: Disruptions of mother-infant relationships during the stress hyporesponsive period (SHRP) can alter the programming of behavioral and physiological responses to stress in adulthood. We investigated whether sustained corticosterone secretion during the SHRP induced by maternal deprivation on postnatal day (PND) 11 altered behavioral and hormonal stress responses in adult male rats. To this purpose, 33 mixed sex litters were used: 16 were undisturbed (control group = CTL) and 17 were deprived from their mothers for 24 h (deprived group = DEP) on PND 11. Two hours before the end of the deprivation period, one half of the litters were injected with saline (0.1 ml/10 g of body weight) to induce an intense and sustained CORT secretion (DEP+SAL, N = 7), whereas the other half was not stimulated (DEP+NSAL, N = 10). NDEP litters were also distributed into NSAL (N = 8) and SAL subgroups (N = 8). At the end of the deprivation period or immediately after the SAL injection for NDEP group, litters and mothers were reunited and maternal behavior was assessed for 1 h at 10:00 h, 14:00 h and 17:30 h. Every 3 min, the cage was observed and the predominant behavior of the mother was registered, making up for 20 observations/h. Behavioral tests begun on PND 70, when males were assessed in the following tests: novelty suppressed feeding (measures the motivation and anxiety to eat in novel environments), sucrose negative contrast test (measures the capacity of the animal to perceive a sudden change in hedonic value of a palatable solution), social investigation (evaluates the motivation to explore an unknown conspecific) and elevated plus maze (classic test of anxiety-like behavior), after which rats were decapitated in four different time-points for blood sampling: Basal (not-tested in the behavioral tasks) or 15 min, 45 min or 70 min. The main results of this study were: 1) Maternal deprivation (regardless of the stressful stimulus) increased arched-back nursing and anogenital licking/grooming in the first hour upon reunion of the litters and mothers; 2) DEP+SAL males displayed smaller latency to start eating in the NSF test, but the amount consumed was the same for all groups; 3) There were no changes in the other behavioral tests; 4) All groups had a similar stress response profile, with the peak corticosterone secretion occurring 15 min after the stressor. These findings suggest that increased maternal care induced by separation of the litters from their mothers for 24 h may have protected adult animals from displaying overtly behavioral and hormonal stress responses.

Title: Alternation of fundamental frequency of ultrasonic vocalizations by neonatal rats in response to distance from their mother

Authors: *M. NAKAMURA[1], M. TANICHI[2], H. TODA[2], S. MITSUYOSHI[1], S. SHINOHARA[1], Y. OMIYA[3], K. SHIMIZU[4], A. YOSHINO[2], S. TOKUNO[1];
[1]Verbal analysis of pathophysiology, The Univ. of Tokyo, Yokohama-shi, Japan; [2]Dept. of Psychiatry, Natl. Defence Med. Col., Tokorozawa-shi, Japan; [3]PST inc., Yokohama-shi, Japan; [4]Div. of Behavioral Sci., Natl. Defence Med. Col. Res. Inst., Tokorozawa-shi, Japan

Abstract: Neonatal rats elicit caregiving behavior of their mothers using ultrasonic vocalizations (USVs). Separation of neonatal rats from their mothers can cause severe impact on their survival therefore it is assumed that separated neonatal rats will change their behavior to call their mothers according to estimated distance from their mother.
We recorded USVs of neonatal rats with varying distance from their mothers and analyzed changes in features of the USVs according to the distance. A neonatal rat and its mother were put in two cages separately. In first half of the recording we gradually increased the distance between the two cages. In latter half of the recording, we gradually decreased the distance between the two cages. We recorded the USVs for five minutes per every condition (distance). We evaluated the USVs with respect to their fundamental frequency.
We found that USVs of higher fundamental frequency were observed more often as we increase the distance between the two cages. In contrast, we confirmed that USVs of higher fundamental frequency were decreased as the two cages got closer in the latter half of the recording. Average of fundamental frequency also altered responding to this tendency whence the average peaked when the distance was largest.
These results infer that the change in the shift of the fundamental frequency of USVs by neonatal rats does not depend much on duration of separation from their mothers if the dependency on duration of separation is monotonic. Also behavior of the mother rats altered depending on the distance from their pups. These findings suggest that interaction between neonatal rats and their mothers separated from each other change their phase of calling and searching with their estimated distance. The results imply a possibility of predicting psychological stress on neonatal rats from their USVs.

Title: Perinatal SSRI exposure affects social behavior and related neurobiology in juvenile rat offspring

Authors: *M. GEMMEL[1], M. HAZLETT[1], E. CSÁSZÁR[3], C. VESEL[1], S. DE LACALLE[2], J. PAWLUSKI[1,4];
[1]Dept. of Biol. Sci., [2]Dept. of Biomed. Sci., Ohio Univ., Athens, OH; [3]Dept. of Reproductive Toxicology, Inst. of Exptl. Pharmacol. and Toxicology, Slovak Acad. of Sci., Bratislava, Slovakia; [4]Univ. of Rennes 1, Rennes, France

Abstract: Selective serotonin reuptake inhibitor medications (SSRIs) are the most common antidepressant medications for treatment of maternal mood disorders during the perinatal period. SSRIs cross the placental barrier and are present in breast milk, suggesting an impact on offspring development. Previous clinical research shows effects of SSRI exposure on children's social behavior; however, further work is needed to determine how perinatal SSRI exposure may affect social behaviors and behavior-related neurobiology. The aim of the present study was to determine how perinatal exposure to fluoxetine, a popular SSRI used during the perinatal period, affects social play behaviors and related neurobiology in the hippocampus and prefrontal cortex of juvenile male and female rat offspring. To mimic aspects of maternal depression, prior to breeding, Sprague-Dawley rat dams were subjected to chronic unpredictable stress, and were treated with fluoxetine (10mg/kg/day) or vehicle via oral administration from gestational day 10 to postnatal day 21. Juvenile male and female offspring from the following four groups were used: 1. Control+Vehicle, 2. Control+Fluoxetine, 3. Preconception Maternal Stress+Vehicle, 4. Preconception Maternal Stress+Fluoxetine. Offspring underwent a social interaction test one week after weaning, and brains were preserved for immunohistochemical work. Results show that perinatal fluoxetine exposure, regardless of maternal stress, had a more remarkable effect on juvenile female offspring resulting in increased social behaviors, increased presynaptic immunoreactivity, via synaptophysin, in the dentate gyrus of the hippocampus and decreased postsynaptic immunoreactivity, via PSD95, in the prefrontal cortex. Perinatal fluoxetine exposure also increased social behavior in juvenile male offspring, but to a lesser degree. Exposure to maternal stress prior to conception had a more pronounced effect on juvenile male offspring resulting in decreased presynaptic immunoreactivity in the dentate gyrus of the hippocampus and decreased postsynaptic immunoreactivity in the prefrontal cortex. This work

indicates an effect of perinatal SSRI exposure on brain and behavior, but that these effects are often sexually differentiated. Further work will investigate other measures of plasticity as well as how these early life exposures affect the hypothalamic-pituitary-adrenal system. Investigating the impact of SSRI exposure on neurobehavioral development will further our understanding of the benefits and risks of these medications during the perinatal period.

Title: Sex specific cognitive deficits following early life stress: A role for parvalbumin in the orbitofrontal cortex

Authors: ***H. GOODWILL**, S. LIN, G. MANZANO-NIEVES, A. COHEN, K. BATH; Brown Univ., Providence, RI

Abstract: Adverse early life experiences influence emotional development and increase the risk for and severity of affective pathology. Women are at increased risk of developing stress-associated pathology, and have a two-fold higher risk of developing PTSD, anxiety disorder, and depression when compared with men. In a mouse model of early life stress (ELS), we found that female mice, but not male mice, go on to develop a depressive-like phenotype. Depressive pathology is highly comorbid with cognitive impairments and inflexibility, which is thought to result predominantly from altered frontal lobe function. The prefrontal cortex (PFC), which orchestrates the integration of cognitive and emotion through cortical and subcortical pathways, is especially sensitive to ELS. However, it is largely unknown whether ELS effects cognitive function in a sexually dimorphic manner, and what the underlying mechanisms of disruption are. Here, we use a combination of behavioral, molecular, and optogenetic approaches to examine a possible mechanism underlying sex-specific vulnerability following ELS in mice. Using an attentional set-shifting task, we found that female mice exposed to ELS were impaired on the rule-reversal phase of learning ($p < 0.01$), and observed no differences between groups during initial rule learning or extra-dimensional rule shifts. Fast spiking (FS) GABAergic interneurons containing the calcium binding protein Parvalbumin (PV), have been implicated in PFC-

dependent cognitive functioning, and have been shown to be sensitive to ELS. However, their specific role in reversal learning and cognitive function following ELS remain unclear. Here, we find a decrease in PV and GAD67 mRNA levels in the orbitofrontal cortex (OFC) of female mice following ELS. To test a potential role for PV interneurons in reversal learning, we employed an optogenetic approach using halorhodopsin to selectively silence PV+ cells in the OFC during different test phases of the attentional set shifting task. Findings related to these experiments will be discussed, and have implications for understanding the molecular and cellular mechanisms underlying stress-induced impairments in cognitive function, and sex differences in risk for pathology development.

Title: Early life stress alters the development of the fear recall and expression in pre-adolescent mice

Authors: *G. MANZANO-NIEVES[1], K. G. BATH[2];
[1]Dept. of Neuroscience, Brown Univ., Providence, RI; [2]Dept. Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Acute traumatic events and/or prolonged stress incurred early in life increase the risk of developing anxiety and depressive-like behaviors in both humans and animal models. However, the effect of early life stress (ELS) on neural development, and their consequences on circuit activation are not well understood. To investigate the effect of ELS on the development of the conditioned fear circuit we took advantage of an ELS paradigm that consisted of reducing maternal access to bedding and nesting materials during postnatal days 4 to 11 (Rice CJ et al., 2008). Subsequently, we investigated the development of fear learning and expression in control reared and ELS mice using an auditory fear conditioning paradigm. Briefly, male and female

mice were exposed to six tones (30s), each of which co-terminated with a foot-shock (1s; 0.57mA) on postnatal day (P) 16, 21, 28, or 50. Interestingly, at postnatal day 21 both ELS reared mice showed significantly diminished levels of freezing during recall testing at 6 hrs. (% time freezing: 45% Controls vs. 17% ELS; $P < 0.01$) and 24 hrs. (% time freezing: 65% Controls vs. 22% ELS; $P < 0.01$) but not at 7 days (% time freezing: 62% Controls vs. 53% ELS; $P = 0.33$) post conditioning. To study the changes in the development of the fear circuit induced by ELS we used a combination of distinct immunohistochemical markers to study late developing neurons. Interestingly, we found that P21 ELS animals had a significantly increased number of parvalbumin positive neurons (PV+; late differentiating inhibitory neurons) when compared to controls at P21 and ELS animals at P16 in both the amygdala and hippocampus but not in the medial prefrontal cortex (mPFC). This data suggests that ELS animals may be undergoing early maturation of subcortical, but not cortical structures, which may be causing an impairment in the mPFC - amygdala communication, resulting in the inability of ELS mice to express the conditioned memory at normal levels. To test if ELS animals could express a freezing response when basal lateral amygdala (BLA) activity is increased during each tone of fear conditioning, we optogenetically inhibited, using halorhodopsin, PV+ neurons in BLA. The inhibition of PV+ neurons in BLA at P21 resulted in a significant increase of freezing in ELS animals (% time freezing: 41% ELS Controls vs. 76% ELS Halo; $P < 0.02$) to levels comparable to controls (% time freezing: 69% UHC Controls). However, it remains unclear whether ELS effects the development of mPFC inputs into BLA or whether ELS may be resulting in lowered responses to fear condition as a result of heightened activity thresholds in BLA or downstream structures. Ongoing experiments aim at answering these questions.

Title: Brain-derived neurotrophic factor: a potential driver of the accelerated neurobehavioral development induced by early-life stress

Authors: *K. B. HUNTZICKER[1], G. MANZANO-NIEVES[1], T. M. MOSS[1], K. G. BATH[2]; [1]Dept. of Neurosci., [2]Dept. of Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Exposure to early life stress is known to increase the risk of anxiety-like and depressive-like behaviors in both human and mice models. While a great deal of research has investigated the long-term implications of early-life stress (ELS) in adulthood, its effects on development and the mechanisms driving aberrant outcomes remain largely unknown. We hypothesize that these outcomes are the consequence of stress-associated changes in the timing of neurodevelopmental events, ultimately impacting circuit structure and function. We further predict that alterations in neurodevelopment result from atypical expression of trophic factors (BDNF), which drives an acceleration in maturation. To test this hypothesis, we used a mouse model of ELS, maternal bedding restriction from postnatal days (P) 4-11. Using this manipulation, we have previously found that ELS leads to an earlier emergence of the latent period of contextual fear inhibition and earlier expression of markers of circuit maturation. Here, we collected hippocampal brain tissue from mice across early development and assessed the effects of ELS on neurotrophin expression, and found that ELS was associated with an earlier rise in BDNF as well as suppressed expression of TrkB.T1 (an endogenous dominant negative receptor for BDNF), as assessed by realtime qPCR. Using immunohistochemistry, we also observed an earlier onset of parvalbumin expressing neurons (PV+), compared with control reared mice, a process that is known to be initiated by developmental changes in BDNF levels. To test if changes in BDNF are necessary and sufficient to alter the timing of neural and behavioral development following ELS, we employed a genetic approach in which we attempted to block developmental changes in BDNF signaling following early life stress or if elevating BDNF in the absence of stress was sufficient to drive aberrant development. Specifically, we tested if the presence of the BDNF Val66Met polymorphism, a model of diminished BDNF release, blocks accelerated neurodevelopment following ELS as well as if genetic deletion of the TrkB.T1 receptor, in the absence of ELS, leads to accelerated neurodevelopment. Based upon preliminary results, BDNF is both necessary and sufficient for ELS associated changes in the timing of neurodevelopment.

Title: Effects of maternal deprivation on anxiety-like behaviors in wistar and wistar kyoto rats

Authors: *C. VEGA BAUTISTA, C. LÓPEZ RUBALCAVA;
Neuropharm. and Exptl. Therapeut., CINVESTAV, Mexico City, Mexico

Abstract: Several studies have shown that the development of anxiety disorders in adulthood might be a consequence of chronic stress in early life. In Wistar rats it has been reported that after the exposure to maternal deprivation, animals present depression- and anxiety-like behaviors that persist into adulthood. The Wistar Kyoto (WKY) rat strain, widely used to study hypertension related diseases, has also been proposed as a good model for the study of depression- and anxiety-like behavior, because of its exacerbated responses to stressors stimulus evidenced by increased levels of ACTH and corticosterone. The objective of the present study was to compare the effects of chronic stress during early life development in adult Wistar and WKY rats, using as chronic stressor the maternal deprivation protocol. Briefly, this protocol consists in separating the dams from their pups during 3 hours daily from postnatal day (PND) 7 to 21. In control groups, the litters stayed together until the weaning day. To avoid hormonal fluctuations only male rats were chosen. The animal model used to study the anxiety like-behavior was the defensive burying test. Animals were subjected to this test at PND 90. The results showed that maternal deprivation increases anxiety-like behaviors in Wistar rats but decreased them in the WKY strain. The WKY rats showed increased general activity and exploratory behavior. Results suggest that the WKY rat strain presents a different adaptive mechanisms to chronic stress stimulus during early life experiences.

Title: Behavioral, endocrine and physiological effects of maternal separation on Sprague-Dawley dams and pups

Authors: S. L. WEINER, R. A. HEALY, *C. R. MCKITTRICK;
Drew Univ., Madison, NJ

Abstract: Stress serves an adaptive function by causing the body to react to perceived threats to homeostasis. While acute stress is largely beneficial, chronic stress can have deleterious effects through over-activation of the hypothalamic-pituitary-adrenal (HPA) axis. Previous research has demonstrated that chronic stress associated with early life traumas can have adverse effects lasting into adulthood. This study investigated the behavioral and endocrine effects of chronic maternal separation on Sprague-Dawley pups and dams. Cohort I included 4 litters of 12 pups each; pups were separated from dams once daily for 3 hours, along with the rest of their littermates, from postnatal day 7 to 14. Cohort II included 6 litters of 8 pups each; pups were separated from their dams for 4h per day from postnatal day 6 to 21 and were kept in pairs during separation. Control animals were briefly handled and returned to their dams. The effects of maternal separation (MS) on depression-like behaviors were assessed in the forced swim test (FST); anxiety-like behaviors were tested using the elevated zero maze. In addition, effects on spatial learning and memory were tested in the Morris water maze (MWM). Approximately 5 weeks after separation and weaning, juvenile pups were subject to a single episode of restraint stress novel during which tail blood was collected for measurement of baseline, stress and post-stress corticosterone levels. In Cohort I, MS pups showed decreased latency to immobility and more time spent immobile in the forced swim test (FST); they also gained less weight than their control counterparts. Maternal separation also led to a significant impairment in learning in the MWM, although there was no effect on memory. We also observed several sex differences, as females had greater locomotor activity but took longer to reach the platform in both the learning and memory trials in the MWM. Finally, preliminary studies of the dams separated from their pups indicate trends for increases in both depression- and anxiety-related behaviors. These studies indicate that maternal separation may have negative behavioral consequences for both mothers and their offspring.

Title: Early-life stress and reduced MET expression interact to disrupt neuronal morphology and behavior in mice

Authors: *H. HEUN-JOHNSON[1,2], P. LEVITT[1,2];
[1]USC, Los Angeles, CA; [2]Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: A common hypothesis is that early adverse experiences, combined with genetic influences, increase risk of anxiety, mood, and post-traumatic stress disorders in adulthood. Previously, our lab has identified a functional single nucleotide polymorphism in the promoter region of *MET* (rs1858830 'C' allele) that has been associated with altered functional and structural brain connectivity, and increased risk of autism spectrum disorders. In mice, reduced expression of MET results in altered anxiety-like behavior and fear acquisition and memory, reduced neuronal arbor complexity and synaptogenesis, and precocious maturation of neurons based on measures of synaptic function. Here, we induced early-life stress (ELS) using limited nesting material in *wild-type* mice and mice with reduced MET protein expression ($Met^{+/-}$) in the brain. In post-pubertal mice, we analyzed neuronal morphology of pyramidal neurons in the CA1 region of the ventral hippocampus that project to the basolateral amygdala, as well as anxiety-like behaviors, social interaction, and contextual fear acquisition, memory and extinction. We observed an increased number of affected behavioral domains in $Met^{+/-}$ mice that experienced ELS, and $Met^{+/-}$ mice were more affected by ELS than *wild-type* mice in the social interaction test. Surprisingly, we observed an absence of altered dendritic arbors of CA1 neurons in $Met^{+/-}$ mice exposed to ELS, but disruption with ELS or genetic reduction of *Met* alone. The altered responsiveness to ELS in neurons with reduced expression of *Met* may be due to the precocious maturational state. These novel gene-environment interaction findings suggest that developmental perturbations may differentially impact distinct functions that may exhibit distinct vulnerabilities.

Title: Early and recent life stress influence cortisol awakening response as a function of serotonin transporter genotype

Authors: *G. DEDEOGLU, E. A. DUMAN;
Bogazici Univ., ISTANBUL, Turkey

Abstract: Research investigating the role of early and recent life stress on cortisol response yielded conflicting results, which were exacerbated by the inclusion of serotonin transporter genotype as a moderator. In this study, we aimed to investigate the combined effect of these factors on Cortisol Awakening Response (CAR). We hypothesized a lower CAR with increased recent life stress and an interaction between early life stress and serotonin transporter genotype such that S-carriers would show an increased CAR with higher early life stress, while the opposite pattern would be seen in LL homozygotes. Participants were 92 undergraduate students (75% female) providing saliva samples 0, 30 and 45 minutes after awakening for two days. Additional saliva samples were collected for genotyping. Early life stress was assessed by the Childhood Trauma Questionnaire and recent life stress was assessed by the Perceived Stress Scale. Sleep duration and time of awakening were taken as covariates because of their potential influence on CAR. For Day 1, there was a main effect of recent life stress (F (1, 82) = 4.20, p = .044) such that those with high stress showed lower CAR than those with low stress. In addition, there was a significant interaction between serotonin transporter genotype and recent stress (F (1, 82) = 4.63, p = .034) such that S-carriers showed lower CAR independent of stress, while LL homozygotes showed a decreased CAR with higher stress. In terms of early life stress, there was a significant interaction with serotonin transporter genotype (F (1, 82) = 9.74, p = .002) such that S-carriers showed increased CAR with increased early life stress, while LL homozygotes showed the opposite pattern. Finally, there was a trend level interaction between early and recent life stress on CAR (F (1, 82) = 2.63, p = .110). For individuals with high early life stress, recent stress did not influence CAR, while for those with low early life stress, increased recent stress was associated with decreased CAR. For Day 2, we observed similar trends for all analyses. Our results suggest differential effects of early and recent life stress on CAR as a function of serotonin transporter genotype that may altogether alter individuals' vulnerability for psychological disorders like depression.

Title: Social isolation rearing influences epigenetic regulation of dorsal raphe $GABA_B$ receptor and responses to social stimulation in mice.

Authors: *R. ARAKI[1], Y. HIRAKI[1], S. NISHIDA[1], N. KURAMOTO[1], K. MATSUMOTO[2], T. YABE[1];
[1]Setsunan Univ., Hirakata, Osaka, Japan; [2]Univ. of Toyama, Sugitani, Toyama, Japan

Abstract: In rodents, social isolation rearing during childhood induces behavioral abnormalities such as hyperlocomotion, aggression and depression-like behavior, and neurochemical abnormalities such as dorsal raphe hyperexcitability and an increase in extracellular serotonin level in the prefrontal cortex. Previous studies have showed that these neurochemical abnormalities are involved in a part of these behavioral abnormalities, suggesting that dysregulation of dorsal raphe function triggers abnormal behaviors. It is known that serotonergic neurons are mainly regulated by GABAergic systems in the dorsal raphe nucleus (DRN). In this study, we examined the impact of isolation rearing on dorsal raphe GABAergic function. We also studied the involvement of isolation rearing-induced dorsal raphe GABAergic dysfunction in the abnormal behaviors. Both mRNA and protein levels of $GABA_{B1a}$ (a $GABA_B$ receptor subunit) were increased in the DRN of isolation-reared mice. DNA hypomethylation and histone H3 hyperacetylation around the transcription start site of $GABA_{B1a}$ were observed in the DRN of isolation-reared mice. Intra-DRN microinjection of 0.3 nmol phaclofen (a $GABA_B$ receptor antagonist) attenuated encounter-induced hyperactivity and aggressive behavior of isolation-reared mice. These findings indicate that an increase in dorsal raphe $GABA_{B1a}$ expression via epigenetic regulation may be associated with abnormal responses to social stimulation such as encounter-induced hyperactivity and aggressive behavior in isolation-reared mice.

Title: Early adversity uncouples preference formation from anxiolysis in mice

Authors: *H. S. KNOBLOCH, E. J. KIM, Z. YE, T. K. HENSCH;
MCB, Harvard Univ., Cambridge, MA

Abstract: Early adversity impacts emotions, behavior, cognitive abilities and susceptibility to psychiatric illnesses throughout life. One link may be that early life stress (ELS) alters the timing of biological critical periods for circuit maturation. Under typical rearing conditions, juvenile rats appear to be protected from exhibiting anxiety, whereas after adverse rearing, fear learning appears more mature, making stressful memories persist (Callaghan et al, 2013). Whether this is due to a shifted onset, closure or duration of a critical period remains unclear. Here, we leveraged a novel prefrontal critical period for the acquisition of preference behaviors in mice with a clearly defined window of plasticity (Yang et al, 2012). Exposure to music between postnatal day P15-25 induces a lifelong preference for that acoustic environment over the animal's innate bias for silent shelter. Acquisition of such a preference is at the same time anxiolytic, increasing open field center crossing or stress measures on an elevated platform. Adult animals can be made to acquire preference / anxiolysis if plasticity is extended or reopened by the pharmacological (HDAC inhibitors) or genetic (NgR) disruption of molecular 'brakes' on plasticity (Yang et al, 2012). Here, to study the impact of ELS on critical period timing, we examined a 'fragmented' maternal care (FC) paradigm in mice, in which reduced nesting material creates a stressful situation that disrupts mother-infant interaction during P2-9 (Ivy et al., 2008). We found that female offspring in particular exhibited heightened anxiety in adulthood. Strikingly, they failed to acquire a music preference despite exposure at various time windows after hearing onset. Instead, the anxiolytic effect of music was still observed, but only for exposure earlier than normal (P13-18). Our study reveals that preference behaviors and anxiolysis are dissociable, and that strategically timed music exposure may help to counteract some of the debilitating effects of ELS. Ongoing work is exploring the oxytocin system - which develops in an experience-dependent manner during the first postnatal weeks in rodents and underlies the formation of partner preference in voles - as a potential mechanism for critical period shifting by ELS.

Title: Maternal potentiation of ultrasonic vocalizations is not a marker of stress

Authors: *L. M. ROSKO[1], M. ANWAR[1], J. KAIDBEY[2], A. ELLISTON[2], M. G. WELCH[1]; [1]Psychiatry, Columbia Univ. Med. Ctr., New York, NY; [2]Columbia Univ. Inst. of Nutr., New York, NY

Abstract: Our hypothesis is that nurturing reunions will shorten time required to reduce distress from a separation. In our clinical studies, the family nurture intervention repeats calming activities during mother and premature infant reunions. It is known that disruptions in mother-infant interactions decrease weight gain and impair development in human neonates. Paradigms with short periods of maternal deprivation are commonly used in preweaning rat pups to mimic disruptions in nurturing relationships. Many mammalian species, including rats, vocalize after isolation or environmental stress. Few have studied reunions. Maternal cues are deemed important for calling, as pups have higher ultrasonic vocalization (USV) rates after a separation following a brief reunion with a dam than with littermates, a phenomenon called maternal potentiation. Here, we further study the effect of separation/reunion by correlating maternal potentiation with an index of physiological stress—corticosterone (CORT) measurement. Twelve day old Sprague Dawley pups were separated overnight, and USVs were counted the next day to assess whether pups potentiated in the separation paradigm. Plasma CORT was measured in at 30, 60 or 90 minutes after separation after a dam or littermate reunion using a radioimmunoassay. Vocalizations increased an average of 62.3±9.73 for maternally reunited pups while pups reunited with littermates increased by average of 3.24±1.71. Baseline CORT in animals was 99.3±7.08 ng/mL. At 60 minutes, CORT levels were significantly higher in pups reunited with littermates compared to the dam group ($p=0.042$). Taken together, reunion type significantly changes corticosterone levels. Therefore, our data suggests that maternal potentiation is not a marker of stress since the pups that potentiated had a lower CORT response then those that did not. The lower CORT response in maternally reunited pups aligns with the idea that maternal potentiation is a pup's expression of an expectation that the dam is close enough to return upon calling. Taken together with our findings that vagotomy blocks potentiation, the low CORT response in maternally reunited pups signal the primacy of the dyadic relationship. Extrapolating to human preterm infants, our results suggest that babies who have a reunion with their mother, albeit a brief one, may be able to better cope with the stress of maternal separation.

Title: Effects of maternal separation on vulnerability to methamphetamine and synaptic plasticity

Authors: J. N. HAMDAN[1], S. SAUCEDO, Jr.[1], G. A. LODOZA[1], J. A. SIERRA-FONSECA[1], L. E. O'DELL[2], *K. L. GOSSELINK[3];

Abstract: Methamphetamine addiction affects roughly 1.2 million people nationally, and stress has been previously shown to affect the incidence and progression of addictive behaviors. It is not fully understood, however, which stress-induced mechanisms in the brain are involved in mediating these effects. We hypothesized that exposure to stress during early life can cause significant and long lasting changes in the brain, leading to enhanced vulnerability to methamphetamine addiction. Male Wistar rats were maternally separated (MS) from their dams for 3h/d from postnatal day (PND) 2 to PND14 and were assessed in adulthood (PND 70-80). Proteins involved in dopaminergic signaling [dopamine transporter (DAT), dopamine receptor-2 (D_2), tyrosine hydroxylase (TH)] or synaptic plasticity [post-synaptic density 95 (PSD95), NMDA receptor-1, and α-synuclein] were evaluated by Western blot in adult MS and control animals. Brain regions in which the levels of these proteins were quantified included the prefrontal cortex (PFC), hippocampus, dorsal striatum, and the nucleus accumbens (NAcc). Preliminary data have shown a significant increase in the expression of DAT in the dorsal striatum ($p=0.035$), as well as a trend toward decreasing expression of α-synuclein in the PFC ($p=0.099$) following MS. Separate groups of animals that underwent the same MS procedure were behaviorally tested for conditioned place preference (CPP) with 1 mg/kg methamphetamine, to identify changes in drug sensitivity caused by MS. Stressed animals did not demonstrate a change in preference for methamphetamine at this dose, compared to controls. Future studies will test different doses of methamphetamine to evaluate changes in preference or aversion caused by MS.

Title: Microglial alterations after maternal separation in rodents

Authors: *L. TELISKA[1], R. ROTOLO[2], C. LITTLE[1], T. STRANGE[1], T. MEDWID[2], L. FRUEHAUF[1], A. ROSELUND[1], K. JONES[2], A. J. BETZ[1];
[1]Psychology, [2]Hlth. Sci., Quinnipiac Univ., Hamden, CT

Abstract: There is a great demand for therapeutic advancements with respect to mood disorders and a significant link between stress and major depressive disorder (MDD) exists. Maternal separation in rodents is a widely used animal model used to induce early-life stress. This model has reliably demonstrated an increased risk of depressive-like behavior later in life. Existing research also supports that individuals with MDD have learning and memory deficits. Two regions of the hippocampus, the dorsal and the ventral regions, are suggested to be functionally different while the dorsal hippocampus is involved in cognitive function and the ventral hippocampus is involved in emotion and stress. Additionally, microglia activity is associated with causing the atrophy and pathology of these brain regions and may be implicated in MDD. The proliferation and stability of microglia across the development into adulthood differs. We aimed to examine the expression of dorsal and ventral hippocampal microglia in rats that experience postnatal maternal separation during development. In the present study, Sprague Dawley male and female rat pups were separated from the dam from PND 2 to PND 14 for three hours a day. A control condition of non-separated pups was maintained. Experiment 1 examined behavioral tasks during adolescence in males and during adulthood in females. Alterations in hippocampal IBa1, CD11b and cytokine expression were observed and may provide insight as to the molecular mechanisms responsible for hallmark MDD pathogenesis and possible therapeutic remedies.

Title: The role of oxidative stress in the effect of prenatal stress on the fetal brain

Authors: ***J. BITTLE**, S. J. LUSSIER, J. MICHAELSON, H. E. STEVENS;
Univ. of Iowa, Iowa City, IA

Abstract: Stress experienced by the mother during pregnancy is linked to an increased risk of psychiatric disorders in her offspring. However, the molecular mechanisms that link prenatal stress (PS) and psychiatric outcomes have yet to be elucidated. Oxidative stress has been shown to be a mediator of the impact of multiple environmental exposures, making it a prime candidate for mediating the effects of in utero environmental changes like PS. The balance between oxidative and reductive processes is critical during rapid periods of cell growth and differentiation, so small changes in the level of reactive oxygen species (ROS) during embryonic brain development could have significant effects. We used two approaches to investigate oxidative stress as a mechanism for PS, both utilizing a mouse model of repetitive restraint stress starting on embryonic day 12 (E12). First, we examined changes in gene expression in E13 brain after PS by Illumina microarray and qPCR validation. Second, we evaluated the impact of antioxidant administration during PS on GABAergic migration delays. After correcting for multiple comparisons, we found 5177 genes significantly altered in E13 ventral forebrain after one day of PS. Panther analysis of these genes revealed that 38 pathways were enriched for differentially expressed genes-- the oxidative stress pathway was the third most significant pathway changed ($p= 0.0000027$). In addition, four of the six genes annotated with “antioxidant

activity" by Panther were differentially expressed, including sestrin 1, sestrin 3, glutathione peroxidase, and catalase. 421 genes were found to be differentially regulated by PS in males versus females. Two of the top 15 genes from this analysis were within pathways contributing to ROS-- *Aifm1* and *Idh2*. When examined by qPCR, both *Aifm1* and *Idh2* were significantly changed only by PS, with no effect of sex. These results reveal that genes in oxidative stress and antioxidant pathways are a significant component of PS changes in the fetal brain. In the second experiment, N-acetylcysteine (NAC), a common antioxidant supplement, was administered in drinking water to pregnant dams starting at E0 with half of dams undergoing PS at E12 and half maintained as controls. We have shown previously that PS delays GABAergic progenitor migration. Pilot data showed maternal NAC administration normalized GABAergic migration at E13, but not E14, suggesting that oxidative stress may only play a role in acute, but not prolonged, changes after PS. Oxidative stress may play a significant role in the elusive mechanisms by which persistent cellular changes are induced in the developing brain by maternal PS.

Title: Single dose ketamine injection does not alter behavioral parameters in rats exposed to both prenatal and chronic unpredictable mild stress

Authors: *E. ULUPINAR[1], E. POLAT CORUMLU[2], O. AYDIN[2], E. GULHAN AYDIN[3]; [2]INTERDISCIPLINARY NEUROSCIENCE DEPARTMENT, [3]DEPARTMENT OF PHARMACOLOGY, [1]Eskisehir Osmangazi Univ., Eskisehir, Turkey

Abstract: In recent clinical trails, NMDA receptor antagonist ketamine has been shown to act as an antidepressant, due to its rapid action and efficacy on treatment-resistant patients. Antidepressant effects of a single dose of ketamine might start within hours and sustain for up to 2 weeks. Early life stress can cause long-term behavioural and morphological alterations in the central nervous system. Likewise, chronic unpredictable stress can cause depressive-like effects. In experimental models, we have previously demonstrated that exposure to either prenatal or chronic unpredictable stress paradigms can induce depressive-like behavioral deficits, as well as morphological alterations in the rat brains. The aim of this study was to investigate the behavioral effects of single dose ketamine injection in rats exposed to combination of both

prenatal and chronic unpredictable mild stress, in a gender dependent manner. Pregnant rats were exposed to immobilization stress during the last week of their gestation for 3 hours a day. Then, beginning from postnatal day 95, a random pattern of unpredictable mild stressors was applied daily, for 28 days. At the end of stress period, one group of animals received a single dose (10mg/kg) of intraperitoneal ketamine injection, whereas the other group received same amount of saline injections. Next day, behavioral responses of animals were evaluated in the forced swim, sucrose preference, open field and suspension tests. In these tests, no significant differences were observed between groups. Two-way ANOVA results showed that ketamine injections cause similar effects on both female and male animals. Although these results are in accordance with our previous findings in animals exposed to chronic unpredictable stress, it displays some controversies with the literature. Therefore, antidepressant efficacy of ketamine needs to be explored in different animal models of depression caused by various stressors. Future studies are underway to compare gender-dependent morphological and molecular effects of single dose ketamine injections.

Title: Reductions in hippocampal AMPA receptor and NMDA receptor subunit expression are associated with impaired learning in adult male rats following prenatal exposure to Dexamethasone

Authors: C. R. DODSON, *K. C. PAGE;
Bucknell Univ., Lewisburg, PA

Abstract: Antenatal glucocorticoids (GC) have been used clinically to enhance lung maturation in the fetus at risk for preterm birth. However, exogenous Dexamethasone (Dex) has been associated with a disturbance of the normal relationship between components mediating glucocorticoid action in the hippocampus. It is possible that these agents may increase the risk for physical, neurological, and behavioral alterations. Perturbations in GC programming in the fetal brain could affect neuritic outgrowth, synaptic activity and cell signaling through

glutamatergic and serotonergic circuits. We hypothesized that exposure to excess glucocorticoid during fetal development exerts a deleterious effect on expression of hippocampal genes mediating synaptic function and behavior in adult male rats. Pregnant rat dams were injected once daily with 150ug/kg of Dex (sc) from gestation-day 14 through 19. Control dams were injected with vehicle. At 120 days, male offspring were tested for learning and memory function using the Morris Water Maze. At 150 days, whole hippocampi were rapidly dissected and frozen using liquid nitrogen. Gene Expression was measured using real-time PCR. Using the Morris Water Maze protocol, we found that the Dex-exposed males spent more time trying to find the platform even after 5 days of training (longer latency, $p = 0.05$). Expression of key genes known to mediate this behavior was also perturbed as follows: In the Dex-exposed animals, a significant reduction was detected in AMPA receptor subunits GluR1 and GluR2 ($p =0.002$ and $p<0.02$, respectively) as well as the NMDA receptor subunits NR2A and NR2B ($p<0.02$ and $p =0.002$, respectively). The mRNA expression for the NR1 subunit, a constitutive subunit for NMDA receptors, was not significantly altered. Interestingly, the mRNA expression for serotonin receptors 5HT1A, 5HT1B and 5HT2A was significantly increased in the Dex-exposed male offspring, perhaps due to a compensatory response. Synaptotagmin and SNAP-25 mRNA expression was not significantly altered. These data support the observation that gene-environment interactions during critical periods of neurogenesis lead to developmental changes that persist into adult life. More specifically, prenatal exposure to synthetic glucocorticoid at key points of brain development disturbs glutamatergic and serotonergic function which may be associated with learning and memory deficits in adult hood.

Abstract: Stress causes deleterious effects in health and may occur at different stages of life, even in the gestational period. Prenatal stress (PS) is capable of disrupting hippocampal physiology through maternal glucocorticoids (GC), decreasing glucocorticoid receptors in that brain structure, causing alterations in learning and memory in the adult. Thus, the aim of this study was to evaluate learning and memory in prenatally stressed rats and whether these changes are associated with alterations in serotonin and noradrenaline release in the dorsal hippocampus. Pregnant females were assigned to control or stress groups. Spatial learning and memory were evaluated with the Morris Water Maze (MWM) in 2 ½ months old offspring. Cannulas were implanted in the dorsal hippocampus of other adult offspring. The dialysates were collected each hour before and after administration of high doses of potassium. Neurotransmitters were detected by HPLC-ED. The results showed greater escape latencies as well as less time in the platform quadrant and platform-site crossovers, compared to the control rats. Additionally, basal serotonin and norepinephrine release were greater in the PS group than in the control. However neurotransmitter release decreased after high doses of potassium, suggesting that serotonin and norepinephrine neurotransmission is disrupted by prenatal stress.

Title: Prenatal stress induced depressive-like behaviour associated with serotonin release in the ventral hippocampus

Abstract: Major depressive disorder or major depression is a common disorder that affects people worldwide and combines symptoms at psychological, physiological, and behavioural levels. This disorder is predicted to be the second cause of disability in 2020. Animal models of major depression caused by stress are relevant to the better understanding the aetiology of depression. Thus, the aim of this work was to evaluate whether prenatal stress induces depressive-like behavior and if this behaviour is related to changes in serotonin content and release in ventral hippocampus of the adult rats. Pregnant female Wistar rats weighing 250 grams were randomly assigned to the control group or stress by immersion in cold water from day 15 to 21 of pregnancy. At 21 days of age, pups were sexed and males were separated. Depressive-like behaviour was assessed by forced-swim tasks and sucrose intake test in male offspring at 8–12 weeks of age. Rats displaying depressive-like behaviour were selected and cannulas were stereotactically implanted into the right ventral hippocampus. The dialysates were collected and basal serotonin release was evaluated HPLC-ED. The results indicate that prenatal stress caused depressive-like behaviour, with increased immobility in the Porsolt test, as well as decreased sucrose intake (considered as anhedonia) in adult male offspring. Serotonin release was higher in prenatally stressed males. Administration of high doses of potassium did not stimulate the neurotransmitter system. These findings suggest that prenatal stress is able to induce depressive-like behaviour in adult male offspring and this could be related to disruption in serotonin release in the ventral hippocampus.

Title: Changes in cortical GABAergic maturation after prenatal stress and the role of oxidative stress

Authors: P. W. ABBOTT, S. J. LUSSIER, *H. E. STEVENS;
Univ. of Iowa, Iowa City, IA

Abstract: Objective: Our lab seeks to understand the mechanisms by which early developmental events increase the risk of psychiatric illness. The purpose of this ongoing study is to determine further how prenatal stress (PS), specifically, perturbs cortical maturation.
Background: We have found previously that PS delays GABAergic progenitor migration and postnatal pruning of cortical populations during development in mice. These delays may contribute to disruptions of cortical inhibitory circuitry theorized to be a component of psychiatric pathology. How PS may affect other aspects of cortical maturation is not clear. The formation of extracellular perineuronal nets (PNNs) around GABAergic neurons has been implicated in regulating developmental plasticity. PNNs, their maturation, and their "protection" of GABAergic neurons may be influenced by oxidative stress, a possible mechanism by which PS influences the brain. To examine these issues, we measured multiple aspects of cortical GABAergic neuron maturation in a mouse model of PS, targeting one possible mechanism, oxidative stress, through administration of a known antioxidant N-acetylcysteine (NAC).
Methods: In a cohort of pregnant female CD1 mice, half underwent PS which consisted of 45 minutes within a restraint tube three times a day starting at embryonic day 12 (E12), seven days prior to parturition. In the perinatal period, mothers and pups were given either normal drinking water or NAC (2 mg/mL) in drinking water. Offspring were tested on behavioral tasks at weaning age and in adulthood. By using stereology with immunostaining, we examined GABAergic neurons, their activation (by cFOS) and surrounding PNNs in medial frontal cortex (mFC) at postnatal day 24 (P24) and in adulthood.
Results: PS resulted in reduced sociability in adulthood as well as increased anxiety and motor inhibition at P24 and in adulthood. Pilot data suggest amelioration of some of these behavioral changes with early postnatal NAC administration. We have previously found that PS increases mFC GABAergic cell number at P24 but not in adulthood. We have new data suggesting that PS decreases PNN+ GABAergic cells at P24 and cFOS+ GABAergic cells at P24. Findings from mFC at P24 suggest that early NAC exposure normalized GABAergic population numbers and may show some amelioration of PNN+GABAergic proportions.
Conclusion: This ongoing study provides initial evidence that PS may affect multiple aspects of GABAergic interneuron maturation in mFC, coincident with behavioral abnormalities. Postnatal enhancement of antioxidant systems may affect some but not all of these maturational changes after PS.

Title: Late prenatal dexamethasone exposure and induced fetal programming of behavioural deficiencies

Authors: *C. LALONDE[1], J. GRANDBOIS[2], K. ZIMANY[2], S. KHURANA[5], S. THARMALINGAM[5], T. C. TAI[2,5,3,4];

Abstract: Prenatal exposure to stress during critical periods of fetal growth and development has serious behavioural and health implications for the offspring. The effects of prenatal exposure to stress are poorly understood; evidence is accumulating that these vulnerabilities span future generations. To investigate the potential behavioural deficits on multiple generations of offspring, pregnant Wistar-Kyoto rats were exposed to one of two treatment regimes during the equivalency of the third trimester (beginning on gestational day 15): daily IP injections until birth of 1) a synthetic glucocorticoid, dexamethasone (DEX; 100µg/kg/day) or 2) vehicle (4% ethanol with 0.9% saline). A third group received only physical manipulation to serve as a naive control. The offspring from each litter (F1 generation) were allowed to mature and were tested during week 17 for indications of anxiety and depression through use of the Elevated Plus Maze (EPM) and the Porsolt Swim Test (PST) respectively. Randomly selected males and females were bred with new naive animals and the following generation of offspring (F2) were allowed to mature and underwent the same behavioural testing. Further, a third generation (F3) was generated using the animals from the F2 generation. Neural tissue from each generation was collected and stored at -80°C for histological and immunohistochemical (IHC) processing to investigate deficits in neurogenesis and changes in glucocorticoid receptor expression. Preliminary results indicate exposure to prenatal DEX predisposes adult offspring to exhibit depressive-like behaviours that spans several generations. The PST results for the F1 generation primarily show a significant effect on the first day of testing for total time spent immobile during the procedure ($\chi^2 = 10.002$, $p < 0.001$), and a similar trend with other generations. EPM results from the F1 generation show a main effect ($Z = -1.952$, $p < 0.05$), where females spend significantly more time in open arms than males. The F2 and F3 generations exhibited the same sex effect with females spending more time in open arms than males ($p < 0.05$). The F2

generation also showed a significance between groups ($F(5, 44) = 2.62$, $p = 0.037$), whereby naive males and females spent significantly more time in open arms than DEX F1 male offspring. Altogether, these results suggest that late prenatal exposure to stress causes long-term behavioural changes in the offspring that is also apparent in subsequent generations.

Title: Prenatal dexamethasone exposure alters the postnatal leptin surge in rats

Authors: *B. HAMMOND, M. K. THOMPSON, L. MADHAVPEDDI, T. M. HALE, R. J. HANDA;
Univ. of Arizona, Phoenix, AZ

Abstract: Overexposure to glucocorticoids during gestation increases the risk in adulthood for developing disease such as metabolic syndrome. However, little is currently known about the mechanisms underlying the fetal programming of adult disease by glucocorticoids. In rodents, a potential target for the programming of metabolic syndrome is the development of hypothalamic circuity that controls food intake, metabolism and adiposity which is largely dependent on a surge of leptin during the second week of postnatal development. This study investigated the effects of maternal exposure to synthetic glucocorticoids (sGCs) on the surge of leptin during early postnatal development as a candidate hormone for the fetal programming of adult disease. In this study, time-pregnant dams were administered 0.1 and 0.4 mg/kg dexamethasone (Dex) daily during days 18-21 of gestation. Blood was collected from offspring on postnatal days (PD) 0, 7, 10, and 13 and plasma was then assayed for leptin levels using an enzyme-linked immunosorbent assay. Prenatal Dex treated animals were significantly smaller at birth and as we have previously reported, when allowed to grow to adulthood, these animals exhibit some signs of metabolic syndrome such as macrovesicular hepatic steatosis as detected by Oil Red O staining in liver. During neonatal life, there was a significant elevation in plasma leptin levels which peaked in vehicle treated animals at PD 10 (8.2 ± 1.1 ng/ml) and 13 (10.2 ± 1.9 ng/ml). Moreover, 0.1 mg/kg Dex significantly reduced plasma leptin at PD 10 (4.0 ± 0.3 ng/ml) and 13

(6.7 ± 0.7 ng/ml), while 0.4 mg/kg Dex significantly reduced plasma leptin at PD 13 (6.9 ± 1.3 ng/ml) as compared to vehicle-treated controls. We are currently determining the consequences of alterations in the leptin surge during early postnatal development by prenatal Dex treatment. An altered leptin surge could dramatically alter the development of hypothalamic circuity controlling food intake and adiposity, thereby shedding light on a potential mechanism by which maternal exposure to sGCs programs adult metabolic syndrome.

Title: Effect of prenatal restraint stress in a DN-DISC1 mouse paradigm for schizophrenia

Authors: *S. N. REID[1], K. S. JONES[2], M. C. GONDRE-LEWIS[1];
[1]Dept. of Anatomy, Lab. for Neurodevelopment, Howard Univ. Col. of Med., Washington, DC;
[2]Dept. of Biol., Howard Univ., Washington, DC

Abstract: Schizophrenia is a devastating disorder with a worldwide prevalence of 0.5-1.2% (Kessler et. al., 2005), generally presenting in late adolescence and early adulthood (Kessler et al., 2007). Previously, a majority of gene-environment studies involving dominant-negative Disrupted-in-Schizophrenia-1 (DN-DISC1) have focused on prenatal infection and immune activation (Abazyan et al., 2010; Hida et al., 2013; Lipina et al., 2013). It is unclear how the interplay between the presence of a susceptibility gene and exposure to environmental stressors, in particular prenatal stress, increase the risk of neuropsychiatric disorders, such as schizophrenia. Putative vulnerability genes, such as DISC1, when exposed to excessive trauma, may act in concert and produce disruptions in neurodevelopmental events.
Here, we examine alterations in reciprocal circuits of the amygdala and hippocampus in a DN-

DISC1paradigm submitted to prenatal restraint stress. Biochemical and immunohistochemical data suggest expression of DN-DISC1 appears to reduce expression of the calcium binding protein, parvalbumin, and glutamate receptor subunits, GluN1 and GluA1, in the hippocampus and amygdala. These data imply alterations in the amygdalo-hippocampal circuit that may be central to the pathophysiology of fear circuits in schizophrenia and may be severely altered when the genetic predisposition is combined with early life stress.
Since neurodevelopmental landmarks and the molecular mechanisms that govern fear memory are highly implicated in the etiology of schizophrenia, the impact of DN-DISC1 expression combined with prenatal stress exposure in fear circuitry was examined using a battery of behavioral tests and biochemical assays. Fear conditioning, specifically contextual and cued conditioning, suggest potential effects between the presence of expressed DN-DISC1 and *in utero* stress via restraint of the pregnant dam.
While one particular gene may not cause schizophrenia, characterizing the gene-environment interaction in this disorder will help to further our understanding of its etiology and provide insight into the risk of its development possibly creating interventions to help target or alleviate its symptoms. As mentioned previously, there is an abundance of evidence to suggest that the GABA system is associated with dysfunction in cognitive processing, especially fear memory. By defining the GABA system within fear circuitry after prenatal stress exposure in the presence of expressed DN-DISC1, we may be able to find new evidence to target the developmental time points significant to the onset of schizophrenia.

Title: Effects of birth mode on developmental cell death in the mouse brain

Authors: *A. CASTILLO-RUIZ, M. MOSLEY, N. G. FORGER;
Georgia State Univ., Atlanta, GA

Abstract: Birth involves dramatic changes in a newborn's environment and the processes associated with birth prepare key peripheral organs for the transition to postnatal life. However, little is known about how birth influences the brain and behavior. We previously found that birth mode (Vaginal "V" vs Cesarean "C") may alter neurobehavioral development. In this study, we further investigated the effects of birth on brain development by focusing on cell death, a key feature of nervous system development. There is increased cell death across many brain regions around the time of birth in mice, but whether birth induces cell death, and whether mode of birth influences cell death has not been addressed. We manipulated birth mode in timed-pregnant C57BL/6 mice and collected the brains of offspring *in utero* at embryonic day (E)18.5 and E19 and *ex utero* at postnatal day (P)0 (3h after birth), P1, P3, and P23 for the histochemical detection of activated caspase-3, a cell death marker. We found that C born mice had higher cell death perinatally across many brain regions, including hypothalamic, epithalamic, hippocampal and midbrain subregions. We are currently assessing whether these differential patterns of cell death induce long-lasting effects on regional cell number and volume. We are also processing the brains for the histochemical detection of microglia, the brain's resident immune cells. Uterine inflammation triggers labor, and parturition activates the peripheral immune system of the offspring. Our previous results show that birth is associated with dynamic changes in pro- and anti-inflammatory cytokines in the periphery. Whether the immune activation at birth extends to the brain is not known and will be investigated here. Together our results suggest that birth may be an important event for brain development and deviations from the natural mode of birth may alter brain and behavioral development.

Title: Influence of *In utero* stress on fear memory consolidation in adulthood.

Authors: A. E. EASTON, *B. G. DIAS;
Emory Univ., Atlanta, GA

Abstract: Early life stress has been recognized to have profound and long-lasting effects in humans, catalyzing the development of neuropsychiatric disorders such as depression, anxiety disorder and Post-Traumatic Stress Disorder (PTSD). To understand how early life stress exerts these effects, diverse rodent models have shown varying but significant effects on physiological and behavioral endpoints in adulthood. However, little research has been done exploring the effects of *in utero stress* on fear learning in adults: an influence that may have direct consequences for the development of PTSD. We explored the relationship between *in utero* stress and the formation of fear memories using classical conditioning. Pregnant female C57/Bl6J mice were administered five un-signaled mild foot-shocks, once per day for 3 days, causing *in utero* stress to the gestating offspring on embryonic days 17-19 post-fertilization. In adulthood, F1 males were first tested in an Elevated Plus Maze to test anxiety-like behavior, and no differences were noted between non-stressed F1 offspring (F1-Control) and F1 animals that experienced *in utero* stress (F1-Stressed). Animals then underwent auditory fear conditioning where neutral tone presentations co-terminated with mild foot-shocks. Using freezing as a measure of learning and memory, the acquisition of fear was examined during training, and the consolidation of fear memory was examined one day later by presenting the same tone in a different context. F1-Control and F1-Stressed males did not acquire fear any differently from each other during training. In contrast, F1-Stressed males demonstrated lower levels of freezing upon tone presentations on the second day compared to F1-Control males suggesting that *in utero* stress impairs the consolidation of fear memory. These data suggest that stress experienced *in utero* results in deficits in the consolidation of emotional memories, which may contribute to the development of neuropsychiatric disorders like PTSD.

Abstract: Chronic stress is a risk factor in the development of depression and anxiety disorders. However, variability in the stress response to chronic stress depends on the individual genetic and epigenetic background, and also on the neonatal programming of the stress response system development. Maternal stress during gestation was reported to affect fetus developing brain morphology and adult offspring behavior, by inducing changes in gene and protein expression. We have previously demonstrated that prenatal stress (PS) induces persistent changes in the expression of plasticity-related genes such as *gpm6a* and *bdnf* in the male offspring hippocampus at adulthood. Here we evaluated gestational stress consequences on dams and on prepubertal male offspring behavior and stress response. Stressed dams showed lower body weight gain in comparison with unstressed control (C) rats, despite finding similar food and water intake between both experimental groups. At post-weaning stages stressed dams spent more time immobile in the *open field* and in the *Porsolt test*, pointing out that chronic stress during pregnancy increased depression-like behavior in the rat. Conversely, PS male offspring displayed a higher ratio in the open arms entries in an elevated plus maze, indicating a reduced anxiety-like behavior than C counterparts, and they also showed a reduced depression-like behavior (*Porsolt test*). Corticosterone levels did not differ between groups after an acute stress or 2h later. Overall, our findings indicate that although stress during pregnancy negatively affected the mother behavior, offspring did not show such effects. PS offspring seemed to perform better in the behavioral tests than C rats. Thus, we propose that exposure to an adverse intrauterine environment may provide individuals useful skills to deal afterwards with harsh external conditions. This "adaptive developmental plasticity" requires of persistent changes in gene expression. Since PS modulates the expression of the plasticity-related genes *gpm6a* and *bdnf* by changes in their methylation pattern, we propose that the methylation machinery (*dnmts, methyl binding proteins, tets enzymes*) could regulate the gene expression underlying the offspring behavior.

Title: Chronic adolescent stress alters the adult rat transcriptome in a sex specific manner

Authors: *G. N. NEIGH[1], S. A. ROWSON[2], M. BEKHBAT[2], S. D. KELLY[2], Q. ZHAOHUI[2]; [1]Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA; [2]Emory Univ., Atlanta, GA

Abstract: Women are more likely to develop depression and other stress-related disorders than men. Animal models have proven to be useful in studying this sex effect. Adult rats have been found to exhibit behavioral and molecular changes following exposure to chronic adolescent stress (CAS). While the behavioral alterations persist to adulthood, whether the molecular changes persist is unknown. We assessed the hippocampal transcriptome at baseline and in response to an acute stressor in adult rats with and without a background of chronic adolescent stress to assess whether molecular changes continue into adulthood. Male and female Wistar rats were exposed to a mixed-modality stress paradigm on PND 38-49 or were pair-housed controls. The stress paradigm consisted of isolation, restraint, and social defeat. On PND 94, tissue was collected from six rats per group at baseline or 30-minutes following a forced-swim acute stressor. Total RNA extracts from hippocampal tissue were used for RNA sequencing. Paired comparisons between non-stressed and CAS groups were assessed using EdgeR. Metacore was used to assess pathway enrichment. Male and female rats exposed to CAS exhibited altered patterns of differentially expressed genes at baseline and in response to an acute forced swim stressor. 63 unique genes were differentially expressed in CAS females compared to non-stressed females following an acute stressor, 11 were differentially expressed in males, and 24 genes were altered in both males and females. At baseline, 47 genes were differentially expressed in males exposed to CAS compared to non-stressed controls. No genes were altered in females at baseline. This study provides novel evidence that changes to the transcriptome following CAS are sex-dependent. These data also establish that exposure to adolescent stress results in long-term changes to hippocampal gene expression that are preserved even months removed from stress.

Title: Increased function of D_2 autoreceptors contributes to reduced prefrontal cortex dopamine activity following adolescent social defeat

Authors: *M. A. WEBER, G. L. FORSTER, M. J. WATT;
Div. of Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Greater incidences of psychiatric disorders in early adulthood have been linked to bullying victimization during adolescence. These disorders are characterized by impaired executive function, suggesting stress-induced disruption of the developing prefrontal cortex (PFC) dopamine (DA) system. Rats exposed to repeated social defeat in adolescence, as a model of teenage bullying, display decreased medial PFC (mPFC) DA activity in early adulthood, along with changes in mPFC DA-mediated behaviors. We hypothesize that the reduction in adult mPFC DA results from over-activation of mechanisms for coping with adolescent stress-evoked increases in DA release. In support of this, we have shown that adolescent defeat increases DA transporter-mediated clearance of DA in the adult mPFC. In addition, pharmacological activation of mPFC DA D_2 autoreceptors (D_2AR) in non-defeated adolescent rats decreases adult mPFC DA activity, mimicking the effect of adolescent defeat. Conversely, pharmacological blockade of mPFC D_2ARs during adolescent defeat prevents the later mPFC DA hypofunction. Here, we investigated whether D_2AR function in the adult mPFC is increased following adolescent defeat to further contribute to decreases in DA availability. Adolescent male rats experienced either repeated social defeat or control (novel cage exposure) from postnatal day (P)35-39. In early adulthood (P56), subjects underwent non-recovery stereotaxic surgery, with a unilateral stearate-graphite paste recording electrode implanted directly into the infralimbic (IL) region of the mPFC to measure extracellular DA using *in vivo* chronoamperometry. A stainless-steel guide cannula implanted immediately adjacent to the recording electrode allowed for infusion of vehicle (aCSF) or the D_2 receptor agonist quinpirole (3 nM/5 μL aCSF), with a decrease in extracellular DA after quinpirole infusion indicating preferential activation of D_2ARs. Preliminary data indicate that this dose of quinpirole induces a greater decrease in extracellular DA in the IL-mPFC of previously defeated rats compared to controls, suggesting that the adult mPFC DA hypofunction resulting from adolescent defeat may partly be caused by increased D_2AR function and subsequently enhanced inhibition of DA release. Such increased mPFC

D_2AR function may represent carry over of an initially adaptive mechanism for counteracting stress-evoked increases in DA release. However, its persistence into early adulthood in the absence of further stress would contribute to a lowering of mPFC DA tone, with negative implications for DA-mediated executive function.

Title: Disruptions to adolescent cortical dopamine activity promote seeking of amphetamine-associated cues in adulthood

Authors: ***S. ENGEL**, R. T. PAULSEN, M. A. WEBER, M. J. GERLACH, A. D. KOCH, G. L. FORSTER, M. J. WATT;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Victims of teenage bullying show increased psychiatric disorders in adulthood, including substance abuse. This may result from stress-induced disruption of the developing adolescent brain, which undergoes dynamic reorganization in areas related to impulse control, such as the prefrontal cortex (PFC) dopamine (DA) system. This scenario can be studied using a rodent adolescent social defeat paradigm, a model of teenage bullying, which we have shown enhances seeking of amphetamine-associated cues in adulthood. Adolescent defeat also reduces adult medial PFC (mPFC) DA activity, and pharmacological depletion of mPFC DA is known to increase psychostimulant responses. However, a causal link between decreased adult mPFC DA resulting from perturbations in adolescence, such as those caused by social stress, and later increases in amphetamine responding has yet to be established. Here, we tested this by pharmacologically manipulating mPFC DA activity in non-defeated adolescent males to mimic the effects of adolescent defeat, then determined if this increased adult drug seeking. Adolescent male rats received daily bilateral infusions of either vehicle (aCSF) or the DA D_2 receptor agonist quinpirole (100 ng/μL in 0.3 μL) into the mPFC from postnatal day (P) 35 – 39. This

protocol mimics the adult mPFC DA hypofunction caused by adolescent defeat, presumably by preferentially activating presynaptic D_2 autoreceptors to inhibit DA release and synthesis. Upon reaching early adulthood (>P56), conditioned place preference (CPP) was used to assess drug cue seeking, with animals receiving either saline or amphetamine (1.0 mg/kg ip.). At P63, brain tissue was collected by rapid decapitation and then sectioned to confirm cannula placement, with efficacy of drug infusions in reducing mPFC DA determined using HPLC. Consistent with our hypothesis, adult rats that received repeated quinpirole mPFC infusions in adolescence exhibited decreased mPFC DA content and correspondingly magnified amphetamine CPP compared to vehicle-infused subjects. Findings suggest that over-activation of D_2 autoreceptors in the adolescent mPFC contributes heavily to later DA hypofunction and enhanced psychostimulant responses. Therefore, we are currently testing if pharmacological blockade of mPFC D_2 autoreceptors during adolescent defeat will prevent stress-induced decreases in mPFC DA activity and normalize amphetamine CPP. Establishing this causal link between adolescent social stress, cortical dopamine, and drug seeking is crucial, as it will facilitate development of targeted pharmacotherapies for preventing the onset of drug addiction following teenage bullying.

Title: Multiple stressors during adolescence induce long-lasting changes in dopamine system responsivity resembling schizophrenia

Authors: *F. V. GOMES, A. A. GRACE;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Adolescence is a developmental period of complex neurobiological changes and heightened vulnerability to psychiatric disorders. Evidence suggests that stress during adolescence is an important risk factor in the etiology of schizophrenia, a developmental disorder that typically manifests in late adolescence or early adulthood. Stressful events alter the responsivity of dopamine (DA) system. Additionally, they can precipitate or exacerbate the psychotic symptoms and increase the risk for developing schizophrenia. Thus, we evaluated the

impact of single and combined stressful events during adolescence on schizophrenia-like signs in rats as adults. Male rats were submitted to stressors during adolescence [restraint stress (RS; 1 h session at postnatal day (PD) 31, 32 and 40); footshock (FS; 25 footshocks of 1.0 mA/2s/session daily through PD31-40; or the combination of FS and RS]. At adulthood, animals were tested for anxiety (elevated plus-maze, EPM), cognitive function (novel-object recognition test, NOR) and DA system responsivity [locomotor response to amphetamine and extracellular recordings of ventral tegmental area (VTA) DA neurons]. Electrophysiological parameters evaluated number of DA neurons firing (population activity), their firing rate and amount of burst firing. We also evaluated whether the exposure to the combination of FS and RS in adulthood (PD65-74) produced behavioral and electrophysiological changes similar to the adolescent stressors. All stressors impaired body weight gain and induced anxiety-like responses in the EPM. FS and FS+RS also disrupted cognitive function as assessed by the NOR test. Only animals exposed to the combination of FS and RS showed a DA hyper-responsivity as indicated by augmented locomotor response to amphetamine and an increased number of spontaneously active DA neurons confined exclusively to the lateral VTA, which projects to associative striatal regions analogous to those found to be hyper-responsive in schizophrenia patients. In contrast, no change was observed when rats were exposed to the combination of FS and RS in adulthood, underscoring that adolescence is a developmental period of particular susceptibility. Our results are in agreement with previous studies showing long-lasting changes induced by stressful events during adolescence. The impact on DA system activity, however, seems to depend on higher-level multiple stressors. Hence, stress during adolescence could be a precipitating factor for the transition to schizophrenia later in life, and stress control at this vulnerable period may circumvent these changes to prevent the emergence of psychosis in susceptible individuals.

Title: Adolescent anhedonia provoked by adverse neonatal experience is abrogated by knockdown of amygdala corticotropin-releasing hormone

Authors: *J. L. BOLTON, J. MOLET, L. REGEV, Y. CHEN, D. Z. YANG, T. Z. BARAM; Dept. of Anat. & Neurobio., Univ. of California-Irvine, Irvine, CA

Abstract: Background: Vulnerability to disabling stress-related emotional disorders such as depression is governed in part by early-life experiences. We have previously demonstrated the importance of maternal care, particularly the predictability of sensory signals from the mother, for the maturation of emotional systems within the brain. This long-term programming of risk vs. resilience has been linked to epigenetic reprogramming of specific stress-sensitive neurons, including augmented expression of corticotropin-releasing hormone (CRH) in the central amygdala (ACE). However, the role of augmented CRH in the enduring emotional vulnerability is unclear. We tested if enhanced ACE-CRH following fragmented neonatal experience is necessary for the development of anhedonia, a harbinger of depression.
Methods: We provoked adverse, fragmented neonatal experience by limited bedding and nesting material in the cages (LBN) during (P)2-9, a sensitive developmental period. Adolescents raised in LBN cages had decreased sucrose preference and peer play, indicative of an anhedonia-like phenotype. To determine the role of ACE-CRH in this phenotype, we employed site-specific, siRNA-based knockdown of CRH and determined the effects on emotional outcomes.
Results: The reduction in sucrose preference induced by early-life LBN was completely reversed by ACE CRH knockdown, and analyses of peer play, an independent parameter of pleasure, is ongoing.
Conclusions: Augmented amygdalar CRH is necessary for the development of anhedonia following fragmented neonatal experience. Ongoing studies aim to identify the mechanism of CRH's actions on the neural network underlying reward and anhedonia.

Title: The impact of environmental enrichment in a rat model of adolescent ptsd

Authors: *E. WALSH[1], A. GARRISON[2], C. UKPABY[2], T. KOELTZOW[2];
[1]Psychology, Bradley Univ., Naperville, IL; [2]Psychology, Bradley Univ., Peoria, IL

Abstract: Post-traumatic stress disorder (PTSD) during adolescence represents an increasingly important diagnostic consideration, as prevalence rates are higher among adolescents compared to adults, and symptom severity and duration may differ significantly (Merikangas et al., 2010). We have recently reported a pre-clinical model of PTSD in rats (Garrison et al., 2015) utilizing a modification of the Single Prolonged Stress (SPS) Model described previously (Liberzon et al., 1997). Results indicate that adolescent rats exhibited robust and prolonged alterations in behavioral anxiety and locomotor activity compared to adults. Environmental enrichment (EE) has been previously shown to decreases anxious behavior and promote exploration of a novel environment (see Simpson & Kelly, 2011). The present study exposed adolescent Sprague-Dawley rats (postnatal day 32-35) to the modified SPS procedure (60 minutes restraint followed by 15 minutes of forced swim) or to sham conditions. Behavioral testing (elevated plus maze, spontaneous locomotor activity, response to novelty) was assessed two weeks after SPS induction. For four weeks, half the subjects were subjected to EE (defined as social housing with novel objects and access to an enriched arena five days/week). All rats were then subjected to another round of behavioral testing. In addition, because substance use disorders are frequently comorbid with PTSD, rats were subsequently tested for the locomotor response to cocaine (15 mg/kg). We have hypothesized that EE will rescue the behavioral consequences of SPS, resulting in increased exploration of the open arms of the elevated plus maze and increased exploration of the open field. In contrast, EE is anticipated to increase the locomotor response to cocaine, presumably due to effects on dopamine transporter expression.

Title: Repeated stress impairs prefrontal cortical regulation of the amygdala in rats

Authors: *J. ROSENKRANZ, W. ZHANG;
Cell. and Mol. Pharmacol., The Chicago Med. School/RFUMS, North Chicago, IL

Abstract: The prefrontal cortex (PFC) can impose inhibitory regulation over the activity of the amygdala and thereby regulate emotion. Adolescence is associated with emotional lability and there are hints towards immature PFC regulation over the amygdala in adolescents. Repeated stress produces further dysregulation of emotion. One possible contributing factor for this effect is through impaired control over the amygdala by the PFC. The purpose of this study was to test 1) whether there is less regulation by the PFC over the amygdala in adolescence and 2) whether repeated stress reduces PFC regulation over the amygdala. To accomplish this, adolescent rats were exposed to control handling or repeated restraint stress (P32-41). On P42, rats underwent fear conditioning and extinction or acute in vivo electrophysiological recordings from neurons of lateral (LAT) and basal (BA) nuclei of the amygdala. These adolescent rats were compared to adult rats that were exposed to the same protocol. We found that adolescent rats displayed slower fear extinction, and this was further impaired by repeated stress. In addition, adolescent rats displayed weaker inhibition of LAT and BA neurons upon stimulation of the infralimbic (IL) or prelimbic (PrL) PFC, which was further reduced by repeated stress. Though the mechanism is unclear, these results are consistent with a weaker PFC regulation over the amygdala in adolescent rats, and that this already weaker regulation is disrupted by repeated stress. This may contribute to the harmful effects of repeated stress on affect and mood in adolescence.

Title: Binge alcohol consumption during puberty causes altered DNA methylation in the brain of alcohol-naïve offspring

Authors: *A. ASIMES, A. R. TORCASO, Y. S. RAO, E. PINCETI, C. K. KIM, T. R. PAK;
Cell and Mol. Physiol., Loyola Univ. Chicago Dept. of Cell and Mol. Physiol., Maywood, IL

Abstract: Binge alcohol consumption among adolescents is a major health concern in the United States, with 21% of teenagers reporting binge-pattern drinking behavior in the last 30 days. Binge drinking is defined as raising the blood alcohol concentration above 0.08% within 2 hours. This behavior is associated with an increased risk for anxiety and mood disorders in adulthood. Children of alcoholics also exhibit a higher rate of suicide as well as an increased risk of alcohol addiction. Recently, our lab has shown that alcohol-naïve offspring of animals exposed to alcohol during adolescence show altered gene expression profiles in the hypothalamus, a region of the brain involved in stress regulation. These intergenerational changes might be caused by a mechanism involving epigenetic inheritance. DNA methylation is a stable and heritable epigenetic mark that can be influenced by environmental factors. Aberrant DNA methylation is implicated in several cognitive disorders that are also associated with alcohol use such as schizophrenia, depression, and addiction. Using a rodent model of adolescent binge alcohol exposure, we employed Enhanced Reduced Representation Bisulfite Sequencing (ERRBS) as an unbiased approach to test the hypothesis that parental exposure to binge-pattern alcohol during adolescence alters DNA methylation in the hypothalamus of alcohol-naïve offspring. Wistar rats were administered a repeated binge-EtOH exposure paradigm where they received 3g/kg of 20% (v/v) EtOH via oral gavage once daily for 3 days, then 2 days vehicle and another 3 days EtOH at both early and late puberty (PND37, 67). Animals were paired for mating 24h after the last EtOH dose. Pairs consisted of all combinations of EtOH- and vehicle-treated males and females. Litters were culled to 10 pups per dam and were left until PND7 when all animals were euthanized. The hypothalamus was extracted from male pups and genomic DNA was isolated. We found that male offspring of alcohol-exposed parents exhibited differential DNA methylation patterns and that these patterns varied between maternal and paternal exposure. Differentially methylated cytosines (DMCs) were distinct between all mating pairs, with only nine genes common to all treatment groups. Genes with DMCs displayed alterations in expression, but methylation was not the only predictor of expression levels, underscoring the complexity of transcriptional regulation in this tissue. Overall, we have shown altered DNA methylation in the hypothalamus of alcohol-naïve offspring following parental adolescent binge drinking.

Title: Binge alcohol exposure during puberty alters miRNAs and mRNAs involved in synaptic plasticity in the ventral hippocampus

Authors: *Y. S. RAO[1], C. K. KIM[2], A. ASIMES[2], A. TORCASO[2], C. B. DINGWALL[2], T. R. PAK[2];

Abstract: Puberty is a critical period of postnatal brain development characterized by increased neurogenesis and synaptogenesis. Physical and psychological stressors during pubertal development have been linked with an increased risk for mental health disorders in adulthood, suggesting that perturbations of the hypothalamo-pituitary-adrenal (HPA) axis during this critical period negatively impacts genes regulating these neurodevelopmental processes. Previous studies in our laboratory showed that peri-pubertal episodic binge-pattern alcohol exposure dysregulated HPA axis activity, an effect that persisted in adulthood even after a long period of alcohol abstinence. Further, we showed that alcohol exposure induced long-term alterations in small non-coding microRNAs, some of which were predicted to target key neurodevelopmental genes. The current study extends those findings and we hypothesized that peri-pubertal alcohol exposure dysregulates genes involved in mediating hippocampal synaptogenesis by altering their associated microRNA effectors. To test this hypothesis, peri-pubertal male rats were administered an episodic binge alcohol paradigm as previously described (Przybycien-Szymanska et al., PLoS ONE 2011). Upon euthanasia, the brains were flash frozen and the ventral hippocampus was microdissected. We then used qRT-PCR profiling arrays to measure the expression levels of microRNAs and mRNAs known to be important for neurodevelopment and synaptic plasticity in the ventral hippocampus. Overall, the data revealed that alcohol significantly decreased seven microRNAs (miR-19a/b-3p, miR-29a/c-3p, miR-34a, miR-488-3p, and miR-181d) in the ventral hippocampus. Moreover, alcohol correspondingly increased several genes (mRNAs) associated with synaptic plasticity , suggesting that they were potential targets of the miRNAs that decreased in response to binge alcohol exposure. Together, our data revealed that microRNAs are a putative molecular mechanism mediating alcohol-induced disruption of synaptogenesis during pubertal development.

Title: Food restriction alone, exercise alone or the two combined during adolescence rescue the behavioral deficits resulting from variant BDNF Val66Met polymorphism

Authors: *Y.-W. CHEN[1], F. LEE[2], C. J. AOKI[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Psychiatry, Weill Cornell Med. Col., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) is an important determinant of hippocampal function throughout the lifespan, facilitating neuronal survival and differentiation, synaptic structure and plasticity, long-term potentiation, learning and memory. A single nucleotide polymorphism (SNP), which produces a valine-to-methionine substitution at codon 66 (Val66Met) in BDNF leading to reduced activity-dependent secretion of BDNF. The BDNF Val66Met polymorphism has been associated with anxiety disorder, and abnormalities in hippocampal formation and cognitive function. Previous studies suggest that both food restriction and exercise elevate BDNF levels in the hippocampus. Here, we investigated whether food restriction and/or exercise during adolescence would rescue the behavioral deficits in BDNF-Val66Met knock-in mice. Four experimental groups of male and female pubertal BDNF-Val66Met knock-in mice and their wild-type littermates were evaluated: CON (singly housed mice with no running wheel experience or food restriction), and three experimental groups: EX (housed with a wheel from P36-44), FR (food restricted from P41-44), and FR-plus-EX (housed with a running wheel from P36-44 and food restriction from P41-44). We assessed anxiety-related levels of these animals after recovery from food restriction by elevated plus maze. Spatial and object recognition memory and social preference and recognition of the animals were also tested after recovery from food restriction. Our preliminary data suggest that, during early adulthood, male $BDNF^{Met/Met}$ mice display increased anxiety-like level and show impaired spatial, object recognition memory, and social recognition ability. EX, FR, and FR-plus-EX

during adolescence have no effect on anxiety-like level in $BDNF^{Met/Met}$ mice. However, EX, FR, and FR-plus-EX show differential effects but mostly rescue the spatial, object recognition memory, and social recognition deficits of $BDNF^{Met/Met}$ mice to levels of $BDNF^{Val/Val}$ controls. On the other hand, female $BDNF^{Met/Met}$ mice display normal spatial memory and social recognition ability, but increased anxiety-like level and impaired object recognition memory. EX, FR, and FR-plus-EX can rescue the object recognition memory deficits in $BDNF^{Met/Met}$ female mice. This study highlights sex differences in the effects of BDNF Val66Met polymorphism on cognitive functions, while anxiety-like behavior is similar across the sexes. This study also provides evidence for the effects of food restriction and/or exercise during adolescence on rescuing the behavioral deficits in $BDNF^{Met/Met}$ mice.

Title: Juvenile stressor exposure and diet alters ghrelin sensitivity in adulthood

Authors: *E. ALI[1,2], P. KENT[2,3], A. FREITAS[1], A. AWADIA[3], M. ABU NADA[3], J. JAMES[2], A. ABIZAID[1], Z. MERALI[2,3];
[1]Carleton Univ., Nepean, ON, Canada; [2]Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Juvenile stress is proposed to contribute to the prevalence of obesity in school-aged children by possibly increasing the preference and consumption of calorically dense palatable food (PF). This stressed-induced consumption of PF may lead to long-term detrimental consequences such as obesity in adulthood. There is evidence to suggest that ghrelin, an orexigenic peptide, contributes to this stress-induced preference by mediating dopamine release within mesolimbic structures. More specifically, ghrelin binds to the growth hormone secretagogue receptor which are expressed at the ventral tegmental area and can stimulate dopamine release to the nucleus accumbens. Ghrelin increases reward-associated behaviors such as conditioned place preference for drugs of abuse, motivation and enhancing cocaine hyperlocomotor activity. As such, the objective of the present study was to assess how access to PF in combination with juvenile stressor exposure alters sensitivity to exogenous administered

ghrelin. In this study, two groups of male Wistar rats were subjected to an episodic stressor exposure during the juvenile period on post-natal days (PD) 27-29. Both groups received ad lib access to chow however one group had daily limited access to PF. In addition, there were two non-stressed diet counterpart groups. In adulthood (PD 61), rats were subjected to a central injection (ghrelin (10ug) or vehicle) and given ad lib access for two hours to one of the two diets: a novel palatable diet (cookie dough) or chow. Consumption was recorded. Afterwards, locomotor activity was compared between an intraperitoneal injection of cocaine (10mg/kg) with and without a peripheral pretreatment of ghrelin (10ug). Our findings indicate that in adulthood, central ghrelin administration did not increase consumption of cookie dough in PF fed rats regardless of stressor exposure, however in previously stressed chow fed rats an increase in cookie dough intake was observed. Interestingly, a pretreatment of ghrelin did not increase cocaine hyperlocomotor activity in PF fed rats; yet enhanced cocaine hyperlocomotor activity was displayed in chow fed rats. These findings suggests that access to PF dampens ghrelin signaling regardless of juvenile stressor exposure and that juvenile stressor exposure enhances ghrelin signaling in chow fed rats. It is proposed that stressor exposure during this sensitive developmental period can elicit a sensitization to rewarding stimuli (PF and drugs of abuse) in adulthood that is mediated by enhanced ghrelin signaling.

Title: Effects of juvenile stress exposure on adult behaviour and physiology in convict cichlid fish

Authors: *B. HOPE[1], K. FJELLNER[2], N. BATTY[1], P. HURD[2];
[2]Psychology, [1]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Stress coping style is a major personality dimension in fish and may be assessed using behaviours related to anxiety. Anxiety is indicated by freezing and hiding behaviour, while ambulatory behaviour indicates a lack of anxiety. Moderate stress exposure during development can result in stress inoculation, such that individuals display more active coping styles compared

to those without stress exposure. This study investigates how developmental stress exposure affects adult stress coping styles in the convict cichlid (*Amatitlania nigrofasciata*) to explore possible stress inoculation effects on behavioural and physiological responses to stress. Fish were net chased for two minutes per day for two weeks immediately after becoming free-swimming, and then their behavioural (i.e., exploration patterns in open field and plus maze tasks) and cortisol responses to stress were assessed at nine months of age. Cortisol levels by weight were significantly correlated to treatment, such that stressed fish had lower cortisol levels than controls. This result is consistent with the stress inoculation hypothesis that moderate juvenile stress exposure will result in lower stress reactivity (i.e., lower cortisol levels) later in life. In the plus maze task, there was a significant effect of treatment on the amount of time spent in open and closed arms but no effect of cortisol levels. Stressed fish spend more time in open arms than control fish, which is also consistent with stress inoculation, as the stressed fish are employing a more active coping style than the control fish. In contrast to plus maze, open field task showed a significant relationship between amount of time spent in inside squares and cortisol levels and no effect of treatment. Fish with lower cortisol levels spent more time in inside squares, while fish with higher cortisol levels spent less time in inside squares. A significant interaction effect between cortisol levels and treatment on exploration rate of inside squares, such that stressed fish with low cortisol levels explored faster and those with high cortisol levels explored slower, while control fish had medium exploration rates independent of cortisol levels. It is possible that stress exposure influences the hormonal profile, as expected by the relationship between cortisol levels and treatment, which is supported by the interaction effect on exploration rate. This suggests that plus maze behaviour may be affected more by personality, such as anxiety, while open field may be more influenced by physiology, such as hormonal profiles. Further research will be done to delve deeper into this dichotomy.

Title: Food restriction-evoked voluntary exercise increases the number of varicosities and average lengths of noradrenergic axons in the hippocampal hilus of adolescent female rats

Authors: *A. EVANS, A. AKAD, Y.-W. CHEN, C. AOKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Anorexia nervosa (AN) is a disorder characterized by intentional food restriction, severe weight loss and excessive exercise and is often comorbid with anxiety and depression. The onset of AN is most often during adolescence, a period of heightened neurogenesis in the dentate gyrus. Little is yet known about the structural and developmental impact of AN on adolescent brains. While it has been shown that the peripheral noradrenergic (NA) system is perturbed in patients diagnosed with AN, whether the NA system within brain is also altered has not been reported. In order to explore brain changes that could be associated with AN, we used an animal model, called activity-based anorexia (ABA), whereby food restriction evokes voluntary food restriction and excessive exercise (possibly, as a form of foraging behavior) within 24 hrs, causing some to die unless removed from the food restriction-plus-wheel environment. Animals' daily wheel running distances and body weights were measured for 8 days, from P35 or 36. Food restriction was imposed during the last 4 of those 8 days. The extent of weight loss and increase in wheel running during the food-restricted period varied across individuals, with weight loss ranging from 11% to 23% and wheel activity increasing 0 to > 6-fold among 8 ABA rats. On P44, all animals were euthanized by transcardial perfusion with 4% paraforlamdehyde. Brain tissue was immunolabeled for norepinephrine's rate-limiting synthetic enzyme, dopamine β-hydroxylase. Neurolucida 360's AutoNeuron feature was used to automatically trace, then count the number and measure lengths of NA axons contained within the hilus from coronal vibratome sections (10 µm x 131.5 µm x 175.5 µm). Neurolucida (version 10) was also used to manually trace 10 randomly selected axons per animal, together with all of their associated varicosities, within the hilus. Compared to age-matched rats without food restriction or wheel access (N=8, CON), the inter-varicosity distances along NA axons was reduced by 26% ($p<0.05$) within the hilus of ABA animals, while the average axonal length was increased by 34% ($p<0.05$), together increasing the potential release sites of norepinephrine. Pearson correlation analyses revealed that resilient animals, characterized by minimal weight loss or minimal FR-evoked running, exhibit more varicosities ($r=.67$, $p=.07$) and longer axonal segments ($r=-.69$, $p=0.05$). Thus, individuals with the greatest adaptability for survival by suppressing wheel running are also the ones able to increase NA innervation the most. Enhanced NA signaling may support behavior that is adaptive to food deprivation within confine of a cage, namely to eat, rather than run.

Title: Acute corticosterone treatment increases anxiety and dendritic elongation and arborization in the orbitofrontal cortex in mid-adolescent but not early-adolescent male rats

Authors: *N. L. REMPEL-CLOWER, T. EARNEST, M. YETTER;
Grinnell Col., Grinnell, IA

Abstract: Stress during adolescence is a risk factor for anxiety and mood disorders, and has been shown to induce morphological changes in neurons in the prefrontal cortex and amygdala. As in adults, adolescent exposure to stressors activates the HPA axis, leading to increased corticosterone (CORT) levels in rats, and the hormonal response to stress is enhanced during adolescence. Previous research has found varying effects of exposure to stressors on anxiety associated with age of exposure and age of testing. Although the orbitofrontal cortex (OFC) and basolateral amygdala (BLA) participate in managing cognitive and emotional responses to stress, little is known about how acute stress during specific periods of adolescence affects the dendritic structure of neurons in these regions. The aim of the present study was to elucidate age-dependent effects of acute CORT treatment during adolescence. Specifically, we investigated if a single CORT injection increases anxiety-type behavior in adolescent rats and if it causes OFC and BLA dendritic remodeling. Male adolescent Sprague-Dawley rats were given CORT (10 mg/kg) or saline control injections in early adolescence (28 days old) or given CORT or saline control injections in mid-adolescence (36 days old). Anxiety was assessed with the elevated plus maze and open field test 12 days after injection, while rats in both groups were still within the adolescent period. One day after behavioral testing, rats were euthanized and brain tissue was Golgi-stained for assessment of dendritic morphology of neurons in the OFC and BLA using Neurolucida. In the elevated plus maze, mid-adolescent CORT-treated rats spent significantly more time in the open arms than the age-matched control group, indicating an increase in anxiety-type behavior. Early-adolescent CORT-treated rats, in contrast, did not exhibit any behavioral effects of the treatment. Similar age-specific effects of CORT were observed in OFC neuronal structure. In the mid-adolescent CORT-treated rats, morphological analysis revealed evidence of elongation and arborization of apical dendrites of OFC neurons. No changes were detected in basal dendrites of these neurons. CORT treatment during early adolescence had no effect on dendritic morphology of OFC neurons. In BLA neurons, no changes in dendritic morphology were observed after CORT treatment during either early adolescence or mid-

adolescence. Taken together, these findings suggest that acute CORT administration in mid-adolescence causes increased anxiety and dendritic expansion in the OFC later in adolescence, but these effects are not present after acute CORT administration in early adolescence.

Title: Divergent morphological effects of repeated social stress on rat prefrontal cortical pyramidal neurons in adolescent compared to adult male rats.

Authors: *E. GENG;
Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Chronic stress can lead to psychiatric illness characterized by impairments of executive function, implicating the prefrontal cortex as a target of stress-related pathology. Previous studies have shown that multiple types of chronic stress reduce dendritic branching, length, and spines of medial prefrontal cortex (mPFC) pyramidal neurons. However, these studies focused on layer 2/3 pyramidal neurons in adult rats. Whereas these neurons process incoming information, layer 5 is the major output layer. Because the prefrontal cortex develops throughout adolescence, stress during this period may have a greater impact on structure and function than stress during adulthood. In this study, male adolescent (42-48 days old; n = 36 neurons from 4 controls, 30 neurons from 4 stressed rats) or adult (68-72 days old; n=37 neurons from 4 controls, 32 neurons from 4 stressed) rats were exposed to repeated social stress as 5 days of resident-intruder stress or control manipulation. Brains were processed for Golgi staining 24 h after the final manipulation, cells were visualized on a Nikon Eclipse scope, and Neurolucida was used to reconstruct and analyze dendrites. Repeated social stress induced age- and layer-specific effects. In layer 2/3, there was an interaction of age*stress such that stress increased basal dendritic length in mid-adolescents, but decreased it in adults [$F(3,119)=5.38$, $p=0.0003$]. There was an overall stress-induced decrease in basal dendrite branching [stress effect: $F(3,119)=6.15$, $p<0.0001$]. Mid-adolescent neurons had significantly more apical branches than

adults [age effect: F(3,119)=11.85, p=0.003] and stress decreased apical branches in mid-adolescents but not adults [age*sex interaction: F(3,119)=11.85, p=0.014). In layer 5, basal dendrites of mid-adolescents were longer [age effect: F(3,134)=16.44, p<0.0001 and had more branches [age effect: F(3,134)=17.56] Stress increased basal dendrite length [age*stress interaction: F(3,134)=16.44, p=0.0004] and branching [age*stress interaction: F(3,134)=17.56, p<0.0001] only in adults, and decreased branching in mid-adolescents. Stress also increased apical dendrite length only in adults [age*stress: F(3,134)=6.35, p=0.0028] . Likewise, stress increased apical branching in adults but decreased it in mid-adolescents [F(3,134)=7.08, p=0.0002]. These findings demonstrate divergent morphological effects of social stress on mPFC dendritic structure of adolescent and adult male rats that suggest an increased vulnerability of adolescents to cognitive-impairing effects of social stress and the development of an opposing response that may be adaptive in adulthood.

Title: TrkB stimulation blocks long-term behavioral consequences of adolescent corticosteroid exposure

Authors: *E. T. BARFIELD[1], K. J. GERBER[2], S. L. GOURLEY[3];
[1]Grad. Program in Neuroscience, Yerkes NPRC, [2]Mol. & Systems Pharmacol., [3]Grad. Program in Neuroscience, Yerkes, Dept of Pediatrics, Dept of Psych & Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: In humans and rodents, stress regulates reward-related decision-making. For instance, prolonged stressor and corticosteroid exposure impair the ability of rodents to select actions based on their consequences. However, neurodevelopmental factors remain largely uncharacterized. Here, we exposed mice to oral corticosterone (CORT) and found that subchronic exposure in early adolescence, but not in adulthood, impaired goal-directed decision-making in adulthood. The pattern of behavioral deficiencies was reminiscent of that following

hippocampal damage, so we characterized the expression of tyrosine receptor kinase B (trkB) in the ventral hippocampus (vHC) and interconnected regions – the medial prefrontal cortex and amygdala – following CORT. CORT exposure decreased the ratio of the full-length (active) trkB receptor to the truncated (inactive) form of trkB in all regions and in both adolescents and adults. However, CORT decreased phosphorylation of the signaling protein ERK1/2 (downstream of trkB) selectively in the vHC of adolescent mice. Administration of the trkB agonist, 7,8-dihydroxyflavone (7,8-DHF), in adolescence blocked CORT-induced decision-making and motivational deficits in adulthood in both males and females and induced resilience to depressive-like behavior in the forced swim test. These findings implicate vHC trkB-ERK1/2 signaling in habit-based behaviors and motivational deficiencies following stress hormone exposure in early adolescence.

Title: Stress in early puberty produces impulsive quitters

Authors: *L. F. GONZALEZ MARTINEZ, J. D'AIGLE, S. LEE, H. J. LEE, Y. DELVILLE; Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Traumatic experiences during childhood or adolescence can alter behavioral responses and are a risk factor for mental disorders later in life. In animals, individuals attacked by adults during puberty become themselves aggressive once adults. Perhaps, enhanced aggression observed as repeated attacks towards opponents is associated with a lack of impulse control or a deficit in adjusting behavior when environmental rules change (behavioral flexibility). We analyzed impulsivity and behavioral flexibility in male golden hamsters exposed daily to aggressive adults from postnatal day 28 to 42. Later in adulthood, the animals were tested in a Go-NoGo task to evaluate action inhibition. In the Go-NoGo task subjects were trained to respond to a “go” cue (lever press in the presence of a light) and inhibit response to the “no-go” cue (withhold lever press in the presence of a combined tone and light cue). Previously stressed hamsters were less likely to inhibit a conditioned lever pressing response during NoGo trials. Since this effect could be the result of a lack of behavioral flexibility, the animals were tested to

evaluate their response when the reward associated with conditioned lever presses was fully omitted. However, all animals were equally capable of changing their behavior and decrease the frequency of conditioned response across sessions. Behavioral flexibility was further addressed by testing responses when a previously immediate reward was delayed by 60 seconds after lever pressing. Previously stressed animals showed decreased lever pressing on the first day of testing, abandoning the chamber area with the lever within minutes. These studies show that stress in early puberty causes a reduction in action inhibition as seen in the Go-NoGo task and selective impairment in behavioral flexibility as seen when the reward was delayed but not when it was omitted.

Title: Impact of arterial stiffness on cognitive and cerebrovascular functions

Authors: *M. F. IULITA[1], G. MUHIRE[1], D. VALLERAND[1], M. GRATUZE[2], F. R. PETRY[2], G. FERLAND[1], E. PLANEL[2], H. GIROUARD[1];
[1]Univ. De Montreal, Montreal, QC, Canada; [2]Univ. Laval, Quebec, QC, Canada

Abstract: Arterial stiffness is a common condition associated to aging and hypertension, and it is emerging as a strong risk factor for cognitive decline and dementia. Arterial stiffness refers to the reduced capability of an artery to buffer the pulsatile blood flow from ventricular ejection. When large arteries loose elasticity, the resultant increased pulsatility may lead to downstream microvascular damage. The cellular and molecular mechanisms linking arterial stiffness to cognitive dysfunction remain poorly understood. Thus, using a novel murine model based on carotid calcification, we aimed to examine the effects of arterial stiffness on learning and

memory, neurovascular coupling, blood-brain barrier (BBB) permeability and features of Alzheimer's disease pathology. Arterial stiffness was induced by the application of a 0.3M $CaCl_2$ –soaked pad on the right carotid artery (20 min) of C57BL/6 male mice aged 10-12 weeks. Control mice received 0.9% NaCl, in identical conditions. Animals were sacrificed between 2 and 3 weeks after surgery. Results show that carotid calcification leads to a slower spatial learning acquisition, as assessed by the Morris water maze test. In this paradigm, mice with arterial stiffness further exhibited significant impairments in spatial reference memory. Arterial stiffness also attenuated the cerebral blood flow response to whisker stimulation and to the topical application of the endothelium-dependent vasodilator acetylcholine, monitored by laser-Doppler flowmetry *in vivo*. Although modest, arterial stiffness led to a shift in the Aβ40/Aβ42 ratio in the frontal cortex, without affecting tau protein phosphorylation. Analysis of cerebral autoregulation and BBB permeability are underway. These initial results show that arterial stiffness has a negative impact on cognitive and cerebrovascular functions, and should therefore be considered as target to protect the brain. In the long-term, we plan to use this model to test experimental therapeutics.

Title: Is cerebral hemodynamic variability needed to maintain cognition?

Authors: *S. KESLACY, G. ACOSTA, J. RAMIREZ, J. BENAVIDEZ, C. DY; Kinesiology, CSULA, Los Angeles, CA

Abstract: Acute exercise has been recognized to modulate cerebral blood flow (CBF), but the relationship between changes in CBF and cognitive performance is unclear. **Purpose:** (i) to assess the effects of exercise intensity on CBF (ii) to assess the effects of exercise on cognitive performance (iii) to determine the relationship between exercise-induced changes in CBF and cognition. **Methods:** 31 sedentary adults (19 males and 12 females, 26 ± 3 yrs.) participated in a crossover study and performed a light (20% of power max) and moderate (65% of power max) constant-load cycling exercise for 10 minutes. Middle cerebral artery (MCA) blood flow velocity

(CBFv), peak and pulsatility index (PI) were continuously monitored during exercise using transcranial Doppler ultrasonography. Cognition was assessed using the Cogstate brief battery test: detection task (for psychomotor function / speed of processing), identification task (for visual attention), one card learning (for visual learning & memory), one back task (for working memory) and Groton maze (for visuospatial memory) were performed before and immediately after exercise. **Results:** CBFv increased significantly during exercise at 20% ($p=.02$) and tend to decrease during exercise at 65% ($p=.06$). CBFv significantly increased during the Groton Maze test at rest ($p=.02$) but not during any other cognitive test. There were no changes in CBFv during the cognitive testing following exercise at 20%, however, CBFv decreased and PI increased ($p<0.01$ and $p<0.04$ respectively) for all the cognitive testing following the exercise at 65%. Cognitive performance did not change following exercise despite the change in CBFv. **Conclusion:** Exercise regardless of intensity did not result in changes in cognitive performance. Thus, CBF hemodynamic variability may be necessary to preserve cognitive performance.

Title: Sex and intensity modulate cerebral hemodynamic symmetry during exercise

Authors: *J. RAMIREZ, J. BENAVIDEZ, G. ACOSTA, C. DY, S. KESLACY;
Kinesiology, California State Univ. Los Angeles, Los Angeles, CA

Abstract: A very tight cerebral blood flow (CBF) hemodynamic response is essential for brain function. Most of the studies on CBF using the middle cerebral artery (MCA) have been investigating only one hemisphere (predominantly right). Thus, lateralization in blood flow response to stimulus is not well understood. At rest, CBF symmetry is expected; whereas asymmetrical flow can be an indicator of psychological or physiological pathology. It is possible that asymmetries in cerebral hemodynamics also exist as a normal and healthy response to stimulation in order to maintain cognition. **Purpose**: To assess bilateral symmetry in MCA blood

flow during a physiological stress. **Methods**: Participants (N = 33, 15 femals and 18 male) performed 10 minutes of light (20% of max power) and moderate (65% of max power)cycling exercise. Brain hemodynamics measures of mean velocity, peak velocity, and pulsatility index were monitored bilaterally for the MCA by two 2-MHz Doppler probes. Sample sizes were set to 10 mm and depth ranged from 50 to 60 mm. Data was processed using commercially available software (Sonara Medical Systems, Carefusion). Statistical significance in bilateral asymmetry was assessed using a mixed model analysis of variance with gender (male vs female) and exercise intensity (light vs moderate) as between-subjects factors (IBM, SPSS) and significance was set as $p < 0.05$. **Results**: At rest, no significant differences in right versus left CBF mean velocity (mean = 50.5 vs. 46.4 cm s^{-1}), peak (mean = 80.3 vs. 78.2 cm s^{-1}), or pulsatility index (mean = 1.1 vs 1.2) were observed ($p > 0.05$ for all measures). During exercise, assessment for the main effect of exercise intensity revealed significantly greater right compared to left side peak velocity during moderate exercise ($p < 0.05$), but not during light exercise. No significant gender-specific asymmetries were detected as main effects. A significant interaction amongst right/left asymmetry, exercise, and gender was detected in both mean velocity and peak velocity ($p < 0.05$). Post-hoc analysis revealed greater right compared to left CBF mean velocity and peak velocity during light exercise in females ($p < 0.05$ for both measures). The same was also observed in males, but for moderate intensity exercise ($p < 0.05$ for both measures). **Conclusion**: Hemispheric differences in MCA blood flow exists in response to metabolic stress, although level of intensity and gender can influence the nature of the asymmetry in cerebral hemodynamics. These findings lead the way for future study to better understand mechanisms driving cerebral blood flow asymmetry during exercise.

Title: Regional CNS differences in rapid oxygen and pH changes during neurovascular coupling determined using fast-cyclic voltammetry

Authors: *P. S. HOSFORD[1], J. MILLAR[2], J. WELLS[1], I. N. CHRISTIE[1], A. V. GOURINE[1]; [1]Univ. College, London, London, United Kingdom; [2]Barts and The London Sch. of Med. and Dent., London, United Kingdom

Abstract: The mechanisms of neurovascular coupling (NVC) match brain energy supply with demand. The molecular events that trigger functional hyperemia are under debate, and may not be regionally uniform. There is a lack of experimental techniques with sufficient spatio-temporal resolution to probe changes in parenchymal O_2 concentration, PCO_2 and pH at the level of individual CNS nuclei. Here we used fast-cyclic voltammetry (FVC) to monitor changes in tissue PO_2 and pH in the somatosensory cortex and brainstem during neuronal activation *in vivo*. A voltage ramp is applied to carbon fiber microelectrodes (CFM; ⌀ 7μm) from 0v to -1v at 200V/s, 4 times every second. Molecular oxygen and protonated groups on the surface of the CFM are reduced. Currents generated from these reactions are proportional to the concentration of oxygen and protons. Adult male rats (~300g) were anesthetized with α-chloralose (75mg kg^{-1}). Blood gas tensions and pH were maintained within the physiological ranges. CFM was placed in the somatosensory region of the cortex or in the brainstem's nucleus of the solitary tract (NTS). Electrode placements were confirmed by recording extracellular potentials evoked by the electrical stimulation of the forepaw or the vagus nerve (1mA, 1Hz). Exposed tissue was sealed from the air.

To confirm voltammetric oxygen and pH sensitivities, systemic hypoxia and hypercapnia were induced. During apnea (30s) expected rapid decreases in cortical brain tissue PO_2 were recorded(n=3). Systemic hypercapnia (10% CO_2; 5min) caused a decrease of brain parenchymal pH by 0.17±0.04 units (n=5).

Electrical forepaw stimulation evoked biphasic changes in cortical parenchymal pH and PO_2. Initially, PO_2 increased (by 12±1mmHg; n=6), followed by a decrease of 8±3 mmHg. This profile of PO_2 changes was similar to the time course of BOLD signal recorded under similar experimental conditions in a 9.4T small animal MRI scanner (Agilent). Changes in pH followed a similar profile with an initial increase (by 0.1±0.02 units; n=6) followed by a decrease (by 0.06±0.01 units) before returning to the baseline. In the brainstem, electrical stimulation of the vagus nerve triggered an initial decrease in PO_2 (by 7±2mmHg; n=5) followed by an increase (by 3±1 mmHg; n=5). pH decreased (by 0.15±0.04 units) before returning to the baseline.

These data demonstrate that pH and PO_2 changes associated with NVC vary between different brain regions. FCV allows simultaneous electrochemical detection of blood flow-related changes in brain parenchymal PO_2 and pH with sufficient spatio-temporal resolution required to investigate the physiological significance of these differences.

Title: Coupling of spontaneous and sensory evoked hemodynamic signals to neural activity in the barrel cortex of awake mice

Authors: *A. WINDER[1], P. J. DREW[2,3,4];
[2]Engin. Sci. and Mechanics, [3]Dept. of Neurosurg., [4]Dept. of Bioengineering, [1]Pennsylvania State Univ., University Park, PA

Abstract: Hemodynamic signals are used to infer neural activity in the absence of overt behavior or tasks using non-invasive imaging techniques such as fMRI. However, it is not clear whether spontaneous neural activity and sensory evoked neural activity are coupled to hemodynamic changes in the same way. We simultaneously measured neural activity, cerebral blood volume (CBV), and behavior in the somatosensory cortex of awake, head-fixed mice in order to compare neurovascular coupling across behavioral states. Whisker position was monitored to detect periods of attentive active sensing and the whiskers were periodically stimulated with brief puffs of air. This allowed the measured CBV and neural data to be categorized according to three behavioral types: sensory-evoked, volitional whisking, and rest, which was defined as the absence of discernible behaviors. The variance in CBV was significantly larger during passive sensation and volitional movement than during rest. The hemodynamic response function (HRF), which is the linear kernel that relates neural activity to the measured CBV, was similar for all three behaviors. This indicates that neurovascular coupling is conserved across behaviors, but that large "spontaneous" CBV changes are driven by volitional movement. To determine the amount of CBV variance explained by neural activity, the HRF was used to predict CBV changes from the measured local neural activity on individual trials and for averaged data. The HRF performed well at predicting sensory evoked CBV changes, accounting for ~80% of the CBV variance. However, <10% of the CBV fluctuations at rest could be accounted for by the local neural activity. The unpredicted component of the CBV fluctuations was concentrated around 0.1 Hz. To test whether a portion of resting-state CBV was driven independently of local

neural activity, we infused muscimol into the barrel cortex while measuring CBV and neural activity. Muscimol decreased the amplitude of sensory-evoked CBV response and the CBV variance at rest, confirming that spontaneous hemodynamic fluctuations depended strongly on local neural activity. The power of remaining CBV fluctuations was concentrated at 0.1 Hz. Our results suggest that large spontaneous hemodynamic signals are driven by volitional, active behaviors, and confirm that spontaneous hemodynamics are associated with local neural activity. However, the poor performance of the HRF during rest suggests a complex relationship between measured neural activity and spontaneous hemodynamic fluctuations.

Division, Athinoula A. Martinos Ctr. for Biomed. Imaging, Dept. of Radiology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: The regulation of cerebral blood flow (CBF) and oxygen supply to match neuronal functional activity is regulated by synchronous action of different cell types -- neurons, vascular cells such as vascular smooth muscle cells and endothelium, and glia -- comprising the neurovascular unit. Pericytes, mural cells of the capillary vessel wall, are critical for the stabilization of the capillary wall, maintenance of the blood-brain barrier and have recently been implicated in the regulation of capillary diameter. However, their role in regulation of neurovascular coupling remains debatable. Using pericyte-deficient Pdgfrβ+/- mice, we show that pericyte reduction *in vivo* leads to delayed capillary dilation in response to neuronal stimulus, and reduced red blood cell flow velocity in capillaries carrying oxygen to activated brain sites, in spite of intact arteriolar response and vasoactivity. We show that diminished cortical CBF responses to stimulus in pericyte-deficient mice leads to metabolic stress, which over time leads to impaired neuronal excitability and neurodegenerative changes. Together, these data imply that pericytes play an important role in neurovascular coupling and oxygen supply to the brain, and that pericyte degeneration contributes to neurovascular uncoupling. Degeneration of pericytes, likely contributes to neurovascular dysregulation, leading to neurovascular dysfunction and eventually neurodegeneration.

Title: Serotonergic modulation of neurovascular coupling: receptor and pathway specific effects.

Authors: A. SPAIN, G. BREZZO, J. BERWICK, C. HOWARTH, *C. J. MARTIN;
The Univ. of Sheffield, Sheffield, United Kingdom

Abstract: The rapid and local adjustment of cerebral blood flow in relation to changing neuronal activity is termed neurovascular coupling. Whilst our understanding of the physiological mechanisms underpinning neurovascular coupling has advanced substantially in recent years, empirical work has focussed on the role for excitatory, glutamate-mediated neurotransmission in neurovascular coupling, with little research into how important modulatory neurotransmitters such as serotonin (5-HT) might affect neurovascular function. Receptors for 5-HT are found not only upon many neuronal cell types, but also upon non-neuronal neurovascular unit cells. Changes in brain 5-HT and/or in the availability of specific 5-HT receptors has the potential to alter neurovascular function in complex ways which might be dependent upon brain region, neurophysiological (activation) conditions, and neuropathology. To investigate this, we used a rodent model in which acute pharmacological manipulation of the 5-HT system was combined with multi-modal neuroimaging and electrophysiological recording. This enabled us to determine neurovascular coupling relationships in-vivo, by combined measurement of neuronal and hemodynamic parameters under both resting and stimulus evoked (activation) conditions. Under anaesthesia, the skull overlying somatosensory cortex was thinned to translucency for cortical imaging whilst burr holes were made to allow for the insertion of tissue oxygen or laser Doppler probes and recording or stimulating electrodes. Hemodynamic and neuronal data were acquired in cortical (barrel cortex) and subcortical structures under baseline and stimulation conditions, before and after the administration of 5-HT modulating drugs (or control substances), including agents in clinical use. Findings indicate a complex set of effects of serotonergic manipulations upon neurovascular function that depend upon not just specific receptor targets but also upon input pathways to the neuronal circuit under investigation. For instance, increasing serotonin release by intravenous administration of fenfluramine appeared to have minimal effects upon sensory (whisker) stimulation evoked changes in hemodynamics but more substantial effects upon direct cortical stimulation evoked CBF changes, suggesting an interaction of 5-HT modulation and neuronal pathway. Alterations in neurovascular coupling by changes in the function of the 5-HT system may have important implications for the application of functional MRI to investigate drug action. cognitive function, or disease mechanisms that involve 5-HT systems in both humans and animal research models.

Title: Acute effects of systemic inflammation upon neurovascular coupling and neuroimaging signals

Authors: *G. BREZZO[1], J. SIMPSON[2], K. AMEEN-ALI[1], J. BERWICK[1], C. MARTIN[1]; [1]Psychology (Neuroscience), [2]Sheffield Inst. of Translational Neurosci. (SITraN), Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Neuroinflammation is currently defined as any chronic or acute inflammatory process within the central nervous system and is a ubiquitous characteristic of many neurodegenerative diseases including Alzheimer's disease. The precise relationship between inflammatory processes and disease progression is complex and far from understood, but evidence from both animal and human studies suggests that in many cases inflammation may play in important role in the developing neuropathology. Inflammatory processes are mediated by the cells of the extended neurovascular unit, which includes neurons, astrocytes, pericytes, microglia and brain vascular cells. The neurovascular unit is simultaneously the substrate for the precise regulation of brain blood flow in accordance with local tissue requirements (neurovascular coupling). An important question therefore is whether and how the effects of inflammation on neurovascular unit function impact upon neurovascular coupling. Furthermore, it is important to determine how changes that occur at the cellular level in inflammation, for instance activation of glial cells, impact upon blood flow regulation in-vivo. To investigate this, we used an induced acute inflammation rodent model in which cerebral blood flow (CBF), neuronal activity and haemoglobin oxygenation and concentration were measured across a range of sensory stimulation parameters in order to quantify effects of inflammation on haemodynamic and neurovascular coupling measurements. In anaesthetised animals, a thin cranial window was prepared over the left somatosensory barrel cortex to enable recording of CBF using laser speckle contrast imaging as well as haemoglobin oxygenation and concentration with optical imaging spectroscopy. A surface electrode was placed adjacent to the thin window for neuronal activity recording. Data were acquired at two time intervals post lipopolysaccharide (LPS) or vehicle (saline) administration (2mg/kg i.p). Animal's brains were subsequently perfused and

extracted for immunohistochemistry to observe and quantify NVU and blood brain barrier changes including microglia, astrocytes, pericytes and ICAM-1/CD54 expression. This research has implications for understanding whether the effects of inflammation upon neurovascular coupling may constitute an early stage disease biomarker and/or a possible therapeutic target. Findings will also have implications for the interpretation of fMRI signals acquired from patients with neuroinflammation, where neurovascular coupling may be altered.

Title: Serotonergic and noradrenergic modulation of neurovascular coupling in awake behaving mice

Authors: ***Q. ZHANG**[1], D. A. ANDERSON[1], K. W. GHERES[2], A. T. WINDER[1], P. J. DREW[1,3,4];

Abstract: Hemodynamic signals are widely used to infer neural activity in functional brain imaging techniques, such as fMRI. Previous work (Huo, Smith and Drew, J. Neurosci., 2014) has shown that neural activity in the frontal cortex increases without corresponding changes in hemodynamic signals during locomotion, and we sought to understand the mechanism of this decoupling of neural activity from hemodynamic changes. Here, we investigated the effects of acute pharmacological manipulation of the serotonergic (5-HT) or noradrenergic systems on

neurovascular coupling by measuring neuronal and hemodynamic responses to voluntary locomotion in awake, head-fixed mice. Intrinsic optical signal imaging was used to measure cerebral blood volume (CBV) changes of frontal, visual, and somatosensory cortices through a polished thin-skull window, while neural activity (electrocortogram) was measured in the contralateral cortex concurrently. In a separate group of mice, local field potential and multiunit activity were measured in the frontal cortex and/or forelimb/hindlimb (FL/HL) representation in somatosensory cortex. Both neural activity and hemodynamic signals were collected before and after systemic administration of antagonists of 5-HT (trazodone), α1- (prazosin), α2-adrenoceptors (atipamezole), and vehicle controls. Compared to vehicle controls, neuronal responses to locomotion were not changed, CBV responses to locomotion were increased by both trazodone and prazosin in the frontal cortex and the FL/HL representation, and decreased by atipamezole in the FL/HL representation. These results suggest that in addition to local vasodilatory signals released from neurons and astrocytes, changes in neuromodulatory tone play an important vasoconstrictory role in shaping hemodynamic signals during behavior.

Title: Behavioral-state dependent inversion of neurovascular coupling in the somatosensory cortex of juvenile mice

Authors: *K. W. GHERES[1], C. J. ECHAGARRUGA[2], D. A. ANDERSON[3], P. J. DREW[1,4,5]; [1]Huck Inst. of the Life Sci., [2]Bioengineering, [3]Engin. Sci. and Mechanics, Pennsylvania State Univ. Univ. Park, University Park, PA; [4]Engin. Sci. and Mechanics, Pennnsylvania State Univ. Univ. Park, University Park, PA; [5]Neurosurg., Pennnsylvania State Univ. Hershey Med. Ctr., Hershey, PA

Abstract: In the adult somatosensory cortex, voluntary locomotion drives large increase in blood volume and blood flow (Huo, Smith, Drew, J. Neurosci., 2014). As neurovascular coupling can be weaker or inverted in the week or two following eye opening in rodents (Kozberg et al, 2013, PNAS), we sought to understand how neurovascular coupling in juvenile mice might be affected by behavior. Using two-photon microscopy, intrinsic optical signal (IOS) imaging and multielectrode arrays in awake mice, we found that neurovascular coupling under goes a behavioral-state dependent transformation during postnatal development. Stimulation of the vibrissae in the awake mouse caused biphasic (initial dilation followed by a constriction) hemodynamic response in juvenile mice that became adult-like within two weeks of eye-opening. Surprisingly, and in contrast to adults, voluntary locomotion drove a pronounced constriction and decrease in cerebral blood volume (CBV) in juvenile mice. Electrophysiological recordings show increases in spike rates and in the gamma band power of the field potentials power in the gamma band of the field potentials during locomotion in the somatosensory cortex, indicating inverted neurovascular coupling. This work suggests that state- and age-dependent changes in neurovascular coupling need to be taken into account in the interpretation of hemodynamic signals in the developing brain, but also provide insight into what signals might be integrated into the local hemodynamic response beyond local neural activity.

Title: What is an arteriole?

Authors: *M. R. HAMMOND-HALEY[1], D. AMIN[2], F. M. O'FARRELL[2], D. ATTWELL[2], C. HALL[3];

Abstract: Neurovascular coupling is classically thought to be mediated by annular smooth muscle cells around arterioles. Capillaries, in contrast, are traditionally considered to be non-contractile. However, vascular mural cells which extend processes along and around small (4μm) vessels also regulate blood flow (1, 2). These cells are classically considered to be pericytes, and the vessels they lie on capillaries. Recently, however, it has been suggested that these contractile cells are smooth muscle cells, despite their gross difference in morphology from arteriolar smooth muscle, and their position on small vessels (2). We investigated where, along the arteriole-capillary axis, different vascular functions transition from “arteriole-like” to “capillary-like”.

We used genetic and immunohistochemical labelling for markers of different cerebrovascular functions, to relate vascular function to morphology of vascular mural cells and their position in the vascular tree. Slices of adult NG2-DsRed mouse forebrain were labelled with antibodies or fluorescent dyes against PDGFRβ, α-SMA, nestin, GLUT-1 and elastin. For each protein, the point of transition in labelling (if any) along the arteriole-capillary axis was compared with branching order, vessel diameter and mural cell inter-soma distance (an indicator of vascular mural cell morphology).

There was a gradual transition of functions between arterioles and capillaries. Unlike the classical view, nutrient transport and BBB regulation is supported throughout the vascular tree, as shown by expression of the glucose transporter GLUT-1 and BBB-regulator PDGFRβ throughout the cerebrovasculature. Contractile function gradually changes across the vascular bed, with α-SMA being expressed further along the vascular tree than elastin, an arteriole marker. Finally, angiogenic potential, as indicated by expression of nestin, a marker of proliferative potential, is expressed in the capillary bed, in vessels that also express alpha-SMA and are significantly smaller than those expressing elastin.

Appreciating the heterogeneity of functions along the vascular tree will be crucial for understanding how the cerebrovasculature functions in health and disease.

Title: Acid-sensing ion channel-1A regulates CO_2-induced vasodilation

Authors: *R. J. TAUGHER[1], C. M. LYNCH[2], S. C. GUPTA[1], R. FAN[1], F. M. FARACI[2], J. A. WEMMIE[1];
[1]Psychiatry, [2]Intrnl. Med., Univ. of Iowa, Iowa City, IA

Abstract: Regulation of cerebral blood flow (CBF) is critical for normal brain function, and insufficient CBF may contribute to cognitive impairments in neurological conditions such as dementia. Though the regulation of CBF is complex and multifaceted, acidosis, such as that induced by carbon dioxide (CO_2), is a strong regulator of CBF. Nitric oxide (NO) production is thought to be critical for CO_2-induced vasodilation; however, the mechanisms by which CO_2 influences NO production remain unclear. Acid-sensing ion channel-1A (ASIC1A) is a proton-gated cation channel that is activated by extracellular acidosis. Previous work has implicated ASIC1A in the amygdala and bed nucleus of the stria terminalis in CO_2- and acid-evoked behavior. Thus, we hypothesized that ASIC1A might also contribute to the microvascular response to CO_2 and acidosis. To test this hypothesis we genetically and pharmacologically manipulated ASIC1A in mice and assessed the effects on CO_2-induced vasodilation. We found that the effect of CO_2 on vessel diameter was greatly attenuated in *Asic1a*$^{-/-}$ mice and in mice treated with the ASIC inhibitor, psalmotoxin. These manipulations did not alter the vasodilatory effects of acetylcholine, suggesting that endothelial NO production was unaffected, and further suggesting a neuronal source of NO. Thus, we hypothesized that neurons might be the site of ASIC1A action in the microvascular response to CO_2 and we generated mice in which *Asic1a* is specifically disrupted in neurons. We found that the effect of CO_2 on vessel diameter was also attenuated in these mice. To further explore a role for ASIC1A in the regulation of NO production, we measured NO concentrations in whole brain lysates immediately after exposure to CO_2. We found that 10% CO_2 induced NO production in wild-type mice, but not in mice lacking *Asic1a* globally or specifically in neurons. Together, these data are consistent with a

model wherein activation of neuronal ASIC1A by hypercarbic acidosis is critical for CO_2-induced vasodilation and NO production. These studies raise the possibility that ASIC1A may play a critical role in regulating CBF in response to other sources of acidosis, including neuronal activity, metabolism, and pathophysiologic conditions such as seizure and ischemic stroke.

Title: Time-resolved measurements of human cerebral oxygen metabolism using magnetic resonance imaging

Authors: *D. RESS, J. KIM;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Brief neural activation creates a hemodynamic response function (HRF), a stereotypic manifestation of neurovascular coupling. A recent theory (Kim & Ress, Neuroimage, 2016) predicts that the HRF is created by a combination of flow and cerebral oxygen metabolism ($CMRO_2$). Here, we used arterial spin-labeling (ASL) to measure both the HRF and flow, then used our model to obtain estimates of the $CMRO_2$ time course. **Methods**: Subjects ($N = 4$) view a 2-s duration audiovisual stimulus while performing a speeded task. Stimuli were separated by a 30-s interstimulus interval, and repeated 16 times per run for 5 runs to create a total of 80 measurements per session. Combined flow and HRF data were obtained using a pseudo-continuous ASL sequence on a Siemens 3T scanner with 2-mm voxels and TR = 3 s on 13 quasi-axial slices. Stimulus presentations were jittered to increase temporal sampling to 1.5 s. The flow and HRF data were transformed into a high-resolution (0.7-mm) reference anatomy so that they could be averaged within visual areas V1—3, predefined for each subject. The model was then used to estimate $CMRO_2$ time course from the data assuming a gamma-function temporal form. **Results**: All subjects show a significant flow undershoot (Figure), and some show a more

complex oscillatory return to baseline. Standard errors were <5% of peak amplitude for all measurements. Flow response peaks ~4 s earlier than the BOLD HRF. Most $CMRO_2$ estimates are prompt, but 2—4 measurements show a slow return to baseline. **Discussion**: The flow induced by brief stimulation has a strong undershoot and complex late time behavior consistent with underdamped oscillation. HRF responses are substantially delayed from the flow response, consistent with convective time delays as the flow propagates into downstream venous microvasculature that dominates BOLD contrast. The estimated $CMRO_2$ time course suggests that metabolism usually returns to baseline fairly rapidly, but metabolism can sometimes persist long after the activation.

Title: Obligatory role of EP-1 receptors in the increases in cerebral blood flow produced by hypercapnia in the mouse brain microcirculation.

Authors: *K. UEKAWA, P. ZHOU, N. BRUNIER, Y. HATTORI, C. IADECOLA, L. PARK; Feil Family Brain & Mind Reseach Inst., Weill Cornell Med. Col., New York, NY

Abstract: Hypercapnia is a potent vasodilator stimulus in the cerebral circulation. Although it has long been known that prostanoids participate in the cerebrovascular effects of hypercapnia (JCBFM, 14:175-192, 1994), the role of prostaglandin E2 (PGE2) and PGE2 receptors have not been fully investigated. We sought to determine whether cyclooxygenase-1 (COX-1)-derived PGE2 and EP1 receptors are involved in the cerebrovascular response induced by hypercapnia. Male EP1-/- mice and wild type (WT) littermates (age 3-4 months; n=5/group) were anesthetized with urethane-chloralose and equipped with a cranial window overlying the somatosensory cortex. Cerebral blood flow (CBF) was recorded by laser-Doppler flowmetry with controlled blood pressure and physiological variables. In WT mice, neocortical superfusion of the EP1 receptor antagonist SC-51089 (10 μM) attenuated the increase in CBF elicited by systemic hypercapnia (pCO_2=50-60 mmHg) by 41% (CBF increase: vehicle, 69±5%; SC-51089, 41±3%; $p<0.05$). SC-51089 also attenuated the increase in CBF produced by neocortical application of arachidonic acid (AA: 10μM) (AA, 21±5%; AA+SC51089, 9±3%; -56%; $p<0.05$) and PGE2 (5 μM) (PGE2, 16±2%; PGE2+SC51089, 9±2%; -38%; $p<0.05$). These responses were also attenuated in EP1-/- mice. In contrast, in WT mice treated with SC-51089 or in EP1-/- mice the CBF increase elicited by neocortical application of the endothelium-dependent vasodilator acetylcholine (ACh: WT, 24±2%; WT+SC-51089, 23±2%; EP1-/-, 23±2%; $p>0.05$) or the smooth muscle relaxant adenosine (WT, 33±2%; WT+SC-51089, 31±1%; EP1-/-, 31±2%; $p>0.05$) were not affected. Similarly, the CBF increase evoked by whisker stimulation (functional hyperemia) (WS: WT, 24±1%; WT+SC-51089, 23±1%; EP1-/-, 24±2%; $p>0.05$) was not attenuated. In WT mice, the COX-1 inhibitor SC-560 (25μM), but not the COX-2 inhibitor NS-398 (100 μM), attenuated the hypercapnic CBF increase by 50% (vehicle, 62±5%; SC-560, 31±5%; $p<0.05$). Neocortical application of PGE2 (1 μM) did not affect resting CBF ($p>0.05$), but counteracted the attenuation of the hypercapnic response induced by SC-560 (SC-560, 44±4%; SC-560+PGE2, 66±6%; $p<0.05$). In contrast, exogenous PGE2 did not rescue the attenuation induced by SC-51089 (SC-51089, 39±4%; SC-51089+PGE2, 43±5%; $p>0.05$), attesting to the obligatory role of EP1 receptors in the response. The findings indicate that the hypercapnic vasodilatation depends on COX-1-derived PGE2 acting on EP-1 receptors and highlight the critical role that COX-1 derived prostanoids and EP1 receptors play in the regulation of the cerebral circulation.

Title: Imaging of cerebral blood flow in rodent models with SPECT, MRI and autoradiography

Authors: J. RYTKÖNEN, K. LEHTIMÄKI, A. SHATILLO, L. TOLPPANEN, *T. T. AHTONIEMI, A. NURMI, T. HUHTALA;
Charles River Discovery, Kuopio, Finland

Abstract: Regulation of blood flow and oxygen delivery in the brain is essential for survival. In a normal physiological state the cerebral blood flow (CBF) stays very constant due to persistent adjustment of vascular resistance according to blood pressure. Imaging of CBF has clinical relevance as functional abnormalities can signal pathophysiological changes e.g. stroke and neurodegenerative diseases. In this study methods to measure CBF in rodent models are presented. Single photon emission computed tomography (SPECT) imaging after intravenous injection of ^{99m}Tc-exametazime (^{99m}Tc-HMPAO) is a conventional method to asses CBF *in vivo*. It has been shown to correlate strongly with regional brain perfusion and is used in clinical nuclear imaging to detect stroke and other cerebrovascular diseases. Arterial spin labeling allows capturing of brain perfusion with magnetic resonance imaging (MRI). It is a noninvasive method where protons in arterial blood are magnetically labeled and subsequently imaged in the region of interest. Therefore, no injection of contrast agent is needed to obtain information about cerebral perfusion. Arterial spin labeling MRI sequences are increasingly being used in clinical imaging to provide quantification of CBF. Although ^{99m}Tc-HMPAO-SPECT and arterial spin labeling MRI techniques are translational between clinical and pre-clinical studies, differences arise in the required use of anesthesia. One of the major challenges to study neurological function in rodents is due to use of restriction, anesthesia or paralyzing agents. All of these methods have impact to brain perfusion e.g. altering the vasoconstriction and blood pressure. To study immediate neuronal effect, delivery of radiotracer that reaches a cerebral equilibrium in a short time frame will allow imaging with great temporal resolution. ^{14}C-iodoantipyrine has shown a strict linear proportionality between tissue radioactivity and CBF when the data is captured within a brief interval after the tracer injection. As an case example to study CBF without restrain or anesthesia in mice, the animals were cannulated in jugularis vein week prior to administration of radiotracer. Tracer was injected trough cannula connected to a tether, followed by immediate dosing of euthanizing solution. Brains were collected and quantified using autoradiography. Alterations in CBF between studied brain regions were quantified. As a summary, several translational approaches can be applied in rodent models to monitor CBF alterations associated to disease progression or drug effect.

Title: Ethanolic extracts from Morus alba L. fruit induce vasorelaxation of the rat aortic smooth muscle

Authors: H. LEE[1], S. PARK[2], Y. BAE[2], *J. KIM[3], S. YOON[4], S. HAHN[4], H.-J. CHAE[1], S.-W. CHAE[1], B. CHOI[1];
[1]Pharmacol., Inst. for Med. Sci., Jeonju, Korea, Republic of; [2]Physiol., Konkuk Univ. Sch. of Med., Seoul, Korea, Republic of; [3]Med. Col. of Georgia, Augusta Univ., Augusta, GA; [4]Physiol., Col. of Medicine, The Catholic Univ. of Korea, Seoul, Korea, Republic of

Abstract: *Morus alba* L., or mulberry, has traditionally been known to induce antibacterial, antioxidant, and hypolipidemic effects. Recent evidence suggests that an extract of *Morus alba* L. decreases the high blood pressure in diabetic rats. It is unknown whether a *Morus alba* L. extract affects the contraction of vascular smooth muscle. In this study, the aqueous and ethanolic extracts of *Morus alba* L. fruit were evaluated for vasorelaxation of the rat aorta. The endothelium-intact aortic smooth muscle was isolated from 10-week-old Sprague-Dawley rats and its contractile force was measured on a tension transducer. The intactness of the endothelium was confirmed by acetylcholine-induced relaxation. The ethanolic extract (with 40% ethanol) of *Morus alba* L. contained a higher level of cyanidin-3-glucoside than the aqueous extract: 1994 ± 93 mg/100 g and 1746 ± 98 mg/100 g, respectively. To assay the vasorelaxant effect of *Morus alba* L. extracts, the aortic rings were first contracted by serotonin (5-HT), high K^+ (70 mM) and norepinephrine (NE) and then the *Morus alba* L. extracts were applied. The aqueous extracts of *Morus alba* L. did not induce vasorelaxation of aortic rings that were pre-contracted by 5-HT, high K^+ and NE. However, the ethanolic extracts caused vasorelaxation of aortic rings that were pre-contracted by 5-HT or high K^+, but not NE. This study demonstrates that an extract of *Morus alba* L. fruit might act as a vasorelaxant for the aortic smooth muscle. The lack of the effect on NE-treated aorta implies that the vasorelaxation effect of *Morus alba* L. might be mediated by specific signaling cascades, e.g., related to 5-HT or high K^+. The identity of the active ingredient(s) and the underlying mechanisms need to be further determined.

Title: Probing the link between indolent aneurysmal dome infections and brain aneurysm growth and rupture

Authors: ***J. KELLY**[1], T. ST.AMAND[1], J. KROL[2], G. D. EHRLICH[2], D. J. COOK[1]; [1]Queen's Univ., Kingston, ON, Canada; [2]Drexel Univ., Philadelphia, PA

Abstract: *Background*: Vascular inflammation is thought to play an important role in intracranial aneurysm (IA) formation and rupture. Recent studies have shown potential bacterial etiology behind this inflammation. Dental and respiratory microbial DNA has been discovered in unruptured and ruptured aneurysms from patients with no clinically diagnosable infection. However, more comprehensive analyses are required before this interaction can be understood. To this end, we explored the possibility that IA progression is related to indolent, subclinical infection of the aneurysm dome by microorganisms originating from commensal or pathogenic populations existing elsewhere in the host. *Methods*: IA dome samples were collected surgically from patients undergoing IA clippings (7 of each stable, growing and ruptured). Total genomic DNA was extracted from each sample for analysis using the Ibis T5000 Biosensor, allowing for species-specific identification of the microorganisms present. Positive biosensor results were confirmed through sequencing using an Illumina MySeq. Microbial population results were pooled for each sample type and compared amongst each other. Further, pooled results were compared against known commensal and pathogenic populations from elsewhere in the body to deduce the likely source of the organisms. *Results and Discussion*: Populations of commensal organisms were found associated with stable, growing and ruptured aneurysm tested. While results pertaining to microbial etiology of IA progression remain inconclusive, we have successfully provided a metagenomic catalogue of organisms that may be associated with IAs along with their likely point of origin.

Title: Effect of stilbenoid polyphenols on aberrant cerebral artery morphology and mechanics in the spontaneously hypertensive heart-failure (SHHF) rat

Authors: *C. ACOSTA[1,2], H. ANDERSON[1,3], D. LEE[1,3], C. ANDERSON[4,2];
[1]St. Boniface Hosp. Albrechtsen Res. Ctr., Winnipeg, MB, Canada; [2]Pharmacol. & Therapeut., [3]Col. of Pharm., Univ. of Manitoba, Winnipeg, MB, Canada; [4]Kleysen Inst. for Advanced Med., Winnipeg, MB, Canada

Abstract: Hypertension is an important risk factor for cognitive decline and dementia. Further adding risk of heart failure *per se* then cumulatively increases the possibility of cognitive decline and promotes progression to *bona fide* dementia. This may be due, at least in part, to altered morphology and mechanical properties of cerebral arteries and arterioles. We hypothesized that hypertension combined with added risk of heart failure (as found in the SHHF rat) confer morphological and mechanical aberrations in middle cerebral arteries. Resveratrol (trans-3,5,4'-trihydroxystilbene) is a stilbenoid polyphenol that is purportedly linked to improved longevity, cardiovascular health, and benefits in Alzheimer's disease. Although resveratrol is well-tolerated in humans, it is readily metabolized and exhibits low bioavailability. Thus, we also queried whether resveratrol analogues would exert greater vasculoprotective effects. Sprague-Dawley (SD) and SHHF rats (n=8) were treated for 8 weeks by gavage with vehicle control (C) or low doses (2.5 mg/kg/d) of resveratrol (R), pterostilbene (P), and gnetol (G). Blood pressure (BP) was measured by tail-cuff plethysmography. Vascular geometry and mechanical properties of isolated middle cerebral arteries were measured by pressure myography. Systolic BP increased in the SHHF rat (196±3 mm Hg vs. SD 142±7 mm Hg, $p<0.01$), and was unaffected by stilbenoid treatment. SHHF arteries exhibited increased media-to-lumen ratios (15.9±2.4 vs. SD 9.0±0.5, *$p<0.05$*), and were associated with remodelling and growth indices of 58% and 44%, respectively. All three stilbenoids reduced media-to-lumen ratios (SHHF-R 12.3±1.7, SHHF-P 12.8±1.1, SHHF-G 13.2±1.6, *$p<0.01$*). Wall component stiffness (i.e. slope of elastic modulus *vs*. stress) was augmented in SHHF (18.2±2.9 vs. SD 6.1±0.9, *$p<0.01$*), and was attenuated in part by resveratrol and gnetol (SHHF-R 11.8±1.1, SHHF-G 11.5±1.0, *$p<0.05$ vs. SD and $p<0.01$ vs. SHHF-C*) and completely by pterostilbene (SHHF-P 9.4±1.1, *not significant vs. SD and $p<0.0001$ vs. SHHF-C).* In summary, SHHF middle cerebral arteries exhibited a combination of

eutrophic and hypertrophic remodeling. Stilbenoids improved vascular morphology and geometry-independent stiffness independently of blood pressure lowering, suggesting direct actions on the arterial wall. The ability of pterostilbene to entirely normalize wall component stiffness may be related to its reported superior bioavailability. We conclude that further research is warranted on stilbenoid polyphenols as an adjunct to current cardiovascular treatment regimens that might reduce the risk of cognitive decline.

Title: Individual patterns of cognitive impairment after transient ischemic attack

Authors: *L. E. SIMMATIS[1], S. H. SCOTT[1], A. Y. JIN[2];
[1]Ctr. For Neurosci. Studies, [2]Med., Queen's Univ., Kingston, ON, Canada

Abstract: Transient ischaemic attack (TIA) is a major indicator of impending stroke risk. There is evidence that TIA patients display chronic impairment which may persist for days to months after the event. The underlying cognitive and motor deficits which contribute to this chronic impairment have not been elucidated. We assessed a group of 23 TIA patients using both subjective clinical scoring systems and quantitative tools. We administered the Purdue pegboard test (PPB) to test fine motor control, the Chedoke-McMaster Stroke Assessment (CMSA) to determine gross motor impairment stage, the Behavioural Inattention Test (BIT) to test visual neglect, and the Montreal Cognitive Assessment test (MoCA) to detect mild cognitive impairment. We then performed kinematic analysis using the bimanual KINARM robot, which has been previously validated as a reliable tool for studying stroke patients. The battery of 8 KINARM tasks that we used spanned motor, sensory, and cognitive functional domains. We normalized all kinematic data to a healthy control population of over 100 individuals correcting for the influence of age, gender, and handedness in order to derive Z-scores for both parameter-level and task-level performance.
BIT, PPB and MoCA identified a few TIA subjects as impaired (n=5, 5, and 6) and CMSA scores deviated from the ideal healthy range for several subjects (n=8 patients with a score of 5 in at least one component). The robot-based analysis found that motor and sensory tasks were less impacted than cognitive ones. The ability to complete simple motor tasks involving reaching and object hitting was affected in some patients (n=3), as was proprioceptive upper limb sense

(n=5). However, 39% and 30% of our cohort were impaired in spatial working memory and visuomotor integration. There was a broad range of different patterns of impairments across subjects. These results demonstrate that TIA patients show individual patterns of impairment which tend to be biased towards the cognitive domain. Furthermore, cognitive impairments were not detected using traditional clinical assessment tools. This is possibly due to a lack of sensitivity of these tools to the types of mild impairment which are present after a TIA. This work highlights the need for individual consideration of TIA patients on a case-by-case basis and the need for awareness of 'silent' symptoms which may not be readily detectable in the clinic, but may provide functional difficulties at later time points after the event.

Title: White matter hyperintensities in neurologically intact aging individuals impact arm function

Authors: A. M. AURIAT[1], J. K. FERRIS[1], S. E. BLACK[2], *L. A. BOYD[3];
[1]Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada; [2]Sunnybrook, Toronto, ON, Canada; [3]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Introduction: White matter hyperintensities (WMH) are frequent in aging individuals and are known to affect cognition, balance, and gait. However, the affects of WMHs on upper-limb performance are unknown.
Methods: The KINARM robot was used for 4 upper-limb assessments. 1) Visually Guided Reaching: participants moved as quickly as possible to a target. 2) Arm Matching: the robot moved participants' hand to a target positions and the participant had to mirror match the location with the opposite hand. 3) Object-Hit: participants hit virtual balls moving towards them with virtual paddles attached to each hand. 4) Object-Hit and Avoid: cognitive demand of the Object-Hit task was increased, by requiring participants to hit two target shapes while avoiding

all others. Semi-automatic volumetric assessment of covert lesions was completed with magnetic resonance imaging (MRI).
Results: We assessed 26 normally aging individuals (range: 43-80; mean ± SD: 61.48 ± 9.88). Accuracy of visually guided reaching did not relate to the volume of WMHs ($p \geq 0.117$), but higher WMH volume related to increased movement time for dominant and non-dominant arms ($r = 0.542, 0.479$; $p \leq 0.018$). Arm Matching and Object-Hit performance did not relate to WMH volume ($p > 0.05$). However, on Object-Hit and Avoid, WMH volume correlated with median error ($r = -0.574$), hand bias of hits ($r = 0.564$), and hand transition ($r = -0.530$; $p \leq 0.008$).
Conclusion: Individuals with more WMHs took longer to complete target reaching, however, this did not affect accuracy. When difficulty and cognitive demand increased WMHs significantly impaired performance. Specifically, on a bimanual task, individuals with higher levels of WMH shifted limb-use to favor the dominant limb, with a resulting decrement in performance. These findings suggest an important link between WMHs and attenuated motor performance in normally aging individuals.

Title: 20-HETE inhibition protects against intracerebral hemorrhage injury

Authors: ***X. HAN**[1], X. ZHAO[1], X. LAN[1], Y. GAO[1], Z. YANG[1], J. FALCK[2], R. KOEHLER[1], F. GUAN[3], J. WANG[1];
[1]Johns Hopkins Hosp., Baltimore, MD; [2]Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [3]zhengzhou university, zhengzhou, China

Abstract: Background and Purpose: Intracerebral hemorrhage (ICH) accounts for 15% of all strokes. Previous studies have revealed that 20-HETE, a metabolite of arachidonic acid

synthesized by cytochrome P450 4A, plays an important role in ischemic stroke injury and subarachnoid hemorrhage. However, little is known about the role of 20-HETE after ICH. In this study, we examined the hypotheses that 20-HETE inhibition has a protective effect after collagenase-induced ICH injury and that it affects angiogenesis. **Methods**: To investigate the protective effect of 20-HETE synthesis inhibitor N-hydroxy-N'-(4-butyl-2-methylphenyl)-formamidine (HET0016) after ICH, we exposed hippocampal slice cultures to hemoglobin (10 μM) and induced ICH in mice by intrastriatal collagenase injection. Hemoglobin-induced neuronal death was assessed by propidium iodide (PI) after 18 hours in vitro. Lesion volume, neurologic deficits, cell death, reactive oxygen species (ROS) production, neuroinflammation, and angiogenesis were evaluated in mice at different time points after ICH. **Results:** In cultured mouse hippocampal slices, 5, 14-HEDGE, a 20-HETE mimetic, exacerbated hemoglobin-induced neuronal cytotoxicity in the CA1 area, whereas HET0016 treatment attenuated hemoglobin-induced neuronal damage and decreased levels of proinflammatory cytokines and reactive nitrogen species (n=25 slices/group, $p<0.05$). In vivo, HET0016 treatment reduced brain lesion volume and neurologic deficits, and decreased neural death, ROS production, matrix metalloproteinase gelatinolytic activity, and the inflammatory response at 3 days after ICH (n=8/group, $p<0.05$). Src kinase phosphorylation was increased after ICH and decreased by HET0016 treatment (n=8/group, $p<0.01$). However, HET0016 did not affect angiogenesis, as assessed by VEGF, VEGFR2, and CD31 levels on day 28 after ICH (n=6/group*)*. **Conclusion:** These findings suggest that 20-HETE plays an important role in ICH-induced brain damage. Modulating the 20-HETE signaling pathway may provide a viable means to mitigate ICH impairment without angiogenesis inhibition.

Title: Controlling oxidative stress promotes functional recovery after TBI

Authors: *R. VEMUGANTI[1], S. MEHTA[1], T. KIM[1], R. CHANDRAN[1], E. UDHO[2], P. CENGIZ[2], R. DEMPSEY[1];
[1]Neurolog. Surgery, [2]Pediatrics Waisman Ctr., Univ. of Wisconsin, Madison, WI

Abstract: The secondary neuronal death is a known proponent of long-term neurological dysfunction following traumatic brain injury (TBI). Oxidative stress after TBI kills neurons if uncontrolled. Paradoxically, pathways that promote as well as fight the oxidative stress are induced concurrently after TBI. NADPH oxidase subunit NOX2 promotes formation of reactive oxygen species that kills neurons. On contrary, activation of transcription factor Nrf2 promotes the expression of down-stream neuroprotective genes including anti-oxidant enzymes and protein chaperones. We currently evaluated if inhibiting the pro-oxidant NOX2 and/or potentiating the anti-oxidant Nrf2 individually or in combination decreases the motor and cognitive deficits and secondary cortical contusion after TBI. Controlled cortical impact-induced TBI (mild to moderate) in adult mice significantly induced the expression of both NOX2 and Nrf2 in the ipsilateral cerebral cortex at 6h and 24h after injury. Cohorts of mice subjected to TBI were treated with either an inhibitor of NOX2 (apocynin; 10 mg/kg) or an activator of Nrf2 (TBHQ; 25 mg/kg) or both or vehicle. We tested the drug administration at 2 time schedules (each drug given twice; either at 5 min and 24h or at 2h and 24h after TBI). Mice were subjected to motor testing (rotarod test and beam walk test) between days 1 and 7 and Morris water maze test between days 26 to 30 after TBI. Treatment with either apocynin or TBHQ alone significantly improved the motor function after TBI compared to vehicle control. The drug treated mice stayed longer on rotarod and made fewer foot faults in beam walk test. The combination therapy also significantly improved the post-TBI motor function recovery compared to vehicle control, but there was no additive effect of the 2 drugs. The mice treated with the combination of apocynin and TBHQ also performed better in the Morris Water maze test. Animals in the drug groups spent significantly greater time with higher frequency in the platform quadrant as compared to vehicle group. All mice were sacrificed and the secondary cortical contusion was estimated using the serial brain sections stained with Cresyl violet. The cortical contusion volume was not different in either apocynin or TBHQ alone groups compared to the vehicle control group. However, the combo therapy (apocynin+ TBHQ) given either at 5 min/24h or 2h/24h led to a significantly smaller cortical contusion volume compared to vehicle control group. Thus, these studies show that controlling oxidative stress is a potential therapy to minimize post-TBI motor and cognitive deficits and secondary brain damage. Funded by NIH.

Title: HO-1 inhibition delay hematoma cleanup after intracerebral hemorrhage

Authors: L. ZHANG[1], X. ZHAO[2], G. SUN[2], *J. ARONOWSKI[2];
[1]Neurol., Beijing Friendship Hospital, Capital Med. Univ., Beijing, China; [2]Neurol., Univ. Texas HSC - Houston, Houston, TX

Abstract: The red blood cells (**RBC**) and their hemolytic products (including hemoglobin, heme, and iron) which represent main components of brain hematoma after intracerebral hemorrhage (**ICH**), trigger a series of adverse biochemical events leading to secondary brain injury and neurological deficits. The efficient removal of the hematoma components is necessary for achieving inflammation resolution and functional recovery. The inducible heme-oxygenase (**HO-1**) is a key rate-limiting enzyme that catabolizes heme into iron, carbon monoxide, and biliverbin. The present study investigated the spatial and temporal expression of HO-1, as well as its possible function in the hematoma absorption. We found that HO-1 after ICH was upregulated around the hematoma area starting from 6h, reaching the maximum level at 3 - 7days, and persisting for at least 10 days after ICH. HO-1 immunohistochemistry shows that the most HO-1-positive cells are CD68-positive microglia/macrophages (**MΦ**). To explore the pathophysiological role of HO-1 after ICH, a competitive HO inhibitor, tin-protoporphyrin IX (**SnPP**, 7.5 mg/kg), was injected, ip, twice a day, for 7 days. SnPP significantly delayed hematoma clearance by 27.8% and significantly impaired the functional recovery as measured at day 7 after ICH. Histological analyses showed that there are more TUNEL-positive neurons at the hematoma-affected brain tissue in SnPP-treated brains. In addition, we isolated and cultured the rat brain microglia (MΦ). Upon exposing to RBC, MΦ phagocytize/digest the RBC, and HO-1 is induced during this process. Co-incubating 10 μM SnPP with RBC significantly delayed RBC internalization by MΦ. Subjecting primary rat brain neuron-microglia co-cultures to RBC and mild (sublethal) oxygen-deprivation (an ICH-like injury) caused neuronal damage, as measured by neurofilament degradation. Adding SnPP further aggravated the neuronal death. We postulate that HO-1 is important for MΦ-mediated brain hematoma clearance after ICH.

Title: Clinacanthus nutans ameliorated neuronal apoptosis and ischemic brain injury by downregulating HDAC1/6

Authors: *J.-S. WU, H.-D. TSAI, M.-H. KAO, W.-M. CHEUNG, T.-N. LIN;
Neurosci. Division, IBMS Academia Sinica, Taipei, Taiwan

Abstract: BACKGROUND AND OBJECTIVE:
Growing evidence supports epigenetic regulation in the pathogenesis and recovery of stroke. Histone deacetylases (HDACs) inhibition has been shown to confer anti-inflammatory and neuroprotective effects. C. nutans is a folk medicine in Southern Asia for infection, inflammation, cancer, and Diabetes treatment. But, there is no data in treating ischemic stroke yet. In this study, we aimed to investigate whether C. nutans protects brain against ischemic insult via HDAC inhibition.
METHODS:
To investigate the protective effects of C. nutans against stroke. Primary cortical neurons were subjected to oxygen/glucose deprivation-reoxygenation (H-R) *in vitro* hypoxic model. MTT assay was used to detect cell viability. Flowcytometry was used to monitor mitochondrial membrane potential (MMP), apoptosis. Reporter assay was used to detect the transcriptional activity of HDAC1/6. RT/PCR and Western blot were used to detect HDACs mRNA and protein expression. For *in vivo* study, rats were subjected to 3-vessel occlusion (MCAO)/reperfusion. Neurological deficit scores and infarct volumes were used to evaluate functional and cellular damage.
RESULTS:
In vitro: An early induction of HDAC1/2/3/6/8 was noted in neurons after OGD insult. C. nutans extract selectively inhibited HDAC1 and HDAC6 expression, increased cell viability, maintained MMP and attenuated neuronal apoptosis compared to vehicle control at hypoxia 30mins and 1 day reperfusion (H0.5R24). Moreover, C. nutans suppressed hypoxia-induced HDAC1 and HDAC6 transcription. Besides ameliorating neuronal death, C. nutans also protected astrocytes and endothelial cells from hypoxic-induced cell death.
In vivo: C. nutans significantly reduced infarct brain volumes in rat subjected to 30-min ischemia and 1-day reperfusion. Furthermore, C. nutans improved motor functional recovery even after 2-weeks reperfusion.

CONCLUSIONS:
In the present study we reported that C. nutans suppressed post-hypoxic HDACs activation and neuronal death and confers therapeutic potential for ischemic brain damage. This study further opens a new avenue for the use of herbal medicines to via epigenetic regulation control brain injury.

Title: Multiple presentations with plausible CADASIL diagnosis

Authors: *F. P. MELENDEZ[1], D. CASADESUS[2], E. MALA[1], K. SHILLINGFORD[1], C. A. VILLANIA[1], W. ZELEZNAK[1];
[1]Ross Univ. Sch. of Med., Miramar, FL; [2]Jackson Hlth. Syst., Miami, FL

Abstract: Introduction: CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) has variable presentations that mirror other neurological disorders. We offer 3 cases with different presentations in which CADASIL was a plausible diagnosis.
Case Description:
Case 1: 50yo African American woman with PMH of multiple sclerosis (MS) diagnosed 20 years ago, who complained of diplopia. She had been treated by multiple physicians for MS without improvement. She had a prior admission for acute hemorrhage to the right medial midbrain and pons and was discharged home with minimal sequelae. MRI identified multiple areas of hyperattenuation within the white matter which led to the suspicion of CADASIL. Genetic testing confirmed mutation in the NOTCH3 gene and she was treated symptomatically.
Case 2: 48yo Caucasian male with PMH of alcohol dependence, depressive disorder and neurosyphilis was admitted for inappropriate behavior, AMS, ataxia, seizure and unexplained fall. His Hx of alcohol abuse led to the suspicion of Wernicke's encephalopathy which was treated with thiamine. CTA of the neck showed malformation of vertebral arteries and MRA demonstrated fetal-type circulation. Family members were contacted and confirmed a positive family Hx of CADASIL.
Case 3: 43yo Hispanic male with PMH of HTN, obesity, Hx of multiple suicide attempts and polysubstance abuse was admitted for AMS and right sided weakness. He was hypertensive at

246/156mmHg with an NIHSS of 10. Brain CT showed multiple hypodensities within the left caudate nucleus, subcortical and deep white matter related to vessel ischemic changes; confirmed by MRI and MRA. Cerebral angiogram revealed bilateral segmental stenosis in the distal MCA, ACA and PCA branches consistent with vasculitis. Repeat MRI 15 days later, showed new punctate infarcts to the left cerebellum and right corona radiata. NOTCH3 genetic testing was unavailable, therefore, due to no prior family Hx of CADASIL, it was concluded that the etiology of multiple ischemic strokes was likely due to cerebral vasoconstriction and hypertensive urgency. Patient was treated with anti-hypertensive medication and discharged home. At outpatient follow-up 2 weeks later, MRI showed an acute infarct of the ventral pons and patient was subsequently readmitted.
Discussion: CADASIL is a rare disease that has many manifestations. These cases demonstrate a few symptoms, which along with clinical evaluation and detailed history can guide the physician towards an accurate diagnosis. Nonetheless, mutation in the NOTCH3 gene and a positive family Hx of CADASIL are alone, confirmatory for the disease.

Title: Heparan sulfate targets at $VEGF_{165}$ bioactivity enhances vascular angiogenesis: Potential vascular therapy for stroke.

Authors: *S. CHAN[1,2], K. HAYAKAWA[1], A. SMITH[2], V. NURCOMBE[2], E. LO[1];
[1]Radiology, Massachusetts Gen. Hosp., Charlestown, MA; [2]Inst. of Med. Biology, Agency for Science, Technol. and Res. (A*STAR), Singapore, Singapore

Abstract: Brain angiogenesis has been found to exert positive effect in long term recovery among ischemic stroke patients. Several attempts using proangiogenic factor, for instance $VEGF_{165}$ in preclinical stroke experiments is by far encouraging. Despite being one of the most active proangiongenic factor, high concentration of $VEGF_{165}$ was reported to induce vascular permeability. Several studies showed that heparan sulfate proteoglycan glycosaminoglycan (HSPG) plays important roles in modulating VEGF bioactivity. However the specific mechanism remains unresolved. Recent study indicated that HSPC provides high order control of VEGF receptors activation. Here, we have successfully isolated the heparan sulfate glycoprotein

(HS7+ve) that binds to and enhances the bioactivity of $VEGF_{165}$, selective to VEGF receptor 2 (VEGFR) pathway. Our results indicated that HS7+ve complexed with $VEGF_{165}$, significantly increased RBE4 cells proliferation. Furthermore, HS7+ve, when complexed with $VEGF_{165}$, enhanced RBE4 cells tube formation and cell migration. The pro-angiogenic potential of HS7+ve was further confirmed by the activation of VEGFR2 pathway in which, HS7+ve activates pVEGFR2, pErk1/2 and pAkt. To access the HS7+ve effects on vascular permeability, RBE4 cells were treated with oxygen glucose deprivation (OGD) and IL-1β, followed by the detection of the adherence and tight junction proteins. Finally the pro-angiogentic potential of HS7+ve was further assessed in an *in vivo* hemorrhagic model. Our current results demonstrate the potential beneficial effect of glycotherpeutic agents targeting at the augmentation of $VEGF_{165}$ bioactivity against stroke.

Title: Voltage-gated potassium channels are implicated in zinc-mediated retinal ganglion cell death following optic nerve injury

Authors: *R. M. SAND[1], Y. LI[2], L. I. BENOWITZ[2], P. A. ROSENBERG[3];
[1]Neurobio., [2]Neurosurg., [3]Neurol., Boston Children's Hosp., Boston, MA

Abstract: Unlike neurons in the peripheral nervous system, those in the brain and spinal cord are unable to regenerate damaged axons. As a result, injury or disease often leads to permanent motor and cognitive deficits. To address this problem, we have investigated the signaling pathways that promote cell survival and axon regeneration in the central nervous system (CNS) using the mouse retina and optic nerve as a model. We have recently shown that after a crush injury in the optic nerve, free zinc (Zn^{2+}) levels rise significantly in retinal ganglion cells before dying (see poster by Li et al., this meeting). When Zn^{2+} is chelated at the time of crush, cell

survival rates are approximately twice those of control retinas. Remarkably, and unlike most other interventions reported to date, this survival benefit is long lasting, and observed as late as 12 weeks after injury. Since voltage-gated potassium channel (Kv) activation is known to underlie cell shrinkage during apoptotic cell death, we hypothesized that Kv might be involved in the zinc-mediated degeneration of retinal ganglion cells. We tested this hypothesis by injecting several different Kv inhibitors, alone or in combination with the zinc chelator ZX1, into the eye at the time of optic nerve crush. Agents were injected again four days later, and retinal ganglion cell survival and axon regeneration were quantified two weeks post-crush. We found that injecting a low dose of tetraethylammonium (TEA) mimicked and occluded the neuroprotective effect of zinc chelation, confirming that TEA-sensitive Kv share the zinc pathway with respect to cell survival. However, the same dose of TEA blocked the increase in regeneration caused by zinc chelation. At this dose (100 μM injected into the vitreous), TEA only targets members of the Kv1, Kv3, and Kv7 family. Therefore, we tested more specific peptide and small molecule inhibitors of these subfamilies to tease apart the contributions of the various channels to retinal ganglion cell survival and axon regeneration. We also looked at the amount and pattern of expression of specific channel types using immunohistochemistry with and without optic nerve crush. Ultimately, this work will help to illuminate the molecular mechanisms of zinc-mediated neurodegeneration in the retina and in the CNS and may provide new therapeutic avenues for treating neurodegenerative diseases of the eye and brain as well as traumatic CNS injury.

Title: A large fraction of glutamate release in the ischemic penumbra is mediated by redox-dependent changes in membrane permeability

Authors: *A. A. MONGIN[1], P. DOHARE[3], N. H. BOWENS[1], A. VIPANI[1], V. R. YADAV[2], Y.-X. WANG[2], P. J. FEUSTEL[1], R. W. KELLER, Jr.[1];

Abstract: In animal models of stroke, antioxidants potently protect against ischemic brain damage. However, for unclear reasons, the antioxidant treatments have shown little to no clinical benefits in human stroke. While exploring the basis for antioxidant efficacy, we recently found that the superoxide dismutase (SOD) mimetic tempol strongly reduced intraischemic release of the excitotoxic neurotransmitter glutamate (Glu), and this effect correlated with histological and behavioral neuroprotection [P. Dohare et al. FRBM 77: 168, 2014]. Antioxidants with other mechanisms of action did not modify pathological excitotoxin levels, suggesting a new Glu-dependent mechanism for protection by SOD mimetics. Here, we explored the pathways that mediate the redox-sensitive Glu release in rodent transient focal ischemia. Pre-, intra-, and postischemic Glu levels were measured in the rat cortex, in ischemic penumbra using a microdialysis approach combined with 2-h occlusion of the middle cerebral artery. Several candidate release mechanisms were explored by delivering via microdialysis perfusate the following pharmacological inhibitors: dihydrokainate (to block the glial Glu transporter GLT-1), DCPIB (volume-regulated anion channels), 18α-glycyrrhetinic acid (connexin hemichannels), probenecid (pannexins), and L-serine-O-sulfate (cystine/glutamate antiporter). Among the tested inhibitors, only DCPIB and dihydrokainate produced modest (~20-30%) reductions in pathological Glu levels, prompting a question about what pathway mediates the remaining large fraction of the excitotoxin release. To model and explore potential mechanism(s), we exposed primary cultures of glial cells to (a) metabolic inhibition, (b) oxidative stress, or (c) their combination. Only the latter condition produced sustained and non-selective changes in the membrane permeability for amino acids and larger molecules. Such changes were completely dependent on elevations in the intracellular [Ca^{2+}] and likely mediated by activation of phospholipases. Overall, our results paint an unexpectedly complex picture of multimodal redox-sensitive Glu release and tissue damage in clinically relevant ischemic penumbra. The improved understanding of stroke pathology will help in developing new treatment modalities.

Title: Cytoplasmic FMR1-interacting protein 2 (Cyfip2) is a major genetic factor underlying binge eating

Authors: *C. D. BRYANT[1], S. L. KIRKPATRICK[1], L. R. GOLDBERG[1], N. YAZDANI[1], K. I. LANDAVERDE[1], R. K. BABBS[1], J. WU[1], D. F. JENKINS[2], E. R. REED[3], A. BOLGIONI[1], K. P. LUTTIK[1], V. KUMAR[4], W. E. JOHNSON[2], M. K. MULLIGAN[5], P. COTTONE[1]; [1]Pharmacol. and Exptl. Therapeut., [2]Computat. Biomedicine, [3]Bioinformatics, Boston Univ. Sch. of Med., Boston, MA; [4]The Jackson Lab., Bar Harbor, ME; [5]Genetics, Genomics and Informatics, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Eating disorders are lethal and heritable; however the genetic factors are unknown. Binge eating is a highly heritable quantitative trait associated with eating disorders, obesity and neuropsychiatric dysfunction. Identifying the genetic basis of binge eating is essential to understanding neurobiological mechanisms and the development of pharmacotherapeutics. We developed a binge eating paradigm and assessed genetic differences in C57BL/6 substrains that are nearly genetically identical. Quantitative trait locus (QTL) mapping in an F_2 cross followed by gene knockout was used to identify and validate the causal genetic factor. Transcriptome analysis of the striatum via mRNA sequencing (RNA-seq) was used to reveal potential neurobiological mechanisms that bridge genetic variation with behavior. Outbred CFW mice and C57BL/6NJ (B6NJ) inbred mice showed a robust escalation in palatable food (PF) consumption and conditioned food reward whereas the closely related C57BL/6J substrain (B6J) did not. We identified a single genome-wide significant QTL on chromosome 11 that mapped precisely to the location of a missense mutation in *Cyfip2* (cytoplasmic FMRP-interacting protein, 2) that was recently identified for cocaine-induced neurobehavioral plasticity. We validated *Cyfip2* as a causal genetic factor using mice heterozygous for a deletion in *Cyfip2* that demonstrated a complete reversal of compulsive-like binge eating. Transcriptome analysis of the striatum via RNA-seq from a subset of F_2 and knockout mice identified an enrichment of genes associated with psychiatric disorders (eating, substance abuse, depression, bipolar, and anxiety) that likely underlie the neurobiological mechanisms. We also identified differentially spliced genes such as *Homer1*, *Arpp21*, *Map4*, and *Gls* (glutaminase) whose isoforms could functionally contribute to binge-induced structural neuroplasticity in the striatum. To summarize, to our knowledge, *Cyfip2* is the first genome-wide significant genetic factor to be identified for binge eating in mammalian model organisms or humans and demonstrates the utility of our model and approach for future gene mapping efforts in populations with increased genetic complexity.

Title: Effects of diet and obesity on anxiety-like behaviors in obesity-prone and obesity-resistant rats

Authors: *P. J. VOLLBRECHT[1], Y. ALONSO-CARABALLO[2], A. M. CHADDERDON[2], A. L. MATTHEWS[2], E. M. JUTKIEWICZ[2], C. R. FERRARIO[2];
[1]Biol., Hope Col., Holland, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Epidemiological data suggest that body mass index and obesity are strong risk factors for depression and anxiety. However, it remains difficult to separate cause from effect, as predisposition for obesity may enhance susceptibility to anxiety, or vice versa. Here, we examined the effects of diet and obesity on anxiety-like behaviors in selectively-bred obesity-prone and obesity-resistant rats. This model enables us to distinguish effects of pre-existing differences vs. weight gain on anxiety-like behaviors. Food intake and weight gain was recorded over 4 weeks. Measures were made in male rats given standard lab chow (Lab Diet 5001) or 60% high-fat diet (Open Source Diets D12492). Elevated plus maze and open field testing were used to evaluate anxiety-like behaviors, and forced swim and sucrose preference testing were used to examine pro-depressive like behaviors. Prior to weight gain, behavior in the elevated plus maze was similar between obesity-prone and obesity-resistant groups. However, after spontaneous increases in adiposity and weight in chow fed obesity-prone rats, anxiety-like behaviors in the elevated plus maze and open field tests were enhanced in obesity-prone vs obesity-resistant rats. Furthermore, the magnitude of these anxiety-like behaviors was positively correlated with weight gain in obesity-prone, but not obesity-resistant rats. No differences in forced swim behavior were found between groups. Importantly, locomotor behavior in the home cage and standard locomotor chambers was similar between groups, suggesting that differences in anxiety-like behaviors only emerge in anxiogenic environments. Consumption of a 60% high-fat diet produced substantial weight gain in obesity-prone rats, and weight gain in obesity-resistant rats that was comparable to that of obesity-prone rats fed standard chow. However, high-fat diet induced obesity was not sufficient to enhance anxiety-like behaviors in obesity-resistant rats. No further increases in anxiety-like behavior were found in obesity-prone rats, likely due to floor effects. Together, these data suggest that enhanced anxiety-like behavior in obesity-prone rats is not due to basal differences, but instead emerges with the development of obesity.

Title: Effects of perinatal bisphenol A and high fat diet on adult anxiety and social behavior

Authors: *L. M. WISE, S. M. BOAS, J. M. JURASKA;
Dept. of Psychology, Univ. of Illinois, Champaign, IL

Abstract: Bisphenol A (BPA) is an environmental endocrine disruptor that has been detected in the vast majority of the United States population. The current study explores the combined effects of relevant doses of BPA and diet on anxiety and social behaviors. Pregnant dams consumed doses of 0, 40, or 400 ug/kg/day of BPA from gestational day 2 through parturition. After birth, the pups individually consumed the same dose of BPA from postnatal day 1 through 10. The pregnant dams were also fed control or high-fat diet from gestational day 0 (day sperm plug detected) through postnatal day 10.
Elevated Plus Maze. Anxiety behavior in adulthood was assessed via the elevated plus maze. The animals were allowed one five-minute trial to explore an elevated plus maze. Preliminary results suggest a significant sex difference in the number of entries onto the open arms of the maze. However, there was no effect of diet or BPA dose the number of entries onto the open or closed arms of the maze. Also, there was no effect of diet or BPA dose on the time spent in the open or closed arms of the maze.
Social Recognition. Social memory in adulthood was assessed via the social recognition paradigm. A same sex juvenile at was placed in the home cage of the experimental animal, after which the juvenile was removed for a delay period of 15, 45, 90 or 120 minutes. Following the delay, a familiar and novel juvenile were introduced into the adult cage and the amount of time the adult animal spent investigating each juvenile was recorded. There was a significant sex difference in the amount of time spent investigating the familiar and the novel juveniles. However, there was no effect of BPA or high-fat diet exposure on social memory.

Title: Long-term behavioral effects of perinatal exposure to phthalates and maternal high-fat diet in male and female rats

Authors: *J. WILLING[1], D. G. KOUGIAS[2], L. R. CORTES[1], C. M. DRZEWIECKI[2], K. E. WEHRHEIM[1], J. M. JURASKA, 61820[1];

Abstract: Endocrine disruptors and high-fat diets pose major health concerns in our industrialized society. Phthalates, a class of endocrine disrupting chemicals commonly used as plasticizers or solvents, can possess anti-androgenic, estrogenic, and anti-estrogenic activities, as well as suppress other steroid enzymes. Humans are ubiquitously exposed to many different phthalates through a variety of consumer goods, with diet presumed to be the main source of exposure for some phthalates. Moreover, phthalates are more prevalent in fatty foods. Both phthalates and high-fat diets can increase oxidative stress and inflammation, suggesting the need to examine the potential for interactive effects between them. In humans, the gestational period appears to be a particularly vulnerable window to phthalates' endocrine and metabolic disrupting activity. Since the prenatal period through postnatal day (P)10 in rats approximately corresponds to prenatal cortical development in humans, in the present study, we use a rat model of human prenatal exposure to investigate the long-term cognitive effects of gestational/neonatal exposure to phthalates and a high-fat diet. Dams were fed cookies containing an environmentally relevant mixture of phthalates at doses of 0, 200, or 1000 µg/kg/day from the second day of gestation until P10. They also consumed high-fat or control diets during this period. When the pups of treated animals reached adulthood (~P90), behavior was assessed in the elevated plus maze, attentional set shift, acoustic startle, prepulse inhibition, open field, and novel object recognition tasks. Preliminary data indicates that perinatal exposure to high fat diets result in increased

prepulse inhibition. Preliminary data also suggests effects of perinatal phthalate exposure and interactions with the sex of the animal or high fat diet on all measures except the elevated plus maze. Results from these studies will provide insight into the sex-specific effects of developmental exposure to ubiquitous endocrine disruptors and maternal diet on cognitive and emotional behavior.

Title: Perinatal exposure to phthalates and a high-fat diet affects maternal behavior, indices of pup development, and periadolescent behavior

Authors: *D. G. KOUGIAS[1], L. R. CORTES[2], S. G. RHOADS[2], J. M. JURASKA[3]; [1]Neurosci. Program, [2]Psychology Dept., [3]Neurosci. Program & Psychology Dept., Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: Endocrine disruptors and high-fat diets pose major health concerns in our industrialized society. Humans are ubiquitously exposed to phthalates, a class of endocrine disrupting chemicals commonly used as plasticizers or solvents, through a variety of consumer goods and food. Phthalates can possess anti-androgenic, estrogenic, and anti-estrogenic activities, as well as suppress the synthesis of steroidogenic enzymes. They are also more prevalent in fatty foods, which are readily available in the developing world and likely contribute to the increase in obesity rates. Since phthalates and high-fat diets are both capable of increasing oxidative stress and inflammation, which are known to negatively affect cerebral function and plasticity, it is important to study phthalates and high-fat diets together. In humans, the gestational period appears to be a particularly vulnerable window to phthalates' endocrine and metabolic disrupting effects. In this study, we use a rat model of human prenatal exposure to investigate the developmental and behavioral effects of phthalates and a high-fat diet. Since the prenatal period through postnatal day (P)10 in rats approximately corresponds to prenatal cortical

development in humans, the dams were orally dosed (0, 200, or 1000 μg/kg/day) with a mixture of phthalates throughout this period. The dams were also fed high-fat or control diets during this period. Total caloric intake, initial litter size and sex ratio, dam and pup bodyweights, and pup anogenital distance were recorded during the dosing period. Preliminary data indicates that pups had higher body weights at P10 and P25 from litters with dams fed a high-fat diet, and effects of phthalate exposure on body weight varied with age. Also, maternal behavior was observed daily throughout the neonatal period (P3-P15), and dams fed a high-fat diet licked their offspring more and engaged in more nest reorganization. During the periadolescent period, social play behavior will be observed and pubertal onset determined.

Title: Effects of high fat diet on body composition, food and caloric intake, behavioral and thermoregulatory responses of ovariectomized female Wistar rats following estrogen replacement

Authors: *A. R. ABREU[1,2], I. F. CALIMAN[7,3], C. S. BERNABE[3,4,5], R. C. A. DE MENEZES[1], A. SHEKHAR[2,4,6], P. L. JOHNSON[3,4];

Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [7]Physiological Sci., Federal Univ. of Espirito Santo, Vitoria, Brazil

Abstract: Background - Hot flash associated vasomotor symptoms (VMS), which emerge during perimenopause occur in ~70% of women and can persist for years, are thought to contribute to sleep and mood disruption. Another common symptoms that emerges during menopause is weight gain, and recent large cohort clinical studies have determined that increased adiposity is associated with more problematic VMS during menopause transition and early postmenopause

stages (*Thurston et al., 2013 Fert Steril)* and weight loss produces less VMS (*Thurston et al., 2014 Menopause*). Methods - Using an ovariectomy rat model of a surgical perimenopausal state +/- estrogen replacement (ER), we investigated the effects of a 9 week high fat diet (HFD), compared to normal diet (ND), on weight, body mass composition (assessed with an EchoMRI), food and caloric intake, mood/anxiety behaviors and thermoregulatory activity. Results - Following 9 weeks, ND controls and HFD rats has similar increases in weight gain, but even though HFD rats consumed less food it represented more calories and produced higher adiposity. ER was equally effective in reducing weight gain and adiposity in ND and HFD rats. VMS-associated activity was assessed by measuring tail skin temperatures (TST). Although there were no differences in TSTs at baseline or following a VMS inducing drug (systemic injection of FG-7142, an anxiogenic GABA disenhancing drug) in either HFD or ND rats, ER reduced TST activity at baseline which produced a diminished TST responses post FG-7142. Behavioral assessments of anxiety/mood disruption revealed that avoidance behaviors were exacerbated in HFD rats which were reduced with ER. There were no acoustic startle response differences noted between the HFD and ND rats, but ER did reduce startle responses in ND rats. Using a novel object short term memory recognition test, only ER treated HFD and ND OVEX rats showed evidence of recognizing of a novel object (no diet effects were noted). Conclusions - These results showed that although a HFD does not produce worse weight gain post OVEX it was associated with higher fat composition, which among all other measures was only noted to increase avoidance behaviors. ER was effective in reducing weight gain, fat composition, and VMS-associated TST activity, as well as reducing evidence of mood/anxiety disruption (increases in avoidance and startle responses) and restoring object recognition.

Topic: F.04. Stress and the Brain

Title: Modulation of acute stress-induced anorexia by fatty acid amide hydrolase inhibition in rats

Authors: *M. A. STICHT[1], K. A. SHARKEY[1], M. N. HILL[2];
[1]Dept. of Physiol. and Pharmacol., [2]Dept. of Cell Biol. and Anat. and Psychiatry, Univ. of Calgary, Calgary, AB, Canada

Abstract: In rats, acute stress is known to cause a reduction in food intake. This anorectic effect is likely modulated by factors such as stressor intensity, as well as motivation to feed, i.e. hunger/satiety. Many aspects of the stress response are regulated by the endocannabinoid system (ECS), as is food intake, but it is unclear how this system modifies stress effects on feeding. Given that fatty acid amide hydrolase (FAAH) inhibition has previously been shown to attenuate a variety of stress effects through an increase in the endocannabinoid, anandamide (AEA), we tested the hypothesis that AEA regulates stress-induced anorexia. As such, male Sprague-Dawley rats were administered vehicle or the FAAH inhibitor PF04457845 (PF) systemically or via intracerebroventricular (icv) cannulation prior to an acute psychological stressor (restraint stress). Post-stress feeding intake of regular lab diet (Prolab RMH 2500) and animal body weight were subsequently assessed over the following 24hr and 3 days, respectively.
Stress-induced anorexia was not observed when rats were fasted for 24hr prior to a 2hr stressor or with a shorter stress period of 1hr. Among non-food-deprived animals, following exposure to a 2hr restraint stressor (or a 2hr fast to control for food intake in home cage controls), stressed animals consumed significantly less chow within the first hour of testing (1.9g vs 5.4g), and feeding was significantly reduced up to 22 hr post-stress. However, the anorectic effects were not altered by systemic (10 mg/kg) or icv (30 μg) PF administration. Interestingly, PF was found to reduce food intake and normal body weight gain in non-stressed control animals compared to vehicle-treated rats. Taken together, these results suggest that stress-induced effects on feeding are influenced by satiety/hunger signals, which may be affected similarly by FAAH inhibition alone. Current experiments are exploring the mechanism(s) of action underlying this paradoxical effect of FAAH inhibition on stress-induced feeding behaviour.

Title: Should we turn off the lights? The modulation of light-cue value in the augmentation of heroin seeking in chronically food restricted rats

Authors: *F. SEDKI[1], L. MAYERS[2], D. RIZZO[2], S. TRIEU CHAO[2], J. COHEN[2], T. D'CUNHA[2], U. SHALEV[2];
[1]CSBN, [2]Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Disruptions in energy balance can affect motivated behaviors. For example, caloric restriction can increase drug taking and seeking in rats. Recently, we reported an augmented heroin seeking in food restricted rats under withdrawal. The underlying motivational mechanisms driving this effect are unclear. It is possible that exposure to caloric restriction may enhance the incentive value attributed to the drug-associated cues, and in turn augment drug seeking. It is important however to distinguish the incentive value of a light cue independent of the value acquired through its association with a drug. Thus, we investigated the effect of food restriction on the acquisition of a new operant response reinforced solely by heroin- or non-heroin-associated cues. In a separate experiment, we compared heroin- with non-heroin-associated light seeking in a discrete choice paradigm. Male Long-Evans rats were trained lever-press for heroin, for 10 days. Next, rats were moved to the animal colony and maintained on free access to food (Sated) or subjected to 14 days of mild chronic food restriction (FDR). On day 14, rats were tested in the self-administration chambers. Ex.1: During self-administration training, heroin infusions were associated with light/tone cues. On test day, the incentive value of the cues was assessed by training the rats on a novel nose-poke response reinforced solely by the heroin-associated cues. Ex.2: Responses on one lever led to a heroin infusion, and activation of a light/tone cue. Responses on a second lever activated a different light/tone or just a tone cue. On test day, rats were treated as described in Ex.1. Ex.3: Rats were trained on a discrete choice trial, with one lever associated with heroin infusions+light cue, and another lever associated only with a different light cue. On test day rats were exposed to choice trials reinforced by cues alone. Ex.1 results: Rats in the FDR group acquired the novel behavior at a greater rate compared to the Sated group. Ex.2: FDR-induced increase in nose-poke response rate was observed for both heroin-paired and the alternative light cue. Ex.3: Responses for a heroin-associated light cue was greater than responses on for the light cue alone in both Sated and FDR groups. Response rate for the light alone however was greater in the FDR versus Sated group. Our findings suggest that food restriction increases the incentive salience of environmental stimuli, including, but not exclusively, of drug-paired cues.

Title: The role of the paraventricular nucleus of the thalamus in the augmentation of heroin seeking by chronic food restriction

Authors: *A. CHISHOLM, J. IANNUZZI, U. SHALEV;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Drug addiction is a chronic disorder that is characterized by compulsive drug seeking and involves switching between periods of abstinence and relapse. In both human and animal models of addiction chronic food restriction has been shown to increase rates of relapse. Previously, our laboratory has demonstrated a robust increase in drug seeking following a period of withdrawal in chronically food-restricted rats compared to sated rats. To date, the neural mechanisms that mediate the effect of chronic food restriction on drug seeking have not been elucidated. However, the paraventricular nucleus of the thalamus (PVT) appears to be a promising target to investigate. The PVT is uniquely placed to contribute to both homeostatic control and drug seeking systems. Thus, the objective of the current study was to study the effect of PVT inactivation on heroin seeking under food restriction conditions.
Prior to heroin self-administration training, male Long Evans rats were injected with a viral vector carrying an inhibitor Designer Receptor Exclusively Activated by Designer Drug (DREADD) into the PVT. Next, rats were trained to self-administer heroin over 10 days (0.1 mg/kg/infusion; i.v.). Following training, rats were removed from the operant conditioning chambers and were placed into drug withdrawal for 16 days. Over the withdrawal period, rats were exposed to a mild food restriction (90% of baseline body weight) or were given unrestricted access to food. On the 14th and 16th day of the withdrawal period, two drug-seeking tests were conducted in which rats were injected (i.p.) with either CNO (3 mg/kg), to activate the DREADDs, or vehicle, 20 minutes prior to test. Injectors' placement was verified using immunohistochemistry.
All rats reliably learned to self-administer heroin. As expected, food-restricted rats demonstrated an augmented heroin seeking during the heroin-seeking test in comparison to sated rats. PVT inactivation seemed to reduced heroin seeking in all rats regardless of the feeding condition, however this effect did not reach statistical significance.
These results suggest that PVT activity appears to play a role in heroin seeking. However, PVT activity may not modulate the augmentation of heroin seeking following chronic food restriction.

Title: The role of glutamate neurotransmission in the augmentation of heroin seeking induced by chronic food restriction

Authors: ***T. M. D'CUNHA**, M. RUSSO, S. LE NOBLE, A. USYPCHUK, J. IANNUZZI, F. SEDKI, U. SHALEV;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Caloric restriction increases the risk of relapse during drug abstinence in human drug addicts. Our laboratory has demonstrated that chronic food restriction augments heroin seeking following prolonged withdrawal in rats with a history of heroin self-administration. During the heroin-seeking test, food restricted (FDR) rats had elevated extracellular levels of dopamine (DA) in the nucleus accumbens (NAc), and administration of a DA D1 receptor antagonist into the nucleus accumbens decreased heroin seeking in the FDR rats. The NAc receives a multitude of glutamatergic innervation from a variety of brain regions, and previous work has demonstrated that glutamate transmission in the NAc can interact with dopaminergic activity. In this study we investigated extracellular glutamate levels in the NAc shell and core, as well as the role of AMPA receptors in the augmentation of heroin seeking induced by chronic food restriction. First, rats were trained to self-administer heroin for 10 days. Next, rats were moved to the animal colony for 14 days of drug withdrawal. During the withdrawal period some rats were given unrestricted access to food and others were subjected to a mild chronic food restriction until they reached approximately 90% of their original body weight. On the 14^{th} day of food restriction rats were returned to the operant conditioning chambers for a heroin-seeking test under extinction conditions. Extracellular glutamate was assessed using *in vivo* microdialysis and HPLC during baseline conditions in the animal facility and then during the 3 h heroin-seeking test. Food restriction significantly augmented heroin seeking compared to the sated rats. There

were no significant changes in extracellular glutamate levels between the FDR and sated rats. Bilateral administration of the AMPA receptor antagonist NBQX (0.0, 0.3, 1.0 µg/side) into the NAc core decreased heroin seeking but only in the sated rats. Taken together, these results suggest that glutamate transmission in the NAc through AMPA receptors is not involved in the augmentation of heroin seeking induced by chronic food restriction. Future studies will investigate if NMDA or metabotropic glutamate receptors play a role in food restricted-induced augmentation heroin seeking.

Title: Changes in the AMPA/NMDA ratio in neurons of the nucleus accumbens shell associated with chronic food restriction and with withdrawal from heroin self-administration

Authors: ***U. SHALEV**, I. GLOVACI, T. D'CUNHA, A. CHAPMAN;
Concordia Univ., Montreal, QC, Canada

Abstract: Chronic food restriction increases drug craving and the risk to relapse during abstinence in human addicts. Recently, we demonstrated that chronic food restriction augments heroin seeking during withdrawal in rats with a history of heroin self-administration. These food-restricted (FDR) rats demonstrated changes in dopamine transmission in the nucleus accumbens (NAc). Previous research has shown that dopamine in the NAc can modulate glutamatergic synaptic transmission, however, this has not been studied in the framework of food restriction and heroin seeking. Therefore, the purpose of the current study was to assess synaptic plasticity induced by heroin self-administration and by chronic food restriction during heroin withdrawal in the NAc shell. Changes in AMPA and NMDA receptor mediated currents were evaluated in both sated and FDR Long-Evans rats under withdrawal from heroin. Briefly, half of the rats tested were trained to self-administer heroin for 10 days in operant conditioning chambers. Then, rats were moved to the animal colony for 14 days of withdrawal during which one group was food restricted to approximately 90% of their original body weight (Heroin-FDR), or given unrestricted access to food (Heroin-Sated). The second half of the animals were not heroin

trained and served as controls. Of these, one group was free-fed (Naïve-Sated) and the other group was food restricted (Naïve-FDR). In vitro whole cell patch-clamp recordings were performed on the 14th day of withdrawal for all animals. Voltage-clamp recordings were obtained from visually-identified NAc shell medium spiny neurons. AMPA currents were measured at -70 mV, as well as at +40 mV before and after application of the NMDA antagonist APV, and NMDA currents were quantified by subtraction. Cells recorded in the Naïve-FDR group demonstrated a marked reduction in NMDA, but not AMPA, currents, resulting in a strongly increased AMPA/NMDA ratio relative to cells in the Naïve-Sated group. Additionally, our initial results also suggest a decrease in the AMPA/NMDA ratio following heroin administration and withdrawal in the Heroin-Sated group, due to an increase in NMDA currents. In contrast, both AMPA and NMDA currents in the Heroin-FDR group were similar to those in the Naïve-Sated group. Taken together, our results suggest differential effects of heroin self-administration and chronic food restriction during withdrawal on glutamatergic synapses in the nucleus accumbens shell.

Title: Individual differences in the microbiome of rats resilient or vulnerable to the effects of chronic social defeat stress

Authors: *J. PEARSON-LEARY[1], K. BITTINGER, 19128[3], C. TANES, 19128[2], S. BHATNAGAR[1];
[2]CHOP Microbiome Ctr., [1]Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Dept. of Microbiology, Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Chronic exposure to stress is associated with increased incidence of depression, generalized anxiety and PTSD. However, stress induces vulnerability to such disorders only in a sub-population of individuals, as others remain resilient. To model these individual differences in response to stress, our lab, and others, have shown that two subpopulations of Sprague-Dawley rats emerge with repeated social defeat. Approximately half of defeated rats exhibit short latencies (SL) to be defeated averaged over 7 days whereas the other half of rats resist defeat and

exhibit increased latency. SL rats have increased anxiety-like and depressive-like behaviors suggesting that they are stress vulnerable. Behaviorally, LL rats are no different from controls, suggesting they are stress resilient. A current hypothesis is that inflammation mediates vulnerability to chronic stress. Previous data has shown that inflammation can be mediated by the gut microbiome. We hypothesized that vulnerability to stress would be characterized by an inflammation-promoting gut microbiome. We performed shotgun metagenome sequencing on fecal pellets of male Sprague Dawley rats collected prior to, and after social defeat, and nondefeated control rats. SL and LL rats were identified by cluster analyses on latencies to social defeat. In the pre-stress samples, there were no significant differences between control, SL, or LL rats, suggesting that pre-existing differences in the gut microbiome do not predict vulnerability or resiliency. However, repeated social defeat produced robust changes in microbiome composition at the community level. In the LL and SL groups, we found that *Lactobacillus*, *Blautia*, and *Eubacterium* were among the top increased taxa, and social defeat produced a significant increase in the ratio of firmicutes:bacteriodetes. *Collinsella* increased dramatically in LL rats. In the SL rats, four of the five taxa identified were members of the class Clostridia. Clostridia are especially important for regulating immune function. Because SL rats exhibit indices of increased inflammation, we examined this taxon and observed that Clostridia were indeed significantly increased in SL rats. Thus, analyses of gut microbiome profiles suggests that vulnerability and resiliency have unique effects on the microbiome, with vulnerability associated with increased clostridia, which may promote the inflammatory phenotype previously observed in SL/vulnerable rats. Ongoing studies are determining the physiological and neural consequences of increased clostridia in SL rats and the mechanisms by which such effects might be mediated.

Title: Caesarean delivery induces enduring behavioural and physiological effects in mice: reversal by selective targeting of the microbiota-gut-brain axis

Authors: *L. H. MORAIS[1], A. MOYA-PEREZ[2], A. VENTURA-SILVA[2], G. CLARKE[2], K. REA[2], I. RENES[5], J. KNOL[5], S. WANG[6], C. STANTON[3], T. DINAN[4], J. F. CRYAN[2]; [2]APC Microbiome Inst., [3]Teagasc Food Res. Centre, Moorepark, [4]Psychiatry, [1]Univ. Col. Cork, Cork, Ireland; [5]Danone Nutricia Res., Utrecht, Netherlands; [6]Danone Nutricia Res., Singapore, Singapore

Abstract: Increasing evidence points to a role for the microbiome in regulating many aspects of health including brain health. It is now clear that the microbiota-gut-brain axis plays a key role in regulating behaviour and brain function. Early-life is a critical developmental window for the microbiome and brain. The initial seeding of the gut microbiome occurs during birth as the infant emerges through the mother's birth canal. However, birth by Caesarean section (C-section) results in a different pattern of bacterial colonisation compared to naturally delivered offspring. Recently, we have demonstrated that C-section delivered mice present with enduring behavioural and physiological phenotypes. The aim of the present study was to investigate whether these effects were reversible by oral supplementation with prebiotic, probiotic or synbiotics (combination of prebiotics and probiotics) that target the microbiota-gut-brain axis. We assessed a number of translational behavioural and physiological outputs in early-life and in adulthood that are relevant to neuropsychiatric disorders. Following birth by C-Section or *per vaginum* pups were exposed to a dietary intervention with specific probiotic, prebiotic or synbiotic mixtures given to dams during lactation period. Male offspring was weaned to their mother's diet at postnatal day 21 till 14 weeks at which they were sacrificed. Probiotic treatment was administered in the drinking water and the prebiotic was incorporated into the custom-made rodent diet. In early-life, all dietary interventions (prebiotics, probiotics and synbiotics) reversed C-section-mediated increase in ultrasonic vocalisation and impairment in maternal attachment at postnatal day 9 and 10. In adulthood at week 8, the three interventions restored C-section mediated deficits in social cognition and novel object recognition memory. Prebiotic and probiotic treatment independently reduced anxiety in C-section born offspring exposed to the marble burying test, while the probiotic itself displayed anxiolytic effect in the natural born offspring. Furthermore, synbiotics also reduced depression-like behaviour in the natural born. Ongoing analysis at the level of the gastrointestinal tract, the immune system and the brain will illuminate mechanistic insights underlying such effects. In conclusion, our data highlight the importance of the gut microbiome in early life in shaping neurodevelopment and stress-related behaviours. Further, it demonstrated that there are potential microbiota-based strategies to counteract such effects.

Title: Gender differences in adolescent probiotic influence on anxiety

Authors: *L. L. DRISCOLL[1], T. TUMMINO[2], W. HARRIS[2], S. COOKE[2], R. LACH[2]; [1]Colorado Col., Colorado Spgs, CO; [2]Colorado Col., Colorado Springs, CO

Abstract: Nervous system function and psychological health are influenced by the unique composition of one's gut microbiome. However, little is known about the influence of microbiome composition on brain function later in life, and the extent to which gut microbes exert their influence on development of anxious or depressive behaviors through direct neural communication with the brain via the vagus nerve. The purpose of the current study was to elucidate the effects of oral supplementation of the probiotic strain *Bifidobacterium infantis* 35624 on the development of anxiety and depression in healthy adolescent rats, and to identify the unique contribution of the vagus nerve to such effects. As weanlings, rats were subjected to either a subdiaphragmatic vagotomy or a sham surgery and supplemented daily with *B. infantis* or vehicle for two weeks. Anxious behavior in the elevated plus maze (EPM), and depressive behavior in the forced swim test (FST), were assessed in young adulthood. *B. infantis* treatment decreased anxious behavior in a vagally-dependent manner for male rats and in a vagally-independent manner for female rats. In contrast, neither probiotic supplementation nor vagotomy altered FST immobility time. These results suggest that the vagus nerve plays a necessary role in in the anxiolytic effects of *B. infantis* in male rats, but that hormonal or immune benefits conferred by *B. infantis* are sufficient to mediate anxiolysis in female rats.

Title: Anorexia increases sensitivity to cocaine-induced locomotion: evidence for dysregulation of dopamine transporters

Authors: *C. M. GEORGE[1], W. A. OWENS[1], C. P. FRANCE[2], G. M. TONEY[1], L. C. DAWS[3];
[1]Physiol., [2]Pharmacol. and Psychiatry, [3]Physiol. and Pharmacol., Univ. Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Anorexia Nervosa (i.e., anorexia) is a major public health concern compounded by a lack of effective treatments. This complex disorder is most common in females and often manifests during adolescence. Although the etiology of anorexia remains unclear, dysregulation of dopamine (DA) neurotransmission is a consistent finding. The DA transporter (DAT) terminates DA neurotransmission by high-affinity uptake of DA into neurons and is therefore a primary regulator of the strength and duration of DA signaling. Given the important role that DAT plays to clear dopamine together with strong evidence of dysregulated DA neurotransmission in anorexia-related eating disorders, it is possible that DAT function is aberrant in individuals with anorexia. Surprisingly, however, few studies have investigated DAT activity in anorexia. Toward this end, we used the "activity-based anorexia" (ABA) model in rats, which recapitulates key characteristics of anorexia, including hyperactivity and restricted food intake. As an index of DAT function *in vivo*, we examined the effect of the DAT blocker cocaine on locomotion. Adolescent rats with one hour access to food ate less than those with ad libitum access to food, regardless of whether they had access to locked or unlocked running wheel. We determined that "anorexic" adolescent female rats were more sensitive to cocaine than female control rats as evidenced by a leftward shift of the ascending and descending limbs of their dose-response curves. Moreover, females that underwent ABA were more sensitive to the effects of cocaine on locomotion than their male counterparts. Preliminary data generated using high-speed chronoamperometry to measure transporter function *in vivo* indicate that DAT activity was increased in females, but not males, exposed to ABA. Together, these data support the hypothesis that during adolescence, DAT function in females is susceptible to reduced food intake, to hyperactivity or to both in combination, which might contribute to development or severity of anorexia-related behavior.

Title: Antidepressant-like effects of ketamine in serotonin transporter mutant mice and organic cation transporter 3 knockout mice

Authors: *M. A. BOWMAN[1], W. KOEK[2], L. C. DAWS[3];
[2]Psychiatry and Pharmacol., [3]Physiol. and Pharmacol., [1]Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX

Abstract: Twenty percent of adults are diagnosed with major depressive disorder, which is typically treated with selective serotonin reuptake inhibitors (SSRIs). However, this type of medication takes approximately six weeks to produce therapeutic effects. Recently, low doses of ketamine, a noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist, have been shown to produce rapid and long-lasting antidepressant effects. Studies that have begun to examine the mechanisms underlying these effects have focused on intracellular changes mediated by NMDA and/or AMPA receptors. However, the traditional view of the etiology of depression involves the need for an increase in extracellular serotonin to regulate mood. Surprisingly, there appears to be little research into the effects of ketamine on serotonin. One study found an increase in extracellular serotonin while another found an inhibition of serotonin uptake following ketamine treatment. Together, these studies suggest a role for serotonin in the antidepressant-like effects of ketamine, and putatively one involving the serotonin transporter (SERT). To further elucidate this role, we examined antidepressant-like effects of ketamine in SERT mutant mice bred on a C57BL/6J background. SERT knockout, heterozygous, and wildtype adult mice were treated with vehicle or 30 mg/kg ketamine and tested either 24 hours or 7 days later in the tail suspension test, a validated model for detecting antidepressant drug effects. Ketamine had antidepressant-like effects only in SERT knockout mice. Taken together with published findings that SERT knockout mice have increased expression of organic cation transporter 3 (OCT3) relative to wildtype littermates, and that blockade of OCT3 produces

antidepressant-like effects and inhibits serotonin uptake, these results raise the possibility that OCT3 plays a role in antidepressant-like effects of ketamine. Ongoing studies are investigating the dose-response relationship of these effects in SERT mutant mice and in OCT3 knockout mice to investigate a potential role for OCT3 in antidepressant-like effects of ketamine.

Title: Dopamine modulation of sleep and feeding in *Drosophila*

Authors: *A. PAVIN, M. DRISCOLL, D. SITARAMAN;
Dpt. of Psychological Sci., Univ. of San Diego, San Diego, CA

Abstract: Neuromodulators such as dopamine (DA) and serotonin have long been implicated in innate and learned behaviors. Widespread dopaminergic system manipulations depleting DA levels result in sleep regulation deficits in *Drosophila Melanogaster* (the fruit fly). Further evidence suggests that regulation of feeding is also adversely affected when DA levels are diminished. The fly brain contains a total of 200 dopaminergic neurons, 130 of which innervate the mushroom body (MB). The MB is an associative learning network important for decision-making as well as for the control of sleep in *Drosophila.* Approximately 2,000 kenyon cells (KCs) make up the lobes of the MB and synapse onto MB output neurons (MBON) in 15 non-overlapping compartments. The 130 DANs project into these compartments, modulating the synaptic strength of these connections. Activation of specific DANs has been demonstrated to significantly reduce sleep in *Drosophila*. It remains unclear whether the observed sleep deficits are a cause of dopaminergic regulation of arousal, or of a motivational behavior like feeding. Using *Drosophila* as an experimental system, a comprehensive screen of all MB DANs and MBONs was conducted. We analyzed specific subsets of DAN and ON clusters in order to elucidate dopamine's role in the regulation of feeding and motivational behaviors. The goal of these data is to explore a link between dopamine regulation of motivational behaviors and their implications for sleep regulation.

Title: Feeding regulates sphingolipid-mediated signaling in mouse hypothalamus.

Authors: *V. VOZELLA[1], N. REALINI[1], A. MISTO[1], D. PIOMELLI[1,2];
[1]D3, Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [2]Dept. of Anat. and Neurobio., Univ. of California, Irvine, CA

Abstract: BACKGROUND:
Feeding behavior and energy metabolism are regulated by a complex network of central and peripheral signals, of which the hypothalamus is an especially important node (Schwartz MW et al., 2000). The sphingolipids - a class of lipid-derived messengers that include ceramide (Cer), dihydroceramide (dHcer), sphingosine (SO) and sphingosine-1-phosphate (SO1P) - have been recently implicated in the pathogenesis of metabolic dysfunction (Russo SB et al., 2013; Bikman BT, 2012), but the physiological signals regulating their formation and deactivation in the hypothalamus are unknown.
OBJECTIVES:
In the present study, we investigated the effect of food deprivation or high-fat diet (HFD) on sphingolipid levels and on the expression of enzymes involved in sphingolipid metabolism in the hypothalamus.
METHODS:
Male C57BL/6J mice (n=5/group) were subjected to four different feeding conditions: 1) free feeding (FF); 2) 12h food deprivation (FD); 3) 1h refeeding after FD; 4) 6h refeeding after FD. To study the effect of HFD, C57BL/6J mice were divided into two groups: standard diet (2.66 kcal/g) and HFD (5.24 kcal/g) and killed at different time points (1-3-7-14-28 days). Hypothalamic sphingolipids were extracted, identified and quantified by liquid chromatography/mass spectrometry. Gene expression of enzymes involved in sphingolipid biosynthesis was evaluated by qPCR.
RESULTS:
Relative to free feeding, fasting: 1) decreased SO1P levels; 2) increased SO, the precursor of SO1P; 3) reduced the levels of dihydroceramide (d18:0/18:0), a product of *de novo* pathway of ceramide biosynthesis; 4) down-regulated transcription of sphingosine kinases (SK) and ceramide synthase. After 1 day and 14 days, free feeding mice exposed to a HFD showed lower levels of Cer24:0, its precursor dHCer 24:0, and Cer24:1 compared to mice fed standard diet. Significant decreases in SO1P were also observed after 7 and 14 days of HFD.
CONCLUSION:

Intracerebroventricular injections of SO1P reduce food intake and stimulate energy expenditure in rats (Silva VRR et al., 2014). Our results suggest that hypothalamic levels of SO1P, its precursor SO and enzymes involved in the conversion of one into the other (SK) are influenced by the feeding status. Feeding also regulates other aspects of sphingolipid metabolism, suggesting additional roles for this lipid pathway in the control of energy balance.

Title: Effect of resveratrol on food intake, lipid oxidation, GABA levels in rats hypercaloric diets fed

Authors: ***C. SANDOVAL SALAZAR**[1], L. MOSQUEDA-VERA[2], V. BELTRÁN-CAMPOS[2], M. SOLÍS-ORTIZ[3], J. RAMIREZ-EMILIANO[3];
[1]Univ. De Guanajuato, Celaya, Mexico; [2]Enfermería y Obstetricia, Univ. de Guanajuato, Celaya, Mexico; [3]Ciencias Médicas, Univ. de Guanajuato, Leon, Mexico

Abstract: Obesity is associated with psychological factors, genetic predisposition and food habits. Diet composition influence total energy intake and long-term changes to body weight and body composition. Some studies reported that chronic intake of a hypercaloric diet produce changes in the oxidative stress which accompanied by accelerate lipid peroxidation. Natural products, such as flavonoids found in fruits like resveratrol have potential therapeutic agents recognized for their antioxidant activity. The aim of this study was to explore the effect of antioxidant resveratrol, lipids damage oxidative in the frontal cortex of rats hypercaloric diets fed. A total of 50 healthy male rats were divided equally into six groups: first group: the first group= hypercaloric diet 1 (HPC1: sugar 5% + lard 15%), the second group= HPC1 + resveratrol, the third group= (HPC2: sugar 10% + lard 10%), the fourth group= HPC2 + resveratrol, the fifth group= (HPC3: sugar 15% + lard 5%) and the sixth group= HPC3 + resveratrol, the seventh and eighth groups were fed with standard diet (SD) and SD + resveratrol. All the groups were fed during five months, however in the fifth month the second, fourth, sixth and eighth groups received resveratrol during four weeks. Food intake was recordly daily. Lipid peroxidation levels were analyzed by measuring thiobarbituric acid reactive substances. GABA

levels were determinate with ELISA kit. The SD-fed rat intake was approximately 7.77% more lower than the HPC groups and the resveratrol have no effect on food intake. The lipid peroxidation were high in HPC2 and HPC3. The resveratrol decreases lipid peroxidation in the HPC3 group with significant differences. The GABA levels in the HPC-fed rats demonstrated a significant decrease compared with the SD group in the frontal cortex. The GABA levels in the HPC3 + resveratrol appeared to be more elevated without reaching to SD group. This results indicate that exposure to hypercaloric diet decrease the GABA concentration and increase de lipid oxidation in the frontal cortex; this probably suggesting a imbalance in inhibitory process of frontal cortex.

Title: Chrono-nutrition effect of theanine intake on the learning memory and anxiety in mice.

Authors: *A. MUTO, T. SAKAI, Y. TAHARA, Y. KIKUCHI, T. SHIRAISHI, M. YAMASAKI, H. MOTOHASHI, S. SHIBATA;
Fac. of Sci. and Engin., Waseda Univ., Tokyo, Japan

Abstract: Theanine is an amino acid included in green tea, is known to interact with glutamate receptors in the brain nervous system. In the previous studies, theanine has improved the learning memory deficit in mice, and also anxiety in patients with schizophrenia. Circadian rhythm system is important to control the morning /evening difference of physiological functions such as not only body temperature, blood pressure and endocrine secretion, but learning/memory and anxiety. Circadian rhythm system also controls the timing effect of drug intake (chrono-pharmacology) and food/nutrition intake (chrono-nutrition). Therefore, the timing of drug/food may affect their effects. Although human usually takes green tea during daytime but not during late nighttime, there has been no study that has evaluated the effect of theanine on learning memory and anxiety in the morning or evening. Male ICR 3-week-old mice were allowed to acclimatize themselves to the chow (AIN-93G) and tap water for 1 week under a 12-h/12-h

light/dark schedule. After then, the mice were given tap water or 0.3% theanine included tap water ad libitum for 3 weeks. Mice were tested by novel object recognition test for learning/memory and open field test for anxiety. Maintain of learning memory was seen in theanine intake group when novel objective recognition test was conducted in the morning or evening, and theanine was more effective in the morning group compared with evening group. Anti-anxiety effect of theanine was appeared in the morning, but not in the evening evaluated by open field test. In conclusion, theanine was effective for learning memory maintenance and also anti-anxiety with observation of stronger effect in the morning test than the evening test. In the future experiment, we will investigate effect of consistent timing of both theanine intake and behavioral test. Abstract: Due to the high prevalence of obesity in many countries, the study of eating and food-reinforced behavior has become a priority. Several studies have shown that dopamine and its receptors are involved in normal and pathological regulation of food intake. For example, it has been reported that the selective activation of D4 dopamine receptors (D4R) in the paraventricular nucleus of the hypothalamus (PVN) produced a stimulatory effect on standard food intake by

increasing the release of glutamate. Accordingly, it has been suggested that alterations in the hypothalamic dopaminergic signaling pathways that regulate energy homeostasis may facilitate the development of obesity-associated caloric overeating by a D4R dependent mechanism. Accordingly, the aim of this study was to evaluate the effects of the central administration of D4 receptor antagonist, L-745,870, on food intake (standard lab chow) and on the motivation for palatable food (sucrose pellets). Adult male Wistar and Sprague Dawley rats were stereotaxically implanted with microinjection cannulas in the PVN and in the Nucleus Accumbens Shell to locally administrate L-745,870 (1 ug/0.5 uL) and consumption of standard food (1 and 2 hours after injection, Wistar rats) and the motivation for palatable food (45 mg pellets, operant test procedure, Sprague Dawley rats) were evaluated. We found that injection of L-745,870 (1 ug/0.5 uL) in the PVN significantly suppressed standard food intake in the first hour after the intra-hypothalamic injection. Furthermore, local administration of L-745,870 (1 ug/0.5 uL) in the Nucleus Accumbens Shell significantly decreased food-reinforced lever pressing on a progressive ration reinforcement schedule (PR1000). Our results showed that the central D4R modulate feeding behavior by inhibiting motivational and hedonic processes, suggesting that this compound may be useful for the pharmacological treatment of obesity.

Title: Electrical stimulation of the ventral noradrenergic bundle results in frequency dependent norepinephrine release in the paraventricular nucleus of the hypothalamus

Authors: *A. I. GERTH, M. F. ROITMAN;
Psychology, Univ. of Illinois At Chicago Dept of Psych, Chicago, IL

Abstract: The paraventricular nucleus of the hypothalamus (PVN) plays a critical role in a variety of regulatory and homeostatic functions including the autonomic response to stress as well as feeding behavior. Norepinephrine (NE) inputs to the PVN arise from the nucleus of the solitary tract (NTS) and project via the ventral noradrenergic bundle (VNB) to the the parvocellular, dorsomedial portion of the PVN. NTS NE neurons are robustly activated by the

satiety-inducing feeding peptide cholecystokinin and the malaise- inducing agent lithium chloride - supporting a role in intake suppression. They also appear to be critical for the robust food consumption induced by central delivery of agents that interfere with glucose sensing. Thus, the nature of the NE PVN input remains somewhat murky and sampling NE in the PVN will help to resolve its role. Here, we sought to characterize NE release in the PVN using fast-scan cyclic voltammetry - an electrochemical technique that can sample the release of electroactive neurotransmitters, like NE with good analyte specificity and excellent temporal and spatial resolution. In anesthetized rats, a carbon fiber microelectrode was lowered into the dorsomedial parvocellular region of the PVN and its voltage was modulated (-0.4V to +1.3V and back [scan], 400V/s, 10scans/s). Once every 5 minutes, the VNB was stimulated (60pulses, 60Hz, 200μA). A reliable increase in current was observed. Representative cyclic voltammagrams from each experiment were regressed against those obtained during post-recording calibration in a flow injection system where the electrode was exposed separately to 1uM NE and 1uM epinephrine (E). Cyclic voltammograms obtained in vivo compared favorably to NE but not E ($r^2 = 0.84 \pm 0.02$ vs 0.53 ± 0.02, respectively). In vivo NE release was frequency dependent. No release was detected for stimulation frequencies under 10Hz but higher frequencies led to greater release (75.3 ± 6.4 vs 248 ± 35.3 vs 283.45 ± 3.8 nM for 10, 30 and 60 Hz, respectively). Measurement and characterization of phasic NE release in the PVN will aid in resolving its role in feeding behavior.

Title: A dopaminergic circuitry critical for homeostatic protein intake in *Drosophila*

Authors: *L. CHIU, Q. LIU, S. LIU, L. KODAMA, W. HORIUCHI, J. DANIELS, D. BALDONI, M. N. WU;
Johns Hopkins Univ., Baltimore, MD

Abstract: The regulation of food intake is essential for an organism's survival and fitness. During this process, living organisms need to select between food sources that vary in quality and quantity. While progress has been made in our understanding of neural regulation of energy

intake, much less is known about how specific nutrients, such as protein intake is regulated. Accumulating evidences suggest that protein consumption is homeostatically regulated and may have a profound effect on total energy intake. Here we identified a small subset of dopamine (DA) neurons specifically involved in homeostatic regulation of protein intake in *Drosophila.* In order to assess the consumption of protein-containing food, we utilized two behavioral assays in our study. Blue-dye feeding assay was applied to quantify the absolute amount of protein intake and the two-choice assay was performed to measure animals' preference to protein relative to sugar. Female flies have previously been shown to undergo a post-mating dietary switch, with increased intake and preference for protein-enriched food. From a circuit-based screen, we found that DA signaling is required for this post-mating dietary switch. In addition, virgin female and male flies that have been protein-deprived exhibited a similar dietary switch, which was also suppressed by silencing DA signaling. Using an intersectional approach, we identified two DA neurons from the PPM2 subgroup (DA-WED) that are required for increasing consumption and preference of protein-containing food following protein deprivation. Moreover, activation of these neurons is sufficient to induce a protein preference in protein-satiated animals. Functional imaging experiments reveal that the activity of these DA-WED neurons correlates with the physiological drive for protein intake. Together, our study reveals a critical circuit mechanism by which *Drosophila* adjust their dietary strategy to maintain protein homeostasis.

Title: Characterizing motivational and dopaminergic changes resulting from distinct behavioral histories of sucrose access

Authors: *N. ELTOM, K. J. PULTORAK, D. GOMEZ, E. OLESON;
Psychology, CU Denver, Aurora, CO

Abstract: Approximately 2/3 of adults in the United States are either overweight or obese. Studies have shown that on average, Americans consume about 500-800 more calories per day than needed because of the availability of food, more specifically, carbohydrate rich and sucrose enriched foods (Flegal et al, 2000). Characterizing the effects of sucrose access on motivational and neurochemical markers of addiction may help to elucidate the neural basis of obesity. In the present study we are providing rats with either no access, intermittent access or unlimited access to sucrose in their home operant boxes in 23hr cycles over 28 days. Over the 28-day history, we assess for overall and circadian changes in: food intake, sucrose intake, water intake and weight gain. We then use a novel behavioral economic food seeking task and the progressive ratio schedule to assess for changes in motivation for sucrose. Motivation is assessed twice: once immediately after the 1-month history, and then again following a period in which all groups were deprived of sucrose. Immediately after the first motivational assessment, we use fast-scan cyclic voltammetry to assess for changes in transient dopamine responses to sucrose and a conditioned predictor of sucrose access.

Title: Aromatic amino acid metabolites generated by the intestinal microbiome are present in human cerebrospinal fluid

Authors: *G. E. JASKIW[1], M. E. OBRENOVICH[2], Z. RENLIANG[4], C. J. DONSKEY[3];
[2]Res. Service, [3]Infectious Dis. Service, [1]Louis Stokes Cleveland DVAMC, Cleveland, OH;
[4]Proteomics and Metabolomics Core, Lerner Res. Inst. at Cleveland Clin., Cleveland, OH

Abstract: Elevated urinary levels of the aromatic amino acid metabolite 3-(3-Hydroxyphenyl)-3-hydroxypropionic acid (HPHPA) have been reported in patients with schizophrenia and autism (Shaw, 2010). While HPHPA is thought to be generated by the intestinal microbiome and

derived from either tyrosine (TYR) (Curtius et al, 1976), or phenylalanine (PHE) (Shaw, 2010), the precise origin and distribution of HPHPA is not well-defined. We used liquid chromatography/mass spectroscopy (LC/MS) to measure HPHPA/ isomer and other aromatic amino acid metabolites in 3 experiments: 1) *Clostridium difficile*, a pathogen that colonizes the intestinal tract, was cultured *in vitro* on standard medium and the resulting levels of HPHPA and other metabolites were determined; 2) L-TYR or L-PHE 400mg/kg IP was administered to adult mice (Harlan, CFI, female) and metabolites were measured in urine harvested 2h later; 3) Human CSF samples from our clinical laboratory were analyzed. We found that *C. difficile* generated HPHPA/ isomer as well as 3-hydroxyphenyl-propionic acid (HPPA) (another intermediary in aromatic amino acid metabolism) and the structurally similar compound 3,4-Dihydroxyhydrocinnamic acid (DHCA). In mice, the administration of L-TYR, but not L-PHE, resulted in elevated urinary HPHPA / isomer. In human CSF, HPHPA/ isomer and DHCA were detected. Thus, we confirm earlier findings that components of the intestinal microbiome can generate aromatic amino acid metabolites. In mice, we demonstrated that urinary HPHPA/ isomer is derived at least in part from L-TYR. Furthermore, at least some of the analytes generated by the intestinal microbiota can cross the human blood brain barrier. This raises the possibility that aromatic amino acid metabolites differentially generated by gut bacteria in hosts with neuropsychiatric disorders, could directly affect brain function. Further studies will delineate the synthesis, distribution and neuroactive properties of these compounds.

Title: Peptide hormone A has a role in the hypothalamic control of appetite

Authors: *Y. JANG[1,2], J. HAN[1,2], S. KIM[1,2], J. KIM[1,2], M. LEE[1,2], I. RYU[1,2], M. RYU[1,2,3], J. HEO[1,2,4], G. KWEON[1,2,3];

Abstract: Hypothalamic regulation of appetite governs whole body energy balance. Inability of satiety induction is etiologic implication of obesity. Despite the pharmaceutical agents are used to modulate this alteration of anorectic signaling, unexpected effects on neurological or cardiac system are not the issue to disregard. The current study announced that an endogenous peptide hormone A (PHA) had an anorectic effect in hypothalamus. We demonstrated that proopiomelanocortin (POMC) and agouti-related protein (AgRP) neurons, which are the targets of anorectic leptin hormone, located in arcuate nucleus (ARC) of hypothalamus co-expressed PHA. In addition, intracerebroventricular injection of PHA peptide significantly suppressed food intake in mice via increasing α-melanocotye-stimulating hormone (α-MSH) content in hypothalamus. We addressed that the anorectic effect of PHA is presumably via induction of phosphorylation of ERK and reduction of AMPK phosphorylation. Notably, PHA provoked the expression of Janus kinase 2 (JAK2) phosphatases known to be involved in the feedback inhibition of leptin signaling, whereas PHA expression was promoted by STAT3 phosphorylation induced by leptin receptor activation. We suggest that PHA is abundantly expressed in hypothalamus to evoke the anorectic melanocortin pathway and mediates leptin signaling (2014R1A6A1029617, 2014R1A1A1037655, 2014R1A2A1A11051231).

Title: The diverse roles and organisation of lateral hypothalamic inhibitory neurons

Authors: *C. KOSSE[1,2], D. BURDAKOV[1,3];
[1]The Francis Crick Inst., London, United Kingdom; [2]Univ. Col. London, London, United Kingdom; [3]MRC Ctr. for Developmental Neurobio., King's Col., London, United Kingdom

Abstract: The lateral hypothalamus is well known for its role in body weight control, which traditionally has been assigned to weight-loss promoting orexin and weight-gain promoting MCH neurons. Recently, different LH GABAergic neurons that are distinct from MCH and orexin neurons have been described to effect body weight as well. These neurons might be the missing piece to elucidate the LH circuitry underlying body weight control and explaining how weight gain and loss can be coherently coordinated in the LH. However, not much is known about this LH inhibitory network due to its heterogeneous nature. Surprisingly, we found that LH GAD65 neurons are only partially overlapping with LH VGAT neurons and that ≈80% of LH VGAT neurons do not express GAD65. Interestingly, LH GAD65 neurons seem also distinct from NPY and LepRb neurons and thereby adding another component to the LH inhibitory network. Through chemogenetic modulation we found that LH GAD65 neurons display a different effect on body weight and energy expenditure compared to LH VGAT neurons which have been shown to promote weight gain. This apparent functional dichotomy was also reflected in their microcircuitry as LH GAD65 neurons seem to receive inhibitory input from LH VGAT neurons but not from other GAD65 neurons. Our data adds to a coherent understanding of hypothalamic circuitry essential for energy expenditure and compensation and thus opens possible avenues for further neurophysiological investigations of hypothalamic control of body weight.

Title: Palatable diet cycling alters sensitivity to D-amphetamine

Authors: *C. F. MOORE, V. SABINO, P. COTTONE;
Lab. of Addictive Disorders, Departments of Pharmacol. and Psychiatry, Boston Univ., Boston, MA

Abstract: Eating disorders and forms of obesity are associated with brain reward dysfunction. In this study we investigated the sensitivity of the brain reward system of subjects undergoing chronic diet cycling by testing the effects of amphetamine, a dopamine releaser. For this purpose, a group of male Wistar rats was provided a regular chow diet 7 days a week (Chow/Chow), whereas a second group of rats was provided chow for 5 days a week, followed by a 2-day access to a highly palatable sucrose diet (Chow/Palatable). Following 5 weeks of diet alternation, we investigated amphetamine sensitivity during access to the palatable diet ('P Phase') as well as during withdrawal from it ('C Phase'). We measured the effect of amphetamine on locomotor activity and brain stimulation reward (BSR), home-cage self-administration of amphetamine, and amphetamine-induced conditioned place preference. Palatable diet cycling resulted in hypophagia of the standard chow, overeating of palatable food upon renewed access, and compulsive-like eating. During the P, but not the C phase, diet cycled rats showed decreased sensitivity to both the locomotor stimulating and the threshold-reducing effects of amphetamine. In addition, during access to Palatable diet, diet cycled rats showed increased self-administration of amphetamine in the home cage, as compared to controls. Finally, amphetamine-induced place preference was reduced in Chow/Palatable rats during the P Phase, as compared to control rats. These results indicate that diet cycled rats show a phase-dependent deficit in the brain reward system, as revealed by a decreased sensitivity to amphetamine when the highly palatable food access is renewed following withdrawal from diet cycling. In summary these results suggest that, in pathological eaters, brain reward dysfunction may be dependent upon the feeding state of the individuals.

Title: Fluoxetine administration during adolescence decreases chow intake via meal size but does not alter meal patterns later in life

Authors: *Y. TREESUKOSOL[1,2], S. D. IÑIGUEZ[3], T. H. MORAN[2,4];
[1]California State Univ. Long Beach, Long Beach, CA; [2]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Dept. of Psychology, Univ. of Texas El Paso, El Paso, TX; [4]Johns Hopkins Global Obesity Prevention Ctr., Johns Hopkins Univ., Baltimore, MD

Abstract: We have previously reported that exposure to fluoxetine (FLX), specifically during adolescence, results in altered sensitivity to mood-related stimuli in adulthood, as inferred by forced swim and social defeat paradigms. To further investigate how juvenile FLX exposure influences feeding later in life, we compared meal pattern parameters in male rats presented with a chow diet. Postnatal day (PD) 35 rats were injected with FLX (0 or 20 mg/kg) for 15 consecutive days (PD35-49). During adulthood, the animals were exposed to chronic variable stress (CVS) for 14 days (PD74-88). During drug treatment, FLX-exposed rats decreased intake by reducing meal size but displayed no significant changes in meal number. Consequently body weights were significantly lower than that of controls by PD40.No significant group differences in meal pattern parameters were observed after drug treatment completion (PD50), or in body weight by early adulthood (PD65). Furthermore, both groups responded similarly to a palatable diet (45% fat, 17% sucrose) presented during adulthood (PD74-88). Finally, no significant group differences in meal pattern parameters were observed following a CVS schedule. Whereas juvenile FLX administration results in enduring changes in mood-related measures, here, no long-term changes in ad libitum feeding are observed.

Title: Clusterin, a proposed biomarker of food addiction, is upregulated in the Nucleus Accumbens of undernourished rats

Authors: C. RODRÍGUEZ-RIVERA[1], C. GONZÁLEZ-MARTÍN[1], E. LIZÁRRAGA-MOLLINEDO[2], E. FERNÁNDEZ-MILLÁN[2], C. ÁLVAREZ[3,2], F. ESCRIVÁ[3,2], *L. F. ALGUACIL[1];
[1]Univ. CEU San Pablo, Boadilla, Madrid, Spain; [2]Ciber de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM, ISCIII), Madrid, Spain; [3]Univ. Complutense, Madrid, Spain

Abstract: Clusterin is a multifunctional protein that seems to play a significant role in the control of eating behavior. Central administration of clusterin is followed by anorexia in rats, while ODN-induced downregulation results in increased food intake (Gil et al., Nature Commun 4: 1862, 2013). Interestingly, we have recently observed that serum clusterin correlates with loss of eating control in morbid obese patients (Rodríguez-Rivera et al., Eur Neuropsychopharmacol 25 Suppl 2: S628, 2015), a finding that led us to propose this protein as a potential biomarker of food addiction. Despite these antecedents, little is known about the biological role of clusterin within the brain reward system. As a first approach to increase this knowledge, we have quantified by immunoblotting the mitochondrial and cytosolic levels of clusterin in the Nucleus Accumbens (NAc) and Prefrontal Cortex (PFC) of female, Wistar undernourished rats, bearing in mind that malnutrition is known to increase both food and drug reward. Rats undernourished during fetal life and lactation (by restricting mother's access to food), and for 5 additional months after birth, overexpressed mitochondrial clusterin (2-fold) in the NAc, but not in PFC. Clusterin upregulation was not observed when undernourishment was limited to gestation and lactation and animals had free access to standard diet from weaning. Parallel and similar changes were seen in the NAc levels of fumarate hydratase, an enzyme previously related to brain reward alterations induced by either drugs of abuse, high fat foods or undernourishment. Further studies are highly recommended to understand the exact meaning of clusterin upregulation in terms of behavior.

Title: Emesis induced by L-type Ca^{2+} channel agonist FPL64176 in the least shrew (Cryptotis parva) is sensitive to Ca^{2+} channel inhibitors and is mediated by 5-HT_3Rs and NK_1Rs

Authors: W. ZHONG[1], S. CHEBOLU[1], *N. A. DARMANI[2];
[1]Basic Med. Sci., [2]Coll Osteo. Med. Pacific, Western Univ. Hlth. Sci., Pomona, CA

Abstract: Cytoplasmic calcium (Ca^{2+}) mobilization is an important factor in the induction of emesis. We have previously provided the first evidence that the selective L-type Ca^{2+} channel agonist FPL64176 is a fully efficacious emetogen in the least shrew at 10 mg/kg (i.p.). In this study we explored the potential mechanisms associated with this finding. As shown by c-Fos staining, FPL64176 (10 mg/kg, i.p.) activated the brainstem dorsal vagal complex (DVC) emetic nuclei including the area postrema (AP), nucleus tractus solitarius (NTS) and dorsal motor nucleus of the vagus (DMNX). Pretreatment with the L-type Ca^{2+} channel inhibitor nifedipine at 10 mg/kg dose (s.c.) 30 min prior to FPL64176 administration completely abolished FPL64176-induced vomiting and c-Fos introduction. In addition, FPL64176 led to enhancements of serotonin (5-HT) and substance P (SP) immunoreactivity in brainstem sections. We then confirmed the antiemetic potential of the selective serotonin type 3 receptor (5-HT_3R) antagonist palonosetron and the neurokinin 1 receptor (NK_1R) antagonist netupitant, indicating that FPL64176-elicited vomiting is mediated by both 5-HT_3R and NK_1R. Ca^{2+} release from intracellular stores through ryanodine receptors (RyRs) following voltage-dependent Ca^{2+} entry via LTCCs during neuronal depolarization plays an important role in amplifying cytosolic Ca^{2+} levels. Here we found that the RyR antagonist dantrolene (i.p.) attenuated FPL64176-evoked vomiting in a dose-dependent manner. Furthermore, a combination of ineffective doses of nifedipine and dantrolene exerted additive antiemetic effects. These findings demonstrate that FPL64176-induced emesis is dependent on Ca^{2+} mobilization involving extracellular Ca^{2+} through LTCCs and Ca^{2+}-permeable 5-HT_3Rs, as well as RyR-mediated Ca^{2+} release from intracellular stores, which consequently results in the elevation of the cytoplasmic free Ca^{2+} level, the fundamental mechanism for neurotransmitter release.

Title: Muscarinic, nicotinic and GABAergic receptor signaling differentially mediate fat-conditioned flavor preferences in rats.

Authors: *F. M. ROTELLA, K. OLSSON, N. MARTINEZ, A. MORDO, I. KOHEN, A. AMINOV, J. PAGIRSKY, A. YU, V. VIG, R. J. BODNAR;
Psychology, Queens Col. Dept. of Psychology, Flushing, NY

Abstract: Rats display conditioned flavor preferences (CFP) for fats with previous pharmacological analyses revealing that corn oil (CO)-CFP expression was mildly reduced by dopamine (DA) D1 or D2 as well as NMDA or opioid receptor antagonists. Acquisition of CO-CFP was eliminated by NMDA antagonists, and significantly reduced by DA D1 and DA D2, but not opioid antagonists. Muscarinic (scopolamine: SCOP) and nicotinic (mecamylamine: MEC) cholinergic receptor antagonists and $GABA_B$ (baclofen: BAC) receptor agonism reduced fructose-CFP expression, and SCOP, but not MEC or BAC eliminated fructose-CFP acquisition. The present study examined whether systemic administration of SCOP, MEC or BAC altered the expression or acquisition of CO-CFP. For CO-CFP expression, rats were trained over 10 sessions with a CS+ flavor in 3.5% CO and a CS- flavor in 0.9% CO. Two-bottle choice tests with CS+ and CS- flavors mixed in 0.9% CO occurred following vehicle, SCOP (1, 5, 10 mg/kg), MEC (1, 6, 8 mg/kg) or BAC (1.5, 3, 5 mg/kg). For CO-CFP acquisition, eight groups of rats received vehicle, SCOP (1 or 2.5 mg/kg), MEC (4 or 6 mg/kg), BAC (3 or 5 mg/kg) or a limited intake vehicle control 0.5 h prior to 10 CS+ and CS- training sessions followed by six 2-bottle CS+ and CS- choice tests in 0.9% CO. CO-CFP expression was significantly but marginally reduced by SCOP (5 mg/kg: 70%), MEC (8 mg/kg: 85%) and BAC (3 mg/kg: 74%) relative to vehicle (97-98%). CO-CFP acquisition was eliminated (41-59%) by SCOP at a dose of 2.5, but not 1, mg/kg, and was accompanied by a failure to observe CS+ and CS- intake differences during testing relative to vehicle (84-88%) and limited control (91-98%) conditions. In contrast, neither MEC nor BAC altered CO-CFP acquisition. These data implicate the muscarinic cholinergic receptor system in mediating acquisition (learning) of fat-induced preferences in the same manner that it affected acquisition of sugar-induced preferences.

Title: Evidence for Trace Amine-Associated Receptor 1 (TAAR1) as a novel target for compulsive binge-eating

Authors: A. D. HOWELL[1], A. FERRAGUD[1], M. C. HOENER[2], V. SABINO[1], *P. COTTONE[1];

Abstract: Binge eating of highly palatable food constitutes a core feature of some forms of obesity and eating disorders, as well as of the recently proposed disorder of food addiction. Binge eating episodes typically occur in short periods of time, resulting in a high eating rate, and are accompanied by loss of control over eating behavior. Trace amine-associated receptor 1 (TAAR1) is a poorly investigated G protein-coupled receptor expressed throughout the limbic system. Growing evidence suggests that TAAR1 agonism may represent a potential pharmacological treatment for addictive disorders. Here, we investigated the role of TAAR1 in food reward by testing the effects of the TAAR1 agonist RO5256390 on maladaptive feeding behaviors. For this purpose, male Wistar rats were trained to obtain a highly palatable, sugary diet (*Palatable* group) or a standard chow diet (*Chow* group) for 1 h a day, under a fixed ratio 1 (FR1) schedule of reinforcement. Following escalation and stabilization of food responding, the effects of RO5256390 were investigated on: *i*) binge-like eating of a palatable diet in the FR1 procedure, *ii*) excessive eating of a standard chow diet induced by food restriction; *iii*) eating rate measured as inter-food intervals (IFIs), *iv*) compulsive eating in a light/dark conflict test, *v*) anxiety-like behavior in a defensive withdrawal test, *vi*) food reward using a conditioned place preference test, and *vii*) food seeking behavior using a second-order schedule of reinforcement. Our results show that the TAAR1 agonist RO5256390 blocked binge-like eating in the *Palatable* group without affecting intake of the control *Chow* fed group. Interestingly, RO5256390 treatment did not decrease the excessive intake of a standard chow diet in food-restricted rats. In addition, the drug treatment selectively reduced the eating rate in binge-eating rats and fully

blocked compulsive eating, without affecting anxiety-like behavior in *Palatable* rats. Furthermore, administration of the TAAR1 agonist significantly blocked the rewarding effects of the palatable food in a conditioned place preference test, without affecting performance in controls. Finally, RO5256390 blocked food seeking of palatable food. Altogether, these results provide evidence for the involvement of TAAR1 in food reward and propose a novel pharmacological treatment for compulsive binge eating.

Title: Chronic high fructose corn syrup induces metabolic disorder and impaired dopamine function in the absence of obesity

Authors: *A. MEYERS, D. MOURRA, J. BEELER;
Queens Col., Flushing, NY

Abstract: The contribution of high fructose corn syrup (HFCS) to metabolic disorder and obesity, independent of high fat, energy rich diets, is controversial. While high fat diets are widely accepted as a model of diet induced obesity (DIO) and associated metabolic disorder, the value of HFCS alone as a rodent model of DIO is less clear. Though impaired dopamine function is associated with obesity, studies examining changes in dopamine function induced by HFD have yielded inconsistent results. The effect of chronic HFCS on the dopamine system has not been investigated. The objective of this study was to test the effect of both HFCS alone as well as HFCS combined with HFD to assess weight gain, glucose regulation, and evoked dopamine release using of fast-scan cyclic voltammetry (FSCV) in anesthetized mice. Male and female wild-type mice (C57/BL6) received either water or 10% HFCS solution (Best Flavors, HFCS-55) along with ad libitum chow for 15 weeks. Mice consumed an average of 13.5 mL/day of HFCS solution compared to water consumptions of 3.5 mL/day in control mice, contributing 4 kcal/day into their diets. Despite increased caloric load, no significant differences in body weight were observed. Mice consuming HFCS exhibit reduced glucose clearance (1 g/kg glucose tolerance test), less sensitivity to insulin (0.5 U/kg, insulin tolerance test), and reduced evoked dopamine

release in the dorsolateral striatum as measured by FSCV. We then tested the effects of adding HFCS to traditional HFD (Teklad TD. 06414, 60% calories from fat). Mice on combined HFD-HFCS exhibited pronounced weight gain with a greater than 60% increase in bodyweight over 15 weeks compared to controls whose bodyweight increased by only 21%. The HFD-HFCS mice exhibited glucose dysregulation and substantially reduced evoked dopamine release compared to controls. These data suggest that HFCS can induce metabolic disorder as well as altered dopamine function independent of weight gain. The inclusion of HFCS in standard HFD DIO model may better emulate current dietary conditions in Western cultures.

Title: High dietary sugar and fat consumption are associated with microbiota dysbiosis and altered vagal gut brain communication

Authors: ***T. SEN**[1], B. T. IHDE[2], C. R. CAWTHON[3], A. HAJNALD[4], P. M. DILORENZOB[5], C. B. D. L. SERRE[3], K. CZAJA[2];

Abstract: While high fat (HF) diet consumption is well-known to play a central role in development of obesity, the low-fat/high-sugar diet was one of the major dietary advice in 1990s-as reflected by the USDA. On the contrary, recently a growing body of evidence has been pointing to the inadequacy of the "diet" solution for either weight loss or prevention of metabolic syndrome. However, little research has been done to understand the detrimental effect of LF diet on health. Our previous studies show that dysbiotic microbiota can alter gut-brain vagal communication and feeding behavior. Our present study investigate the effect of both HF and LF/high Sugar diet on microbiota composition, gut-brain communication and fat tissue accumulation leading to obesity. Specifically, we tested the hypothesis that both the HF and LF diet can alter the gut microbiota, induce gut inflammation and alter vagal gut-brain communication when compared to control chow diet. Sprague-Dawley rats were fed with either

HF, LF or control chow diet (RD) for 4 wks. Food intake, body weight and body composition were monitored daily and fecal samples were collected weekly. After 4 weeks, animals were sacrificed and gut, brain, liver and nodose ganglion were collected. We found that compare to RD both HF and LF fed rats significantly increased the amount of body fat. 16S rRNA sequencing showed a decrease in total bacterial density and an increase in Firmicutes abundance in both HFD and LFD fed rats, compare to RD. HFD and LFD fed rats exhibited an increase in cecum and serum LPS and expression of pro-inflammatory cytokines like IL-6, IL-1β and TNFα. Gastrointestinal vagal innervation and expression of tight junction protein occludin was decreased in both the HFD and LFD rats compare to RD. The analysis of the gut-brain communication showed the withdrawal of vagal afferents in the gut and nucleus of the solitary tract (NTS). Damaged peripheral nerve branches triggered activation of microglia in the nodose ganglia but not at the CNS areas containing motor perikarya and central afferent terminals of damaged fibers. Taken together, our study indicates that not only HFD but also consumption of low-fat/high-sugar diet induces dysbiosis of gut microbiota, increased gut inflammation, reduces gastrointestinal vagal innervation, disrupts tight junctions and alters vagal gut-brain communication that is associated with the obese phenotype.

Title: Diet-related differences in meal-induced synapsin-1 phosphorylation in the dorsal vagal complex.

Authors: *J. S. NASSE, R. C. RITTER;
Washington State Univ., Pullman, WA

Abstract: Meal size is directly controlled by gastrointestinal signals carried to the brain by vagal afferent fibers that synapse in the dorsal vagal complex (DVC) of the hindbrain. Peripheral vagal afferent endings are activated by gastric stretch and by gut peptides released in response to luminal nutrients. However, we recently reported that peripheral CCK or 4^{th} ventricle melanocortin-4 agonists both increase serine phosphorylation of the synaptic vesicle protein,

synapsin-1, in DVC vagal afferent endings. Phosphorylated synapsin-1 (pSyn-1) increases neurotransmitter release probability thereby increasing synaptic fidelity and strength. We also reported that DVC pSyn-1 levels are elevated after overnight feeding, and recently have observed a positive correlation between the caloric size of the last night-time meal and DVC pSyn-1 levels. Collectively, our observations indicate that DVC pSyn-1 levels may be modulated by both meal-related GI signals and central signals related to body energy status. To evaluate the role of meal-related signals on DVC pSyn-1, we subjected male rats to an overnight fast, and then re-fed them a 5g meal of chow (3.01 kcal/g), high-sucrose (3.85 kcal/g), or high-fat/high-sucrose (4.73 kcal/g) diet, and measured DVC pSyn-1 levels at several time points over a 4-hour period. We found that pSyn-1 was significantly elevated at 30 and 60 minutes after both chow and high-sucrose meals, but returned to pre-meal levels by 2 hours. Surprisingly, the high-fat meal failed into increase pSyn-1 at any time point. To assess the possibility that elevated pSyn-1 following the chow meal was mediated by activation of vagal afferent MC-4 receptors, we made 4^{th} ventricle injections of the MC-3/4 antagonist SHU9119 prior to a 5g chow meal. SHU9119 did not prevent the increase in pSyn-1 following the chow meal indicating that meal-related signals trigger increased pSyn-1 by mechanisms not dependent on MC-4 receptor signaling. Moreover, our results suggest that high-fat meals may be gram for gram less effective at increasing DVC pSyn-1 than low-fat meals. The mechanisms that mediate meal-related modulation of DVC pSyn-1 are under ongoing investigation. However, we speculate that reduced pSyn-1 following high-fat meals might contribute to over consumption and weight gain on high-fat diets.

Title: Feeding and GLP-1 receptor activation stabilize β-catenin in specific hypothalamic nuclei in male rats

Authors: *D. R. GRATTAN[1], H. MCEWEN[1], S. LADYMAN[1], P. SHEPHERD[2];

Abstract: Polymorphisms in the TCF7L2 gene are associated with increased risk of type-2 diabetes and obesity. TCF7L2 is a co-factor that binds with β-catenin to promote gene transcription in the canonical Wnt/β-catenin pathway. Here, we investigated whether β-catenin/TCF signalling is regulated in the hypothalamus during the normal physiological response to food intake. Feeding acutely stablized β-catenin in neurons (increasing detectable cytoplasmic levels) in specific regions of the hypothalamus involved in metabolic regulation. Elevated β-catenin was associated with increased transcription of several TCF-responsive genes. The effect of feeding was mimiced by administration of the GLP1 agonist exendin-4, and was characterized by cAMP-dependent phophorylation of β-catenin at serine residues 552 and 675. The data suggest that β-catenin/TCF signalling might be involved in nutrient sensing in the hypothalamus, highlighting a potential role for altered hypothalamic function contributing to the risk of diabetes conferred by polymorphisms of TCF7L2.

Title: Hedonic food overrides the efficacy of leptin effects on orexin neurons

Authors: *E. LEIDMAA[1,2], M. GAZEA[1], A. PISSIOTI[1], I. KALLO[3], B. LASZLO[3], Z. LIPOSITS[3], N. GASSEN[1], M. A. PHILIPS[4], A. PATCHEV[1], O. F. X. ALMEIDA[1];

Abstract: Food is consumed to obtain energy but its sensory properties play an important role in the motivation to eat specific types of food. Eating that is driven by hedonic motivation poses a challenge to the homeostatic mechanisms that regulate energy balance. The aim of this work was to test how palatability might compete out the effects of leptin, a major satiety signal. We observed that exogenous leptin loses its efficacy to suppress feeding when mice are presented with a palatable food (PF) for a short period (1 h), indicating hedonic overriding of a potent

satiety signal. To explore the basis of this behavior, we focused on the lateral hypothalamus (LH) where leptin normally acts on orexin (OX) neurons to suppress appetite. We found that a short exposure to PF upregulates OX expression in both fasted and satiated mice. Interestingly, hedonic foods do not interrupt leptin signalling; on the other hand, OX neuron activity, as measured by c-fos expression, is not inhibited by leptin in mice exposed to PF. Subsequent experiments and analysis revealed the potential role of the galanin receptor 2 in mediating leptin actions on OX neurons. These findings suggest that interference with galanin-mediated activation of yet unidentified inhibitory inputs to OX neurons contributes to the overriding of leptin actions by PF. Alternatively, PF may increase the activity of other orexigenic circuits/factors that stimulate OX neurons to such an extent that they become refractory to the inhibitory actions of leptin.

Title: Ghrelin changes food preference from high fat diet to chow in schedule-fed rats.

Authors: *S. L. DICKSON, E. SCHÉLE, T. BAKE;
Inst. of Neurosci. and Physiol., The Sahlgrenska Academy, Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Ghrelin is a gut peptide released from the empty stomach that increases food intake. It has also been linked to food-related behaviours such as food motivation, food reward and food anticipatory activity. Ghrelin levels in the blood are linked to meal pattern, increasing prior to feeding. To mimic human meal eating behaviour in animals we used a scheduled feeding (SF) paradigm in which rodents have ad libitum access to chow and in addition 2h access to highly palatable high fat diet (HFD). Previous studies with this paradigm have shown that both rats and mice will rapidly adapt their feeding behaviour and as a result binge-eat on HFD. Here we

sought to investigate the role of ghrelin during binge-like meal eating induced by SF. We utilised a combination of two different animal models: pharmacologically manipulated rats via acute administration of ghrelin or genetically modified mice lacking the growth hormone secretagogue receptor 1A (GHS-R1A). For acute injections of either ghrelin or vehicle into the lateral ventricle (ICV) or intra-VTA, rats were surgically implanted with guide cannulas and then habituated to SF for at least 2 weeks prior to injections. GHS-R1A-KO mice and their wildtype (WT) littermates were scheduled-fed for 4 weeks. Remarkably and unexpectedly, we found that acutely injecting ghrelin ICV or intra-VTA resulted in a shift in food preference from high fat diet towards chow during the SF period without altering total daily energy consumption. However an increase of body weight was observed after ICV ghrelin. A fasting challenge also led to an increase in chow intake during the SF session but HFD intake did not reduce at the same time. GHS-R1A-KO mice were able to adapt and maintain large meals of HFD in a similar fashion as WT mice suggesting that the ghrelin signalling system may not have a critical role in acquisition or maintenance in this kind of feeding behaviour. In conclusion, ghrelin appears to act as a modulating factor for binge-like eating behaviour by shifting the food preference towards a healthier choice (from HFD to chow), effects that were clearly divergent from fasting.

Title: Sleep restriction (4 h of sleep) impairs behaviorally-measured motivation to sham consume (sip and spit) a sweet-tasting beverage in healthy women

Authors: *H. R. KISSILEFF[1], M.-P. ST. ONGE[1], A. SHECHTER[1], P. S. HOGENKAMP[2], A. SCLAFANI[3];
[1]New York Obesity Nutr. Res. Ctr. - Med., Columbia Univ. Med. Ctr., New York, NY; [2]Dept. of Neurosci., Uppsala Univ., Uppsala, Sweden; [3]Psychology, Brooklyn Col. of CUNY, Brooklyn, NY

Abstract: Compared to habitual sleep (HS =9h), restricting sleep to 4 h per night (short sleep = SS) increases blood flow in response to food images in brain loci (AJCN 2012;95:818, 2012) that are active in animals when they encounter rewarding stimuli (Neuroscience 16.865, 2008). In order to test the hypothesis that SS may increase the reward value of, and motivation to consume, foods or beverages, that would lead to increased energy intake, a novel sham drinking sipping task, employing a sipometer (Kissileff, et al, SFN abstracts, 2010) was used. Seven, normal weight healthy women (mean BMI = 21.3 ± 0.5 kg/m^2) were tested on single trial days, after undergoing 3 nights of both SS and HS in randomized order. Sleep periods were separated by an interval of at least 4 weeks. Before each sleep period, they sampled 5 ml of sweet-tasting (10% sucrose equivalent aspartame) or non-sweetened cherry Kool-Aid®, and marked a picture of a cup that showed how much they would "want to drink" of each beverage. After each sleep condition, 7 h after eating a 500-kcal, high-fat, breakfast, they sham drank these beverages, pumped in response to pressure exerted on a straw (a behavioral measure of motivation), in four successive, counter-balanced, trials that consisted of 2 minutes of continuous reinforcement and unlimited time on a progressive ratio reinforcement schedule (PR) for each beverage. After HS, on the PR schedule, cumulative pressure difference between sweet and non-sweet beverage increased as the difference in amount wanted in the sampling test increased (slope = 0.33 PSI/mm ± 0.09, SE = 0.014, r^2 =0.73), but during SS, the slope was not significant. Therefore, SS blocked the behaviorally-measured motivational response of increased pressure difference between sweet and non-sweet beverage, during sipping on the PR schedule. On PR, after HS, sham intake difference increased as difference in post-beverage enjoyment rating (150 ml VAS, "none at all" to "extremely") increased, but after SS sham intake, the difference reversed and decreased (slope = 0.21 g/mm ± 0.16 SE) as difference in enjoyment rating increased. The difference in slopes between the two sleep conditions (0.53 g/mm ± 0.21 SE) was significant (p = 0.03). Therefore, opposite to the hypothesis, SS blunts or reverses the motivation to sham consume a sweet beverage. More data are needed to establish the conditional relationships among sleep patterns, brain activity, and motivated behavior in humans.

Program, Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: Whether neuronal inositol-requiring enzyme 1(*Ire1*) is required for the proper regulation of energy balance and glucose homeostasis is unclear. We found that pro-opiomelanocortin (*Pomc*)-specific deficiency of *Ire1α* accelerated diet-induced obesity concomitant with a decrease in energy expenditure. This hypometabolic phenotype included deficits in thermogenic responses to diet and cold exposure as well as 'beiging' of white adipose tissue. We also demonstrate that loss of *Ire1α* in *Pomc* neurons increased hepatic glucose production as well as impaired glucose and insulin tolerances. At the cellular level, deletion of *Ire1α* in *Pomc* neurons elevated hypothalamic ER stress and predisposed *Pomc* neurons to leptin and insulin resistance. Together, the current studies extend and confirm conclusions that *Ire1α*/*Xbp1s* and associated molecular targets link ER stress in arcuate *Pomc* neurons to aspects of normal energy and glucose homeostasis.

Abstract: Ambient temperature is a strong modulator of both energy expenditure and food intake. Activity of neural circuits controlling energy expenditure and food intake are concomitantly coordinated by thermosensory inputs to ensure the maintenance of energy balance under different temperature conditions. Neurons that express the long isoform of leptin receptor (LepRb) in the preoptic area (POA) are stimulated by warm ambient temperature and mediate warm-adaptive responses by suppressing energy expenditure and food intake. These same neurons are also involved in reproductive functions in female mice by regulating the surge of luteinizing hormone in response to leptin. The excitatory neurotransmitter glutamate is central in mediating warm responses by POA LepRb neurons, but it is not clear whether POA LepRb signaling plays a role during temperature-dependent adaptations. To investigate the function of leptin in POA LepRb neurons in energy homeostasis, LepRb was selectively deleted in the POA by stereotaxic injection of adeno-associated virus that expresses Cre in LepRb-flox mice ($LepRb^{POA}$ KO). 10-week-long follow-up studies after virus injection under either regular chow or high fat diet revealed no significant changes in body weight, food intake, and energy

expenditure in both male and female $LepRb^{POA}$ KO mice, compared to control virus-injected littermates (by repeated measures ANOVA). However, under high fat diet, the number of $pSTAT3^{+}$ cells in the POA was significantly correlated with the % body weight change at 10 weeks post injection (by linear regression, $r = -0.529$, $p < 0.05$). $LepRb^{POA}$ KO mice also maintained normal core temperature and showed no defect with adjusting the level of energy expenditure upon acute ambient temperature changes. Direct electrophysiological recording revealed heterogeneous effects of leptin (300nM) on POA LepRb neurons when presynaptic inputs were blocked (depolarization: 36%, hyperpolarization: 20%, no change: 44%), and this may explain the lack of leptin-induced c-Fos in POA LepRb neurons as a reflection of both inhibitory and stimulatory leptin effects. In summary, LepRb signaling in the POA uniquely contributes to body weight regulation only under a surplus energy state, in which the circulating leptin level is high. We are currently investigating the role of POA LepRb signaling during temperature-dependent adaptation of food intake.

Title: Exploring mechanisms for empathy-like behavior in rats

Authors: ***M. CONTRERAS**, K. G. CRUZ, J. CUMMINGS, A. HATFIELD, J.-M. FELLOUS; Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Empathy is an affective response stemming from the understanding of another individual's emotional state, allowing one to react to social stimuli with appropriate pro-social behaviors. There is increasing support for the idea that a basic form of empathy (i.e. emotional contagion) is evolutionarily conserved and shared across mammalian species. Little is known, however, about higher forms of empathy or about its neurophysiological mechanisms. In humans, intranasal administration of oxytocin, a neuropeptide implicated in a number of social behaviors, increases empathy. Recent neuroimaging studies have also shown that observing

another's distress elicits activity in the anterior insular cortex. In this study we investigated whether the oxytocin system is necessary for the expression of empathic behavior using an operant rodent model of empathy. We next asked whether the neural activity of the rat anterior insular cortex correlates with the expression of empathy-like behavior. Finally, we assessed whether 22 KHz ultrasonic vocalizations, calls emitted by adult rats in aversive situations, were sufficient to produce empathy-like behaviors. Animals were trained to obtain food pellets by pressing either of two cued levers in an operant chamber. During the empathy test, one of the levers was programmed to also deliver a footshock (0.5 mA, 0.5 sec) to a conspecific animal which was placed in full view, in an adjacent chamber. Single lever (forced-choice trial) or both levers (free-choice trial) were cued throughout the course of testing. We observed that cerebro-ventricular administration of an antagonist of oxytocin disrupted the expression of empathy-like behavior, while the infusion of oxytocin exaggerated it. Electrophysiological recordings revealed that the neural activity of the anterior insular cortex decreased during the empathy test. We also observed that the playback of 22 KHz calls alone was generally sufficient to produce empathy-like behaviors in rats that were empathic toward a conspecific. These results give insights in the basic neurobiological basis of empathy and could be used to guide research on treatment of mental disorders in which empathy is deficient.

Title: Unpredictable chronic mild stress (UCMS) causes brain volumetric changes and network reorganization in a mouse model of depression

Authors: *Y. S. NIKOLOVA[1], K. A. MISQUITTA[2], J. ELLEGOOD[3], J. LERCH[3], M. BANASR[2], E. SIBILLE[2,4];
[2]Campbell Family Mental Hlth. Res. Inst., [1]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [3]Mouse Imaging Ctr., SickKids Hosp., Toronto, ON, Canada; [4]Dept. of Psychiatry, Dept. of Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Human magnetic resonance imaging (MRI) studies have associated depression with alterations in the function, morphology and connectivity of a distributed corticolimbic circuitry including the amygdala, hippocampus, and prefrontal cortex. In parallel, stress-based rodent models have provided insight into the disorder's putative molecular mechanisms. To help bridge these complementary lines of research, we used MRI to assess regional brain volume and global structural covariance in the unpredictable chronic mild stress (UCMS) mouse model of depression. Male BALB/c mice were exposed to six weeks of UCMS and behaviorally characterized. High-resolution 7T structural MRI images were collected ex vivo from fixed brains (n=12 UCMS-exposed, n=9 controls). Volumetric comparisons between groups were carried out for 26 regions of interest (ROIs) pre-selected based on the human depression literature. Graph theory analysis using whole-brain (i.e., 155 ROIs) structural covariance metrics was applied to assess group differences in overall brain network organization. We evaluated mean network strength, mean shortest path length (indicative of global efficiency), and transitivity (local clustering), in addition to the degree (i.e., number of connections) and connection strength of the regions showing strongest volumetric effects in the previous analysis. Permutation testing across a range of density thresholds (5-40%) was applied to assess the significance of the observed between-group network attribute differences. UCMS-exposed mice showed volume increases in the amygdala, frontal association cortex, prelimibic cortex and medial orbital cortex, proportional to behavioral change ($p<0.05$). Furthermore, stressed animals showed a trend toward having a lower average network connection strength and transitivity in the 10-35% density range, concurrent with significantly higher degree and connection strength of the amygdala at densities greater than 20%. These changes occurred in the absence of any difference in shortest path length at any network density. No consistent differences in degree and connection strength emerged for the frontal association, prelimbic and medial orbital cortices. The increase in amygdala size and connectivity in UCMS is consistent with human work showing larger amygdala volumes in first-episode depression or following early life stress. The concurrent decrease in mean network connection strength suggests a global reorganization pattern favoring the selective strengthening of nodes involved in the avoidance of threat at the expense of other nodes of potential behavioral relevance.

Title: Ventral hippocampus exerts a dynamic inhibitory influence on the behavioral and physiological responses to stress via the anterior hypothalamic nucleus

Authors: *J. BANG[1], J. KIM[1,2];
[1]Cells and Systems Biol., [2]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Stress initiates the release of glucocorticoid hormones (GCs) by activating hypothalamic-pituitary-adrenal (HPA) axis which then triggers diverse adaptive physiological and behavioral responses. During emotionally stressful experience, the ventral hippocampus (vHPC) is believed to attenuate the HPA-axis activity by indirectly inhibiting the paraventricular nucleus of the hypothalamus (PVN). While much effort has been made to demonstrate the inhibitory influence of vHPC on the HPA-axis during psychogenic stress, the underlying neural pathway has not been directly examined. Using the pathway specific optogenetic approach in mice, we activated vHPC inputs at the anterior hypothalamic nuclei (AHN) during a 30 min-physical restraint stress and examined its effects on stress-induced anxiety behaviors in the elevated plus maze, the successive alleys, and open field tests. We also tested whether this input can change basal anxiety level by activating the same pathway in freely moving mice with no prior stressor during the same anxiety tests. Our findings suggest that the predominantly GABAergic AHN is the functional intermediary structure through which vHPC exerts its inhibitory control on both anxiety behaviors and physiological responses such as respiration and circulating corticosterone level. Together, these results show an important top-down modulation of stress response and anxiety level by the hippocampal-hypothalamic pathway as a key element in the central feedback of HPA-axis and inhibitory regulator of negative affect.

Title: Chronic stress alters fear behavior in a neuromodulator-dependent manner

Authors: *M. HUI, M. ZELIKOWSKY, B. YANG, D. J. ANDERSON;
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Stress is a powerful experience that effects virtually all animal species. We tested the effects of delivering various forms of stress on subsequent fear behavior using an overhead looming stimulus assay as our behavioral readout. Interestingly, we found that various forms of chronic stress produce an increase in persistent fear responding to the looming stimulus, and that this effect is dependent on the type of chronic stressor employed. Given previous results in the laboratory indicating a role for various neuromodulators in the looming assay, we were interested in exploring the possibility of a larger role for neuromodulators in mediating chronic stress. Combining cre-mouse lines crossed to a fluorescent reporter mouse and applying CLARITY to map brain-wide neuromodulator expression, we found that chronic stress produces an increase in expression of various neuromodulators across brain regions known to encode stress and that this increase correlates with the degree of fear persistence produced by each chronic stressor. Consistent with these data, we found that various perturbations of these neuromodulatory systems in stressed mice was able to block this fear persistence, and that conversely, driving this system in unstressed mice was sufficient to induce persistent fear responding. Collectively, our data point to a broad role for neuromodulators in the regulation of chronic stress.

Title: Chronic administration of glucocorticoid receptor ligands increases anxiety-like behavior and selectively increases serotonin transporters in the ventral hippocampus

Authors: *G. L. FORSTER, R. SOLANKI, J. SCHOLL, M. WATT;
Univ. South Dakota, Vermillion, SD

Abstract: Organic cation transporter-3 (OCT3) are involved in the clearance of monoamines in the brain, and are increased during amphetamine withdrawal in several limbic brain regions, including the ventral hippocampus, central nucleus of the amygdala and dorsomedial hypothalamus. Increased OCT3 expression in the ventral hippocampus in particular has been implicated in reduced extracellular serotonin in this region, leading to increased anxiety-like behavior in rats. However, the mechanism by which OCT3 expression is increased is not known. Expression of other organic cation transporters in peripheral tissue are increased by activation of

glucocorticoid receptors (GRs) and amphetamine increases the level of corticosterone. Therefore, we tested the hypothesis that corticosterone, acting via GRs, increases OCT3 expression in the limbic system. Male adult rats were treated for 2 weeks with daily injections of corticosterone (40 mg/kg) in the presence or absence of the GR antagonist mifepristone (20 mg/kg), with elevated plus maze (EPM) behavior, plasma and brains collected 24 hours following the last treatment. Corticosterone treatment decreased time spent in the open arms of the EPM and increased OCT3 receptor expression in the ventral hippocampus (but not amygdala, hypothalamus or dorsal hippocampus), although these effects were not blocked by GR antagonism. Interestingly, mifepristone in the absence of corticosterone treatment reduced plasma corticosterone levels, and increased serotonin transporter (SERT) and GR expression in the ventral hippocampus, with no effect in the amygdala, hypothalamus or dorsal hippocampus. Overall, findings suggest that corticosterone can selectively increase OCT3 receptor expression in the ventral hippocampus and increases anxiety-like behavior independent of actions upon GRs. This provides a mechanism by which amphetamine or chronic stress may alter monoamine reuptake to increase anxiety.

Title: Differential effects of increased serotonin in the central vs. basal amygdala on anxiety-like behavior

Authors: *J. O. STERNBURG[1], A. AFZAL[2], J. SCHOLL[1], G. FORSTER[1];
[1]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD; [2]Loyola Univ., Chicago, IL

Abstract: Anxiety arising during amphetamine withdrawal is associated with drug relapse. In a rat model of amphetamine withdrawal, increased anxiety-like behavior is observed alongside heightened stress-induced serotonin (5-HT) levels in the central nucleus of the amygdala (CeA) when compared to amphetamine-naive rats. Recent studies show that partial 5-HT depletion of basal amygdala (BA) that also encompassed the CeA reduces anxiety-like behavior in rats,

suggesting an anxiogenic effect of 5-HT in these regions. However, it is not known whether increased CeA 5-HT is directly related to anxiety-like behavior as observed during amphetamine withdrawal. To test this, bilateral cannula were implanted into the BA or CeA of adult male Sprague-Dawley rats. Following three days of acclimation to the infusion process, rats were bilaterally infused with either vehicle (0.5 µl per side) or paroxetine (0.5 µl of 0.5 µM per side) to discretely increase 5-HT levels. Forty minutes after the infusion, anxiety-like behavior was measured on the elevated plus maze (EPM). Paroxetine infusion into the CeA did not affect time spent in the open arms of the EPM as compared to vehicle-infused controls. However, infusion of paroxetine into the BA resulted in reduced time in the open arms of the EPM, indicative of increased anxiety-like behavior. Overall, the results show a causal relationship between BA but not CeA 5-HT and anxiety-like behavior and suggest differential roles of 5-HT in the expression of anxiety-like behaviors. Therefore, the effects of amphetamine withdrawal on serotonergic activity in the BA should be assessed as a potential locus for increased anxiety during withdrawal.

Title: Pharmacological inhibition of basolateral amygdala produces affective behavioral disruption of threat processing in rhesus macaques

Authors: *C. ELORETTE, P. A. FORCELLI, L. MALKOVA;
Georgetown Univ., Washington, DC

Abstract: The coordination of threat detection and appropriate behavioral responses involves diverse brain regions within the limbic system and midbrain. Evidence for a rapid-acting subcortical pathway for threat processing has been provided by studies of patients with cortical blindness who failed to showed a deficit in threat detection. This proposed pathway includes midbrain regions (superior colliculus), thalamic nuclei (pulvinar) and limbic structures (amygdala). Investigations into this pathway across species have suggested a role for the basolateral amygdala (BLA) in mediating the affective response to visual threats. Previous studies into this pathway have made use of aspiration or excitotoxic lesions, which produce

irreversible deficits and may damage nearby structures or tracts. We make use of a pharmacological approach, which allows precisely targeted reversible manipulation of a neural structure in an awake, behaving animal. We tested the hypothesis that input from the BLA mediates fearful defense behaviors in rhesus macaques when confronted with either naturalistic or socially relevant threats. Five juvenile male macaques were tested on a behavioral paradigm in which neutral stimuli, either a novel object or naturalistic video, and threatening stimuli, either taxidermy snakes, unfamiliar human, or unfamiliar conspecific, were presented. The animal's latency to retrieve a food reward from a tray above the stimulus was measured along with the time spent looking at the stimulus. Affiliative, defensive, or fearful behavioral responses displayed by the animal were also measured. Two of the animals were tested on this paradigm after receiving 9 nmol (1 μl at a concentration of 9mM) muscimol, a $GABA_A$ agonist, bilaterally to the BLA. Animals showed a significant ($p<0.05$) reduction in latency to retrieve the food reward from the threatening stimulus as compared to untreated animals [and as compared to their own, untreated baseline session] for both the naturalistic (snake) and socially relevant (unfamiliar macaque and human) stimuli. Inhibition of the BLA also produced an alteration in behavior directed towards social stimuli in this task as compared to untreated controls. These results suggest a role for the BLA as a critical mediator of affect and socially directed behavior in the proposed subcortical threat processing pathway.

Title: Novel subdivisions of the mouse anterior basolateral amygdalar nucleus (BLAa)

Authors: *H. HINTIRYAN, N. N. FOSTER, L. GOU, M. S. BIENKOWSKI, M. Y. SONG, M. ZHU, I. BOWMAN, S. YAMASHITA, A. W. TOGA, H.-W. DONG;
USC Stevens Neuroimaging and Informatics Inst., Univ. of Southern California (USC), Los Angeles, CA

Abstract: The anterior basolateral amygdalar nucleus (BLAa) forms part of the basolateral amygdala complex (BLA), which also includes the lateral amygdalar nucleus (LA) and the posterior (BLAp) and ventral (BLAv) basolateral nuclei. Most notably, the BLA is known for the role it plays in the acquisition and extinction of fearful memories. Its direct connections with medial prefrontal cortical areas involved in both fear acquisition and extinction bolster its role in the conditioned emotional response. We examined, in detail, the connections of the infralimbic (ILA) and prelimbic (PL) cortical areas with the BLA in C57Bl/6J male mice. As part of the Mouse Connectome Project (www.MouseConnectome.org), double co-injections of one anterograde (PHAL or BDA) and one retrograde (CTb or FG) tracer were made in the ILA (PHAL/CTb) and in the PL (BDA/FG). These coinjections clearly revealed the medial and lateral aspects of the BLAa. Coinjections in the different subdivisions of the BLAa confirmed these connections, revealed their laminar specific connectivity with the medial prefrontal cortex, and disclosed their connections with other structures throughout the brain. Tracer injections placed in different regions aside from the medial prefrontal cortex, including, but not limited to, the anterior cingulate cortex, agranular insular cortex, entorhinal cortex, caudoputamen, and olfactory tubercle, clearly demonstrated their unique connections with the medial or lateral BLAa, further validating the subdivisions. This structural segregation of the BLAa is indicative of its variegated functional relevance, potentially in different aspects of fear learning and extinction, which can be interrogated using different advanced technologies.

Title: Entorhinal afferents drive feedforward inhibition in basolateral amygdala via distinct interneuronal populations.

Authors: *E. M. GUTHMAN[1], D. RESTREPO[2], M. M. HUNTSMAN[1];
[1]Dept. of Pharmaceut. Sci., [2]Dept. of Cell & Developmental Biol., Univ. of Colorado | Anschutz Med. Campus, Aurora, CO

Abstract: The basolateral amygdala (BLA) is a brain region that plays a vital role in associating specific environmental stimuli with emotionally salient valence information. Excitatory principal neurons (PNs) encode this integrated sensory-valence information (Herry et al, 2008; Paton et al, 2006; Shabel & Janak, 2009) and send this information to other brain regions to guide behavior (Ambroggi et al, 2008; Beyeler et al, 2016; Namburi et al, 2015; Stuber et al, 2011). However, inhibitory interneurons (INs) in the BLA gate the activity and plasticity of BLA PNs (Ehrlich et al, 2009; Bissière et al, 2003; Woodruff & Sah, 2007). One major source of feedforward inhibition to the BLA is the lateral entorhinal cortex (Brothers & Finch, 1985; Mouly & Di Scala, 2006), a region of both the olfactory and parahippocampal cortices associated with sensory object representation (Keene et al, 2016; Price, 1973; Tsao et al, 2013; Xu & Wilson, 2012). We hypothesized that entorhinal afferents to the BLA would target distinct populations of INs to drive feedforward inhibition of BLA PNs. To test our hypothesis, we performed whole-cell electrophysiology in horizontal slices of adult mice. To determine the role of entorhinal input in modulating BLA circuitry, we electrically stimulated lateral entorhinal cortex while recording from neurons in the BLA. Initial results demonstrate that entorhinal afferents reliably synapse onto parvalbumin positive INs (15 of 16 cells tested) to drive monosynaptic EPSCs (66.0 ± 11.6 pA, 7.2 ± 0.4 msec latency, 0.91 ± 0.23 msec jitter, n = 13 cells). These synaptic events are mediated by calcium permeable AMPA receptors (control EPSC: 57.6 ± 3.6 pA, 100μM Naspm: 44.1 ± 2.7 pA, p = 0.0085 Kolmogorov–Smirnov test, n = 7 cells, 67 control EPSC, 83 Naspm EPSC; rectification index = 0.089, n = 2 cells), suggesting that this synapse can undergo plastic changes (Mahanty & Sah, 1998; Nissen et al, 2010; Oren et al, 2009; Polepalli et al, 2010). Future experiments will test the hypotheses that entorhinal afferents target other populations of BLA INs and drive feedforward inhibition in BLA PNs.

Title: Anatomy and physiology of the central extended amygdala.

Authors: *Y. SUN, S. HUNT, L. XU, P. SAH;
Queensland Brain Inst., The Univ. of Queensland, Brisbane, Australia

Abstract: Anxiety disorders represent the most common of psychiatric disorders, affecting nearly one in four adults in the population. The central nucleus of the amygdala (CeA), and its forebrain target the central sublenticular extended amygdala (SLEAc), two key parts of central extended amygdala, have been identified as critical elements of anxiety processing. We have studied the neuronal types and synaptic connections within this circuit using slice electrophysiological recordings in combination with tract tracing and *ex vivo* optogenetics in mice. Injection of retrograde tracers into the SLEAc revealed that the major projections from the CeA to the SLEAc originate in the lateral division of the CeA (CeL). We find that 78% of the retrogradely-labelled cells in the CeL expressed somatostatin (SOM). Using SOM-Cre mice we selectively expressed channelrhodopsin-2 (ChR2) in SOM+ neurons in the CeL. Whole-cell recordings from neurons in the SLEAc demonstrated that optogenetic activation of ChR2-expressing SOM+ terminals evoked inhibitory synaptic responses in most SLEAc neurons. To test reciprocal connections, ChR2 was expressed in neurons in the SLEAc and whole-cell recordings were obtained from CeL neurons in acute slices. Photo-activation of terminals in the CeL shows that the SLEAc sends feedback projections to the CeL, which is largely GABAergic. Together, these results define a reciprocal inhibitory circuit between CeL and SLEAc, which prepare the ground to dissect the functional circuitry of CeL-SLEAc and to examine its behavioral role in anxiety.

Title: Role of the ventral hippocampal projections to the lateral septum in fear and anxiety

Authors: *G. M. PARFITT, J. BANG, R. NGUYEN, A. AQRABAWI, J. KIM;
Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Anxiety behaviour is shaped by a distributed network of forebrain limbic structures, including the septum and the hippocampus. In particular, neural inputs arising from the ventral hippocampus (vHPC) to the lateral septum (LS) are thought to serve as a key component of the anxiety circuit. In the present study, we investigated the behavioural contribution of the vHPC-LS pathway in modulating anxiety-related behaviours in mice. We targeted the LS-projecting vHPC neurons by injecting the retrogradely propagating CAV2-Cre into the LS and injecting Cre-responsive AAV (AAV-hSyn-DIO-hM3D (for activation) or hM4D (for inhibition) into the vHPC. After CNO injection, the animals were submitted to behavioural test paradigms for anxiety: elevated plus maze (EPM), and open field (OF), novelty feeding suppression test (NFST) and fear conditioning (FC). The activation of LS-projecting vHPC neurons using hM3D increased the open arm time in the EPM without changing the locomotor activity. Similarly, in the NFST CNO-treated hM3D mice displayed reduced latency to eat in a novel anxiogenic environment with no effect on food intake in the home cage. In the OF, no alterations were observed in both locomotor activity and center time. In contrast, the inhibition of LS-projecting vHPC neurons using hM4D decreased the open arm time and centre time during the EPM and the OF, respectively. In the FC, the activation of the LS-projecting vHPC neurons during the fear acquisition reduced the freezing level 24h after the acquisition in the hM3D mice. However, the inhibition of the same neuron population did not alter the freezing level in the hM4D mice. In summary, our findings demonstrate that the LS-projecting vHPC neurons modulate anxiety-related behaviours in a bidirectional manner, and their activation can reduce contextual fear memory expression.

Title: Maternal circuits that respond to mouse pup vocalizations: D2 dopamine and oxytocin receptors

Authors: *J. S. YEOMANS[1], B. J. PEREIRA[2];
[2]Psychology, [1]Univ. Toronto, Toronto, ON, Canada

Abstract: Social communication and bonding are associated with dopamine, oxytocin and prolactin signals in many mammalian species. Ultrasonic vocalizations (USVs) in isolated 3-11 day old rodent pups increase maternal behaviors and hormonal responses: retrieval, licking and grooming, nursing, prolactin and oxytocin. Oxytocin projections from hypothalamus to dopamine neurons and nucleus accumbens shell are important for social attachments in rats. For example, blockade of D2 or oxytocin receptors in nucleus accumbens shell reduces maternal responses to pups, and memories of pups (D'Cunha et al., 2011). Oxytocin and D2 receptors are colocalized as heteromers in nucleus accumbens shell where both are critical for maternal responses (Romero-Fernandez et al., 2013). In mice, D2 dopamine receptor gene deletion reduces pup USVs, and maternal retrieval responses and prolactin surges to pup USVs (Curry et al., 2013). Both pup and dam D2 genes influence the number of USVs by pups, as shown by heterozygous and reciprocal crosses, respectively. Oxytocin receptor gene deletions similarly reduce pup USVs and maternal responses to pups (Hidema et al., 2015). Maternal responses to pup USVs depend on the dam's left auditory cortex, where oxytocin receptors improve neuronal sensitivity to pup USVs (Marlin et al., 2015). Oxytocin and vasopressin receptors on olfactory, amygdala and entorhinal cortex neurons are relevant to social recognition and memory. Entorhinal cortex receives sensory information from auditory, olfactory and visual cortex (all with oxytocin receptors), and projects to hippocampal CA2 and CA3 pyramidal neurons with oxytocin receptors. Oxytocin receptors on medial periaqueductal gray neurons needed for vocalizations may improve pup USV production. Therefore, when dams retrieve pups after USVs, oxytocin production in the dam's hypothalamus may facilitate maternal responses via dopamine output, pup recognition, bonding and memory via oxytocin neurons that project to olfactory, auditory, mesolimbic, amygdala, entorhinal and CA2/3 hippocampal circuits.

Title: Use awake rat fMRI to visualise fear memory and weakened fear memory representations in the brain

Authors: A. KOLESNYK[1], A. P. HARRIS[2], M. C. HOLMES[3], *S.-H. WANG[4,5];
[1]Ctr. for Clin. Brain Sci., [2]Ctr. for Cognitive Ageing and Cognitive Epidemiology, [3]Ctr. for Clin. Brain Sciences, Cognitive Ageing, Cadiovascular Sci., [5]Ctr. for Clin. Brain Sciences, Ctr. for Cognitive Ageing and Cognitive Epidemiology, [4]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Functional magnetic resonance imaging (fMRI) is an invaluable and non-invasive tool for visualising the emotional and cognitive processes in the brain at the systems level. While mostly used in humans, recent studies have made advancement in using fMRI in awake rodents to investigate learned behaviours. For example, rodent fMRI has been used to map activated brain regions involved in normal, stressed, and genetically modified animal models. This provides significant translational value, such as development of pre-clinical models to enhance the understanding of brain functions at the network level and to provide biomarkers for drug discoveries. Previous studies have investigated the brain circuits involved in visual fear conditioning by comparing the circuits in conditioned and unconditioned animals. However, several important questions remain to be answered. First, whether fearful memories from different sensory domains activate similar brain circuits or are domain specific, and does the brain represent fearful and neutral memories differently? Second, which brain areas show activity changes when the fear memory is weakened? To answer the first question, we designed an olfactory fear conditioning paradigm, which allowed the rats to associate one odour with the fear while a second odour remained neutral. We found that the rats showed significantly greater freezing when presented with the conditioned odour, compared to the neutral one. They underwent brain imagining in the 7T MR scanner. The results showed the BOLD acyivation signals were stronger in the amygdala, perirhinal and somatosensory cortex when the animals were exposed to the fearful odour than when they were exposed to the neutral odour. To answer the second question, we treated rats with a beta-adrenergic blocker, propranolol, shortly after fear memory reactivation. This has been shown to be an effective method to weaken the persistence of fear memory by blocking memory reconsolidation. The propranolol-treated rats showed significant reduction of conditioned fear responses and significant reductions in brain activitation compared to control rats. Together, we identified similar fear circuits for fear-conditioned stimuli across different sensory domains. Activity changes in these key areas can be used as biomarkers for identifying effective drug targets for treating fear-related disorders.

Title: Dissecting the role of extended amygdala input to the locus coeruleus in motivated behaviors

Authors: *D. L. BHATTI[1,3], M. R. BRUCHAS[2];
[2]Div. of Biol. and Biomed. Sciences, Dept. of Neuroscience, Anesthesiol., [1]Washington Univ. in St. Louis, Saint Louis, MO; [3]Div. of Biol. and Biomed. Sciences, Dept. of Neuroscience, Anesthesiol., Washington Univ., Saint Louis, MO

Abstract: Both the Bed Nucleus of the Stria Terminalis (BNST) and the Locus Coeruleus (LC) are thought to play integral roles in processing stressful stimuli to subsequently elicit suitable behavioral responses. The heterogeneous neuronal populations of the BNST have been shown to influence motivated behaviors related to stress, and LC activity is critical for stress-induced behavioral responses. However, how these regions interact to modulate motivated behavior is unknown. To dissect the interaction between these neuronal populations, we first characterized a dense BNST GABA/CRFergic projection to the LC using anterograde and retrograde viral tracing. Using an *in vivo* optogenetic approach, male VGAT-cre mice were injected with a cre-dependent channelrhodopsin-2 virus (DIO-ChR2-eYFP) in the BNST to selectively target GABAergic neurons. We then implanted optic fibers above the LC to specifically activate GABAergic BNST terminals in the LC region. Activation of BNST-LC^{VGAT} terminals produced frequency-dependent real-time place preference and optical self-stimulation compared to controls. These data suggest that the BNST may send GABAergic inputs which inhibit LC neurons thereby suppressing norepinephrine release to efferent regions to ultimately elicit positively-motivated behavioral responses. We are currently using electrophysiological and pharmacological techniques concurrent with BNST-LC^{VGAT} photostimulation to characterize and examine the receptors modulating LC activity and *in vivo* Ca^{2+} imaging to visualize the network dynamics of LC-projecting BNST neurons.

Title: Functional mapping of central amygdala feeding and reward circuits

Authors: *H. KUCUKDERELI[1,2,3], A. M. DOUGLASS[1,2], M. PONSERRE[1], J. GRÜNDEMANN[4], M. MARKOVIC[4], P. L. ALCALA MORALES[1], C. STROBEL[1], A. LÜTHI[4], R. KLEIN[1];

Sch. for Mol. and Cell. Life Sci. (IMPRS-LS), Martinsried, Germany; [4]Friedrich Miescher Inst., Basel, Switzerland

Abstract: The central nucleus of the amygdala (CeA) is commonly associated with processing negative valance signals to execute aversive behaviour in the context of learnt fear and anorexia. Neurons within the mouse CeA that express protein kinase C-δ (PKCδ) induce feeding suppression under satiety and malaise conditions and when unpalatable foods are encountered. The function of these cells is proposed to be mediated by local inhibitory interactions within the CeA. We have identified a population of PKCδ-negative neurons in the CeA that express Htr2a, which promote food intake and reward related behaviours. We have used electrophysiological and virus-mediated methods to map and test the functionality of the circuits in which $CeA^{PKC\delta}$ and CeA^{Htr2a} function to antagonistically control food intake.
Use of mono-synaptic rabies tracing and ChR2-assisted circuit mapping revealed that $CeA^{PKC\delta}$ and CeA^{Htr2a} neurons reciprocally inhibit each other. We also found that CeA^{Htr2a} and $CeA^{PKC\delta}$ neurons sit within a network of brain regions that have described roles in food intake and energy homeostasis. These neurons also send axons to multiple brain regions including lateral hypothalamus, lateral parabrachial nucleus (lPBN), nucleus of the solitary tract and medulla. ChR2-assisted circuit mapping revealed strong inhibitory connections from CeA^{Htr2a} neurons to lPBN and brain stem. Together, these data suggest that the CeA influences feeding behaviour through both local inhibitory connections and long range outputs. Our study has demonstrated that not only is the CeA important for mediating aversive behaviours but this region also processes appetitive signals to promote reward-related behaviours.

Title: The role of amygdala-striatal circuitry in exploration

Authors: *P. BOTTA[1], M. ANGELHUBER[3], M. VICENTE, 1400-038[2], R. COSTA[2]; [1]Neurobio., [2]Champalimaud Fndn., Lisbon, Portugal; [3]Bernstein Ctr. Freiburg, Freiburg, Germany

Abstract: In a world varying in time and space, exploration of new territories can increase inclusive fitness. Exploratory activity is achieved through the progression of a stochastic selection of motor actions essential to explore and become familiarized with novelty. Such actions are modulated by emotional states. The inability to cope with variable novel situations and environments is symptomatic of serious emotional disorders such as anxiety and depression in humans. Given that the initiation of specific exploratory actions is sensitive to contextual and emotional states, we decided to explore the contribution of limbic brain areas to exploratory activity. The amygdala is a well-known limbic structure important for emotional processing that projects to the medial parts of striatum involved in action selection. Therefore, we investigated the role of amygdala-striatal circuits in action selection computation during exploration. We developed a dimensionality emergence assay to investigate differences in exploratory activity in a habitual and novel environment, and during the process of habituation. In order to specifically target the basolateral portion of amygdala, we characterize a transgenic mouse line specifically expressing CRE recombinase in basolateral amygdala. We found that it expresses in pyramidal calmodulin kinase II expressing neurons. Using this line, we imaged the Cre defined amygdala neuronal ensembles in freely-exploring mice using conditional viral expression of calcium-sensors in the paradigm described above. Principal cells of basolateral amygdala massively project to dorsomedial striatum. The effect of amygdala-striatal projections on locomotor activity and the functional connectivity with dopamine receptor 1 and 2 expressing neurons is currently being tested using optogentic tools combined with slice electrophysiology. These experiments will increase our understanding of the role of a key limbic circuit on processing different contextual and emotional information to favor exploratory motor actions.

Title: To pee or not to pee: defining a limbic circuit from nose to bladder

Authors: ***J. A. KELLER**[1], L. STOWERS[2];
[1]Neurosciences, UC San Diego, La Jolla, CA; [2]The Scripps Res. Inst. / UC San Diego, La Jolla, CA

Abstract: Male mice without previous female experience will reliably countermark (e.g. urinate, micturate) when presented with female urine. We aim to unravel the necessary path that olfactory information must travel to reach the urinary motor system, which is relatively simple at the muscular level. To this end, we have identified the brainstem premotor neurons necessary for this behavior, as well as traced their inputs using modified rabies virus. Because these neurons are embedded in a larger network of autonomic function, precise manipulations using optogenetic and chemogenetic techniques have been necessary to probe animals performing this natural behavior. We hope that the combination of a molecularly-defined input and low-dimensional output in this circuit will ultimately allow a system-level approach to interrogate the function of every synapse from nose to bladder, in order to reveal mechanisms of innate behaviors in mammals.

Title: Do women exhibit greater emotional context effect on eye movements inhibition control?

Authors: A. ABUNDIS[1], R. V. HUERTA[2], *J. RAMOS-LOYO[3], E. MATUTE[1];
[1]Inst. de Neurociencias, [2]Psicología, [3]Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Several studies have shown that an efficient inhibitory control promotes emotional regulation. Accumulating evidence reveals that emotional stimuli have an impact on cognitive processes, either interfering or improving performance in cognitive tasks. Additionally, differences between men and women have been reported in different studies, pointing out differences in strategies used and underlying neural resources during cognitive and emotional processing. The goal of the present study was to identify sexual differences in the effect of emotional stimuli on inhibitory control recording eye movements during a Go/No-go task. Forty young adults (20 women) participated in the study. Participants had to press a key when the arrow in the center of the screen was congruent in color and direction with the bar presented on the left or right side of the screen (Go trials, 75%). However, when those conditions were not met participants must avoid responding (No/Go trials, 25%). Four conditions were included, two non-emotional (no picture, neutral) and two emotional backgrounds (pleasant and unpleasant). Eye movements were recorded using a Tobii eye tracker. Three regions of interest were defined to measure both number of fixations and duration of each fixation. Behavioral data also included reaction time and inhibition errors. Results indicated that the unpleasant context caused a higher number of inhibition errors. Besides, a higher percentage and longer duration of fixations in the arrow than in the surrounding area was observed under the non-emotional conditions than the emotional ones and, the opposite pattern was evident under the emotional conditions. Women showed a higher percentage and longer duration of fixations in the surrounding area than men at the neutral and emotional contexts. In sum, present results confirm the assumption that emotional pictures receive preference attention compared with neutral ones generating more difficulties in inhibition processing. This hindering effect is higher in women than in men.

Title: Monkey face-selective regions differ in their ability to classify facial expressions

Authors: *M. FLESSERT, H. ZHANG, L. G. UNGERLEIDER;
Lab. of Brain and Cognition, NIMH/NIH/DHHS, Bethesda, MD

Abstract: In our prior work (Zhang et al. 2016) we reported that face-selective regions in the human brain differ in their ability to classify facial expressions. Monkeys, like humans, can discriminate and classify different categories of expression automatically and effortlessly. Yet the ability of the various face-selective regions ('face patches') in the monkey brain to discriminate between different facial expressions remains unclear. To explore the underlying neural computations for this ability across the two primate species, we performed a parallel study on macaque monkeys. Here we used fMRI and support vector machine (SVM)-based multi-voxel pattern analysis to examine the ability of macaque face-selective regions to discriminate among different categories of monkey facial expressions.

Three male macaques were injected with MION before fMRI scanning. A slow event-related fMRI experiment was performed in which monkeys viewed 32 monkey face images belonging to 8 different identities and portraying 4 different expressions: fear grin (fearful), threat (aggressive), lip smack (appeasing) and neutral. In separate localizer runs monkeys viewed blocks of monkey faces, objects and scrambled images.

A GLM contrast of faces>objects was used to localize the monkey's face patches in and around the superior temporal sulcus (STS): middle fundus, middle lateral, anterior fundus and anterior lateral. The contrast of faces>scrambled images localized face processing in the amygdala. A GLM of each monkey face was created and the beta-values were extracted for each face patch and the amygdala. A one-versus-others SVM and leave-one-identity-out cross-validation were performed to obtain the decoding accuracy rate.

We found that the decoding accuracy was significant for discriminating fear grin relative to all other expressions in the amygdala. For the face patches in the fundus of STS, the decoding accuracy was significant for discriminating neutral expressions relative to all emotional expressions. These results are comparable to those obtained our earlier study in humans (Zhang et al. 2016), where we found the human amygdala to be significant at discriminating fearful faces from other expressions and the right STS to be significant at discriminating neutral faces from all emotional expressions.

Taken together, our findings suggest that the different face-selective regions in the monkey brain make distinct contributions to the processing of the emotional content within faces. In addition, the monkey fundus face patches may play a role analogous to the human STS in discriminating neutral faces from emotional ones.

Title: Task congruence of disgust expression modulates brain activation and connectivity in cognitive control regions during face judgment

Authors: *E. NG[1], Y.-J. WANG[1], J.-H. POH[1], J. DE SOUZA[1], J. LIM[1], Y.-T. HAN[1], C.-Y. CHEN[1], J. ZHOU[1,2];
[1]Neurosci. and Behavioral Disorders Program, Duke-NUS Med. Sch., Singapore, Singapore;
[2]Clin. Imaging Res. Center, A*STAR-National Univ. of Singapore, Singapore, Singapore

Abstract: Emotional facial expressions capture attention [1]. The perceptual or valence nature of the capture is still debated [2]. With a widely used face judgment task, we hypothesized that, while cognitive control regions should be recruited to maintain task performance [3], a capture by valence should activate additional disgust-related regions more consistently than a perceptual one.
Methods
Young adults (N = 44, 18 F) judged the expression (neutral or disgust) or gender of faces in two separate experimental blocks in one fMRI session (3T, TR 2s). Behavioral data were subject to two-way repeated measures ANOVA (2 expression: neutral or disgust x 2 task: emotion or gender). Similarly, we analyzed brain activation using general linear model and functional connectivity using psychophysiological interaction (PPI; SPM8).
Results
Participants were accurate in both tasks (> 88%), higher in emotion compared to gender condition ($p < .001$). Response to disgust faces was faster than that of neutral faces during emotion judgment but the pattern reversed during gender judgment (interaction $p < .001$). Disgust expression captured attention, with effect contingent on task congruency.

Interaction effect in activation strength (height $p < .001$, extent $p < .05$, unc.) was observed in bilateral insula, right inferior frontal gyrus (IFG), left precentral gyrus (PreCG), and right angular gyrus (ANG). Activation was greater in disgust than neutral in gender condition while the opposite was observed in emotion condition. Insula is implicated in salience detection and perceptual evidence accumulation [4], while precentral and angular gyri are involved in cognitive control [5]. PPI analysis yielded similar expression-by-task interaction on the connectivity between left PreCG and bilateral inferior parietal sulci, and that between right ANG and left PreCG and IFG orbital areas, suggesting connectivity changes only in cognitive control regions [5].

Conclusion

Attention recruitment was less when expression was task-congruent (emotion), but more when incongruent (gender), which may be due to compensation for the capture. The circuit of disgust was not particularly engaged, suggesting that the capture may be perceptual in nature. Participants might need only the visual facial features [2] for quick decisions even when valence information was available. Despite automatic in its processing, the use of emotional information is modulated by current goal and context [6].

Title: Studying the function and connectivity of habenular networks in zebrafish brain

Authors: *E. YAKSI[1], E. BARTOSZEK[2], S. KUMAR JETTI[3], S. FORE[2];
[2]Kavli Inst. for Systems Neurosci., [1]Norwegian Univ. of Sci. and Technol., Trondheim, Norway;

Abstract: The habenula (Hb) is a brain region with increasing popularity due to its strong link to addiction, mood disorders and experience dependent fear. We demonstrated that Hb neurons respond to odors and light asymmetrically. Moreover, we showed that Hb neurons exhibit structured spontaneous activity that is spatially and temporally organized. This spontaneous activity resembles neural attractors, which can switch the preferred state of the Hb and regulate the transmission of sensory information to downstream monoaminergic brainstem nuclei. In order to explore the source of Hb spontaneous activity, we investigate the local connectivity within Hb and the global functional inputs to Hb. We showed that recurrent excitatory connections within Hb is important for maintaining spatio-temporal organization of Hb activity. Moreover, we observed that functional inputs form zebrafish forebrain regions Dm and Dl (corresponding to basolateral amygdala and hippocampus respectively) and sensory inputs from visual and olfactory systems are the major drivers of spontaneous Hb activity. Our results suggested that these limbic and sensory inputs are integrated in Hb in a non-linear fashion and can regulate sensory representations in Hb. We propose that Hb lies in the heart of a brain wide network and act as “a hub” or “a switchboard”, which can regulate or gate the communication of sensory systems and limbic forebrain areas with the monoaminergic brainstem nuclei that control animal behaviors.

Title: Time course of emotional processing: A support vector machine classification study

Authors: *K. BO[1], A. TROGNETRPUNVA[1], Y. LIU[3], A. KEIL[2], M. DING[1];
[1]Dept. of Biomed. Engin., [2]The Dept. of Psychology and the NIMH center for Emotion and Attention, Univ. of Florida, Gainesville, FL; [3]Univ. of California, Davis, Davis, CA

Abstract: Emotional perception involves reciprocal interactions between subcortical and cortical structures. Functional magnetic resonance imaging (fMRI) is the dominant technique for identifying these structures in humans. Owing to the limited temporal resolution of fMRI, the detailed temporal dynamics of emotional processing remains to be further elucidated. We recorded electroencephalogram (EEG) in healthy controls and electrocorticogram (ECOG) in epilepsy patients during passive viewing of emotion pictures. 40 pleasant (erotica, romantic courtship, sport scenes), 40 neutral/calm (house hold scenes, people), and 40 unpleasant (mutilation, human violence, attacking animals) pictures, selected from the International Affective Picture System (IAPS), was presented in random order. Each picture was shown for 1000ms. The inter-trial interval (ITI) varied from 6000 to 9000ms. Applying a support vector machine (SVM) classifier to single-trial EEG and ECOG data we report the following findings. For EEG, the classification accuracy for pleasant versus neutral became significantly above chance level at around 220ms post stimulus onset, and reached a peak at around 480 ms. For unpleasant versus neutral comparison, the classification accuracy became significantly above chance level at around 300ms, and reached a peak at around 520 ms. The main contributing electrodes to the classification accuracy were located in occipital, left temporal and right frontal areas. For ECOG similar time courses were identified. Sites in broadly distributed brain areas contributed to the classification accuracy. Keywords: emotion; single-trial EEG; Ecog; support vector machine

Title: Neural ensemble dynamics underlying a long-term associative memory

Authors: ***B. F. GREWE**[1], J. GRÜNDEMANN[2], J. D. MARSHALL[3], J. LECOQ[4], L. J. KITCH[3], J. LI[3], F. GRENIER[2], A. LÜTHI[2], M. J. SCHNITZER[3];

[1]ETH Zurich, Zuerich, Switzerland; [2]Friedrich Miescher Inst., Basel, Switzerland; [3]Stanford Univ., Stanford, CA; [4]Allen Brain Inst., Seattle, WA

Abstract: The brain's ability to relate different events and stimuli is vital to the formation of associative memories. Extensive past research has examined molecular, synaptic and cellular level substrates of associative memory, but it remains unclear how large neural ensembles encode an associative memory. Using auditory fear conditioning, an established form of associative learning, we studied how neural ensembles in the mouse basal and lateral amygdala (BLA) represent conditioned and unconditioned stimuli (CS and US) and their learned association. To do this we monitored simultaneously the somatic calcium dynamics of ~150-200 individual BLA neurons per mouse using a miniature, head-mounted fluorescence microscope [Ghosh *et al.*,*Nature Methods* (2011)]. This approach allowed us to track the cells' evoked responses to the different stimuli throughout a six-day fear conditioning paradigm. Unforeseen from prior work that supported a simple synaptic Hebbian model in which a set of BLA 'fear neurons' encode the memory through potentiation of their CS-evoked responses, the ensemble codes revealed a combination of up- and down-regulation of individual cells' CS-evoked responses, which were equally important for storing the learned ensemble CS-US association. As mice learned to express conditioned behavioral responses, the ensemble neural representations of the CS and US gained in similarity. Throughout learning, the strength of the ensemble-encoded CS-US association was predictive of each mouse's behavioral performance. These findings extend the synaptic Hebbian model of associative learning to the neural ensemble level model in which activation of the US-representation provides a signal to supervise the transformation of the CS-representation. Overall, our results reveal the basic information processing steps by which BLA neural ensembles reliably encode a long-term associative memory and may generalize to other brain areas and forms of associative learning. Further, our approach to monitoring large populations of amygdala neurons opens the door to time-lapse imaging studies of neural coding in a brain structure that likely plays a central role in several widespread psychiatric disorders. As discussed, we should not write about extinction given that at the behavioral level there was no extinction, not even partial extinction.

Title: Amygdala preferentially projects to face selective areas in the monkey

Authors: *A. MESSINGER[1], J. M. SEIDLITZ[2], C. SPONHEIM[1], R. B. H. TOOTELL[3], L. G. UNGERLEIDER[1];
[1]Lab. of Brain and Cognition, NIMH, Bethesda, MD; [2]Brain Mapping Unit, Univ. of Cambridge, Cambridge, United Kingdom; [3]Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: In both humans and monkeys, emotional faces evoke greater functional MRI (fMRI) responses than neutral faces in the amygdala and in face-selective cortical areas (Pessoa et al. 2002; Hadj-Bouziane et al., 2008). Amygdala lesions eliminate this emotional modulation and impair the discrimination of facial emotions (Hadj-Bouziane et al., 2012; Adolphs et al. 1994). Thus, the correct interpretation of emotional facial expressions relies on amygdala feedback to face processing areas.
To map these feedback projections *in vivo*, we delivered electrical stimulation to specific amygdala nuclei in two rhesus monkeys and simultaneously monitored activity at the site of stimulation and in anatomically connected areas with fMRI (Tolias et al., 2005). Stimulation in the lateral nucleus of the amygdala (7 sites), a structure with primarily afferent projections, resulted in activation of the amygdala and the ipsilateral rhinal cortex, temporal pole, rostrotemporal auditory cortex, and insula. Stimulation in the ventral portion of the basal nucleus (4 sites) produced a similar pattern of activation. In contrast, sites in the dorsal portion of the basal nucleus (8 sites), a structure with primarily efferent projections, generated widespread bilateral activations that included much of the ventral visual stream, auditory cortex, insula, cingulate cortex, orbitofrontal cortex, lateral frontal cortex, and hippocampus. These activations reflect feedback projections from the basal nucleus to these areas, several of which have no reciprocal projections to the amygdala.
Stimulating the dorsal basal nucleus significantly activated both face- and object-selective regions (i.e., face and object patches) in the ventral visual stream, which were mapped in a separate visual fMRI localizer experiment. However, the stimulation-induced signal changes in the face patches were at least 40% greater than those in the object patches for both the stimulated and contralateral hemisphere in each animal. Thus, the amygdala exerted significantly greater influence on activity in ventral visual areas involved in face processing than in areas that process

inanimate objects (t-test, $p<0.01$ in each hemisphere). This stronger coupling with face patches was observed for all but one of the 8 stimulation sites in the dorsal basal nucleus. We conclude that cortical face processing can be particularly modulated by feedback signals from the amygdala, which likely convey the emotional state expressed by others and keep the viewer attuned to the socially salient features of the face.

Title: Effect of contextual word picture pairing on psychophysiological response

Authors: *M. ASTHANA, B. BHUSHAN;
Dept. of Humanities and Social Sci., Indian Inst. of Technol. Kanpur, Kanpur, India

Abstract: Several studies have shown that the presence of emotional stimuli alters brain circuitry. Neuroimaging evidences had affirmed the impaired brain circuitry in patients with *PTSD* during the processing of emotionally valenced word pair. However, it is unclear if processing of emotional valence of word-picture pairs affects the psychophysiological state of healthy individuals or not. In an on-going study we are investigating the alteration in psychophysiological response as a direct effect of emotional valence of the stimuli by comparing the relationship between word-picture association by means of subjective ratings and physiological responses. This study might be able to bring an insight on contextual relevance of word-picture pairing. With this study one might expect that if both word and picture are neutral then a slight alteration in the physiological responses is possible. However, if the word is neutral while the picture is emotional then one might expect a sudden and heightened change in physiological responses compared to the control condition (neutral word-picture pairing). The findings may contribute to the therapeutic approach to pathological learning and memory such as PTSD. Keywords: word, picture, physiological response, context, emotions

Title: Prepulse inhibition of a fear conditioned startle probe

Authors: *E. BJØRKEDAL[1], O. ÅSLI[2];
[1]Univ. of Tromsø, Tromsø, Norway; [2]Psychology, UiT Arctic Univ. of Norway, Tromsø, Norway

Abstract: Emotionally significant stimuli show enhanced neural responses early in sensory processing. This allows them to compete more effectively for processing resources and emotionally significant task irrelevant stimuli can interfere with task performance and capture attention. Prepulse inhibition (PPI) is the phenomenon where a weaker pre-stimulus inhibits the reaction to a later stronger startle-eliciting stimulus. The inhibition functions as a protection of the processing of the prepulse and is thought of as a measure of an automatic pre-attentive process. In the present experiment, the startle-eliciting stimulus was given enhanced emotional significance through fear conditioning in order to create a competition between the inhibition induced by the prepulse and the emotional salience of the startle-eliciting stimulus. If PPI is reduced in this scenario it would be evidence that emotionally salient stimuli interfere with a pre-attentive process at a short timescale. If PPI is unaffected, it would be evidence that the interference of emotionally salient stimuli are reduced by a prepulse. In a pilot study, the group receiving paired presentations of the pulse and the electrical stimulation had significantly smaller PPI after conditioning compared to before. Pilot data and data from main study will be presented.

Title: Impacts of motivational, associated, and inherent emotional valence on face processing: evidence from event-related brain potentials (ERPs)

Authors: *A. SCHACHT[1,2], A.-M. GRIMM[1], W. HAMMERSCHMIDT[1,2], R. JACOB[1], I. KAGAN[3,2];
[1]Univ. of Goettingen, Goettingen, Germany; [2]Leibniz-ScienceCampus Primate Cognition, Goettingen, Germany; [3]German Primate Ctr., Goettingen, Germany

Abstract: Many studies indicate a tight relationship between cognition, emotion and motivation. Emotional as well as motivational factors have been demonstrated to modulate the processing of sensory stimuli at various processing stages, ranging from initial perception to elaborate stimulus evaluation. There is growing evidence that stimuli of emotional and motivational valence are preferentially processed, which is reflected not only on a behavioral but also on a neural level. Recently, it has been proposed that this processing advantage is not limited to stimuli with emotional content - inherently neutral stimuli also have been shown to acquire increased salience through motivational context and learning mechanisms. In the present study, we aimed at disentangling impacts of motivational, associated, and inherent emotional salience on face perception by means of event-related brain potentials (ERPs). During a learning session, participants (N=36) performed a prime-target face-matching task while emotionally neutral target faces were associated with monetary gain, loss or zero outcome, contingent on the matching task performance. Reward conditions were indicated by cues prior to the subliminally presented prime faces. On the following day, participants performed the same task, without monetary feedback, on the previously seen faces and, in addition, on unfamiliar faces showing happy, angry, or neutral expressions. Motivational, associated, and inherent salience types modulated morphologically similar ERP components starting around 200 ms after target onset, i.e. the Early Posterior Negativity (EPN) and the Late Positive Complex (LPC). In the learning session, both positive (gain) and negative (loss) motivational valence similarly boosted EPN and LPC, indicating enhanced attention to and elaborate processing of target faces with incentive value. In the test session, ERPs to associated negative salience were of reduced amplitudes during the delayed testing, whereas ERPs to unfamiliar faces indicated a processing bias towards angry faces. Together, our findings demonstrate qualitatively differential impacts of motivational, associated and inherent emotional valence on face perception.

Title: Frontal theta asymmetry and heart rate differentiate between emotional states in infants

Authors: *E. BOLINGER[1], D. HETTICH[1,2], K. ZINKE[1], V. KOCK[1], H.-V. NGO[1], T. MATUZ[1], J. BORN[1], N. BIRBAUMER[1,3];
[1]Inst. for Med. Psychology and Behavioural Neurobio., [2]Wilhelm-Schickard-Institute for Computer Sci., Univ. of Tübingen, Tuebingen, Germany; [3]Wyss Ctr. of Bio and Neuroengineering, Geneva, Switzerland

Abstract: Emotions dominate behavior. They are genetically predetermined and likely linked to specific brain modes of information processing. Here, we attempt to differentiate basic emotions by examining not only behavioral expression, but also central nervous system EEG activity and heart rate during emotional states in 4 to 6 month old infants. This age group provides a unique condition where positive and negative emotions are robustly expressed but where other cognitive faculties (i.e. language) that could mask emotions, are not yet highly developed. In this experiment, a social interaction paradigm was used to elicit the infant's emotional response in 5 naturalistic conditions, which were designed to evoke either positive or negative emotions. We hypothesized that behavioral differences in positive, neutral, and negative emotional states (which were identified by facial, vocal, and motor behavioral criteria) would lead to distinct changes in EEG rhythms and heart rate. An analysis of brain region (frontal, central, and parietal) and EEG power in the delta, slow theta (3-5 Hz), fast theta (5.5-7 Hz), alpha, and beta bands showed that emotional state had widespread influences on cortical activity, where negative states specifically were associated with high power across most EEG bands. Indeed, only frontal activity significantly differentiated between all three emotional states, with fast theta playing an integral role by discriminating between neutral and positive emotional states, such that positive emotion was accompanied by greater fast theta power. Based on these results, and because previous research suggests theta is involved in emotional processing, frontal asymmetry within the slow and fast theta bands was investigated. Interestingly, frontal asymmetry in these bands together differentiated between negative, neutral and positive states. While negative and positive states were associated with relatively more slow and fast theta power in the frontal left hemisphere, a neutral emotional state was related to greater fast theta power in the right hemisphere. Heart rate, on the other hand, was higher during negative emotional states but did

not differ between neutral and positive states. We conclude that positive and negative emotions manifest in robust changes in EEG theta power and hemispheric asymmetry, together with heart rate changes, already very early in life. Emotions appear to be genuinely connected to specific brain modes of information processing.

Title: Using brain imaging techniques for validation of a biologically-inspired-cognitive-architecture model of human cognition

Authors: *A. V. SAMSONOVICH[1,2], V. L. USHAKOV[2,3];
[1]Krasnow Inst. Adv Study, George Mason Univ., Fairfax, VA; [2]Dept. of Cybernetics, Natl. Res. Nuclear Univ. MEPhI, Moscow, Russian Federation; [3]Natl. Res. Ctr. Kurchatov Inst., Moscow, Russian Federation

Abstract: The aim of this study is to develop an approach to evaluation of a biologically inspired, causal model of cognition that exposes the functional requirements for achieving emotional intelligence and makes testable predictions for neurophysiological measures. A theory of how concepts are represented in the human brain should specify (a) the structure and semantics of concept representations in the brain, and (b) types, formats and specific patterns of neuronal activity instantiating these representations. The key to a biologically-informed human brain model begins with the mapping of (a) to (b): in our case, of the emotional Biologically Inspired Cognitive Architecture (eBICA: Samsonovich, BICA, 2013) to informative features and characteristics of brain activity. The eBICA model is based on three main extensions of the standard building blocks of a cognitive architecture: a moral schema, an emotional state, and an emotional appraisal that is attributed to every cognitive representation in this model and determines dynamics of learning and decision making. The general cognitive cycle of eBICA includes perception, cognition, decision making and learning. The values of emotional appraisals and emotional states are sampled from the weak cognitive map (Samsonovich and Ascoli, 2010), which uses an abstract vector space to represent semantic relations among mental states, schemas

and their instances. This model is tentatively mapped onto the human brain, which allows us to test assumptions and predictions of the model; specifically, mechanisms of emotional thinking underlying behavior generation. The eBICA model can be validated based on this approach via comparison of the computational model behavior, the human participant behavior, and the localized non-invasive brain imaging data. The latter include fMRI, EEG, eye-tracking, ECG, EMG, and other psychophysiological measures. Methods involve the dynamic connectivity calculation and the use of regressors based on EEG and eye-tracking data. In an fMRI study, effective connectivity can be measured using Structural Equation Modeling, Granger Causality Analysis, Transfer Entropy and Dynamic Causal Modeling. The recording and analysis of eye movements provides access to the rapid unconcscious information processing. This approach has been applied to fMRI data collected in our study, representing human brain activity during cognitive tasks modulated by emotional state of the subject.

Title: Difference in emotion information processing between individuals with high or low degrees of alexithymia

Authors: *K. GARCIA[1], K. JOHNS[2], E. DUBON[2], S.-M. KANG[2];
[1]Psychology, California State University, Northridge, North Hollywood, CA; [2]California State University, Northridge, Northridge, CA

Abstract: Alexithymia has been defined as the difficulty or inability of distinguishing, identifying, or expressing emotions (Kooiman, Spinhoven & Trijsburg, 2002). Previous research has demonstrated that individuals with high degrees of alexithymia (HDA) show an early processing deficit compared to individuals with low degrees of alexithymia (LDA) by focusing on P100 and P300 peaks in Event-Related Potential (ERP) patterns (Pollatos & Gramann, 2011). However, few attempts have been made to explore differences in the amplitude of N250 between individuals with high or low degrees of alexithymia, although past literature has shown that N250 is closely related to facial affect processing (Nasr & Esteky, 2009). The main purpose of the current study was to further explore differences in Event-Related Potential (ERP) patterns between individuals with HDA or LDA by focusing on the N250 peak. In this study, a total of 15 participants (6 low and 9 high) were selected based on their performance on the Toronto

Alexithymia Scale (Bagby et al., 1994) from the initial pool of 683 college students. In an individual session, a total of 11 electrodes were manually placed on a participant's head (PZ, CZ, and FZ) and face using the 10-20 international system. Each participant was instructed to identify emotion expressions shown on a computer screen either in the half or whole face condition. A total of 42 faces taken from the NimStim Face Stimulus Set (Tottenham et al., 2002) were used. The faces expressing six basic emotions (happy, fear, anger, disgust, surprise, sad) were presented either in the whole or half face condition. In the half condition, either the top or bottom half of the face was shown. The results of the current study showed that there was a significant 3-way interaction effect among face (whole vs. half) x condition (HDA vs. LDA) x location (PZ, CZ, and FZ) on the amplitudes of N250, F (2, 14) = 3.91, p = .045. This significant effect means that individuals with HDA (M = -5.68, SE = 3.52) tended to put more cognitive effort at the FZ site to configure emotion expressions from the half faces compared to the individuals with LDA (M = -1.37, SE = 3.94). This trend implies that the individuals with HDA need more later cognitive processes to configure emotion expressions, especially when facial information is limited. *Keywords: alexithymia, ERP, HDA/LDA, TAS-20*

Title: Seeing an angry face impairs learning the value of information in an uncertain world

Authors: ***P. PIRAY**, V. LY, K. ROELOFS, R. COOLS, I. TONI;
Donders Inst., Nijmegen, Netherlands

Abstract: Recent theories suggest that emotions influence decision making by modulating the ability to learn the value of information in uncertain environments. However, the computational and neural mechanisms by which emotions modulate learning the value of information are still unclear. Here, we exploit recent advances in computational modeling to fill this gap. Human participants (N=44) underwent functional magnetic resonance imaging while performing a task requiring them to learn contingencies between face cues and financial outcomes. The emotional content of the face cues and the rate of change of the contingencies were independently manipulated. Participants processed emotional contents of cues and distinguished between

stochastic and systematic changes in task contingencies, as quantified with a Bayesian hierarchical learning model. Seeing angry faces made participants less sensitive to the causal statistics of changes in the environment, reducing their estimates of volatility. Neural signals associated with volatility-learning, in the right lateral prefrontal cortex (LPFC), were also disrupted. In contrast, seeing angry faces increased neural signals tracking volatility in the anterior cingulate cortex (ACC) and its volatility-dependent connectivity with the striatum. The change in ACC volatility-tracking induced by seeing angry faces was negatively correlated, across individuals, with the disruption in behavioral estimates of volatility. This observation suggests that ACC might partially compensate for that disruption in volatility tracking. Consistent with the opposite contributions of LPFC and ACC to volatility processing, volatility-tracking signal in ACC and volatility-learning signal in LPFC changed in opposite directions as a function of anger-induced changes in behavioral performance. These complementary and hierarchically-organized neurocomputational effects indicate that anger perception influences human decision-making by modulating higher-order computations related to learning value of information in uncertain environments. This study opens the way to formally characterize how psychiatric alterations of emotional processing change human decision making.

Title: P300 differences in emotion recognition between deaf signers and hearing non-signers

Authors: ***K. W. JOHNS, JR**, K. GARCIA, E. DUBON, S.-M. KANG;
Psychology, CSUN, Lancaster, CA

Abstract: It has been speculated that hearing impairment and early adoption of American Sign Language (ASL) should affect the development of basic mechanisms of face perception among deaf signers (Letourneau & Mitchell, 2011). The lack of auditory information may make deaf signers rely unduly on visual cues in order to recognize faces and emotional states. In addition to this, deaf signers should constantly pay attention to facial expressions (e.g., changes in eyebrow

or mouth shapes) because ASL employs a number of facial expressions as crucial linguistic components of communication (Letourneau, Maslin 2013). Due to this unique behavioral practice among deaf signers, it has been suspected that deaf signers might process facial information somewhat differently compared to normal hearing nonsigners. The current study was designed to further explore the findings from Letourneau and Mitchell's study (2011) using ERPs, focusing on the P300 component. The main purpose of the current study was to explore the differences in latencies and amplitudes of P300 between deaf signers and hearing non-signers, while they engaged in an emotion recognition test. Two emotion recognition tasks were administered to 14 deaf and 27 normally hearing college students, one with 42 full faces and another with 42 half faces, while their ERPs were recorded. The correct responses of the emotion recognition test were also recorded.
The results of the current study showed that there was a significant main effect of face on amplitude, F (1, 39) = 13.23, $p < .001$. For both deaf and hearing group, they significantly had greater amplitudes in the half face condition in comparison to the whole face condition. There was also a significant main effect of hearing condition on latency, F (1, 39) = 5.39, p =.026. The deaf group had a longer latency than the hearing group. The longer latency of P300 among deaf participants implied that they had more difficulty to configure emotional expressions than the other group. This difficulty was reflected in their performance on the emotion recognition test. The results of the analyses on the correct responses of half faces showed that deaf participants tended to have more difficulties to configure facial expressions than the normally hearing participants, t (39) = 1.71, p = .095. The significance and implication of the findings were discussed in details, focusing on the impact of ASL and deafness on emotion information processing. This research was supported by a grant from the National Institute of Mental Health 5SC2MH087466-02 and MARC/MBRS Program.

Title: Non-edited isoform of 5-HT_{2C} receptor affects NPY expression in the nucleus accumbens and behavioral despair in mice

Authors: *M. TANAKA[1], M. AOKI[2], A. TSUJIMURA[3], K. TAGUCHI[1], Y. WATANABE[3]; [1]Anat. and Neurobio., [2]Dent. Med., [3]Basic Geriatrics, Kyoto Prefectural Univ. Med., Kyoto, Japan

Abstract: Serotonin 2C receptors (5-HT_{2C}R) are widely expressed in the central nervous system, and are associated with various neural functions such as emotion, food intake, dependence and stress response. 5-HT_{2C}R mRNA is known to undergo adenosine-to-inosine RNA editing at five sites within its coding sequence, resulting in expression of 24 different isoforms. Several edited isoforms show reduced activity. This fact suggests that RNA editing can modulate serotonergic systems in the brain with causative relevance to neuropsychiatric disorders. Transgenic mice solely expressing the non-edited 5-HT_{2C}R INI-isoform (INI-mice) or the fully edited VGV-isoform (VGV-mice) exhibit various phenotypes including metabolic abnormalities, aggressive behavior, anxiety-like behavior, and depression-like behavior. Here, we examined the behavioral phenotype and molecular changes of INI-mice on a C57BL/6J background. INI-mice showed an enhanced behavioral despair in the forced swimming test (FST), elevated sensitivity to the tricyclic antidepressant, desipramine, and significantly decreased 5-HT in the nucleus accumbens (NAc), amygdala, and striatum. They also showed reduced expression of neuropeptide Y (NPY) mRNA in the NAc and its expression level in wild type (WT)-mice was decreased after 5-HT_{2C}R selective agonist, WAY-629. However immobility time in FST was not significantly changed after microinjection of NPY or NPY-Y1 receptor agonist, [Leu31, Pro34]-NPY, were bilaterally microinjected into the NAc of WT- or INI-mice. Next we examined FST after increased NPY mRNA by stereotactic injection of adeno-associated virus encoding NPY into the NAc, and demonstrated that accumbal NPY overexpression decreased immobility time. Our results suggest that accumbal NPY expression may be regulated by 5-HT_{2C}R RNA editing, and its impairment may be linked to mood disorders.

Sci., Tokyo, Japan

Abstract: Olfaction is dependent on respiration for the delivery of odorants to the nasal cavity. Taking advantage of the time-locked nature of inspiration and olfactory processing, electroencephalogram dipole modeling (EEG/DT) has previously been used to identify a cascade of inspiration-triggered neural activity moving from primary limbic olfactory regions to frontal cortical areas during odor perception. In this study, we combined functional magnetic resonance imaging (fMRI) and EEG in order to re-examine the neural cascade model of human olfactory processing higher spatial and temporal resolution. Twenty right-handed healthy volunteers participated in this study. This study was approved by the ethics committee of Showa University School of Medicine and all participants provided informed consent. The fMRI study was divided into 2 sessions/runs: (i) periods of pleasant odor interleaved with unscented air, and (ii) periods of no-odor interleaved with unscented air. Each session comprised 5 unscented and 5 scented blocks or no-odor blocks, with a duration of 30s each. Subjects were instructed to breathe normally throughout the experiment. Statistical analysis of fMRI data was performed using statistical parametric mapping (SPM12) software, and Drifter toolbox installed in SPM8 was used to remove physiological noises of respiration and cardiac signals from fMRI-BOLD signals. Inspiration-related fMRI activations during olfaction stimuli were observed in the primary olfactory areas including piriform cortex, amygdala, entorhinal cortex and hippocampus. Brain activation identified by both modalities converged within same olfaction-related areas, and EEG/DT was additionally provided that the primary olfactory regions activated occurring approximately 50ms-100ms post-inspiration, and the orbitofrontal cortex that were activated from approximately 150ms to 300ms after inspiration onset. These results provide a partial validation of the spatial profile of the olfactory cascade identified by EEG source modeling, and inform novel future directions in the investigation of human olfaction.

Title: Stress resilient rats show reciprocal changes in the expression of miRNAs associated with regulation of serotonin transporter level in mesocortical circuit

Authors: *D. ZURAWEK, M. KUSMIDER, A. FARON-GORECKA, M. KOLASA, J. SOLICH, P. PABIAN, P. GRUCA, M. DUBIEL, K. SZAFRAN-PILCH, M. PAPP, M. DZIEDZICKA-WASYLEWSKA;
Inst. of Pharmacol. PAS, Krakow, Poland

Abstract: Stress perturbs psychological and physiological balance of an individual. Exposure to prolonged stress can lead to depression. Nevertheless, some individuals are more resilient to stress than the others. In our present study we used Chronic Mild Stress (CMS) paradigm - well characterized animal model of depression. Chronic exposure of rats to unpredictable mild stressors caused behavioral deficits (anhedonia) manifested by decreased consumption of a palatable 1% sucrose solution (significant effect of stress $F_{2,129}=72.42$; $p<0.0001$, time $F_{2,129}=14.57$; $p<0.0001$ and stress x time $F_{4,129}=26.57$; $p<0.0001$ vs control). Moreover, CMS generated a proportion of animals demonstrating resilience manifested as not altered consumption of sucrose solution despite being stressed. Thus, CMS model mimic natural variety in behavioral response to stress observed among people because not all subjects experiencing chronic stress develop depression. Recently, epigenetic regulation of a gene expression associated with microRNA (miRNA) is considered as an important factor modulating biochemical response to stress. In our present study, based on our previous work and literature survey, we investigated changes in the expression level of 7 miRNAs (i.e. miR-18a-5p, miR-34a-5p, miR-135a-5p, miR-195-5p, miR-320-3p, miR-674-3p, miR-872-5p) in mesocortical circuit - crucially involved in stress response in order to find differences between stress susceptible (anhedonic) and resilient phenotype. Our bioinformatic analysis using MirWalk2.0 software showed that all miRNAs of interest have a potential to regulate serotonin transporter (SERT) expression. RT-qPCR analysis revealed that exposure to 2 weeks of CMS caused global increase in the expression of measured miRNAs in ventral tegmental area (VTA) of stressed rats followed by parallel decrease in miRNA expression in prefrontal cortex (PCx). This effect was more profound in resilient animals than in anhedonic ones. Next, we examined binding of [^{3}H]paroxetine to SERT to check whether global changes in the expression of miRNAs potentially regulating SERT may be associated with altered SERT expression in vivo. After 2

weeks of CMS we observed decreased level of SERT in VTA of resilient rats ($F_{2,11}$= 9.15, p< 0.01 vs control and anhedonic). Our findings show that mesocortical circuit is involved in the response to a challenging conditions and this phenomenon is more efficient in resilient animals. This response is shown at the level of miRNA expression what, in turn, influenced downstream biochemical pathway associated with SERT expression. This work was supported by the NCN grant UMO-2012/07/B/NZ7/01164, Poland.

Title: Contrasting expression patterns of inflammation-related genes in mouse models of depression and psychosis

Authors: *H. KOSHIMIZU, H. HAGIHARA, T. MIYAKAWA;
ICMS, Fujita Hlth. Univ., Toyoake, Japan

Abstract: Previously, we showed the existence of pseudo-immature brain cell states in the dentate gyrus (DG) of mouse models of psychiatric disorders, including schizophrenia and bipolar disorder. It was also demonstrated that some brain cells can undergo rejuvenation in response to the external stimulation, such as treatment with antidepressant (fluoxetine; FLX), pilocarpine-induced seizure, and physiological stimulation. Pseudo-immature brain cell states are often associated with inflammation. Recently, via bioinformatics analysis, we indicated transcriptomic “hypermaturity” in the DG of mice overexpressing the glucocorticoid receptor (GRov mice), which show increased depression-like and anxiety-like behaviors and are considered potential animal models for mood disorders, and the hippocampus of the glutamate dehydrogenase 1 (Glud1) transgenic mice and mice treated with PF-04447943, a selective phosphodiesterase-9 (PDE9) inhibitor. However, it is largely unknown whether there is any common molecular basis for “hypermature” and pseudo-immature brains. Here, we compared genome-wide gene expressions in the DG of GRov mice with those in inflammation by using a bioinformatics tool, NextBio. The gene expression patterns in the DG of GRov mice showed

statistically significant similarity to those in the inflammation-associated events, such as poly(I:C) infection and colitis. Among genes that were upregulated or downregulated in "hypermature" brains, there were significant enrichments in signal pathways related to inflammation and immune reactions. Both these enrichments were also observed for pseudo-immature brains. Of the inflammation and immune-related genes in the pseudo-immature brains, the number of upregulated genes was significantly greater than that of downregulated genes. In contrast, in the "hypermature" brains, downregulations were dominant to upregulations in the inflammation and immune-related genes. These observations indicate that inflammation is commonly involved in both pseudo-immature and "hypermature" brains, and each of them may represent unique inflammation-related events.

Title: Role of dendritic-targeting bdnf transcripts on depression- and stress-associated phenotype

Authors: *H. OH[1], D. LEWIS[2], S. WATKINS[3], S. PIANTADOSI[2], E. SIBILLE[1];
[1]Dept. of Psychiatry, CAMH, Toronto, ON, Canada; [2]Dept. of Psychiatry, [3]Dept. of Cell Biol. and Physiol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: *Introduction.* A parallel downregulation of brain-derived neurotrophic factor (BDNF) and somatostatin (SST), a marker of inhibitory γ-amino-butyric acid (GABA) interneurons which target pyramidal cell dendrites, has been reported in multiple brain areas of subjects with brain disorders, including major depressive disorder (MDD). Our previous study revealed that BDNF transcripts with long 3' untranslated region (3' UTR), which have been reported to migrate to distal dendrites, are selectively downregulated and highly correlated with markers of dendritic-targeting interneurons including SST, in the prefrontal cortex of MDD subjects and of chronically stressed mice. The aim of this study is to investigate if altered dendritic BDNF is causal to the MDD- and stress-associated molecular, structural and behavioral changes. *Methods.* Using small hairpin RNA (shRNA) targeting long 3' UTR of BDNF mRNA, we knocked down dendritic BDNF transcripts in primary mouse cortical neurons and measured total length, number of segments of dendrites. AAV expressing BDNF long 3' UTR targeting shRNA or scrambled

shRNA were injected into the mPFC of male C57BL/6J mice and changes of MDD-associated synaptic gene expression and depressive-/anxiety-like behavior were analyzed. *Results.* Suppression of long 3' UTR (+) BDNF mRNA decreased the length of dendrite of primary cortical neurons without changing number of dendritic segments. BDNF long 3' UTR as well as total BDNF level were significantly reduced in post-surgery week 4, and SST level was changed along with BDNF mRNAs in week 6. Gene manipulation exacerbated depressive- and anxiety-like behavior in mice in response to stress. *Conclusions.* Knockdown of dendritic BDNF recapitulated MDD- and chronic stress-associated phenotypes, namely impaired integrity of distal dendrites, increased behavioral emotionality and reduced SST gene expression. These findings provide evidence for a novel pathogenic mechanism in MDD linking local neurotrophic support, pyramidal cell structure and dendritic inhibition.

Abstract: Major depressive disorder (MDD) is a complex pathology where multiple cell-specific pathways interact to produce heterogeneous phenotypes. Growing evidence shows that MDD is associated with molecular changes within GABA cells, astrocytes and synapses in the prefrontal cortex (PFC). Similar changes are reported in stress-based rodent models of depression. GABA cells and astrocytes are closely interacting to regulate synaptic neurotransmission. However the sequence of changes affecting these compartments is poorly understood in the context of MDD.

Here, we aim to identify dynamic changes in cell type markers during chronic stress exposure and their correlations with the onset of depressive-like behaviors. Using the chronic restraint stress (CRS) paradigm (1h restraint stress, 2 x day) in C57/BL6 male and female mice, we determined CRS effects on behavior at different time points (1 to 5 weeks) and on the expression of markers for GABA cells, astrocytes and synapses. We assessed the progressive CRS effects on anxiety-like behavior (acute response to a 1h spotlight stressor in home cage-like setting), anhedonia-like deficits and coat deterioration. Characterization of the cellular alterations induced by CRS was performed using western blot and qPCR on PFC samples. Results show that CRS induced time-dependent deficits in anxiety-like and anhedonia-like behavior. Indeed, CRS-exposed mice exhibit an increase in latency to normalise to control level after the light challenge. This residual avoidance behavior was significant after 1, 2 and 5 weeks of CRS. Moreover, CRS induced a time dependent increase in anhedonia-like behavior assessed by a reduction of sucrose consumption significant from the 3rd week of CRS. At the cellular level, western blot analysis confirmed the reductions in GABAergic (GAD67), astrocytic (GFAP, glutamine synthetase (GS)) and synaptic (PSD-95, Syn1) markers following 5 weeks of CRS. Preliminary analyses suggest that GFAP and GS expression profile correlates with anhedonia-like deficits trajectory, while GAD67 expression follows the increased avoidance phenotype in response to acute stress challenge. In addition, synaptic markers progressively decreased over the course of the CRS exposure. Ongoing experiments will confirm these dynamic changes using qPCR and extend this study to GABA neuron subtypes and other astrocytic and synaptic markers. Here we confirm that chronic stress is a multiphasic process engaging short-term changes that progressively lead to a pathological state. Our results suggest that different cellular systems are altered at those stages, in parallel to different behavioral outcomes.

Title: Behavioral and metabolic characterization in subchronic social defeat model of mice

Authors: *A. TOYODA[1,2], T. GOTO[1], H. OTABI[1], S. TOMONAGA[3], D. KOHARI[1,2], T. OKAYAMA[1,2];

Abstract: Previously, we developed a depression model of mice using the paradigm of subchronic mild social defeat stress (sCSDS) (Goto *et al*., Behav Brain Res 2014). sCSDS mice (C57BL/6J, male) showed increased body weight gain, polydipsia, and social avoidance. Also, sCSDS mice severely delayed nest building process (Otabi *et al*., Behav Process 2016). The social avoidance behavior in sCSDS mice were affected by the diet purity, namely sCSDS mice fed non-purified diet (MF, Oriental Yeast, Japan) showed more resilience compared to sCSDS mice fed purified diet (AIN-93G, Oriental Yeast) (Goto *et al*., Nutr Neurosci *in press*). To assess these underlying mechanisms, metabolites in plasma, liver, and cecum digesta of sCSDS mice were analyzed by metabolomics using a gas chromatography-mass spectrometry system under two different feeding conditions, purified pellet diet (AIN-93G) and non-purified pellet diet (MF). Four test groups were set as 'sCSDS + AIN-93G diet', 'sCSDS + MF diet', 'control (without sCSDS) + AIN-93G diet', and 'control + MF diet'. The sCSDS mice were produced as previously. Two-way ANOVA were used to compare the factors ‘stress’, ‘food’, and ‘stress × food’. To control the *p*-value for multiple comparisons, the false discovery rate was determined. The significance threshold was set at $Q < 0.1$. Metabolome analysis revealed that the diet effect on metabolites is larger than the stress effect. Namely, 22, 27, and 31 of metabolites in plasma, liver, and cecum, respectively, were significantly changed by diet, while 8 and 5 of metabolites were significantly changed by sCSDS in plasma and liver, respectively. Also, in the interaction of stress and diet, 5 and 1 of metabolites were significantly changed in plasma and cecum, respectively. Possibly, these metabolites have important roles in resiliency and vulnerability to psychosocial stress, which will be assessed in the future study.

Abstract: After exposure to a highly stressful situation, some individuals become at high-risk to develop depression later in life. A low serum Brain Derived Neurotrophic Factor (sBDNF) level one month after stress exposure signs this state of vulnerability in both rodents and Human. We used electroencephalograms (EEG) recorded during active waking periods to test for the presence of predictive EEG biomarkers of vulnerability to depression before a highly stressful situation in rats. EEG and sBDNF were analyzed before (Baseline), 5 (Post-stress) and 31 days (Recovery) after social defeat (SD) in 43 rats. We show that future vulnerable animals could readily be identified before SD by higher high theta and alpha spectral relative powers and lower beta-2 main peak frequency. These differences were maintained after SD. Low beta-2 main peak frequency was predictive of future vulnerability. Such biomarker could easily be used to identify human populations at-risk for depression.

Title: Unpredictable chronic mild stress induces correlated depressive-like behavioral and MRI brain volume changes in mice

Authors: *K. A. MISQUITTA[1,2], Y. S. NIKOLOVA[1], B. ROCCO[1], J. ELLEGOOD[4], J. LERCH[4], M. BANASR[1], E. SIBILLE[1,2,3];

Abstract: Major depressive disorder (MDD) is a severe mental illness characterized by low mood, anhedonia, and often associated with heightened anxiety. Human magnetic resonance imaging (MRI) studies have described structural alterations in key brain regions involved in MDD including amygdala, hippocampus, and prefrontal cortex. Parallel studies in stress-based rodent models have provided insight into the putative molecular mechanisms underlying these morphological and behavioral changes; however, a clear link between these features has yet to be determined. To help bridge this gap, we used MRI to assess brain morphology in the unpredictable chronic mild stress (UCMS) mouse model of depression, after behavioral characterization. Using Noldus phenotypers apparatus, we monitored the weekly baseline behavior (time spent in drinking, food, shelter zones) of 8-12 week-old BALB/c mice (n=12/group) to obtain longitudinal measures over the course of the UCMS protocol. At the end of the UCMS protocol we administered acute behavioral tests including the elevated plus maze, open field, novelty suppressed feeding, cookie test, forced swim test and sucrose consumption. A principal component analysis (PCA) was used to obtain a summary measure of UCMS-induced heightened emotionality across tests. Finally, brains were perfused with contrasting agent and submitted to 7T MRI to assess volumetric MRI changes of twenty-seven brain regions associated with human MDD. Our longitudinal assessment of behavior demonstrated that UCMS exposure induced a progressive increase in the time spent hiding in shelter in disfavor of other zones within the arena. This increase in hiding behavior in the UCMS group was further exacerbated by an acute stress challenge (spotlight over the food zone). UCMS-exposed animals showed higher scores on the top behavioral principal component and clear separation from control mice ($p = 8 \times 10\text{-}7$) capturing 23.5% of variance across tests. Finally, we demonstrated an increase in volume of the amygdala, hippocampus, frontal association, prelimbic and cingulate cortices of UCMS animals, relative to the controls. These morphological changes were positively correlated with the top principal component of the behavioral data. Experiment in progress will determine the cellular correlates associated with UCMS-induced increases in volume of the amygdala. Altogether this work will identify cellular and morphological substrates underlying depressive-

like behaviors and will provide a translational perspective on the biological mechanisms involved in human MDD.

Title: Differential gene expression in blood cells and brain regions of resilient and vulnerable animals after acute, uncontrollable and severe stress

Authors: X. YAO[1], J. SHOBLOCK[1], *G. CHEN[2];
[1]Janssen R & D, San Diego, CA; [2]Neurosci. Drug Discovery, Janssen R&D, LLC, Janssen Pharm. Comp. of JNJ, San Diego, CA

Abstract: Stress disorders such as depression and Post Traumatic Stress Disorder (PTSD) are outcomes of the interplay between the genetic polymorphisms and early life insults derived resilient and vulnerable factors and the ongoing psychological and physical stress; however, the molecular identities of the resilient and vulnerable factors are still largely unknown. Similar to the chronic social defeat stress paradigm, the learned helplessness model offers an opportunity to explore the identities of potential resilient and vulnerable factors under the acute, uncontrollable and severe stress. After unavoidable foot shocks delivered in random intervals, a portion of animals develops deficits in the active avoidance test, which has been considered as a measure of behavior despair. Samples of peripheral blood mononuclear cell (PBMC), prefrontal cortex, hippocampus, amygdala and cerebellum were collected and then submitted to gene expression analysis using RNA sequencing platform. The expression of numerous genes was up or down-regulated in all tissue types after the stress. More genes were up- or down regulated in the amygdala than other brain regions, a finding consistent with the known function of amygdala as the stress relay center. More genes in PBMC than in brain regions were differentially changed in resilient and vulnerable animals. The bioinformatics revealed that the large portion of the differentially regulated genes belongs to the neuroendocrine and immune response systems or involved in cell structure and cellular resilience. This data provides starting information to further explore the genes and gene networks in model animals and human subjects in order to develop novel treatments, prevention measures, and predictive and diagnostic biomarkers for depression and PTSD.

Title: Search for plasma biomarkers of depression by metabolome analysis in an animal model and clinical samples

Authors: *Y. KAGEYAMA;
Osaka City Univ., Osaka-Shi, Japan

Abstract: There is an urgent need for biomarkers of major depressive disorder to optimize its treatment. Although various candidate biomarkers were reported, no one has been established. The purpose of the present study was to search for novel biomarkers using human plasma samples and depression mouse model (mutant *Polg* 1 transgenic mouse) that spontaneously showed depressive episode-like behavioral changes. We measured plasma metabolites, by capillary electrophoresis time-of-flight mass spectrometry, in the mutant mice (10 euthymic state and 10 depressive episode-like state) and human participants matched age and sex with no medication (8 major depressive disorder and 19 healthy controls). The animal experimental protocols were approved by the Wako Animal Experiment Committee, RIKEN. The human study was approved by the ethics committees of Hannan Hospital, Osaka City University, RIKEN, and National Center of Neurology and Psychiatry and conducted in accordance with the Declaration of Helsinki. Plasma concentration of betaine ($p=0.024$), glutamic acid ($p=0.040$), and creatine ($p=0.049$) were higher in the mouse model of depression-like state than euthymic state. Plasma concentration of cis-aconitic acid was higher in patients with major depressive disorder than healthy controls ($p=0.039$). Betaine, glutamic acid and creatine did not show significant change between patients with major depressive disorder and healthy controls. These three metabolites were not a marker of major depressive disorder but warrants further regression

analysis and investigation in a larger number of samples to draw a conclusion whether there is a state-dependent alteration. We also measured plasma metabolites in patients with bipolar disorder and schizophrenia and will discuss the results in the poster.

Title: Riluzole prevents the onset of anxiety-, anhedonia-, and helplessness-like deficits in two rodent models of stress-related illness.

Authors: *C. J. FEE[1,2], E. SIBILLE[1,3,2], R. M. BERMAN[4], V. CORIC[4], G. SANACORA[5,4], M. BANASR[1,4];
[1]Campbell Family Mental Hlth. Res. Inst., Ctr. For Addiction and Mental Hlth., Toronto, ON, Canada; [2]Pharmacol. and Toxicology, [3]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [4]BioHaven Pharmaceuticals, New Haven, CT; [5]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Anxiety, anhedonia, and helplessness are common symptoms associated with major depressive disorder (MDD), schizophrenia (SCZ), and post-traumatic stress disorder (PTSD). Dysregulated glutamate function is thought to underlie these symptoms across disorders. Riluzole decreases glutamate transmission as an enhancer of glutamate uptake and a sodium channel blocker. Previous studies suggest riluzole possesses antidepressant-like and anxiolytic properties. However, therapeutic indication in other psychiatric mood disorders has not been established. Here, using two stress-based rodent paradigms that model the negative symptoms of SCZ and PTSD-like deficits, we examined riluzole's ability to prevent the development of these behavioral deficits. We first sought to determine the behavioral efficacy of riluzole in mice exposed to unpredictable chronic mild stress (UCMS) using tests measuring anhedonia and anxiety. We then examine riluzole effects on helplessness-like deficits using a learned helplessness (LH)/active avoidance (AA) paradigm.
Adult C57BL/6J mice underwent 5 weeks of randomized mild stressors (2-4/day). Riluzole (60 µg/mL) was administered in sweetened drinking water (saccharin 0.1%) throughout UCMS exposure. Elevated plus maze (EPM), open field test (OFT), and novelty suppressed feeding

(NSF) were performed to measure anxiety-like behavior. Sucrose consumption (SC) measured anhedonia-like behavior only, while novelty induced hyperphagia (NIH) measured both anxiety- and anhedonia-like behavior. Behavioral changes were assessed by Z-scoring across tests measuring similar outcomes. In a separate cohort, riluzole was administered for 14 days prior exposure to LH. Mice received 60 inescapable footshocks (0.35 mA) and then tested in AA (30 trials). Escape failures was recorded as an index of helplessness-like deficits. The composite Z-anxiety score, calculated for EPM, OFT, NSF, and NIH, demonstrated significantly heightened emotionality following UCMS that was prevented by riluzole. This effect was driven by an attenuation of UCMS-induced effects in NIH and EPM. Riluzole treatment also prevented UCMS-induced anhedonia z-scored from NIH and SC. The anti-anhedonia effect of riluzole was highly significant in both tests. In the LH paradigm, riluzole significantly attenuated helplessness-like behavior, as indexed by a reduction in escape failures. This data supports the utility of riluzole as an indication for treating, and possibly preventing, anhedonia and anxiety symptoms associated with stress-related disorders, including MDD, SCZ, and PTSD.

Title: Pre-existing differences in white matter diffusivity correlate with behavioral response to acute social defeat in mice

Authors: *Y. GROSSMAN[1], D. DUMITRIU[2];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Depression is a neuropsychological disorder that affects millions of people. There are currently no predictors for susceptibility to depression and a large proportion of afflicted individuals are resistant to available treatments. The ability to predict selective psychosocial vulnerability and resilience to stress holds great promise in preventing this debilitating disorder. Social defeat (SD) is a highly validated mouse model of depression. Previously, we had demonstrated using a model of acute social defeat (ASD), that animals exhibiting socially avoidant (susceptible) and resilient behavioral responses possessed differences in functional responses to acute social stress. Here, we probe the neuroarchitecture that could provide a foundation for these variances observed in functional connectivity. We performed diffusion-weighted imaging (DWI) one week prior to ASD then correlated the diffusivity of various brain regions with behavioral response to ASD. We found a positive correlation between anisotropy and resilience to ASD, indicating that differences in white matter connectivity may be a pre-existing condition that contributes to the differences in functional connectivity that we had previously reported.

Title: Ancestral stress induces sexually dimorphic effects in depressive-like behaviours of aging rats

Authors: *M. AMBESKOVIC[1], O. BABENKO[1], E. A. FALKENBERG[1], Y. ILNYTSKYY[2], I. KOVALCHUK[2], G. A. S. METZ[1];
[1]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Lethbrigde, AB, Canada; [2]Dept. of Biol. Sci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: INTRODUCTION: Exposure to stress in early life represents a powerful impact on fetal brain development and hypothalamic-pituitary-adrenal (HPA) axis activity. Moreover, adverse early life experiences may also increase the susceptibility to affective disorders, such as depression, in adulthood. Our previous studies showed that recurrent prenatal stress across generations has cumulative effects on brain plasticity and generates new behavioural traits. Here we proposed that recurrent prenatal stress also compromises mental health trajectories in older age.
This study investigated in rats the effect of: (1) aging on depression-like behaviours, stress response and epigenetic regulation by microRNAs; (2) cumulative ancestral prenatal stress (APS) on aging in terms of depression-like behaviour in males versus females.
METHODS: Male and female F4 generation offspring were derived from a rat lineage in which their ancestral mothers (F0-F3) were stressed during pregnancy. A non-stress lineage served as control. Depression-like behaviours were assessed at the age of 6 (young), 12 (middle aged) and 18 (aged) months using a forced swim task. Behavioural outcomes were related to plasma corticosterone levels, and microRNA expression in the prefrontal cortex.
RESULTS: Aging raised the incidence of depression-like behaviours in both males and females regardless of APS. APS however further exacerbated depression-like behaviour in males along with decreased cortical expression of miR-124, a recognized biomarker and therapeutic target in depression. In contrast, APS reduced age-associated depression-like symptoms in females and increased cortical miR-124 expression. In addition, aging and stress synergistically disturbed HPA axis activation and accelerated an age-associated decline in affective state in males.

CONCLUSION: Ancestral programming by stress may represent a significant determinant of lifetime mental health trajectories, a major contributor to sexually dimorphic phenotype, and a risk factor for common age-related diseases through altered epigenetic regulation. MiR-124 may be used as predictive biomarkers of age-related diseases in males.

Title: P11, an essential cell-specific molecular determinant for stress-induced depression

Authors: *J.-S. SEO[1], J. WEI[2], L. QIN[2], Z. YAN[2], P. GREENGARD[1];
[1]The Rockefeller Univ., New York, NY; [2]Dept. of Physiol. and Biophysics, Sch. of Med. and Biomed. Sci., State Univ. of New York, Buffalo, NY

Abstract: Chronic stress plays a crucial role in the development of psychiatric diseases, such as anxiety and depression. Dysfunction of the medial prefrontal cortex (mPFC) has been linked to the cognitive and emotional deficits induced by stress. However, little is known about the molecular and cellular determinants in mPFC leading to stress-associated mental disorders. Here we show that chronic restraint stress induces the selective loss of p11 (also known as annexin II light chain, S100A10), a multifunctional protein which binds to 5-HT receptors, in layer II/III neurons of the prelimbic cortex (PrL), as well as depression-like behaviors, both of which are reversed by selective serotonin reuptake inhibitors (SSRIs) and the tricyclic class of antidepressant (TCA) agents. In layer II/III of the PrL, p11 is highly concentrated in dopamine D2 receptor-expressing ($D2^+$) glutamatergic neurons. Viral expression of p11 in $D2^+$ PrL neurons alleviates the depression-like behaviors exhibited by genetically manipulated mice with $D2^+$ neuron-specific or global deletion of p11. In stressed animals, overexpression of p11 in $D2^+$ PrL neurons rescues depression-like behaviors by restoring glutamatergic transmission. Our results have identified p11 as a key molecule in a specific cell type that regulates stress-induced depression, providing a framework for the development of new strategies to treat stress-associated mental illnesses.

Title: Gene deficiency and pharmacological inhibition of soluble epoxide hydrolase confers resilience to repeated social defeat stress: role of BDNF-TrkB signaling

Authors: *Q. REN[1], M. MA[1], T. ISHIMA[1], C. MORISSEAU[2], J. YANG[2], K. M. WAGNER[2], J.-C. ZHANG[1], C. YANG[1], W. YAO[1], C. DONG[1], M. HAN[1], B. D. HAMMOCK[2], K. HASHIMOTO[1];

Abstract: Depression is a severe and chronic psychiatric disease, affecting 350 million subjects worldwide. Although multiple antidepressants have been used in the treatment of depressive symptoms, their beneficial effects are limited. The soluble epoxide hydrolase (sEH) plays a key role in the inflammation which is involved in depression. Thus, we examined here the role of sEH in depression. In both inflammation and social defeat stress models of depression, a potent sEH inhibitor TPPU displayed rapid antidepressant effects. Expression of sEH protein in the brain from chronically stressed (susceptible) mice was higher than of control mice. Furthermore, expression of sEH protein in postmortem brain samples of patients with psychiatric diseases, including depression, bipolar disorder, and schizophrenia, was higher than controls. This suggests that increased sEH levels might be involved in the pathogenesis of certain psychiatric diseases. In support of this hypothesis, pretreatment with TPPU prevented the onset of depression-like behaviors after inflammation or repeated social defeat stress. Moreover, sEH knock-out (KO) mice did not show depression-like behavior after repeated social defeat stress, suggesting stress resilience. The sEH KO mice showed increased brain-derived neurotrophic factor (BDNF) and phosphorylation of its receptor TrkB in the prefrontal cortex (PFC),

hippocampus, but not nucleus accumbens, suggesting that increased BDNF-TrkB signaling in the PFC and hippocampus confer stress resilience. All these findings suggest that sEH plays a key role in the pathophysiology of depression, and that epoxy fatty acids, their mimics as well as sEH inhibitors could be potential therapeutic or prophylactic drugs for depression.

Title: Investigation of the oral microbiome for candidate markers of depression.

Authors: ***C. R. LAPSLEY**[1], M. MCLAFFERTY[2], A. MCDOWELL[1], A. J. BJOURSON[1], S. M. O'NEILL[2], E. K. MURRAY[1];
[1]Northern Ireland Ctr. for Stratified Med., Ulster Univ., Derry, United Kingdom; [2]Psychology, Ulster Univ., Magee Campus, Derry, United Kingdom

Abstract: Depression is a complex disorder with multiple symptoms, including a persistent low mood, anhedonia and cognitive impairments, and is currently the third leading cause of global disability. The underlying pathophysiology of depression is poorly understood, and the overall diagnosis and selection of treatment course for depression is largely subjective, reliant on patient self-report and clinical judgment. There is therefore an urgent need for new biological markers of depression and treatment response. A growing body of evidence supports an important role for the microbiome in the aetiology of depression and other psychiatric disorders. While much interest is currently focused on the role of the microbiome-gut-brain axis in brain physiology and neurochemistry, the importance of the oral microbiome has received little attention. The aim of this study is to characterise the oral and dormant blood microbiome in adults with moderate and severe depression versus matched controls with no history of the disease. To achieve this, participants were asked to complete an online validated mental health survey and to provide a saliva sample. We identified 46 individuals who met the DSM-V criteria for severe depression

and 46 age and sex-matched controls with no history of depression. Bacterial DNA was extracted from the saliva samples and 16S rRNA surveys were conducted using next generation sequencing. Differences in the bacterial community composition of the oral microbiota between patients and controls were determined, and validated using qPCR. Charting the oral/ blood microbiomes in depressed patients could therefore provide new insights into the development of the condition, and the identification of novel diagnostic and therapeutic response biomarkers.

Title: Effects of repeated paroxetine and fluoxetine exposure on hippocampal BDNF functioning in adolescent rats

Authors: *J. M. DHARGALKAR, K. N. RUDBERG, A. SOLIS, Z. R. HARMONY, E. J. MACEDO, L. C. ROMERO, C. A. CRAWFORD;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed class of antidepressant drugs, largely because of their effectiveness and favorable side-effect profiles. Unfortunately, the use of SSRIs in pediatric populations is limited due to reduced efficacy and their tendency to induce suicidal ideation in adolescents. Recently, we found that repeated treatment with fluoxetine and paroxetine caused increased anxiety-like behaviors in adolescent rats, as measured on the elevated plus maze and light/dark box. Moreover, adolescent rats did not show the adult-typical response of decreased serotonin utilization after repeated paroxetine treatment. The purpose of the present study was to determine if changes in brain derived neurotropic factor (BDNF) functioning are responsible for mediating these age-dependent behavioral and neurochemical effects. The rationale for this study was based on a growing body of evidence suggesting that the therapeutic effects of antidepressants are

dependent on BDNF-mediated increases in neurogenesis. To test our hypothesis, we measured the expression of BDNF and the BDNF receptor, TrkB, after repeated paroxetine and fluoxetine treatment. Male and female adolescent Sprague-Dawley rats (*n*=6-7) were injected with paroxetine (2.5 or 10 mg/kg), fluoxetine (5 or 10 mg/kg), or vehicle for 10 consecutive days starting on postnatal day (PD) 35. On PD 45, the hippocampus of each rat was removed and then assayed for BDNF and TrkB expression using western blotting. In both male and females rats, BDNF expression was decreased after fluoxetine (5 and 10 mg/kg) treatment. Paroxetine (10 mg/kg) also decreased BDNF levels, but only in male rats. In contrast, TrkB expression was increased after SSRI treatment; however, this increase was only significant for male rats treated with the high dose of fluoxetine (10 mg/kg). In summary, repeated treatment with the SSRIs paroxetine and fluoxetine led to decreased BDNF expression in adolescent rats. This reduction in BDNF levels may be responsible for the reduced efficacy of SSRIs during adolescence. Interestingly, paroxetine had a greater effect on the BDNF functioning of male rats than females.

Title: The role of medial prefrontal corticosterone and dopamine in the antidepressant-like effect of exercise

Authors: *S. NAKAGAWA[1,2], C. CHEN[2], Y. KITAICHI[2], Y. AN[2], M. KOGA[2], I. KUSUMI[2]; [2]Psychiatry, [1]Hokkaido Univ. Grad Sch. Med., Sapporo, Japan

Abstract: Despite the well-documented beneficial effect of exercise on stress coping and depression treatment, its underlying neurobiological mechanism remains unclear. This is further complicated by a 'side effect' of exercise: it increases basal glucocorticoid (CORT), the stress hormone, which has been shown to be a mediator linking stress to depressive disorders. Here we show that three weeks of voluntary wheel running reduced rats' immobility in the forced swim

test (FST), an antidepressant-like effect. Monitoring extracellular fluids in the medial prefrontal cortex PFC (mPFC) using microdialysis we found that, wheel running was associated with higher baseline CORT, but lower FST-responsive CORT. Further, wheel running resulted in a higher dopamine (DA) both at baseline and following FST. Interestingly, the antidepressant-like effect of wheel running was completely abolished by intra-mPFC pre-microinjection of a D2R (haloperidol) but not D1R (SCH23390) antagonist, at a dose that does not affect normal rats' performance in the FST. It suggests that exercise exerts antidepressant-like effect through upregulated DA and in a D2R dependent way in the mPFC. Importantly, the antidepressant-like effect of wheel running was also abolished by intra-mPFC pre-microinjection of a GR antagonist (RU486). Finally, intra-mPFC pre-microinjection of RU486 also downregulated the originally elevated basal and FST-responsive DA in the mPFC of exercise rats. These results suggest a causal pathway linking CORT, GR, DA, and D2R, to the antidepressant-like effect of exercise. In conclusion, exercise achieves antidepressant-like effect through the CORT-GR-DA-D2R pathway and that the increased basal CORT by exercise itself may be beneficial rather than detrimental. This research was supported by Japanese Ministry of Education, Culture, Sports, Science and Technology, grant-in-aid No. 23591667 (S.N.) and a grant from Hokkaido University Clark Memorial Foundation (C.C.).

Title: 3,5,6,7,8,3′,4′-heptamethoxyflavone, a citrus flavonoid, ameliorates depression-like behavior and brain-derived neurotrophic factor expression

Authors: ***A. SAWAMOTO**, S. OKUYAMA, K. YAMAMOTO, Y. AMAKURA, M. YOSHIMURA, M. NAKAJIMA, Y. FURUKAWA;
Col. of Pharmaceut. Sci., Matsuyama Univ., Matsuyama, Ehime, Japan

Abstract: The decreases in hippocampal BDNF levels are correlated with stress-induced depressive behavior and that antidepressant enhances the expression of BDNF. Our findings that 3,5,6,7,8,3′,4′-heptamethoxyflavone (HMF), a citrus flavonoid, has the potential for increasing the expression of the BDNF in the hippocampus of a transient global ischemia mouse model prompted us to investigate whether HMF has anti-depressive activity. A depression mice model

was developed through subcutaneous administration of corticosterone (20 mg/kg/day for 25 days), and HMF was simultaneously administered with corticosterone. As results, we observed that the HMF treatment ameliorated (1) corticosterone-induced body weight loss, (2) corticosterone-induced depression-like behavior, (3) corticosterone-induced reductions in BDNF production in the hippocampus, (4) corticosterone-induced reductions in neurogenesis in the dentate gyrus subgranular zone and (5) corticosterone-induced reductions in the expression levels of phosphorylated calcium-calmodulin-dependent protein kinase II and extracellular signal-regulated kinase1/2. These results provide that HMF has a possibility to prevent the onset of depression as an antidepressant by inducing the expression of BDNF.

Title: Rapid antidepressant spine formation is influenced by $GABA_B$ receptor activation of mTORC1

Authors: *C. F. HEANEY[1], E. R. WORKMAN[2], E. K. ERICSSON[2], K. F. RAAB-GRAHAM[1]; [1]Wake Forest Baptist Med. Hlth., Winston Salem, NC; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Treatments for patients with major depressive disorder often take several weeks to become effective. Further, patients may not respond to the prescribed drug and thus begin a cycle of dose and drug changes. N-methyl-D-aspartate glutamate receptor (NMDAR) antagonists have emerged as rapid antidepressants, acting within hours of administration. What is more, these drugs are effective at treating patients who are treatment resistant. However, the cellular mechanisms associated with how these ligands produce their effects are unclear. NMDAR antagonists have been demonstrated to increase neurogenesis and activate the mammalian target of rapamycin (mTOR). Our lab has previously demonstrated that the administration of NMDAR

antagonists causes a functional shift in metabotropic gamma-aminobutyric acid (GABA) receptors ($GABA_BRs$). This shift decreases the coupling of $GABA_BRs$ to potassium channels and instead promotes coupling to calcium channels. Blocking $GABA_BRs$ reverses this effect. Here, we examined the interaction of rapid antidepressants and $GABA_BR$ ligands on synapse formation in order to further characterize this pathway. We demonstrate that these synaptic changes are likely newly formed synapses requiring protein synthesis. These data suggest a beneficial role of $GABA_BR$ signaling in rapid antidepressant mechanisms.

Abstract: The majority of pharmacological agents used for the treatment of depression target the serotonin system. However, these drugs like selective serotonin reuptake inhibitors (SSRIs) are not ideal because only a fraction of patients achieve remission. New targets for antidepressant drugs are needed for this 'treatment resistant' population and additionally for patients who suffer from intolerable side-effects stemming from SSRI administration. The recent discovery that the effective antidepressant tianeptine (Stablon) is a full agonist at the mu-opioid receptor (MOR) has revealed a potential novel target for drug development. Our studies are aimed at

understanding the neural circuits through which tianeptine exerts its antidepressant effects. Using genetic and pharmacological models we tested whether the behavioral effects of tianeptine are mediated by MOR. We found that MOR knockout mice have no measured behavioral response to tianeptine. Additionally, the behavioral effects are also abolished by pretreatment with an MOR antagonist. Tissue-specific MOR knockout mice are now being tested to dissect the circuitry which underlies the opioid-dependent antidepressant action. Preliminary evidence suggests that the antidepressant phenotype is dissociable from the classic opiate phenotype including effects on activity, feeding, pain, and reward. Additionally, unlike other classic opiates, there seems to be no tolerance or withdrawal formed following chronic administration of tianeptine to mice. Taken together, these results point to a novel entry point to understand the neural circuits underlying depression, and a potential avenue for the development of a new class of antidepressant drugs.

Title: Discovering common molecular signatures underlying antidepressant response

Authors: *E. CARAZO[1], C. ANACKER[1], B. A. SAMUELS[3], M. J. MEANEY[4], R. HEN[2]; [1]Integrative Neurosci., Columbia Univ., NEW YORK, NY; [2]Psychiatry, Neuroscience, and Pharmacol., Columbia Univ., New York, NY; [3]Psychology, Rutgers Univ., New Brunswick, NJ; [4]Ludmer Ctr. for Neuroinformatics and Mental Hlth., Douglas Mental Hlth. Univ. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Anxiety and depressive disorders have a prevalence of 31% and 17% respectively in the United States population. Affecting over 40 million people, together they comprise the most common mental illnesses in the country. Despite the large number of patients suffering from anxiety and depressive disorders, there are limited treatment options. Antidepressants such as SSRIs are amongst the most common treatment options for depressive disorders. However,

despite being so widely used, only one-third of patients experience remission after up to four months of treatment with SSRIs, pointing to a clear need for a better understanding of the molecular and cellular mechanisms underlying SSRIs effects in order to develop better treatment options. On a neuroanatomical level, the dentate gyrus of the hippocampus has been shown to be a crucial mediator of antidepressant effects on behavior. Our aim is to study the neurobiological and genetic basis of antidepressant response and treatment resistance in order to identify novel molecular targets that mediate antidepressant treatment responses. We combined next-generation RNA sequencing and microarray data of fluoxetine treated mice, in order to identify molecular signaling programs that mediate the response to fluoxetine in the Dentate Gyrus. For this purpose we have used three complementary mouse models of chronic stress: social defeat, chronic corticosterone, and chronic oral gavage. All three models were similarly treated with fluoxetine for 28 Days, in order to elicit a common fluoxetine-induced genetic signature. Treatment effectiveness was determined in our models by segregating the fluoxetine responders and non-responders. The measure of responsiveness to fluoxetine was given by the levels of anxiety exhibited in behavioral tasks such as the social interaction test or novelty suppressed feeding after fluoxetine treatment. RNA from both dorsal and ventral dentate gyrus was extracted from the samples and processed by Microarray or RNA-sequencing. Our preliminary analysis point at a differential gene expression between dorsal and ventral dentate gyrus upon fluoxetine treatment. Furthermore, there are similarly regulated genes in fluoxetine responders across the datasets such as Npas4 and genes belonging to the activin/inhibin pathway, both of which have been implicated in antidepressant response. Ongoing efforts are aimed at identifying a common genetic signature that is specific to antidepressant responders and non-responders.

Title: Altered membrane protein clustering in peripheral lymphocytes in an animal model of depression parallels protein clustering observed in patients with depression: a translational approach

Authors: R. ROMAY-TALLON[1], E. Y. FENTON[5], M. A. MITCHELL[2], L. E. KALYNCHUK[3], *H. J. CARUNCHO[4];
[1]Dept. of Med., [2]Psychology, [3]Col. of Med., [4]Col. of Pharm. and Nutr., Univ. of Saskatchewan, Saskatoon, SK, Canada; [5]Ctr. for Drug Res. and Develop., Vancouver, BC, Canada

Abstract: Membrane protein clustering (MPC) in peripheral lymphocytes is altered in depression and has been proposed as a putative biomarker of therapeutic efficacy in major depressive disorder (reviewed in Frontiers in Cellular Neuroscience, 2016,10:48). In this experiment, we analyzed the clustering of four transmembrane proteins in lymphocytes from rats repeatedly treated with corticosterone (CORT), a well-characterized animal model of depression. Male rats received 21 days of daily CORT injections (40 mg/kg) or vehicle injections. On day 22, rats were subjected to the forced swim test and blood samples were collected by cardiac puncture. Lymphocytes were extracted from the blood samples and processed for immunocytochemical analyses of the serotonin transporter (SERT), serotonin 2A receptor (5-HT2A), beta-2 adrenergic receptor (β-2AR), and the cellular prion protein (PrPc). CORT produced a depressive phenotype evidenced by significant increases in immobility behavior in the forced swim test. CORT also altered the pattern of clustering for all examined proteins. We found significant increases of 13%, 6% and 12% in the average size of SERT, 5-HT2A and PrPc clusters respectively, in the CORT rats compared to the vehicle rats. However, the β-2AR clusters were 7% smaller in the CORT rats. No changes were found in the number of SERT, 5-HT2A and β-2AR clusters per lymphocyte, but there was a 20% increase in the number of PrPc clusters in the CORT rats. We also found a positive correlation between the size of SERT, 5-HT2A and PrPc clusters and immobility behavior in the forced swim test. Importantly, the pattern of SERT and 5-HT2A protein clustering seen after CORT treatment is very similar to what we have previously observed in naïve depression patients. This suggests that parallel changes in protein clustering can be seen across a preclinical animal model of depression and the clinic, offering significant translational potential. In addition, our novel observation of altered β2AR and PrPc protein clustering in the animal model should be confirmed in a patient cohort. Overall, we believe that mapping changes in protein clustering in both patients and an animal model will better identify biomarkers for depression diagnosis and treatment responsivity.

Title: *In vivo* pharmacological testing of novel, short-acting kappa opioid receptor antagonists

Authors: S. PAGE[1], E. ROBERTS[2], H. ROSEN[2], D. PUTTICK[1], M. MAVRIKAKI[1], W. A. CARLEZON, Jr.[1], *E. H. CHARTOFF[3];
[1]Psychiatry, Harvard Med. Sch., Belmont, MA; [2]Chem., The Scripps Res. Inst., La Jolla, CA; [3]Psychiatry, Harvard Med. Sch. Dept. of Psychiatry, Belmont, MA

Abstract: Kappa opioid receptors (KOR) are expressed in brain areas implicated in motivation, emotion, and learning. Although selective KOR agonists share the antinociceptive effects of opiates, they tend to produce aversive- and stress-like effects in humans and laboratory animals. In contrast, selective KOR antagonists have antidepressant-like and anxiolytic-like effects, and can block drug-seeking behaviors in rodent models of addiction. These types of findings have stimulated interest in the therapeutic potential of KOR antagonists. However, prototypical KOR antagonists such as JDTic and norBNI have exceptionally long durations of action, complicating their use in clinical trials. Here we present initial pharmacological and behavioral data on a novel KOR antagonist, CYM 52220, synthesized at The Scripps Research Institute. CYM 52220 has high selectivity for KORs compared to other opioid receptors and favorable pharmacokinetic and distribution to brain (>4:1 brain-plasma ratio) profiles. Using the Tail Flick Assay (TFA), we performed dose-effect and time course experiments to quantify the ability of oral administration of CYM 52220 to block the antinociceptive effects of the KOR agonist U50,488 (30 mg/kg, IP). For comparison, we also tested the KOR antagonists JDTic and LY2456302, which have long and short durations of action, respectively. Consistent with previous reports, oral administration of JDTic (20 mg/kg; PO) blocked U50,488-induced increases in tail flick latency in the TFA for at least 24 hrs whereas the KOR antagonist effects of LY2456302 (0.9 mg/kg; PO) in the TFA were only observable for 1 hr after oral administration. CYM 52220 (0.0 – 30 mg/kg; PO) dose-dependently blocked U50,488-induced increases in tail flick latency when administered 2-hr prior to testing. An AD_{80} dose of CYM 52220 (6.0 mg/kg; PO) attenuated the analgesic effects of U50,488 for more than 2 hrs. In conclusion, CYM 52220 is a novel, potent, selective, and orally active KOR antagonist with a relatively short duration of action that may have therapeutic potential.

Title: The function of P-glycoprotein after chronic treatment with antidepressant drugs in the mice

Authors: *A. SHOHEI, K. OSADA, T. HAGA, T. WATANABE, H. KOCHA;
Neuropsychiatry, St.Marianna Univ. of Med., Kawasaki/Kanagawa, Japan

Abstract: P-glycoprotein (P-gp) is a 130-kDa adenosine triphosphate (ATP)-dependent drug transport protein that is abundantly distributed in the apical side of brain capillary endothelial cells forming the tight junctions of the blood-brain barrier (BBB). Utilizing ATP hydrolysis as an energy source, P-gp belongs to a large and growing group of transmembrane transporters, which are increasingly recognized as an important part of the blood-brain and blood-cerebrospinal fluid (CSF) barriers. P-gp is expressed by and was first discovered in multiple drug-resistant (MDR) cancer cells, but can also be found in normal tissue. P-gp has been demonstrated to influence the absorption, distribution, and elimination of many commonly used drugs. It has, furthermore, been shown that P-gp influences the distribution of drugs across the BBB. The location of P-gp at the BBB is of importance for the delivery of psychotropic drugs such as antidepressant and antipsychotic medications. Recently, it has also been demonstrated that the intracerebral concentrations of some psychotropic drugs and opioids can be up to several-fold higher in P-gp knock-out mice than in wild-type mice. Among these drugs are the antidepressants nortriptyline, escitalopram, sertraline, venlafaxine and fluvoxamine, the antipsychotic drugs olanzapine and risperidone, as well as the substrates for P-gp. But we do not know how the P-gp function after the chronic treatment with antidepressant drugs in the brain. Then we investigated which chronic treatment with the antidepressant drugs as the substrates for P-gp was changed the function of P-gp in the brain. C57BL/6N mice (weighing 20-25 g) were orally administrated of 10 mg/kg/day antidepressant drugs once daily for six weeks. To quantify the amount of mRNA in mice brain, we performed real-time PCR (7500 Fast Real-Time PCR System)by using TaqMan Fast Universal PCR Master Mix (life technologies). A PCR reaction mixture of 20µl containing 10µl of TaqMan Fast Universal PCR Master Mix, 9 µl of cDNA and 1 µl TaqMan Gene Expression Assays. We examined that the expression of RNA P-glycoprotein after chronic treatment with the antidepressant drugs and compared with before treatment.

Abstract: Post-ictal burst-suppressing electroencephalographic (EEG) activity has been proposed to underlie the neuroplastic and therapeutic effects of ECT (*electroconvulsive therapy)*. This hypothesis prompted researchers already decades ago to test and show that deep brief isoflurane anesthesia bring rapid antidepressant effects in some patients. The hypothesis was never tested experimentally however. Instead, some of the subsequent human trials produced conflicting results and thereby reduced the interest to further evaluate isoflurane as a substitute for ECT. We demonstrate here that burst-suppressing EEG is not prerequisite for the ability of isoflurane to regulate signaling responses implicated in the antidepressant actions of NMDA-receptor blocker ketamine: activation and inhibition of TrkB-mTor-p70S6k pathway and GSK3β, respectively. Indeed, and similarly with ketamine, already subanesthetic doses of isoflurane and *gamma*-hydroxybutyrate (GHB), another putative sedative antidepressant acting predominantly through NMDA/AMPA-independent pathways, regulate these signaling pathways in the adult rodent brain. Interestingly, TrkB and GSK3β signaling are similarly regulated by various pharmacologically different sedatives (but not with stimulant amphetamine) but, as expected based on huge amount of previous literature, these responses are not (always) co-associated with antidepressant-like behavioural and functional changes. Moreover, ketamine dose-dependently regulates TrkB and GSK3β signaling. Collectively these intriguing observations suggests that increased neuronal inhibition - rather than excitation - readily induce some of the intracellular signaling alterations intimately connected with rapid-acting antidepressant responses in the adult rodent brain. Obtained data urge to rethink and update some of the current antidepressant hypotheses and will guide subsequent experiments to find shared neurobiological mechanisms underlying rapid antidepressant actions.

Title: Human amygdala engagement moderated by early life stress exposure is a biobehavioral target for predicting recovery on antidepressants

Authors: *A. N. GOLDSTEIN-PIEKARSKI[1,2], M. S. KORGAONKAR[4], E. GREEN[1,3], T. SUPPES[1,3], A. F. SCHATZBERG[1], T. HASTIE[5], C. B. NEMEROFF[6], L. M. Abstract: Amygdala circuitry and early life stress (ELS) are both strongly and independently implicated in the neurobiology of depression. Importantly, animal models have revealed that the contribution of ELS to the development and maintenance of depression is likely a consequence of structural and physiological changes in amygdala circuitry in response to stress hormones. Despite these mechanistic foundations, amygdala engagement and ELS have not been investigated as biobehavioral targets for predicting therapeutic intervention outcomes in translational human studies of depression. To address this question 70 patients from the International Study to Predict Optimized Treatment in Depression (iSPOT-D) were scanned using fMRI when unmedicated, randomized to one of three antidepressants and re-assessed 8 weeks post-treatment. An established emotional face task probed amygdala engagement. ELS was measured with the Early Life Stress Questionnaire. Therapeutic outcome was assessed by a combined measure of symptoms (HAM-D and QIDS) and function (SOFAS). Hierarchical logistic regression and receiver operating characteristic analyses were used to test the predictive performance of models using amygdala engagement and ELS as targets for probing therapeutic outcome following an antidepressant intervention. The interaction between amygdala engagement by emotional stimuli and ELS predicted therapeutic functional remission on antidepressants with greater than 80% cross-validated accuracy. In depressed people exposed to high ELS, the likelihood of remission was highest when the amygdala was hyper-reactive to

socially rewarding stimuli, whereas for those with low ELS exposure, remission was predicted by a state of amygdala hypo-reactivity to both rewarding and threat-related stimuli. This full model predicted functional remission over and above the contribution of demographics, symptom severity, ELS and amygdala reactivity alone. These findings identify a human target for elucidating the mechanisms of antidepressant functional remission and offer a target for developing novel therapeutics. The results also offer a proof of concept for using neuroimaging as a target for guiding neuroscience-informed intervention decisions at the level of the individual person.

Title: Trip8 interaction with hcn regulates trafficking and antidepressant like behavior.

Authors: ***Y. HAN**, R. HEUERMANN, K. LYMAN, D. FISHER, Q.-A. ISMAIL, D. CHETKOVICH;
Northwestern Univ., Chicago, IL

Abstract: Major depressive disorder (MDD) affects millions of people worldwide. Most of the existing antidepressants target monoaminergic neurotransmitters, but many individuals don't respond to these therapies. As such, there is a need for new MDD treatments targeting novel mechanisms. Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels mediate I_h, an important current for controlling neuronal excitability. Brain HCN channels are tightly regulated by an auxiliary subunit, TRIP8b (tetratricopeptide repeat-containing Rab8b-interacting protein). Animals lacking either TRIP8b or HCN have increased antidepressant-like behavior, suggesting that inhibiting HCN channels could effectively treat depression. Unfortunately, directly targeting HCN channels throughout the body is not a viable therapeutic approach because these channels are critical in controlling heart rate. We reasoned that inhibiting brain-specific TRIP8b would be a safer way to target HCN channels and treat MDD. Here we employed an *in vivo* viral rescue approach in TRIP8b knockout mice to examine the function of HCN-TRIP8b interaction in mediating HCN channel trafficking and influencing antidepressant-like behavioral effects. We found that AAV-TRIP8b restored trafficking of HCN channels in TRIP8b KO mice. Furthermore, AAV-TRIP8b reversed the antidepressant-like behavioral phenotype of TRIP8b KO mice. We next generated a mutant TRIP8b construct in which binding to HCN subunits is impaired (AAV-TRIP8b (N13A)). Injection of AAV-TRIP8b (N13A) into the hippocampi of TRIP8b KO mice further decreased trafficking of HCN channels. As predicted by the hypothesis that HCN trafficking is important for behavior, AAV-TRIP8b (N13A) augmented the antidepressant-like behavioral phenotype of TRIP8b KO mice. These observations demonstrate that HCN channel trafficking bidirectionally regulates antidepressant-like behaviors and HCN-TRIP8b interaction might be a novel pharmacological target for MDD.

Title: Evaluation of scopolamine and muscarinic sub-type selective compounds in models of depression with greater translational value

Authors: *J. SHOBLOCK, W. A. ECKERT, III, W. CHEN, N. WELTY, G. CHEN; Neurosci., Janssen Res. & Development, L.L.C., San Diego, CA

Abstract: Recently, scopolamine has been shown to be a rapid-acting antidepressant in several clinical trials. This has initiated preclinical research to characterize the antidepressant-like effects of scopolamine, but so far such research has focused on immobility tests like forced swim. Immobility tests lack construct validity and respond acutely to antidepressants that require chronic clinical dosing. Therefore, we sought to characterize scopolamine in additional preclinical depression models, which have perhaps greater construct or predictive validity. We tested scopolamine in active avoidance, with either catecholamine depletion, serotonin depletion, or pre-exposure to inescapable shocks (the learned helpless model) used to induce a helpless-like state. Active avoidance test is typically insensitive to acute administration of traditional antidepressants, but responds to rapid-acting antidepressants like ketamine. Scopolamine significantly increased escapes in active avoidance test under all three conditions, indicating a rapid-acting antidepressant-like response. Post-test drug levels indicate effectiveness at 25 ng/ml in plasma and 67 ng/ml in brain in active avoidance. We then sought to use the learned helpless model to further characterize the mechanism of action of scopolamine's effect. Previous published data implicated the M2 subtype and we confirmed that an M2 antagonist was antidepressant-like in immobility test. This could be due to blockade of M2 autoreceptors, leading to increased acetylcholine and stimulation of nicotinic receptors, because the effect was blocked by the nicotinic antagonist mecamylamine and mimicked by a nicotinic a6b2/a4b2 agonist. However, mecamylamine did not block scoplamine's effect in learned helpless and the nicotinic agonist was without effect in learned helpless. On the other hand, an M5 positive allosteric modulator was able to attenuate scopolamine's effect in learned helpless. Thus, while M2 blockade may contribute to some antidepressant-like effect of scopolamine, it likely does not mediate the rapid-acting effects, whereas M5 may be involved. These data highlight the need for improved translational models when characterizing clinical drugs.

Title: Effects of probiotic treatment (Bifidobacterium Infantis) in male and female rats exposed to chronic high levels of corticosterone

Authors: G. S. HAAS, S. M. MOONEY-LEBER, W. WANG, K. V. ZARIC, *S. BRUMMELTE;
Psychology, Wayne State Univ., Detroit, MI

Abstract: Previous research suggests that probiotics such as Bifidobacterium Infantis (B. infantis) may have beneficial health effects. The current study investigates whether B. infantis can alleviate depressive symptoms in a rodent model of depression. For this, 24 male and 24 female Sprague-Dawley rats received daily s.c. corticosterone (40mg/kg; to induce depressive-like behavior) or oil injections (control) coupled with voluntary consumption of a hazelnut cacao spread that was either pure (placebo) or mixed with one capsule of B. infantis for 21 days. Animals performed the Open Field Test and Forced Swim Test I and II on days 18, 20 and 21, respectively and several blood samples were collected to investigate basal as well as stress-induced corticosterone levels. Preliminary results revealed no significant difference in body weight or forced swim test behavior between the probiotic and placebo groups, but the expected decrease in body weight and increase in immobility in the Forced Swim Test in the corticosterone-treated animals. These results suggest that B. infantis may not be sufficient to improve depressive symptoms in our animal model. However, the effects on the brain and Hypothalamic-Pituitary-Adrenal axis are still under investigation and a trend for weight and behavior changes in females indicates that more research is needed to better understand potential sex difference concerning the health effects of probiotics.

Title: Hyperforin potentiates antidepressant-like activity of AZD 6765 in the tail suspension test in mice

Authors: B. POCHWAT, *B. SZEWCZYK, K. KOTARSKA, G. NOWAK;
Inst. of Pharmacol. PAS, Krakow, Poland

Abstract: Depression is one of the most debilitating medical problems concerning modern societies. Unfortunately, current pharmacological strategies in the treatment of depression are not sufficient, thus the new pharmacological solutions are desirable. Possible route to improve the pharmacotherapy of depression is the use of N-methyl-D-aspartate receptor (NMDAR) antagonists. These compounds have faster onset of action than classic antidepressants and have potential to be used in the acute episodes of depression or even in life threatening cases. However, the administration of NMDAR antagonists is limited because of their serious side effects. Thus, the strategies that help to decrease the doses of NMDAR antagonists or to extend duration of action of these compounds are needed. The aim of the present study was to potentiate the antidepressant-like activity of selected NMDAR antagonist by modulator of transient receptor potential cation channel, subfamily C, member 6, (TRPC6). As the pharmacological tools, we choose hyperforin which is well-known TRPC6 positive modulator and AZD 6765 which is a low trapping NMDAR antagonist. We have revealed that hyperforin in two doses (2,5 and 5 mg/kg) exerts its antidepressant-like activity 1 hour and 24 hours after administration in tail suspension test (TST) in mice. Similar effects have been observed for the AZD 6765 in the dose of 10 mg/kg. Furthermore, hyperforin enhanced the antidepressant-like effect of AZD 6765. In details, co-administration of non- effective dose of hyperforin (1 mg/kg, administered 1 hour before test) with non-effective dose of AZD 6765 (2,5 mg/kg, administered 1,5 h before test) showed antidepressant-like activity in TST. Additionally, co-administration of effective doses of hyperforin (2,5 or 5 mg/kg) with effective dose of AZD 6765 (10 mg/kg) increased duration of antidepressant effects for 72 hours. These results indicated that hyperforin, the positive modulator of TRPC6 may be a useful compound to potentiate the antidepressant activity of NMDAR antagonists.

Title: Disinhibition of somatostatin-positive interneurons produces antidepressant-like consequences in mice

Authors: *S. J. JEFFERSON[1], T. FUCHS[1], A. HOOPER[2], P. YEE[1], J. MAGUIRE[2], B. LUSCHER[1];
[1]The Pennsylvania State Univ., University Park, PA; [2]Tufts Univ. Sch. of Med., Boston, MA

Abstract: Major Depressive Disorder (MDD) is associated with deficits in the inhibitory neurotransmitter γ-aminobutyric acid (GABA) and antidepressant treatment can normalize these deficits. $GABA_A$ receptor-deficient mice exhibit a depressive-like phenotype that is normalized by conventional antidepressant treatment as well as subanesthetic ketamine injection. We hypothesized that enhancing GABAergic transmission in mice through disinhibition of somatostatin (SST)-positive interneurons, a subset of GABAergic interneurons that has been implicated in depressive disorders, would be sufficient to produce antidepressant-like behavioral consequences. To this end, we deleted the γ2 subunit gene of the $GABA_A$ receptor (*Gabrg2*) selectively in SST^+ interneurons (SSTCre:$\gamma2^{f/f}$ mice). To facilitate recordings from SST^+ interneurons we further crossed these mice with a Rosa26-YFP Cre-reporter (SSTCre:$\gamma2^{f/f}$ x Rosa26-YFP). A reduction in inhibitory input to SST^+ cells was confirmed by voltage clamp analysis, which showed a decrease in frequency and amplitude of spontaneous inhibitory postsynaptic currents (sIPSCs). SST^+ cells also showed increased excitability, as evidenced by an increase in input resistance and in the number of current-evoked action potentials. Consistent with potentiation of inhibitory synapses of target cells, we observed an increase in sIPSCs in pyramidal cells in L2/3 of the cortex and the hippocampal CA1 region. As predicted, the behavior of these mice mimicked the effect of anxiolytic and antidepressant drugs. Similar to mice treated with rapidly-acting antidepressants, SSTCre:$\gamma2^{f/f}$ mice showed reduced phosphorylation of the eukaryotic elongation factor eEF2 in extracts from the hippocampus and medial prefrontal cortex (mPFC). However, unlike mice treated with some rapidly-acting antidepressant drugs, the altered eEF2 phosphorylation observed in these mice was independent of altered mTOR signaling. Finally, SST mRNA and protein levels were unaltered in brain extracts from SSTCre:$\gamma2^{f/f}$ mice, indicating that potentiation of GABAergic synapses on principal cells alone is sufficient to produce an antidepressant-like behavioral and biochemical phenotype.

Title: Specificity of the discriminative stimulus properties of the noncompetitive N-Methyl-D-aspartate (NMDA) receptor antagonist in C57BL/6 mice

Authors: *J. H. PORTER, S. E. CARLAN, S. E. YOUNG, T. J. BRAXTON, M. H. KHAN, H. NANGUNURI, H. NANGUNURI, R. PANDEY, C. W. KALINOWSKI, K. W. LOVELESS, D. SMITH, K. A. WEBSTER;
Psychology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The noncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist ketamine has been shown to produce both rapid and long-lasting antidepressant effects in patients with major depressive disorder, including treatment-resistant patients; however, its abuse liability limits its outpatient use. Identification of the receptor mechanisms that mediate ketamine's therapeutic effects could help lead to development of novel drug treatments for depression. Using a two-lever drug discrimination procedure, we previously reported that the discriminative stimulus properties of ketamine are shared by other NMDA antagonists (phencyclidine, MK-801 and memantine), but not by the antidepressants imipramine and fluoxetine, indicating that ketamine's interoceptive effects appear to be independent of its antidepressant-like properties. In the present study selective receptor ligands and drugs from other therapeutic classes were tested to further explore the underlying mechanisms that mediate ketamine's discriminative stimulus properties. Male C57BL/6 mice were trained to discriminate 10 mg/kg of ketamine from vehicle in a two-lever drug discrimination task (10 min injection time, SC). Mice rapidly acquired the ketamine discrimination and a generalization curve (2.5 mg/kg - 20.0 mg/kg) was conducted and yielded an ED_{50} = 4.38 mg/kg (95% = CI 4.03 mg/kg-4.76 mg/kg). Substitution testing was conducted with raclopride (dopamine $D_{2/3}$ antagonist), quinpirole ($D_{2/3}$ agonist), d-amphetamine (dopamine reuptake inhibitor), quipazine (serotonin [5-HT] agonist), ritanserin (5-HT_2 antagonist), ketanserin (5-HT_{2A} antagonist), scopolamine (cholinergic muscarinic antagonist), pyrilamine (H_1 histamine antagonist), prazosin ($alpha_1$ adrenoceptor antagonist), yohimbine ($alpha_2$ adrenoceptor antagonist), methadone (opioid mu agonist), naloxone (opioid mu antagonist), dextrorphan (NMDA antagonist), and the benzodiazepine chlordiazepoxide ($GABA_A$ positive modulator). None of the selective ligands substituted for ketamine's discriminative stimulus, nor did chlordiazepoxide. The only compound that produced ketamine-appropriate responding was the NMDA antagonist dextrorphan. It produced 85.8% ketamine-lever responding at 30 mg/kg. These findings replicate our previous report that only NMDA antagonists mimic ketamine's discriminative stimulus, and also replicate findings in ketamine discrimination studies with rats.

Thus, ketamine's discriminative stimulus properties appear to be primarily mediated by antagonism of glutamatergic NMDA receptors.

Title: Estimation of response probabilities to 10 common antidepressants based on the geographic distribution of Single Nucleotide Polymorphisms (SNPs) associated with treatment responses

Authors: S. POSPOS, *A. BASKYS;
Riverside Psychiatric Med. Group, Riverside, CA

Abstract: Antidepressant selection on a "trial and error" basis often leads to poor treatment outcomes, significant adverse effects and poor treatment adherence. While genetic polymorphisms can influence antidepressant responses, their prevalence varies across geographic areas. Here we calculated response probabilities to 10 common antidepressants based on antidepressant response associated SNP distribution among CEU, MXL, ASW and CHB populations (population definitions from HapMap.org). SNPs associated with antidepressant responses were rs7997012 for 5-hydroxytryptamine (serotonin) receptor 2A or HTR2A (venlafaxine XR), rs2770296 for HTR2A (bupropion), rs352428 for FK506 binding protein 5 or FKBP5, rs1954787 for glutamate receptor ionotropic kainate 4 or GRIK4 (citalopram), rs61888800 for brain-derived neurotrophic factor or BDNF, rs25531 for solute carrier family 6 (neurotransmitter transporter, serotonin) member 4 or SLC6A4, rs242941 for corticotrophin-releasing hormone receptor 1 or CRHR1 (fluoxetine), rs10042486 and rs1364043 for 5-hydroxytryptamine (serotonin) receptor 1A or HTR1A, rs6314 for HTR2A, rs2472304, rs2470890, and rs4646425, rs762551, and rs4646427 for cytochrome P450, family 1, subfamily A, polypeptide 2 (CYP1A2), rs6265 for BDNF (paroxetine), rs10042486 and rs1364043 for HTR1A, rs4680 for catechol-O-methyltransferase or COMT (fluvoxamine), rs6265 for BDNF (mirtazapine), rs352428 for FKBP5 (escitalopram), rs10042486 and rs1364043 for HTR1A

(milnacipran) and rs61888800 for BDNF (desipramine) [Baskys 2015]. For each antidepressant response associated SNP, we calculated allele frequencies associated with the increased response.
CEU and MXL were most likely to respond to bupropion, ASW to mirtazapine and CHB to desipramine. The highest response probability for each antidepressant was: CEU, fluvoxamine (0.44), milnacipran (0.42); MXL, milnacipran (0.42); ASW, mirtazapine (1.00), bupropion and escitalopram (0.98), venlafaxine XR (0.95), paroxetine (0.60) and milnacipran (0.42); and CHB, desipramine (0.98), fluoxetine (0.88) and citalopram (0.72). The highest response probability for each population was fluvoxamine and milnacipran (CEU), milnacipran (MXL), mirtazapine, bupropion, escitalopram, venlafaxine XR, paroxetine and milnacipran (ASW) and desipramine, fluoxetine and citalopram (CHB).

Title: Bioenergetics of Fluoxetine: a functional proteomic study

Authors: *F. FERRARI, A. GORINI, R. F. VILLA;
Dept. of Biol. and Biotech., Univ. of Pavia, Pavia, Italy

Abstract: BACKGROUND - Neuroimaging studies on depressed patients showed brain energy metabolism abnormalities, followed by the normalization of cerebral bioenergetics after antidepressants (ADs) treatment [1]. However, in some experimental studies, ADs are inhibitors of mitochondrial function, while in others they have positive effects on mitochondrial energy metabolism. These conflicting results are likely due to macro-heterogeneity of brain areas and to ADs differential effects on pre-synaptic and on post-synaptic terminals, not considered before when evaluating ADs effects on brain mitochondria.
METHODS - The effects of 21-day treatment with the selective serotonin reuptake inhibitor Fluoxetine (10 mg/kg, i.p.) were evaluated on energy metabolism of rat frontal cerebral cortex.

Two populations of intra-synaptic mitochondria ("light" - LM; "heavy" - HM) were isolated according to Villa et al. [2] and the following enzyme activities have been assayed: citrate synthase (CS), succinate dehydrogenase (SDH), malate dehydrogenase (MDH) for Krebs' cycle; NADH-cytochrome c reductase (CCR), cytochrome oxidase (COX) for Electron Transport Chain; glutamate-oxaloacetate transaminase (GOT), glutamate-pyruvate transaminase (GPT) for glutamate and related amino acids metabolism.
RESULTS - In controls, SDH, COX, GOT and GPT activities were higher in LM *versus* HM, whose metabolic individuality is reflected by enzyme kinetics, as previously shown in physiological aging, experimental physiopathology and pharmacological treatments [3, 4]. Fluoxetine treatment (1) decreased MDH, SDH and GPT activities in LM; (2) enhanced COX and (3) decreased GPT activities in HM.
CONCLUSIONS - Fluoxetine modified the catalytic properties of energy-linked enzymes differentially respect to the types of intra-synaptic mitochondria, explaining at subcellular level the conflicting results about the effects of ADs on mitochondria reported in Literature. Fluoxetine exerted selective effects on the energy metabolism of pre-synaptic terminals, coherent with those previously obtained after Desipramine treatment. From a bioenergetic point of view, these results integrate pharmacodynamic features Fluoxetine. This study will proceed evaluating the effects of Dsipramine and Fluoxetine on other brain areas.

Title: Examining the influence of aerobic exercise and bilateral movement on frontal alpha asymmetry

Authors: *R. A. HICKS, W. E. MCILROY;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Aerobic exercise has been commonly associated with decreased risk of developing major depression. The neurophysiological mechanisms by which this occurs are not fully understood and are key for fully utilizing aerobic exercise as a potential intervention for the disorder. One common neurophysiological marker associated with depression risk is the frontal alpha asymmetry (FAA). FAA is a ratio of resting brain activity between the left and right PFC measured via alpha frequency (8-13 Hz), which relate to approach and withdrawal motivational networks respectively. Previous research has shown that aerobic exercise, independent of load, positively influences resting state FAA to promote activity less associated with depression risk. The fact that changes in FAA are observed after low level exercise intensities raises the possibility that this influence on cortical activity is linked to movement rather than the cardiorespiratory demand. This work aimed to determine if effects of exercise on FAA observed was due to the physiological demand of exercise or rather the bilateral rhythmic movement that is common across exercise modes such as running or cycling. The specific purpose of this study was to investigate the influence of a moderate aerobic exercise bout and a matched "no load" bilateral movement task on FAA. Twelve young healthy subjects (5M, 7F; age 22.3 ±3) underwent three sessions in which they performed an experimental condition of either: 1) moderate aerobic exercise, 2) "no load" bilateral rhythmic movement or 3) sitting rest. FAA was measured pre intervention and 6-38 minutes post intervention. Results showed aerobic exercise significantly increased FAA at 22-38 minutes post exercise compared to pre exercise FAA levels. There was no significant effect of bilateral movement on FAA at any time period. These results suggest that in order for physical activity to cause a beneficial change in FAA, it must require some degree of physiological effort or demand to complete.

Title: Acute administration of a selective serotonergic reuptake inhibitor suppresses functional connectivity in the frontal-striatal circuit.

Authors: *H. T. HAMADA[1], K. HIKISHIMA[2], N. TAKATA[3], Y. SAKAI[4], K. TANAKA[3], K. DOTA[1];

Abstract: Serotonin is a crucial neuromodulator which plays multiple roles including the regulation of mood. Human resting-state fMRI (rs-fMRI) studies revealed that serotonergic drugs such as selective serotonin reuptake inhibitors (SSRIs) decrease functional connectivity (FC) among brain regions regulating mood. While chronic administration of serotonergic drugs reduces the symptoms, such as loss of pleasure and depressive mood, in depression patients, their acute administration sometime worsens the symptoms. Here we hypothesize that acute administration of serotonergic drugs changes functional connectivity among mood-related brain regions under resting-state and test it using 11.7 tesla MRI scanner with a cryoprobe (Brucker Biospin) with healthy male C57BL/6J mice (voxel size: 150x150x300 (μm); TR: 3.0(s); imaging time per session: 10 (min)). Two groups were prepared (n=7 for each group). A group was administered with a SSRI, escitalopram (10mg/kg) resolved in saline, while another group was administered with only saline. For each group, we administered SSRI or saline one hour prior to imaging. Seed-based FC analysis was conducted with functional connectivity toolbox (CONN) using 20 seed regions such as the Right/Left amygdala, the Right/Left anterior cingulate cortex (ACC), the Right/Left orbitofrontal cortex, and the Right/Left caudate putamen (CPu) from the Australian Mouse Brain Mapping Consortium (AMBMC). In line with our hypothesis, FC of the left lateral orbital cortex (LO) with the right CPu and right dorsolateral orbital cortex (DLO) was significantly reduced ($p<0.05$, positive false discovery rate for multiple tests (p-FDR)). Reduction of FC between the right CPu and the right ventral orbital cortex (VO) was also found ($p<0.05$, p-FDR). Reduction of functional connectivity in the frontal-striatal circuit was observed. This concurs with the reduced FC of the circuit in mental disorders including the major depression. The frontal-striatal circuitry is known as a pivotal circuit for reward processing and motivation. Reduction of the FC in the circuit indicates that acute administration of serotonergic drugs suppresses reward processing and motivation, and this suppression might be a mechanism causing loss of pleasure under acute administration of serotonergic drugs.

Title: Reversal effects of the antidepressant desipramine on resistance of U251/TR cells to temozolomide

Authors: J. MA[1], Y.-R. YANG[1], J.-J. LIU[1], F.-F. LI[1], M.-H. CHEN[1], H. WANG[1], L. WANG[1], L.-L. SUN[1], F.-Z. WANG[2], D.-C. WANG[1], *H. ZHANG[3,1];

Abstract: Temozolomide (TMZ) is the most effective chemotherapeutic agent for treatment of glioma. However, the efficacy of glioma treatment is severely reduced by the resistance to TMZ. Since depressive disorders are common comorbidity in patients with advanced cancer, antidepressants have been considered as conventional adjuvant agents for treatment of cancer comorbid with depression. Here we examined the effect of desipramine (DMI) on resistance of U251/TR cells to temozolomide (TMZ) and the related mechanism. Incubation of U251/TR cells with DMI (20-80 μM) or TMZ (0.5-10 mM) alone for 24 h inhibited the cell growth with the IC50s 33.4 (± 2.17) μM and 2.5 (± 0.19) mM, respectively (r^2=0.983,0.982,$P < 0.05$). This was significantly potentiated by combined treatment with TMZ (1 mM) and DMI (30 μM), indicating synergistic cytotoxicity, as also demonstrated by significant nuclear fragmentation and condensation following combined treatment with both drugs. In addition, DMI and TMZ in combination produced apoptosis in U251/TR cells, which was attenuated by knockdown of CHOP using specific short interfering RNAs (siRNAs) that target CHOP. The results suggest that DMI reverses resistance of U251/TR cells to TMZ through activation of the CHOP-dependently apoptosis pathway. The current study provides a primary basis for treatment of advanced glioma cancer, particularly with comorbidity of depression, using combination of antidepressants such as DMI and anti-tumor drugs such as TMZ.

Title: The role of brain fatty acid binding protein on sucrose consumption and the forced swim test

Authors: *J. HAMILTON[1], B. CLAVIN[1], C. KOUMAS[1], S. HAJ-DAHMANE[1], D. DEUTSCH[2], M. KACZOCHA[3], P. K. THANOS[1];

Abstract: Recent research on the mechanisms of intracellular transport of the endocannabinoid anandamide by Fatty Acid Binding Proteins (FABPs) and subsequent development of SBFI26, (a pharmacological inhibitor of two brain-specific FABPs 5/7) has shown increases in extracellular anandamide. The goal of this study was to examine the role of FABPs on sucrose reward and depressive-like behavior in wild type and FABP5/7 deficient mice. Results showed that acute SBFI26 administration did not have any effect on sucrose preference or consumption in male mice. Similarly, SBFI26 treatment did not have any significant difference (compared to vehicle) in the forced swim test (FST). Male and female FABP 5/7 deficient mice, however, showed significant increases in sucrose consumption compared to their WT counterparts (21.0% and 19.5% increases, respectively). Assessment of the FST data revealed that FABP5/7 deficient mice showed overall lower immobility time. The fact that such differences were seen between the acute pharmacological approach and the genetic approach (gene deletion) of FABP inhibition needs to be further investigated. It may point to the actions of oleoylethanolamide (OEA) and/or palmitoylethanolamide (PEA) which activate the nuclear peroxisome proliferator-activated receptor α (PPARα); these related *N*-acylethanolamines (NAEs) have been previously reported to be elevated in FABP KO animals, but not with SBFI26 administration. These findings help characterize the behavioral profile for inhibiting FABPs on sucrose reward and depression. Further research will be needed to identity the individual contributions FABPs have on AEA, OEA, and PEA in reward-related functioning.

Title: Hippocampal NR2B-containing NMDA receptors are critical for the antidepressant actions of ketamine

Authors: *C. T. LAGAMMA[1], J. C. MCGOWAN[1,2], S. C. LIM[3], D.-O. SEO[4], M. R. DREW[4], R. A. BRACHMAN5[5], C. A. DENNY[3,6];

Ctr., New York, NY; [6]Dept. of Psychiatry, Columbia Univ., New York, NY

Abstract: Background: Major depressive disorder is one of the most prevalent and pervasive mental illnesses that affect our population today. Current antidepressant treatment often takes weeks to have an effect, and many patients do not show substantial clinical improvement. Ketamine, an N-methyl-D-aspartic acid receptor (NMDAR) antagonist, has been shown to have rapid, long-lasting antidepressant effects in treatment-resistant patients. Here, we investigate whether ketamine's efficacy as an antidepressant is dependent on adult hippocampal neurogenesis in concert with the NR2B subunit of the NMDA receptor.
Methods: We utilized a transgenic approach to ablate the NR2B subunit of NMDAR's in 6-week-old adult-born hippocampal neurons in mice. We used two additional models to confirm ablation effects on 6-week-old adult born hippocampal neurons: x-irradiation and a GFAP-thymidine-kinase (TK) genetic model. Mice with or without NR2B were then administered either

saline or ketamine. We assessed antidepressant effects of ketamine in the forced swim test (FST), contextual fear conditioning (CFC), and novelty suppressed feeding (NSF) paradigms.
Results: Consistent with previous findings, we found that in mice containing NR2B, ketamine had antidepressant effects in FST, pro-cognitive effects in CFC, and anxiolytic effects in NSF. Deletion of NR2B from 6-week-old adult-born neurons occluded all these effects. Whole cell ablation in the genetic or x-irradiation models prevented some of ketamine's effects.
Conclusions: These data suggest that 6-week-old adult-born hippocampal neurons expressing NR2B are critical for modulating ketamine's rapid antidepressant response.

Title: Longitudinal effects of ketamine on dendritic architecture *In vivo* in the mouse medial frontal cortex

Authors: *A. C. KWAN, V. PHOUMTHIPPHAVONG, F. BARTHAS, S. HASSETT; Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: A single subanesthetic dose of ketamine, an NMDA receptor antagonist, leads to fast-acting antidepressant effects. In rodent models, systemic ketamine is associated with higher dendritic spine density in the prefrontal cortex, reflecting structural remodeling that may underlie the behavioral changes. However, turnover of dendritic spines is a dynamic process in vivo , and the longitudinal effects of ketamine on structural plasticity remain unclear. The purpose of the current study is to use subcellular resolution optical imaging to determine the time course of dendritic alterations in vivo following systemic ketamine administration in mice. We used two-photon microscopy to visualize repeatedly the same set of dendritic branches in the mouse medial frontal cortex (MFC) before and after a single injection of ketamine or saline. Compared to controls, ketamine-injected mice had higher dendritic spine density in MFC for up to 2 weeks. This prolonged increase in spine density was driven by an elevated spine formation rate, and not

by changes in the spine elimination rate. A fraction of the new spines following ketamine injection was persistent, which is indicative of functional synapses. In a few cases, we also observed retraction of distal apical tuft branches on the day immediately after ketamine administration. These results indicate that following systemic ketamine administration, certain dendritic inputs in MFC are removed immediately, while others are added gradually. These dynamic structural modifications are consistent with a model of ketamine action in which the net effect is a rebalancing of synaptic inputs received by frontal cortical neurons.

Title: In-vivo characterization of effects of psychoactive compounds, with novel therapeutic profile for MDD (ketamine and VU0409106) in a rodent model of anhedonia

Authors: *S. SAKTHIVEL[1], J. GARNELL[1], J. GRANDJEAN[1], A. THOMPSON[2], S. SERAMANI[1], C. LINDSLEY[2], C. JONES[2], K. BHAKOO[1];
[1]Singapore Bioimaging Consortium, A*Star, Singapore, Singapore; [2]Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ., Nashville, TN

Abstract: The current antidepressants for major depressive disorder (MDD) present a delayed therapeutic response, which can negatively impact compliance and/or have severe consequences for MDD patients suffering from suicidal ideations. We had previously characterised combination treatment strategies [SSRI's & SNRI's with 5-HT_{1A} & alpha2-adrenoceptors antagonists, resp.] to hasten antidepressant responses. Currently 'inhibition of NMDAR neurotransmission' represents an exciting & novel approach for rapid response, though the precise mechanism of action of such potential/novel psychoactive compounds are not yet fully characterised. Our drugs of interest were the NMDA antagonist, Ketamine (KET), an old drug but with new indications in MDD and VU0409106, a novel, potent & efficacious $mGlu_5$ negative allosteric modulator, which produces changes in signalling pathways comparable to KET, exemplified by its behavioural effects in our preclinical models of antidepressant-like activity. We have employed *in-vivo* MR Single Voxel Spectroscopy (SVS) to document the dynamic

neuro-metabolite changes (live flux profiles) over 2hrs, using ultra-high field 9.4T MRI, with & without these drug challenge. Male Wistar rats were used in this study; several cohorts went through a robust chronic mild unpredictable stress (CMUS) protocol. (I) CMUS led to reduced sucrose preference [CMUS: -41.3%, Naive: 0.05%, t-test: p=0.00022], reflecting a lack of reward-seeking behaviour (anhedonia). (II) CMUS led to marked change in metabolism: both glutamate (Glu) & glutamine (Gln) concentrations relative to total creatine were markedly decreased in CMUS compared to controls [Glu: p=0; Gln: p=2.7x10-9], consistent with the biogenic amine depletion hypothesis of MDD. Both inositol & total visible choline (glycerophosphocholine + phosphocholine) were increased in the CMUS group [Ins: p=4.4x10-13, GPC+PCh: p=0.0015], which may reflect inflammation & membrane metabolism changes respectively, consistent with our previous work in a mouse model of chronic social defeat. Less marked decreases in N-acetylaspartate [NAA: p= 0.0039] & Taurine [Tau: p=0.053] were also observed in CMUS compared to control. (III) Acute KET leads to Glu depletion over time in the control group specifically [Glu: p=0.00049]. (IV) Behaviourally KET & VU0409106 treatment increased the sucrose preference in CMUS animals compared to controls [CMUS+KET: 79%, CMUS+VU0409106: 74%, Naive: 48%, p<0.01 vs. CMS-Veh]. Our SVS results indicate a metabolic fingerprint similar to MDD; further documenting live flux profile with drug challenge offers novel insights, with high translational value to MDD clinical research.

Title: A role for JAK2 signaling in ketamine-induced mTOR activation in the orbitofrontal cortex

Authors: *S. M. ADLER, M. PATTON, D. MORILAK, M. GIROTTI;
Pharmacol., Univ. of Texas Hlth. Hlth. Sci. Ctr. A, San Antonio, TX

Abstract: Because depression treatment is often ineffective and slow, ketamine's rapid antidepressant effects provide an exciting alternative. In the past, our lab has shown that acute injection of a low dose of ketamine reverses chronic-stressed induced deficits in cognitive flexibility mediated in the prefrontal cortex that model cognitive symptoms of depression. One such form of cognitive flexibility is reversal learning, mediated in the orbitofrontal cortex (OFC), which is compromised by chronic cold stress. We have further demonstrated that acute ketamine administration rapidly induces Janus Kinase 2 (JAK2) signaling in the OFC, and that this signaling is important for the therapeutic effect on reversal learning in chronically stressed rats. We are now investigating the mechanism by which JAK2 signaling in the OFC may mediate ketamine's therapeutic effects on reversal learning. Because ketamine is known to activate mammalian target of rapamycin (mTOR) in the pre-frontal cortex (PFC), we tested if this signaling molecule is also activated by ketamine in the OFC. We then tested a potential role of JAK2 in this activation.

In a cohort of female Sprague-Dawley rats, half underwent chronic intermittent cold stress treatment for 14 days. On day 15, they were given an acute injection of ketamine (10 mg/kg, i.p.) and sacrificed 90 min. OFC tissue was collected for western blot analysis. Ketamine induced a significant increase in the phosphorylation of ribosomal protein S6, a downstream marker of mTOR activation ($p<.05$). We also observed that the stressed female rats exhibited a trend toward a deficit in phosphorylated S6 levels, which was restored to non-stressed control levels by ketamine administration.

To determine if JAK2 participates in the activation of the mTOR pathway by ketamine, male Sprague Dawley rats were administered ketamine (10 mg/kg, i.p.) followed 10 min later by a JAK2 inhibitor, AG490 (10 mg/kg, i.p.). Two hr after ketamine administration, the animals were sacrificed for OFC tissue collection. We examined phosphorylation of S6 as well as Akt, a signaling protein that phosphorylates and activates mTOR. We observed a trend for AG490 to block the ketamine-induced increase of phosphorylated S6. In addition, JAK2 inhibition significantly reduced ketamine-induced Akt phosphorylation ($p<.05$). These results show that ketamine activates the mTOR pathway in the OFC, and JAK2 participates in the ketamine-induced activation of mTOR.

We plan on pursuing this further by administering AG490 to male and female Sprague Dawley rats that undergo chronic intermittent cold stress.

Title: Phenotypic profiling of ketamine at different concentrations for its antidepressant signature

Authors: *O. H.-U. SCHROEDER, K. JÜGELT, B. BADER;
NeuroProof GmbH, Rostock, Germany

Abstract: Primary neuronal cultures on micro-electrode arrays have a long tradition and are well characterized and validated. There is a plethora of literature data documenting their physiological relevance in research and drug discovery. Neuronal cell cultures derived from murine and human stem cells are delivering increasing insights in neuronal micro-circuitry and are powerful tool in phenotypic drug screening. Here we studied ketamine and its effects in a frontal cortex micro-circuitry. Primary cell cultures show brain region-specific activity pattern which can be clearly distinguished by pattern recognition methods. We describe and analyze these activity patterns with 204 spike train parameters computed by our in-house software NPWaveX. In case of ketamine we performed concentration response experiments with 8 concentrations added to these neuronal cell cultures each in an accumulative manner. For each concentration we recorded in a stable phase of 30 minutes of spike train activity and calculated for these phases all 204 spike train parameter. Afterwards we performed a similarity analysis for these data records with our compound profile database of 40 approved clinical drugs at their estimated therapeutic concentrations. We separated our data records of ketamine data into low concentrations up to 100 nM and second for all above. With these two sets we performed a similarity analysis against our database. Ketamine showed clearly different induced activity patterns below 100 nM and above 100 nM. At high concentrations we saw similarities to NMDA antagonists and anesthetics. In the low concentration range we saw similarities mostly to antidepressants, which is in agreement with the discussion of ketamine and its anti-depressant action at low concentrations. As a control we tested PCP, which didn't show similarities to anti-depressant compounds, suggesting different effects on neuronal function. With this show case we demonstrate the power of phenotypic screening with the micro-electrode array technology and a comprehensive multi-variate data analysis. It still remains open to understand the functional changes of activity pattern by anti-depressants in greater detail. This we will study functional models of depression in the future.

Title: Prophylactic ketamine reduces fear expression but does not facilitate extinction

Authors: *J. C. MCGOWAN[1,2], S. C. LIM[3], M. TSITSIKLIS[2], Y. NERIA[4,5], R. A. BRACHMAN[3,4], C. A. DENNY[3,4];
[1]Barnard Col. of Columbia Univ., New York, NY; [2]Doctoral Program in Neurobio. and Behavior, Columbia Univ., New York, NY; [3]Div. of Integrative Neuroscience, New York State Psychiatric Inst. (NYSPI) / Res. Fndn. for Mental Hygiene, Inc. (RFMH), New York, NY; [4]Dept. of Psychiatry, Columbia Univ., New York, NY; [5]Dept. of Epidemiology, Columbia Univ., New York, NY

Abstract: Background: Ketamine, an *N-methyl-D-aspartate (NMDA)* glutamate antagonist, has been reported to be an efficacious antidepressant for depression and posttraumatic stress disorder, and most recently, to be a prophylactic against stress-induced depressive-like behavior. It remains unknown, however, when ketamine should be administered relative to a stressor or depressive episode in order to maximize its beneficial effects. Furthermore, it is unknown if ketamine can be prophylactic against subsequent episodes. Here, we systematically tested the utility of ketamine relative to a fear experience in order to determine the best interval for

ketamine to be administered in order to reduce fear or to prevent subsequent aversive episodes.
Methods: Using a 3-shock contextual fear conditioning (CFC) paradigm, we tested if ketamine could alter how 129SvEv mice respond to fear. Mice were administered a single dose of saline or ketamine (30 mg kg^{-1}) at varying time points before or after CFC, extinction, or reinstatement.
Results: Mice administered prophylactic ketamine 1 week before, but not 1 month before, CFC training exhibited reduced freezing behavior when compared with mice administered saline. In contrast, ketamine administration following CFC or during extinction did not alter subsequent fear expression. Interestingly, mice administered ketamine 1 h before CFC exhibited increased freezing behavior when compared with mice administered saline.
Conclusions: These data indicate that ketamine can diminish the fear response when given as a prophylactic, but not when given immediately before or after an aversive episode. Therefore, ketamine may be most useful if administered in a vaccine-like fashion in order to protect against fear-inducing stimuli.

Title: BDNF and VEGF but not GDNF are associated with an anti-suicidal response to ketamine

Authors: L. E. NEWMAN, E. M. RICHARDS, E. D. BALLARD, D. A. LUCKENBAUGH, M. PARK, P. YUAN, R. MACHADO-VIEIRA, *C. A. ZARATE, JR;
Div. Intramural Res. Program, NIMH, Bethesda, MD

Abstract: BACKGROUND: The U.S. suicide rate has not significantly changed over the past 50 years, due, in part, to limited knowledge of suicide neurobiology. An emerging body of literature suggests that the N-methyl-D-aspartate receptor antagonist ketamine, which produces a fast-acting antidepressant effect, may also elicit a rapid anti-suicidal response. Brain-derived neurotrophic factor (BDNF), vascular endothelial growth factor (VEGF) and glial-derived neurotrophic factor (GDNF) are altered in major depressive episodes and are thought to contribute to antidepressant response. Further, research suggests that plasma BDNF and VEGF levels may be associated with suicidal behavior. Given these findings, the present study aimed to

assess whether BDNF, VEGF and GDNF differed by anti-suicidal response to ketamine. METHODS: Fifty-three patients with treatment resistant depression (major depressive disorder or bipolar disorder types I or II) and current suicidal ideation received intravenous ketamine hydrochloride (0.5 mg/ kg) over 40 minutes. Suicidal ideation was assessed using the Hamilton Depression Rating Scale (HAMD) suicide item and replicated using Montgomery-Asberg Depression Rating Scale (MADRS) suicide item and the first five items of the Scale for Suicide Ideation (SSI5). Clinical assessments and blood draws occurred at 60 minutes before, 230 minutes after and one day after ketamine infusion. ELISAs were used to determine BDNF and VEGF plasma levels. Magnetic Luminex multi-analyte kit was used to measure GDNF plasma levels. T-tests were used to compare responders and non-responders across measurements where responders reported no suicidal thoughts after infusion. RESULTS: On the HAMD, baseline BDNF (p=.015) and VEGF (p=.009) were lower in anti-suicidal responders to ketamine at 230 minutes post-ketamine infusion. Responders had greater increases in BDNF (p=.005) and decreases in VEGF (p=.005) at 230 minutes. One day after infusion, responders had an increase in BDNF (p=.025). GDNF was not significantly different in responders versus non-responders to ketamine. Effect sizes suggested results of analyses using the MADRS suicide item and SSI5 were generally comparable to those using the HAMD. CONCLUSIONS: This study demonstrates that plasma levels of BDNF and VEGF but not GDNF were different in anti-suicidal responders to ketamine. While analysis is necessary to determine the mechanisms by which these molecules are altered, our results suggest that BDNF and VEGF require further investigation in the search for biomarkers related to suicide risk.

Title: Desipramine interacts potently with MK-801, but not with ketamine in behavior

Authors: *J. A. TEMPLE, T. T. TOWNER, A. ROCHA, K. A. TRUJILLO;
California State Univ. San Marcos, San Marcos, CA

Abstract: Many patients suffering from major depressive disorder (MDD) are resistant to traditional antidepressant medications such as selective serotonin reuptake inhibitors or tricyclic antidepressants. The primary pharmacological action of traditional antidepressants is thought to be acting through blockade of monoamine reuptake, however, recent evidence suggests that other neurotransmitters may be involved. Glutamate is the most abundant neurotransmitter in the brain, and research supports the idea that N-methyl-D-aspartate (NMDA) glutamate receptors might play a role in the therapeutic effect of antidepressants. Ketamine, an NMDA receptor antagonist,has promising antidepressant effects in humans, including individuals resistant to currently available medications, and this has been replicated in animal models. Ketamine produces significant side effects and is abused by some individuals, so it is unlikely to replace traditional antidepressants. It is therefore important to better understand ketamine's antidepressant effects and develop alternatives. Past work in our laboratory and others has demonstrated that the combination of an NMDA receptor antagonist with a traditional antidepressant produces a profound increase in the locomotor stimulant effect of the NMDA antagonist. This action points toward potent interactions between traditional antidepressants and NMDA receptors. In the current study we examined the locomotor effects of ketamine or MK-801 in combination with desipramine (DMI), a tricyclic antidepressant, in Sprague Dawley rats. We hypothesized that a combination of an NMDA receptor antagonist and DMI would produce a stimulation of activity greater than either drug alone. MK-801 (0.1 mg/kg) alone produced a mild stimulant effect, and DMI (5.0 mg/kg) alone produced a slight locomotor depression when compared to the saline control group. As hypothesized, the stimulant effects of MK-801 were enhanced when combined
with DMI, supporting the idea that DMI interacts with glutamatergic systems. Ketamine (10 or 30 mg/kg) alone produced a short-lived stimulation of locomotor activity. However, in contrast to MK-801, DMI inhibited the locomotor stimulant effect of ketamine. The results suggest that ketamine differs from MK-801 and other NMDA receptor antagonists in its interaction with DMI. We are investigating potential explanations for the unique actions of ketamine.

Title: Frontal EEG predictors for treatment outcome of subanesthetic - dose ketamine infusion in medication resistant depression: using wireless EEG

Authors: *T.-P. T. SU[1], Z.-H. CAO[2], M.-H. CHEN[3], C.-T. LI[3], C.-T. LIN[2];
[1]Veterans Gen. Hosp, Taipei, Taiwan; [2]Dept. of Electrical and Computer Engin. & BRC, Inst. of Electrical Control Engineering, Natl. Chia-Tong Univ., Hsin-Chu, Taiwan; [3]Psychiatry, Taipei Veterans Gen. Hosp, Taipei, Taiwan

Abstract: Objective: Intravenous infusion of low-dose ketamine, a glutamate N-methyl-D-aspartate (NMDA) receptor antagonist, was found to have a rapid and robust antidepressant effect in treatment resistance depression (TRD), which was paralleling with increased glucose metabolism in the frontal area by PET-FDG. The aim of the study is to investigate the role of frontal EEG as predictor for clinical response to Ketamine in treatment resistance depression (TRD) via a wireless EEG device. **Methods: p**atients received a randomized, controlled trial of a single dose of ketamine infusion, comparing the effect of active dose (0.2 ~ 0.5 kg/mg)(N=36, F/M=30/6, age: 47.0 ± 12.8 years) and placebo (normal saline)(N=18, F/M = 13/5, age ± SD: 51.0 ± 7.6 years). All patients received mood evaluation(HAMD_17) before and after infusion. Responder was identified (>= 50% reduction of baseline depression symptoms at 240 minutes post-infusion). Five - minute electroencephalography (EEG) was recorded via a wireless EEG device with 4 prefrontal dry-contact sensors in baseline (0 min) and post-treatment (240 min), respectively. EEG power and hemispheric asymmetry were calculated in the delta, theta, low alpha and high alpha bands. **Results:** In active dose group, we found 16 responders and 20 non-responders with HAMD_17 score reduction of 51% and 17%, respectively vs. 20% in the placebo. During pre-treatment, the EEG power analysis indicated that ketamine responders had lower relative theta and low alpha power relative to non-responders ($p < .05$). Using machine-learning technology, we classified responders and non-responders with 80.0 ± 9.8% accuracy, 81.5 ± 8.4 % sensitivity and 92.4 ± 7.6 % specificity based on EEG power features. Further, in the responders, we found that ketamine increased the low relative alpha power ($p<0.01$) and decreased its hemispheric (Fp2-Fp1) asymmetry over bilateral frontals ($p < .05$), which was observed in neither non-responders nor placebo controls. **Conclusion:** The results of this study provided the evidence of immediate changes of frontal activity may account for rapid clinical

response of ketamine and the pre-treatment frontal brain activity measured by simple EEG device might be a biomarker for better outcome prediction.

Title: Ketamine and S(+)-ketamine modulate the extracellular levels of monoamine- and amino acid neurotransmitters monitored by microdialysis in the prefrontal cortex and ventral hippocampus of awake rats

Authors: ***J. KEHR**[1,2], F. ICHINOSE[1], F.-H. WANG[1], S. SCHMIDT[1], S. YOSHITAKE[1], T. YOSHITAKE[2];
[1]Pronexus Analytical AB, Stockholm, Sweden; [2]Dept. of Physiol. and Pharmacol., Karolinska Institutet, Stockholm, Sweden

Abstract: Ketamine (Ketalar®) is currently evaluated in clinical trials for its efficacy in treatment of major depression. The objective of the study was to evaluate, by use of microdialysis, the effects of acute administration of racemic ketamine and its isomer S(+)-Ketamine on extracellular levels of neurotransmitters Glu, GABA, DA, NE, 5-HT and their acidic metabolites DOPAC, HVA and 5-HIAA in the medial prefrontal cortex (mPFC) and ventral hippocampus (vHPC) of awake rats and mice. Amino acids, monoamines, their metabolites were measured by liquid chromatography with tandem mass spectrometry (UHPLC-MS/MS). Both S(+)-ketamine (30 mg/kg) and ketamine increased the Glu levels to about 160% of controls at 40 min and 90 min, respectively. Similarly, the DA and NE levels increased to 178% and 145%, respectively, whereas the 5-HT and GABA levels were not affected. Concentrations of ketamine and S(+)-ketamine in the brain microdialysates were correlated to the levels of neurotransmitters allowing to estimate the PK/PD relationship.

Title: Repeated ketamine treatment induces sex-specific behavioral and neurochemical effects in stress-naive C57BL/6J mice

Authors: *C. THELEN[1], J. SENS[1], J. MAUCH[1], R. PANDIT[2], P. PITYCHOUTIS[1];
[1]Biol., Univ. of Dayton Dept. of Biol., Dayton, OH; [2]The Ohio State Univ., Columbus, OH

Abstract: One of the most striking discoveries in the treatment of major depression was the finding that infusion of a single sub-anesthetic dose of the N-methyl-D-aspartate (NMDA) receptor antagonist ketamine induces rapid and sustained antidepressant-like effects in treatment-resistant depressed patients and in animal models of depression. However, ketamine's antidepressant-like actions are transient and can only be sustained by repeated drug treatment. Despite the fact that women experience major depression at roughly twice the rate of men, research regarding the neurobiological antidepressant-relevant effects of ketamine has focused almost exclusively on the male sex. Notably, knowledge regarding the sex-differentiated effects, the frequency and the dose on which repeated ketamine administration stops being beneficial and becomes harmful, is limited. In the current study, we investigated the behavioral, neurochemical and synaptic molecular effects of repeated ketamine treatment (10 mg/kg; 21 days) in C57BL/6J mice of both sexes. We report that ketamine induced beneficial antidepressant-like effects in male mice, but induced both anxiogenic (i.e. decreased time spent in the center of the open field arena) and depressogenic effects (i.e. enhanced immobility duration in the forced swim test; FST) in their female counterparts. Moreover, repeated ketamine treatment induced sustained sex-differentiated neurochemical and molecular effects, as it enhanced hippocampal synapsin protein levels and serotonin turnover in males, but attenuated glutamate and aspartate levels in female

mice. Taken together, our findings indicate that repeated ketamine treatment induces opposite behavioral effects in male and female mice, and thus, present data have far-reaching implications for the sex-oriented use of this drug in both preclinical and clinical research settings.

Title: Dissociating the antidepressant-like and abuse-related effects of ketamine by selective activation of the ventral hippocampus in rats.

Authors: *G. T. COLLINS[1,3], F. R. CARRENO[1,2], D. J. LODGE[1,2], A. FRAZER[1,2,3]; [1]Dept of Pharmacol., [2]Ctr. for Biomed. Neurosci., UT Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [3]South Texas Veterans Hlth. Care Syst., San Antonio, TX

Abstract: Despite very promising rapid and sustained antidepressant effects, the use of ketamine to treat refractory depression is limited by adverse effects, including those related to its abuse. Previously, we demonstrated that activation of a circuit from the ventral hippocampus (vHipp) to the medial prefrontal cortex is both necessary and sufficient for ketamine's sustained antidepressant-like effects in rats. In order to test the hypothesis that augmentation of hippocampal activity is capable of producing a sustained antidepressant-like response without also producing abuse-related effects, we evaluated effects of L-655,708, a negative allosteric modulator of alpha-5 GABAA receptors, as these receptors are selectively expressed in the hippocampus. Similar to ketamine, systemic administration of L-655,708 produced an antidepressant-like effect in the forced swim test that was apparent one week following a single administration. Transient bilateral inactivation of the vHipp by lidocaine at the time of L-655,708 administration prevented this effect, suggesting that hippocampal activity at the time of drug administration is necessary for its sustained antidepressant-like effect. Unlike ketamine, which disrupted the inhibition of acoustic startle response by a weak prepulse stimulus intensity, L-655,708 did not affect prepulse inhibition suggesting that it does not impair sensory-motor gating. In addition, when evaluated in rats trained to self-administer ketamine, L-655,708 failed to maintain responding at levels that were any different than vehicle suggesting that it would have no (or low) abuse liability. Taken together, these findings suggest that selective activation of the vHipp by a negative allosteric modulator of alpha-5 GABAA receptors is capable of

producing a sustained antidepressant-like effect in the absence of any psychotomimetic or abuse-related effects. By identifying pharmacological interventions that recapitulate the therapeutic effects of ketamine without its psychotomimetic and abuse-related effects, it should be possible to provide novel, safe, and effective approaches for treating patients suffering from refractory depression.

Title: Ketamine inhibits pyramidal neurons in the prefrontal cortex in chloral-hydrate anesthetized rats

Authors: ***G. SHEN**, W.-X. SHI;
Dept. of Pharmaceut. and Administrative Sicences, Sch. of Pharm., Loma Linda Univ., Loma Linda, CA

Abstract: At subanesthetic doses, ketamine has been shown to be a fast acting antidepressant. However, ketamine is also psychotomimetic at the same doses. Evidences suggest that the prefrontal cortex (PFC) plays a major role in both the antidepressant and psychotomimetic effects of ketamine. To further understand the mechanism of action of ketamine, we investigated the effects of ketamine on PFC pyramidal neurons using in vivo single-cell recording in chloral hydrate-anesthetized male rats. PFC local field potentials (LFP) recorded from the same electrodes were also studied. We found that under baseline conditions, PFC LFP showed a pronounced slow oscillation (0.3-1.5 Hz) between the up and down states. The recorded pyramidal neurons fired only during PFC up states. Ketamine at doses starts from 1.25 mg/kg (i.v.) significantly reduced the firing activity of pyramidal neurons and decreased the duration of up states. Both effects were mimicked by the selective NMDA receptor channel blocker MK801 (0.125-1mg/kg), but not by Ro 25-6981(2.5-10mg/kg), an antagonist selective for NMDA receptors containing the NR2B subunit. The dopamine (DA) receptor antagonist fluphenazine (1mg/kg), previously shown to block the inhibition of PFC neurons induced by phencyclidine (an analogue of ketamine) (Gratton, Hoffer and Freedman. 1987), failed to prevent or reverse the effect of ketamine. These results suggest that ketamine inhibits pyramidal neurons by blocking

NMDA receptor, and the effect does not involve DA receptor activation. The finding that MK801 but not Ro 25-6981 mimicked the effect of ketamine further suggests that non-NR2B containing NMDA receptors play a major role in the inhibitory effect of ketamine on PFC pyramidal neurons.

Title: Effects of ketamine on dendritic spine plasticity in animal depression model

Authors: *C. S. LAI, L. H. L. NG, Y. HUANG, R. C. C. CHANG;
Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Depression is a mental disorder that is affecting 350 million people worldwide. Although the number of individuals with depression is constantly growing, the understanding of the pathogenesis of depression is still insufficient and effective treatments are lacking. Functional and structural deficits in the prefrontal cortex have been shown in major depressive disorder patients and chronic restraint stress (CRS) depression animal model, for example, retraction of dendrites, loss of dendritic spines, reduced expression of synaptic proteins, and altered synaptic transmission. Ketamine, a N-methyl-D-aspartate receptor antagonist, has gained interest as an antidepressant in recent years based on its rapid antidepressant effects in clinical studies. It has been proposed that ketamine enhances excitatory drive through disinhibition of excitatory pyramidal neurons by preferential suppression of parvalbumin interneurons and promotes synaptogenesis. However, the effects of ketamine on dendritic spine plasticity in animal depression model remain unclear. Here we used high resolution transcranial two-photon microscopy to investigate the effects of CRS and ketamine on the dendritic spine plasticity of layer V pyramidal neurons in the frontal association cortex. We found that CRS significantly increased the rate of spine elimination and reduced the rate of spine formation before the onset of depression-like behavioural symptoms. In addition, we found that ketamine reversed the effects

of CRS on dendritic spine plasticity. We will further investigate the potential involvement of parvalbumin interneurons in the antidepressant effects of ketamine on dendritic spine plasticity in the CRS depression model.

Title: Deciphering racemic ketamine, its two enantiomers mechanisms of analgesic, anesthetic and antidepressant actions

Authors: *E. F. DOMINO, M. HIRASAWA-FUJITA;
Univ. of Michigan, Ann Arbor, MI

Abstract: Racemic ketamine is well known as an N-methyl-D-aspartate (NMDA) receptor antagonist for its many useful clinical effects as well as a schizomimetic drug of abuse. Depending on its concentration or dose racemic ketamine also interacts with non-NMDA glutamate receptors, hyperpolarization-activated cyclic nucleotide channels, nicotinic, muscarinic, cholinergic and monoaminergic neuromodulation including serotonin and dopamine, kappa, delta and mu opioid receptors, nitric oxide/cGMP system, neurosteroids, and L-type Ca^{2+} channels. The concentrations of racemic ketamine for clinical and basic research studies both in vivo and in vitro very widely from 50 to 10,000 ng/mL (0.21 - 42.1 nmol/ml). Human anesthetic blood concentrations are greater than 2,000 with peak levels as high as 10,000 ng/ml. Patients return to consciousness ~1,000 ng/ml. Racemic ketamine with plasma concentrations of ~400 ng/ml via i.v. and as low as 40 ng/ml via oral administration has analgesic and antidepressant effects. Since 1963 S(+)-ketamine was found to be the more potent and effective enantiomer than R(-)-ketamine. However, in 2014, Zhang et al. (Pharmacology, Biochemistry and Behavior 116 (2014) 137-141) reported R(-)-ketamine in equal doses to be a more potent antidepressant in mice than S(+)-ketamine with no psychomotor effects.For low dose racemic ketamine, its NMDA antagonism and serotonin reuptake inhibition appear to be its major mechanisms of action. Compared to S(+)-ketamine, the less potent enantiomer R(-)-ketamine requires many additional studies for its analgesic and antidepressant effects.

Title: Sex differences in the antidepressant-like effect of low dose ketamine in C57BL/6 mice

Authors: ***A. M. DOSSAT**, K. N. WRIGHT, C. E. STRONG, M. KABBAJ;
Biomed. Sci., Florida State Univ., Tallahassee, FL

Abstract: Females are twice as likely to suffer from depression as compared to males, with many experiencing mood disorder symptoms during periods of ovarian hormone fluctuations. In addition to disparity in depression prevalence among the sexes, there are also established sex differences in antidepressant response. The NMDA receptor antagonist, Ketamine (KET), has shown promise as a rapid-acting antidepressant, exerting effects within hours of treatment. There is a growing wealth of data regarding the neural mechanisms that mediate the rapid antidepressant effect of KET (e.g., BDNF and mTOR), yet sex differences in the molecular mechanisms of KET remain to be resolved. Our group previously reported that female rats are more sensitive to the antidepressant-like effect of KET, an effect mediated by the ovarian hormones estrogen (E2) and progesterone (P4). The present study aimed to: 1) determine if C57BL/6 mice display sex differences in KET sensitivity, 2) determine the role of endogenous ovarian hormones and their respective receptor subtypes to promote KET sensitivity, 3) and examine whether the same molecular mechanisms mediating ketamine antidepressant effects described previously in male rodents also apply to females. KET (0, 1.5, or 3 mg/kg, i.p.) was delivered 30 min prior to a forced swim test. Consistent with prior reports, male mice had reduced time immobile following 3 mg/kg KET. Females had reduced immobility after treatment with both 1.5 and 3 mg/kg KET; this increased sensitivity to KET was observed exclusively in proestrus (Pro, ovarian hormone peak) and not in diestrus females (D1, ovarian hormone nadir). We then treated D1 females with an agonist for ERα (PPT), ERβ (DPN), or P4 24 h prior to treatment with KET (1.5 mg/kg). Only PPT- and DPN-treated mice exhibited less time immobile when treated with KET, suggesting that E2 increases KET sensitivity via action at both ERα and ERβ. Since many of the rapid intracellular signaling cascades initiated by KET within the

hippocampus (HPC) (e.g., PI3K, mTOR) are also influenced by E2, we used Western blot to investigate their shared targets. Our analysis revealed an ovarian hormone-mediated sex difference in levels of KET-induced phosphorylation (p-) of Akt, p-CaMKIIα, and p-mTOR at the lowest KET dose but not at the highest dose. Together these data suggest that E2 increased behavioral sensitivity to KET at the lowest dose by enhancing KET effects on PI3K, CaMKIIα, and ultimately mTOR within the HPC to enhance translation of synaptic proteins. We are now conducting functional studies to firmly implicate some of these cascades and their targets in the E2-mediated enhancement in ketamine sensitivity.

Title: Both D1 and D2 receptor-expressing striatal neurons encode positive as well as negative reward prediction error.

Authors: ***J. SHIN**, M. JUNG;
KAIST, Taejon-City, Korea, Republic of

Abstract: Basal ganglia are considered as a key structure for reward-based learning and voluntary motor control. Traditionally, D1 and D2 receptor-expressing striatal neurons have been considered to be segregated as direct and indirect pathways and play opposing roles in motor control and reward-based learning. However, recent studies have shown that the direct and indirect pathways are not clearly segregated and that the two pathways are activated concomitantly in association with movement initiation, suggesting complementary roles of the direct and indirect circuits in the functioning of the basal ganglia. In this study, under the hypothesis that the direct and indirect pathways are involved in learning from both positive and negative outcomes, we examined neural activity related to positive and negative reward prediction errors in each pathway. For this, we recorded responses of optogenetically-tagged D1 and D2 type medium spiny neurons (MSNs) in the dorsomedial striatum of D1 and D2 Cre mice, respectively, performing a probabilistic Pavlovian conditioning task. Some of D1 (10 out of 40, 25%) as well as D2 type (11 out of 39, 28%) MSNs showed significant linear response to positive reward prediction error in rewarded trials. In unrewarded trials, a larger proportion of D2 type MSNs (15 out of 39, 38%) responded significantly to negative reward prediction error compared to D1 type MSNs (7 out of 40, 17%; χ^2-test, p=0.0377). These results, although

preliminary, suggest that both D1 and D2 type MSNs encode positive as well as negative reward prediction errors, and that D2 type MSNs may play a more dominant role in signaling negative prediction error.

Title: Effect of dopamine depletion on reward prediction error signals in the striatum

Authors: *S. HUH[1,2], J. LEE[3], N. HUH[1,2], M. JUNG[1,2];
[1]Inst. for Basic Sci., Daejeon, Korea, Republic of; [2]Dept. of Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [3]Dept. of Neurobio., Howard Hughes Med. Institute,Harvard Med. Sch., Boston, MA

Abstract: Phasic discharges of midbrain dopamine neurons are correlated with reward prediction error (RPE). Traditionally, dopamine has been thought to broadcast RPE signals to different areas of the brain. However, previous studies have shown that signals necessary to computer RPE, namely chosen value and trial outcome signals, converge in dopaminoceptive regions of the brain, such as striatum and orbitofrontal cortex, suggesting local computation of RPE. To address this issue, we examined RPE-related neural activity in the dorsal striatum of rats performing a probabilistic Pavlovian conditioning task after depleting dopaminergic fibers with 6-hydroxy dopamine, which was confirmed by amphetamine-induced rotational bias. We found that the fraction RPE-coding striatal neurons in dopamine-depleted animals was no smaller than that in sham-lesioned animals. Our results support the view that RPE is computed locally in the striatum rather than being driven by dopaminergic inputs.

Title: Comparison of striatal and prefrontal neuronal activity during temporal discrimination

Authors: *J.-E. KIM[1], E. HER[2], M. JUNG[1];
[1]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [2]Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Even though the frontal cortex-basal ganglia circuit is known to play an important role in interval timing, it remains unclear how different components of this circuit contribute to interval timing. We have shown previously that some neurons in the rat medial prefrontal cortex (mPFC) convey temporal information in the form of monotonically changing (ramping) activity in a temporal bisection task, and that mPFC neuronal ensemble activity is tightly correlated with time interval discrimination behavior of the rat (Kim et al. 2013). In the present study, we examined neuronal activity in the dorsomedial and dorsolateral striatum in rats performing the same temporal bisection task and compared with the previously recorded mPFC neuronal activity. Few striatal neurons showed prolonged ramping activity found in the mPFC, and the majority were active only briefly during specific epochs of a sample interval. Also, compared to mPFC neurons, striatal neurons showed weaker tendency for logarithmic encoding of time, and their activity was less closely correlated with the animal's judgement of time. Our results show that the mPFC and striatum convey temporal information based on distinct underlying neural processes, and suggest that the mPFC plays a more important role than the striatum in controlling interval timing behavior.

Title: Value-related activity and stimulation effects of parvalbumin-expressing neurons in the orbitofrontal cortex

Authors: ***Y. JANG**[1], S. JO[2], D. KIM[3], M. JUNG[1,2,3];
[1]Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejon, Korea, Republic of; [2]Ctr. for Synaptic Brain Dysfunctions, Inst. for Basic science, Daejeon, Korea, Republic of; [3]Grad. Sch. of Med. Sci. and Engineering, Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: We have shown previously that strong neural signals for chosen value and choice outcome converge in the orbitofrontal cortex (OFC) in rats performing a dynamic foraging task. OFC neuronal activity was correlated with both bidirectional reward prediction error (RPE) and updated chosen value, suggesting local computation of RPE and value updating in the OFC. As a first step toward investigating neural circuit mechanisms of value computation in the OFC, we examined discharge patterns and stimulation effects of parvalbumin (PV)-expressing neurons in the mouse OFC. For this, we injected Cre-dependent virus carrying channelrhodopsin into the left or right OFC of PV-Cre mice, and trained them in a dynamic foraging task in a modified T-maze. We then implanted an optical fiber and an array of tetrodes in the OFC, and recorded unit signals with and without optical stimulation. We found that optogenetically-tagged PV neurons convey neural signals necessary to compute RPE, namely chosen value and choice outcome signals, when the outcome of the animal's choice was revealed. This finding suggests that PV-expressing neurons in the OFC participate in RPE computation and value updating. Unilateral optical stimulation during the reward period, during which RPE computation and value updating are thought to be accomplished, strongly suppressed discharges of optogenetically-untagged OFC neurons. However, optical stimulation had no effect on behavioral performance, and value-related neural activity in the subsequent behavioral stages was not significantly different between optically stimulated and unstimulated trials. These results indicate that locally suppressed value-related neural activity in the OFC can be readily recovered.

Title: Responses of different neuron subtypes to expected value and trial outcome in medial prefrontal cortex

Authors: *D. KIM[1,3], H. JEONG[2,3], J. LEE[2], M. JUNG[1,2,3];
[1]Grad. Sch. of Med. Sci. and Engin., [2]Dept. of Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [3]Ctr. for Synaptic Brain Dysfunctions, Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: Neuronal discharges in the prefrontal cortex (PFC) are strongly influenced by expected value and trial outcome. However, responses of different PFC neuron subtypes to these variables are not clearly understood. In this study, we monitored discharges of optogenetically identified parvalbumin (PV)- and somatostatin (SOM)-expressing neurons in the mouse prelimbic cortex during a probabilistic classical conditioning task. We found that PV and putative inhibitory interneurons (fast-spiking cells that were not optogenetically tagged) decrease and increase their firing rates following reward and punishment, respectively. By contrast, putative pyramidal neurons (regular-spiking cells that were not optogenetically tagged) were activated by reward and inhibited by punishment. SOM neurons, as a population, showed inconsistent responses to reward and punishment. During the cue and delay periods, SOM and putative pyramidal neurons showed stronger cue-specific responses than PV and putative inhibitory interneurons. In conclusion, PV neurons signaled both reward and punishment, with their response directions opposite from those of putative pyramidal cells, and SOM neurons and putative pyramidal neurons conveyed expected value signals.

Title: Effect of optogenetically stimulating mossy fiber terminals on spatial firing of CA3 neurons

Authors: *J. LEE[1,2], E. CHO[1], Y. KANG[1], J. LEE[1], M. JUNG[1,2];
[1]Ctr. For Synaptic Brain Dysfunctions, IBS, Daejon-City, Korea, Republic of; [2]Biol. Sci., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: It is unclear whether and how discharges of dentate gyrus (DG) granule cells shape spatial firing of CA3 neurons in behaving animals. To investigate this matter, we injected Cre-dependent virus carrying a channelrhodopsin-2 variant (ChETA) to the dorsal DG of Rbp4-Cre mice that were trained to navigate a circular track to obtain water reward at two opposite locations. We then implanted an optical fiber and an array of tetrodes in CA3 region, and examined effects of optogenetically stimulating mossy fiber terminals on spatial firing of CA3 neurons. We found that some CA3 neurons could be reliably activated by optogenetic stimulation of mossy fiber terminals. As a consequence, their spatial firing on the maze was changed during optogenetic stimulation. Further, a subset of them maintained altered spatial firing even after turning off the stimulation. These results indicate that optogenetic stimulation of mossy fiber terminals can drive discharges and influence spatial firing of CA3 neurons in behaving animals. It is difficult to directly map our findings to effects of granule cell discharges on CA3 neuronal activity under natural conditions, because our stimulation is likely to activate a large number of mossy fiber terminals simultaneously. To address this issue, examining effects of inactivating DG granule cell inputs on CA3 neuronal activity is currently under way.

Title: Spatial sequence-dependent discharges of hippocampal neurons

Authors: *B. BHATTARAI[1,2], J. W. LEE[2], M. W. JUNG[1,2];
[1]Korea Advanced Inst. of Sci. and Technol., Daejeon 34141, Korea, Republic of; [2]Ctr. for Synaptic Dysfunctions, Inst. for Basic Sci. (IBS), Daejeon 34141, Korea, Republic of

Abstract: In order to investigate hippocampal neural substrates of sequence memory, we recorded CA1 neuronal activity in rats performing a spatial sequence discrimination task. The maze contained a figure 8-shaped section through which the rats could navigate in one of four different spatial sequences (left-left, left-right, right-left and right-right) to obtain water reward. Each session consisted of four blocks of trials that were associated with four different correct sequences. The order of correct block sequences was pseudo-randomly determined, and each block consisted of a training (5 trials) and a test (15 trials) phase. We found three types of CA1 neural activity that conveyed sequence information. First, place fields in the common part of the maze were completely or partially remapped across different blocks. Second, neuronal population vector during the delay period (2-s time period before the onset of navigation through the figure 8-shaped section) changed across blocks. Third, a brief (~400 ms) and rapid replay of a particular place cell sequence during the period of immobility was found to be correlated to the place cell sequence in the current block more than expected by chance. Our results show that CA1 has multiple mechanisms for conveying spatial sequence information. It remains to be determined how they are related to remembering and generating spatial sequences.

Title: Inactivation of dorsal CA1, but not dorsal CA3, impairs value learning in a dynamic foraging task

Authors: *Y. JEONG[1,2], J. LEE[1,2], J. LEE[2], M. JUNG[1,2];
[1]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of; [2]Ctr. for Synaptic Brain Dysfunctions, Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: We have shown previously that dorsal CA1 of the rat hippocampus conveys robust value signals. Here we examined behavioral effects of inactivating dorsal CA1 and CA3 on value-based decision making. We injected Cre-dependent *hM4Di* virus bilaterally into dorsal CA1 and CA3 of Camk2a-Cre and Grik4-Cre mice, respectively, and trained them in a dynamic two-armed bandit task. The mice were then tested in the task following clozapine-N-oxide (CNO, 5mg/kg, i.p.) or vehicle (DMSO) injection. A reinforcement learning model-based analysis revealed that learning rate (α) was slightly, but significantly lower in CNO- compared to vehicle-injected Camk2a-Cre mice. However, the randomness in action selection (β) was not significantly different between the two animal groups. Consistent with these results, the proportion of rewarded trials was significantly lower in CNO- compared to vehicle-injected Camk2a-Cre mice during the dynamic state (early trials after changing reward probabilities), but not during the steady state (late trials after changing reward probabilities). No significant effect of CNO injection was found whatsoever in Grik4-Cre mice. These results show that inactivation of dorsal CA1, but not CA3, impairs value learning without influencing value-dependent action selection. Our results suggest the involvement of dorsal CA1 not only in episodic learning, but also in incremental value learning.

Title: Assessment of working memory and monoamine neurotransmitters in methamphetamine-treated adult male rats

Authors: *A. GUTIERREZ[1,3], C. V. VORHEES[2,4], M. T. WILLIAMS[2,4];
[1]Neurosci. Grad. Program, [2]Div. of Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [3]Col. of Med., [4]Dept. of Pediatric Neurol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Chronic methamphetamine (MA) abuse produces long-term cognitive deficits on learning and memory (L&M). We have demonstrated that allocentric L&M in rats is disrupted by treatment with a neurotoxic regimen of MA as assessed using the Morris Water Maze (MWM). Human studies also demonstrate that long-term MA usage negatively impacts working memory. Rodent models, however, have only demonstrated subtle or transient effects on working memory. The aim of this study was to examine whether a neurotoxic binge MA model (4 x 10 mg/kg at 2 h intervals) in adult male Sprague-Dawley rats would result in deficits in working memory. Two separate experiments were conducted. Rats were treated with MA or Saline and allowed to recover for 2 weeks. In the first experiment, a MWM matching-to-sample (MTS) procedure was used with one sample trial and two recall trials given each day for 6 days. The first recall trial occurred immediately after the sample trial, while the second recall trial occurred 30 min after the sample trial. In the second experiment, brain tissue was collected for analysis of monoamines 2 weeks after treatment. Monoamines were analyzed by HPLC-ECD. In the MTS task, a significant effect of MA was detected at the time point immediately following the sample trial, i.e., animals treated with MA were negatively affected in their ability to find the platform compared with controls. Animals treated with MA also performed worse than controls at the 30 min time point, although this only approached significance. Further analysis revealed that animals treated with MA had more difficulty switching strategies as evidenced by spending significantly more time in quadrants where the platform resided the previous day. Analysis of monoamines showed significantly decreased levels of dopamine and serotonin in the dorsal striatum and nucleus accumbens. Serotonin levels were also significantly decreased in the hippocampus. These data provide a foundation to examine the mechanism underlying working memory deficits following MA neurotoxicity.

Title: Functional Interaction between Orexin 2 and CB1 receptors within the ventral tegmental area in the lateral hypothalamic-induced place preference in the rats

Authors: *A. KASHEFI[1], M. MORADI[2], A. HAGHPARAST[2], M. ZABIHI[3];
[1]Univ. De Brasilia, Brasilia, Brazil; [2]Neurosci., Shahid Beheshti Univ. of Med. Sciences, Tehran, Iran, Tehran, Iran, Islamic Republic of; [3]Islamic Azad Univ. of Semnan, Semnan, Iran, Islamic Republic of

Abstract: Lateral hypothalamus (LH) orexinergic system has direct connections with the ventral tegmental area (VTA) and this areas have a key role in the acquisition of conditioned place preference (CPP) induced by chemical stimulation of the LH. Nevertheless, it remains unknown what is the function of two kinds of orexin receptors and the interaction between the orexinergic and cannabinoid systems in the reward circuit. In this study, we tried to clarify the involvement of orexin-2 (OX2) and CB1 receptors within the VTA in development of CPP after chemical stimulation of the LH by carbachol. Rats were implanted by two separate cannulae into the LH and VTA, unilaterally. The CPP paradigm was done; conditioning scores and locomotor activities were recorded by Ethovision system. Results showed that administration of TCS OX2 29 as a selective OX2 receptor antagonist (1, 3 and 10 nM/0.3 µl DMSO) and AM251 as a selective CB1 receptor antagonist (5, 25 and 125 µM/0.3 µl DMSO) into the VTA just 5 min prior to microinjection of carbachol (250 nM/0.5 µl saline) into the LH during the 3-day conditioning phase, could inhibit the development of CPP. On the other hand, concurrent injection of effective doses of TCS OX2 29 and AM251 into the VTA could reduce conditioning scores significantly. In addition, ineffective doses of both antagonists into the VTA concurrently did not have any effects on the LH-induced CPP. Our findings showed that OX2 and CB1 receptors have a critical role in modulating the reward circuit in the VTA. Moreover, results of this study suggest that cannabinoid and orexinergic systems within the VTA act through the same post receptor mechanism to show the rewarding effects of LH stimulation in the rats.

Title: Disrupted brain networks in obesity and alcohol use disorder: a data-driven graph theory approach

Authors: *K. BAEK[1,2], P. KUNDU[3], V. VOON[2];
[1]UNIST, Ulsan, Korea, Republic of; [2]Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom; [3]Departments of Radiology and Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The efficient organization and communication of brain networks underlies cognitive processing and pathological behaviors. However, few studies have focused on whole-brain networks in the maladaptive consumption behaviors such as obesity and alcohol use disorders. Here we use a novel multi-echo resting state functional MRI technique along with a data-driven graph theory approach to assess global and regional network characteristics in obesity, alcohol use disorder (AUD) and binge drinking (BD). Multi-echo resting state functional MRI scans were taken from 40 obese subjects, 39 AUD subjects, 61 BD subjects and their matched healthy control groups. The normalized correlation across 90 regions of interest (ROI) from the Automated Anatomical Labeling template was estimated, and global and regional network properties were computed in the binarized networks. Group difference in region-to-region connectivity was assessed using Network Based Statistics. We show that obese subjects have significantly reduced local efficiency and modularity exhibiting disrupted local clustering and small-world network properties. Obese subjects also showed decreased connectivity of cortico-striatal- thalamo-cortical networks related with motor function along with increased nodal degree in visual cortices. Subjects with alcohol use disorders showed significantly increased network assortativity along with decreased connectivity of both motor and prefrontal cortico-striatal networks. That subjects with binge drinking lacked significant differences from healthy volunteers suggests a role for chronic alcohol exposure in mediating these findings. Using a data-driven graph theory analysis approach, we highlight impairments in cortico-striatal networks across both obesity and alcohol dependence. These findings are consistent with theories of habit formation implicating a shift towards putaminal regions. Alterations in brain networks may act as potential biomarkers and therapeutic targets in disorders of addiction.

Title: Trace fear conditioning can affect previously acquired context memories.

Authors: ***D. S. REIS**, E. K. ROTONDO, F. J. HELMSTETTER;
Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: It is generally accepted that prior experience can have a significant impact on subsequent learning. This can be seen in work on fear generalization in which prior fear conditioning can induce generalized fear responses to stimuli that were never explicitly paired with an aversive stimulus but are similar, in various ways, to the paired stimuli. How prior experience can influence exactly what is being learned during subsequent tasks remains less clear. We compared the effects of training with trace fear conditioning (TFC), in which the pairing of an auditory conditioned stimulus (CS) with an aversive foot shock (UCS) is separated by a brief stimulus free period, or explicitly unpaired presentations of the CS and UCS, on the behavioral expression of previously acquired contextual memories. On day 1 (L1) in context A (CXT A), animals were given 1 of 4 different experiences. They either remained in the home cage (HC), or received an unsignaled foot shock immediately upon being placed into CXT A (IMM), shock after a 180s delay (CFC), or not at all (CE). These treatments allowed us to delineate the effects of a second learning experience on groups of animals that learned different things about CXT A. Rats were given TFC or unpaired CS/UCS presentations as a second learning procedure (L2) in a novel context (CXT B) 24 hours after L1. Memory for the L1 training experience was tested in CXT A 48 hrs after L2 training. Previous work has shown that time spent in the training context prior to foot shock presentation is required for the formation of a context fear memory. For example, foot shock presentation 180s after being placed in the training context but not when presented immediately results in robust context freezing 24 hrs later. Our results support this immediate shock deficit but only when rats received unpaired CS/UCS presentations as L2. In comparison, when given TFC as L2, rats given immediate shock at L1 showed fear responses when tested in CXT A. Interestingly, no differences were found in CXT A freezing for the context exposure (CE) group, regardless of L2 treatment suggesting that, in general, the way in which later learning can influence the expression of prior context memories may depend on what was learned during those previous experiences. Current work is investigating the contributions of the amygdala, hippocampus and prefrontal cortex in mediating this effect.

Title: Exploring contributions of stimulus modality and stimulus-stimulus contingencies to the cortical organization of remote fear memory

Authors: *E. K. ROTONDO, D. S. REIS, N. C. FERRARA, J. C. CICHON, F. J. HELMSTETTER;
Psychology, Univ. of Wisconsin- Milwaukee, Milwaukee, WI

Abstract: Long-term memories may undergo *systems consolidation*, a gradual transition to distributed neocortical memory storage that develops through time-dependent changes in cortico-cortical functional connectivity. How the specific information encoded at the time of learning shapes the organization of this remote form of memory in the brain is not well understood. Here we begin to examine modality-specific and cross-modal involvement of secondary sensory cortices in remote fear memories by manipulating the modality of and predictive relationship between multiple sensory cues at the time of learning. Specifically, using second-order fear conditioning with discrete auditory and visual cues, learning-dependent neural plasticity in secondary auditory (AuV/TeA) and visual (V2L) cortices was examined. Time-dependent increases in the expression of the synaptic marker synaptophysin were observed as a function of conditioning with auditory and visual stimuli in AuV/TeA and V2L, respectively, which is consistent with the idea that patterned changes in cortical synaptic connectivity reflect the specific content of stored information. Functionally**,** remote retrieval of either the first-order auditory conditional stimulus or the second-order visual conditional stimulus was associated with significantly greater expression of the neuronal activity marker zif268 in AuV/TeA relative to recent retrieval controls. These data suggest that secondary sensory cortices may store modality-specific information at remote time points, but may also exhibit cross-modal recruitment at the time of retrieval if the initial learning involves the association of multiple cues. Together, these results support an encouraging new approach to understanding the organizational principles of neocortical memory storage.

Title: Medial geniculate nucleus input modulates amygdala encoding during fear memory discrimination

Authors: *N. FERRARA, P. K. CULLEN, E. K. ROTONDO, F. J. HELMSTETTER; Psychology, Univ. of Wisconsin--Milwaukee, Milwaukee, WI

Abstract: The generalization of fear is characterized by abnormal fear responding to safety cues and elevated amygdala activity, and is common in individuals diagnosed with post-traumatic stress disorder. Differential fear conditioning provides a way to measure learned fear responses, as well as the factors contributing to the generalization of fear. During conditioning, two auditory cues are presented where one is consistently paired with a foot shock (CS+) and one is never paired with shock (CS-). Differential responding between cues demonstrates discrimination, while heightened responding to the CS- is considered generalization of fear. Discrimination learning depends on a network of brain structures, with a majority of the work focusing on elevated amygdala activity as a critical component underlying generalization. Synapses in the amygdala, representing information from auditory cortex (ACx) and medial thalamus (MgN), undergo plastic changes in response to fear conditioning and are major contributors to the degree of fear expression to both CS+ and CS-. Heightened ACx or MgN presynaptic input contributes to elevated amygdala activity underlying fear generalization. However, the contribution of MgN and ACx inputs to the amygdala leading to generalization remain unclear. Recent work illustrates that ACx activity may not be the primary factor underlying elevated responding to safety cues, while the MgN has been implicated in the encoding of a differential fear memory and generalization of auditory cues. The effects of MgN inhibition on amygdala activity as well as the molecular mechanisms underlying MgN-dependent fear memory discrimination and generalization have not been directly tested. Persistent fear responding is mirrored by surface expression of amygdala AMPA receptors, which can serve as molecular markers for fear memory formation. Amygdala AMPA receptor are immediately post synaptic to MgN terminals, providing an approach to measure thalamo-amygdala synaptic modifications related to fear learning. Here we characterize the role of the MgN in supporting differential fear memory formation and expression and looked at molecular mechanisms underlying increases in fear expression to CS-. We found that protein synthesis dependent plasticity in the MgN is critical for the consolidation of a differential fear memory as well as the update from low to high generalization of fear. Furthermore, MgN protein synthesis modulates amygdala synaptic scaffolding and AMPA receptor expression underlying fear memory formation.

Title: Behavioral expression of a fear memory is maintained by neural activity in a distributed brain network throughout CS presentation

Authors: *P. K. CULLEN[1], N. C. FERRARA[2], S. E. PULLINS[2], J. M. HINTZ[2], F. J. HELMSTETTER[1];
[1]Psychology, Univ. of Wisconsin, Milwaukee, Milwaukee, WI; [2]Univ. o f Wisconsin, Milwaukee, Milwaukee, WI

Abstract: It is well accepted that the amygdala is required for the acquisition, retrieval and expression of a conditional fear memory. For instance, presentation of the conditional stimulus (CS) elicits neural spiking in the lateral amygdala (LA) that correlates with fear acquisition/expression. However, behavioral expression of fear persists well beyond bursts of LA activity, suggesting that LA activity does not maintain behavioral fear responses during the entire CS period. Recent evidence suggests that activity of the prelimbic cortex (PL) is required for conditional fear expression and that PL unit activity persists throughout presentation of the CS at retrieval. Fear expression also depends on activity in both the medial central nucleus of the amygdala (CeM) and the ventrolateral part of the periaqueductal gray (vlPAG). However, our present understanding of LA, PL, CeM, and vlPAG function comes primarily from electrophysiological recordings and pharmacological manipulations or lesions that render the structure(s) impaired for an imprecise duration of time following drug administration. To understand the specific time-dependent role of the LA-PL-CeM-vlPAG circuit during memory retrieval, activity within each of these regions was optogenetically inhibited using virally-mediated expression of the light-driven proton pump ArchT (AAV-CAG-ArchT-GFP) in a temporally precise manner during auditory CS presentations. Animals were trained with auditory fear conditioning and exposed to two 30-second white noise CS presentations during a retrieval session. In one condition, laser stimulation occurred simultaneously with the CS (100% temporal overlap). In a second condition, animals received an equal amount of laser stimulation that was shifted starting 15-seconds after CS onset (50% temporal overlap). We found that: 1) inactivation of LA only impaired CS freezing in the 100% overlap condition; 2) inactivation of the PL, CeM and vlPAG impaired CS freezing in both the 100% and 50% overlap conditions; 3) inactivation of ArchT-containing CeM inputs terminating in the vlPAG during CS presentation impaired freezing. These results indicate that fear expression is triggered by initial LA activity and

maintained by persistent neuronal firing of the PL, CeM and vlPAG. By achieving within-CS temporal resolution of neural inhibition, the current study provides new insight into the neural network responsible for maintaining behavioral control during memory retrieval. A deeper understanding of how fear is maintained through a distributed neural network will provide new therapeutic targets for aberrant fear memory expression exhibited in many psychiatric disorders.

Title: Activity-dependent protein degradation and age-related memory impairment.

Authors: *S. E. PULLINS, P. K. CULLEN, N. C. FERRARA, J. R. MOYER, Jr., F. J. HELMSTETTER;
Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Humans and rats exhibit deficits in episodic/explicit memories with normal aging. Recent research implicates ubiquitin proteasome system (UPS)-mediated protein degradation as a key factor in the synaptic plasticity supporting memory formation and retrieval. In rats, normal aging leads to decreased basal proteolytic activity in several brain structures known to support acquisition and retrieval of trace fear conditioning (TFC) memory. Using adult (3 months), middle-aged (15 months), and aged (22 months) F344 rats, we show that UPS-mediated protein degradation in the amygdala and prefrontal cortex is decreased in aged rats following TFC memory retrieval, as evidenced by reduced phosphorylation of RPT6, a known regulator of 26S proteasome activation. Additionally we show decreased clearance of polyubiquitinated protein in the amygdala of aged rats following retrieval. Compared to young adult animals, aged rats also displayed altered levels of a known target of the AMPA receptor associated synaptic scaffolding protein SHANK – a UPS target – following retrieval. Finally, we investigated whether impairing proteolysis in the amygdala of young adult rats would lead to a deficit in TFC. Pre-training infusions of the proteasome inhibitor clasto-Lactacystin ß-lactone into the amygdala of adult rats significantly impaired trace fear memory when tested 24 hours following acquisition. These data suggest that the deficit in TFC observed in aged rats may be due, in part, to a decrease in

plasticity-dependent protein degradation. These experiments augment the growing body of literature indicating that stimulation of the proteasome could offer a novel means of treating cognitive decline during normal aging.

Title: Activity-dependent protein degradation and GluR2 endocytosis in the amygdala regulate reconsolidation-dependent reevaluation of a contextual fear memory

Authors: N. C. FERRARA[1], T. J. JAROME, 53201[1], P. K. CULLEN[1], J. L. KWAPIS[1], *F. J. HELMSTETTER[2];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Deptartment of Psychology, Univ. of Wisconsin Milwaukee Dept. of Psychology, Milwaukee, WI

Abstract: Memories for associations learned during Pavlovian fear conditioning are rapidly acquired, robust and long lasting and provide an ideal model for studying long-term fear memory formation and storage. During training, a conditional stimulus (CS) acquires aversive value through pairings with an unconditional stimulus (UCS), and memory for this association is stored through a protein-synthesis dependent consolidation. During retrieval, re-exposure to the CS renders the memory temporarily labile and new protein synthesis is necessary for the transfer of the memory back into long-term storage, a process called reconsolidation. Reconsolidation is thought to occur each time a memory is retrieved, providing a potential means of intervention to disrupt or modify established fear memories. The reconsolidation process is dependent on protein degradation, *de novo* protein synthesis, and GluR2-AMPA receptor trafficking in the amygdala and occurs in the presence of new information during the retrieval session (e.g., Jarome et al., 2015). Interestingly, the association learned during fear conditioning can be updated or "reevaluated" during retrieval, allowing for strengthening or weakening of the original memory. Very little is currently known about the mechanisms responsible for modification during retrieval and how it relates to reconsolidation. Here we characterized behavioral and molecular mechanisms underlying contextual fear memory updating in rodents by

modifying the memory during a brief retrieval session. We trained rats to associate a novel context (CS) with a foot shock (UCS) and the following day changed the value of the UCS by weakening the shock intensity. Surprisingly, we found the presentation of two foot shocks of weaker intensity during retrieval heightened fear responding on a later test, suggesting that the addition of new information during retrieval modifies the original aversive value which is reflected in elevated fear expression. Furthermore, we found that inhibiting proteasome activity or GluR2 endocytosis in the amygdala prevented memory strengthening, suggesting that updating was likely occurring through reconsolidation of the original memory trace. These results may have important therapeutic implications for memories for traumatic events that are resistant to modification. In future experiments, we plan to determine if destabilization occurs in the same cells that are activated during retrieval dependent reevaluation.

Title: Autophagy induction enhances memory destabilization beyond reconsolidation boundary

Authors: *M. H. SHEHATA[1,3], Q. ZHAO[1,3], K. ABDOU[1,3], M. MATSUO[2], H. NISHIZONO[2,3], K. INOKUCHI[1,3];

Abstract: There is a wide interest in memory reconsolidation as a target to treat pathogenic memories; despite, mechanistically vague boundary conditions have been described that constrain the likelihood of a memory from being destabilized after recall. It has been reported that inhibiting synaptic protein degradation prevents memory destabilization. However, whether the reverse relation is true and whether it can be utilized to overcome these boundary conditions is still unknown. Here, we show that induction of autophagic protein degradation enhances synaptic destabilization in a long-term potentiation (LTP)-reconsolidation model in freely moving rats, and enhances fear memory destabilization in a contextual fear reconsolidation paradigm in mice. Furthermore, autophagy induction overcomes a boundary condition for auditory fear memory reconsolidation. The autophagy induction effects are dependent on AMPA receptor endocytosis and correlates with its degradation in ensemble neurons. Our results complement the evidence for a causal relationship between protein degradation and memory destabilization, give more insight on the mechanisms of memory destabilization and the boundary conditions, and suggest autophagy inducers as a useful tool for the treatment of memory-related psychological diseases such as post-traumatic stress disorder (PTSD).

Title: Adult neurogenesis in maintenance of the hippocampal learning capacity

Authors: *M. ALAM[1,3], T. KITAMURA[4], Y. SAITOH[1,3], N. OHKAWA[1,3], T. KONDO[2], K. INOKUCHI[1,3];

Abstract: Saturation of the hippocampal long-term potentiation (LTP), a cellular basis of learning and memory, impairs hippocampus-dependent learning. This impairment recovers in parallel with the LTP decay. However, the driving factor that regulates the recovery of learning capacity remains unclear. Neurogenesis occurs in the brain of adult mammals throughout life and is involved in the decay process of hippocampus-dependency of memories. Here we show that adult neurogenesis plays a crucial role in the maintenance of hippocampal capacity for learning. Delivery of repeated high frequency tetanic stimulation (rHFS) to perforant pathway saturated the dentate gyrus LTP and impaired the learning capacity in contextual fear conditioning (CFC), a hippocampus-dependent learning task, whereas it had no effect on the hippocampus-independent learning. The impaired learning capacity completely recovered after 14 days when LTP decayed. Ablation of neurogenesis by X-ray irradiation retained the hippocampal LTP and delayed the recovery of learning capacity from the saturation. Similar results were obtained when repeated maximum electroconvulsive shock was employed to saturate the hippocampal LTP. Moreover, enhancing neurogenesis by running wheel speeded up the decay of LTP from the rHFS-induced LTP saturation and exhibited an earlier recovery of learning in the CFC task. These results indicate that the learning capacity gradually recovered in parallel with the gradual decay of LTP and decreased neurogenesis delayed the recovery of learning by retaining the rHFS-evoked LTP level whereas increased neurogenesis accelerates the recovery process. Our findings unravel a new role for neurogenesis, suggesting that adult neurogenesis is crucial for renewal of the hippocampal memory circuits.

Abstract: Memory retrieval process is imbued with multisensory cues such as sights, sounds, smells and tastes, which lead to its prior memories and emotions. These distinct units of information that have been stored in the brain are sometimes reactivated excessively and interact to generate a new associative memory, which can leads to psychiatric disorders. Previous studies suggested that retrieval-induced reactivation of emotional memory plays a potential role in the interaction with pre-existing memory.
However, it has been uncertain at the level of neuronal ensemble how two distinct memories are reorganized to generate and integrate an associative memory.
Here, to address this issue, we conceived of the combination of two amygdala-dependent behavioral paradigms, conditioned taste aversion task (CTA) and auditory cued fear conditioning (AFC). Mice were trained in CTA and AFC independently, where animals did not associate these two paradigms. After each memory was formed, animals received, in the reactivation session, synergistic and repetitive presentations of the condition stimuli (CS) for CTA and AFC, which induced the retrieval of both associative memories at the same time. We found that presenting the CS of CTA triggered the condition response of AFC such as freezing-like behavior, suggesting that the reactivation session leads to the interaction between CTA and AFC memories. After undergoing both CTA and AFC retrievals, Arc/Homer1a catFISH analysis elucidated an increase in the ratio of co-sharing neuronal subpopulation (overlapping ensemble) in the basolateral amygdala (BLA). We then optogenetically silenced AFC ensemble in BLA, which was specifically activated in the conditioning, during the reactivation session by applying the tet-OFF lentiviral vector encoding archaerhodopsin (ArchT) to the c-fos tTA transgenic mice. Suppression of the AFC ensemble activity impaired the freezing-like behavior that was, in control case, triggered by presenting the CS of CTA and decreased the proportion of the overlapping ensemble between the CTA-retrieval and AFC-retrieval ensembles. We also found that optogenetic silencing the activity of the overlapping ensemble, which was generated by repeated activation during AFC and CTA retrieval, was sufficient to reduce the freezing-like behavior. Importantly, original memories in both CTA and AFC were intact through the whole test sessions but only the linkage between CTA and AFC memories was interrupted.
Taken together, our findings provide new insight into a specific neuronal ensemble shared with two independent memories, which was generated through multiple reactivations, subserve an associative memory.

Title: Optical manipulation of parietal association cortex regulates contextual fear memory

Authors: *A. SUZUKI[1,2], S. KOSUGI-USHIJIMA[1,2], N. OHKAWA[1,2], M. MATSUO[3], H. NISHIZONO[3,2], K. INOKUCHI[1,2];

Abstract: In the usual contextual fear conditioning, the animals have two types of learning [(1) learning the context (CS) and, (2) learning the association between the context (CS) and the shock (US)]. Because these types of learning co-occur during conditioning, it is difficult to identify brain regions required for CS-US association. In this study, we modified behavioral paradigm, context-pre-exposure facilitation effect (CPFE) paradigm, in which the mice received paired or unpaired presentations of the CS and US during conditioning. Using this behavioral paradigm, we performed Arc CatFISH method to detect brain regions required for the CS-US association and found that parietal association cortex (PtA) responded to CS-US signals. To elucidate roles of PtA in CS-US association, we examined whether manipulating the PtA activity by optogenetics technique generate artificial CS-US associative memory. By employing lentivirus harboring 3GTRE-ChR2-EYFP and cfos-tTA transgenic mice, we labeled a subset of PtA neurons that responded to CS context. Optical stimulation of these PtA neurons, when mice received footshock in a different context, generated a false memory, in which mice showed a freezing response in the initial context where mice did not received footshock. These finding

suggest that optical stimulation of the PtA cellular ensemble is capable of generating an artificial CS-US associative memory. Furthermore, we asked whether manipulating the PtA activity by optogenetics technique regulates CS-US associate memory that has been once formed. We labeled with ArchT-EYFP a subset of PtA neurons of cfos-tTA transgenic mice that responded during reactivation. Optically silencing these PtA neurons, when mice were exposed to CS context 24h after reactivation, suppressed associative memory. However when mice were again tested 24h later, mice showed high freezing, indicating that PtA regulates memory retrieval. On the other hand, 15min optical silencing immediately after CS exposure 24h after reactivation suppressed fear memory when mice were tested 24h later without optical silencing, indicating that manipulating the PtA activity by optogenetics technique erase CS-US associative memory. From these findings we concluded that optical manipulation of PtA activity regulates contextual fear memory.

Title: DREADD-mediated inhibition of hippocampal neurons during memory retrieval and consolidation

Authors: ***J. N. KRUEGER**[1], A. P. CRESTANI[3], L. M. STRAEHLE[1], B. J. WILTGEN[1,2]; [1]Ctr. for Neurosci., [2]Dept. of Psychology, Univ. of California Davis, Davis, CA; [3]Neurosci. Grad. Program, Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil

Abstract: The current experiments examined the effects of DREADD-mediated inactivation of hippocampal neurons on memory retrieval and consolidation. To do this, we expressed the inhibitory DREADD hM4di (driven by the synapsin1 or CaMKII promoter) in the dorsal hippocampus of wild-type mice. Two weeks after AAV infusions, animals were trained in contextual fear conditioning. For the retrieval experiments, animals were tested one hour after receiving an IP injection of either CNO or DMSO. For the consolidation experiments, animals were given water bottles containing either CNO or DMSO 1 day after training. Ten days later, they were tested. Freezing was used as an index of memory and expression of the immediate-

early gene (IEG) c-Fos was used as a measure of neuronal activation. As expected, Syn-Hm4Di animals treated with CNO showed impaired memory retrieval and consolidation. Unexpectedly, these same animals showed significantly higher levels of c-Fos expression (3x) than their DMSO-treated counterparts. Our results are consistent with a recent paper that demonstrated promoter-specific effects of Hm4Di inhibition in the dorsal hippocampus (A. Lopez et. al, 2016). In this paper (and in our experiment) the behavioral effects of synapsin1-promoted Hm4Di are likely due to silencing of inhibitory neurons, which then increases the activity of pyramidal cells (A. Lopez et. al, 2016). In our CaMKII-Hm4Di experiment, we found that animals receiving CNO did not exhibit impaired memory retrieval despite showing significantly lower levels of c-Fos expression than their DMSO-treated counterparts. This lack of an effect may reflect compensation by other brain regions at the time of testing as has been reported by other groups when prolonged silencing methods are used (Goshen et. al., 2011) Studies are currently being conducted to determine if CaMKII-hM4Di mediated silencing impairs memory consolidation.

Title: Interactions between the hippocampus and cortex during remote memory retrieval

Authors: ***A. HAMIDI**[1], Y. OTA[2], D. MARDINI[2], S. L. SUAREZ[2], B. J. WILTGEN[3]; [1]Univ. of California Davis, Davis, CA; [3]Dept. of Psychology and Ctr. for Neurosci., [2]Univ. of California, Davis, Davis, CA

Abstract: According to the theory of systems consolidation, the brain circuits required to successfully retrieve a memory depends on the age of the memory itself. Specifically, the theory claims that newer (recent) memories are hippocampal dependent while older (remote) memories are hippocampal independent. The claim that the hippocampus plays a temporally-limited role in memory retrieval is based partly on data from patients with hippocampal/medial temporal lobe

(HPC/MTL) damage who exhibit temporally-graded retrograde amnesia. This observation led to the idea that, over time, memories undergo a stabilization process (i.e. consolidation) which transforms or transfers the initial representation from the hippocampus to cortical networks. This transfer is thought to depend upon the hippocampus reinstantiating specific patterns of neuronal activity in corresponding cortical networks. Our group recently provided direct evidence (Tanaka et al., 2014) that reactivation of a specific ensemble of hippocampal neurons is necessary (1) for the successful retrieval of a recently formed memory and (2) for the normal reactivation of cortical (entorhinal, retrosplenial, and perirhinal) ensembles. Using similar methods, the current study aims to extend these findings by testing the time-dependent involvement of the hippocampus at remote time points. To do this, we performed bilateral infusions of a viral construct containing a double-inverted floxed version of the light-sensitive proton pump, archearhodopsin (FLEX-ArchT). Following a one-week recovery period, mice were handled daily for 5-7 days, then taken off of doxycycline for three days prior to context fear training. During context fear training, active neurons expressed ArchT and were tagged with H2B-GFP. Immediately after training, mice were placed back on doxycycline to prevent any non-specific tagging and were left undisturbed until testing day. 14 days later, mice were randomly assigned to a Laser-ON or a Laser-OFF group and tested in the same training context. Our preliminary data suggest that selective silencing of the tagged HPC ensemble (Laser-ON group) at 14 days does not impair memory retrieval, compared to the Laser-OFF group. Subsequent analyses will include a characterization of reactivation in the hippocampus and in corresponding cortical regions to determine which brain circuits are most critical in the successful retrieval of remote memories.

Title: Microcircuit level effects of MEK inhibitors on threat memory disruption

Authors: A. BATTLE[1], S. GILES[1], J. COYNER[2], R. J. URSANO[3], *L. R. JOHNSON[4]; [1]TRI IHBI QUT, Brisbane, Australia; [2]Program in Neurosci., USU Sch. of Med., Bethesda, MD; [3]Ctr. for the Study of Traumatic Stress, USU Sch. of Med., Bethesda, MD; [4]Translational Res. Institute, IHBI, QUT, Brisbane, Australia

Abstract: Memories formed as a result of threatening events can have debilitating effects on quality of life. Solutions to treat these memories are limited to behavioural therapies and non-specific pharmacotherapy. Neither behavioural therapies nor current pharmacotherapy have a lasting effect on memories and quality of life. Pavlovian threat (fear) conditioning results in changes to neural plasticity in the amygdala, specifically in the dorsal subdivision of the lateral amygdala (LAd), where plastic changes to the microcircuitry occur. Plastic changes include increases in the number of neurons expressing pMAPK/ERK activity and changes to the structure and shape of the neuron including changes to dendritic spines. Modifications to plasticity occur during both initial memory consolidation and subsequent reconsolidation of fear memories. MEK inhibitors, upstream inhibitors of pMAPK/ERK activity are known to block pMAPK/ERK activity when administered both intra brain and systemically and also block initial consolidation and reconsolidation of threat memories. However the precise effect of MEK inhibitors on different sub-regional microcircuitry is unknown. Our initial data suggests that the number of neurons in the LAd expressing pMAPK/ERK is significantly reduced (by up to 90%) following a systemic injection of the MEK inhibitor SL327. In conclusion these data provide initial microcircuit level analysis of the effects of MEK inhibitor on neural microcircuits underlying threat memories.

Title: Brain dynamics in fear memory: a small-animal Positron Emission Tomography study of its expression, labilization and reconsolidation.

Authors: *V. DE LA FUENTE[1], C. MEDINA[1], G. FALASCO[2], L. URRUTIA[2], S. VÁZQUEZ[2], M. E. PEDREIRA[1], A. ROMANO[1];

Abstract: It is now very well stated that consolidation is the process by which new information is encoded in neural circuits. However, once a memory is consolidated it does not remain stable indefinitely. Not only can it change with time but also with experience. In particular, when a reminder of the learning event is presented to an animal that has learnt something new, the memory and thus the neural circuits that encode that memory become labile and need a process of reconsolidation to be re-stabilized. This is crucial for the modification of existing memories as it enables changes in its strength and/or content. For the past decades, labilization/reconsolidation processes have been extensively studied from behavioral, cellular and molecular approaches but no whole-brain studies have emerged to elucidate neural circuits and brain areas subserving memory dynamics during these processes in small animals. In this work, we studied the male mouse brain from a functional perspective using small-animal Positron Emission Tomography (PET), and [18F]-deoxyglucose (FDG) as the radioactive compound, thus measuring differential glucose consumption. The main objective was to study which brain areas were involved in labilization/reconsolidation of fear memory using a contextual fear conditioning paradigm in mice. For that purpose we injected the mice with FDG intraperitoneally at different times pre/post re-exposure to the training context, then anesthetized the mice with isoflurane and acquired images through a PET scanner. We found differences in glucose consumption mainly in zones comprising the ectorhinal cortex, the temporal association cortex, hippocampus and amygdala in re-exposed animals compared to non-re-exposed animals. The differences in glucose consumption showed a marked temporal course, were context-specific, and were either hyper- or hypo-consumptions. Moreover, animals that only evoked but did not labilized the memory trace showed significant differences compared to mice that labilized and reconsolidated. Our work opens new insights in the study of the dynamics of activation of brain areas during memory labilization/reconsolidation by using a novel technique for the field, which in combination with others like immunofluorescence, DREADDS and electrophysiology helps to unravel the pending question about circuits involved in labilization/reconsolidation.

Title: Increased spine density in Arc-expressing neurons after contextual fear memory retrieval in the mouse hippocampus

Authors: K. MINATOHARA[1], M. AKIYOSHI[1], Y. TAKAHASHI[1], H. BITO[2], *H. OKUNO[1]; [1]SK project, Med. Innov Ctr., Kyoto Univ. Grad Schl of Med., Kyoto, Japan; [2]Dept. of Neurochemistry, The Univ. of Tokyo Grad. Sch. of Med., Tokyo, Japan

Abstract: The expression of immediate early genes (IEGs) such as *Arc* and c-*fos*, which is rapidly induced after learning in a subset of neurons in the brain, is required for long-term memory formation. These IEG-expressing neurons likely encode and retain information that is required for memory recall. When a memory is recalled, at least some of these neurons are reactivated, thus inducing IEGs that facilitate memory reconsolidation and updating. However, synaptic changes related to memory reconsolidation/updating in the neurons activated during memory retrieval remain unclear. To address this question, we analyzed morphological changes of dendritic spines in the activated neurons expressing *Arc* after contextual fear memory retrieval. We previously generated transgenic mice expressing a destabilized yellow fluorescent protein, Venus, with the C-terminal PEST sequence under the control of *Arc* promoter (Arc-pro-Venus-pest Tg mice) to specifically label neurons that express *Arc* in response to neuronal activation (Vousden et al., 2015). We trained these Tg mice in a contextual fear conditioning paradigm; the mice showed comparable ability with wild-type mice to retain fear memory assessed 24 hours after training. To evaluate the levels of *Arc* expression induced by memory retrieval in hippocampal CA1 pyramidal neurons, we quantified fluorescent intensities of the Venus reporter in the somata of the hippocampal neurons in brain sections fixed 2 hours after the retrieval test. This analysis revealed that the CA1 neurons displayed graded Venus intensities rather than an all-or-none profile, consistent with the immunofluorescence analysis for endogenous Arc expression. In order to visualize and analyze dendritic spine structures of these neurons, we sparsely labeled these neurons with a red fluorescent protein by adeno-associated viral infection, and classified them into two groups based on the Venus intensities in their cell bodies: high-Arc-expressing and low-Arc-expressing neuron groups. Comparing spine densities and spine morphology between these two groups revealed increased spine density and decreased spine head size in the high-Arc-expressing neurons ($P < 0.05$ for both; Mann-Whitney U test).

These results suggest that plastic changes in synaptic connections specific to the neurons activated during memory recall may play critical roles in updating and reorganizing previously acquired memory traces.

Title: Rats accumulate and discount evidence in a changing environment

Authors: ***A. PIET**[1], C. BRODY[2], A. EL HADY[2];
[1]Neurosci., Princeton Univ., Princeton, NJ; [2]Neurosci., HHMI/Princeton Univ., Princeton, NJ

Abstract: How are choices made within constantly-changing noisy environments ? The gradual accumulation of noisy evidence is considered to be a fundamental component of decision making. Previous work has characterized the evidence accumulation process in a static environment, finding that rats and humans can accumulate evidence with a memory time constant longer than the trial duration (Brunton, Science 2013). However, complex decisions involve environments with statistics that change over time. In a changing environment, the optimal evidence accumulation strategy involves the additional task of discounting old evidence that may no longer inform the current state of the world (Glaze et al., eLife 2015; Veliz-Cuba et al., arXiv 2016; Barack et al., 2016). We trained rats on an auditory decision making task in a changing environment, to assess if and how rats can accumulate and discount evidence. Using high-throughput behavioral training and quantitative modeling, we find that rats can discount

evidence under such changing conditions. We are currently gathering data to determine the specific linear or nonlinear discounting strategy. Our study offers the first evidence that, within a dynamically changing environment, rats can perform a gradual evidence accumulation decision-making task. This opens up the opportunity to use rodents towards unraveling the complex interplay between accumulation and discounting of evidence in an environment where the statistical structure changes over time.

Title: Flexible feature selection for decision-making in rats

Authors: ***M. PAGAN**[1], C. D. BRODY[1,2];
[1]Princeton Univ., Princeton, NJ; [2]Howard Hughes Med. Inst., Princeton, NJ

Abstract: A hallmark of higher cognition is our ability to flexibly select, based on context, the information relevant to guiding our decisions. Understanding the neural mechanisms underlying this fundamental cognitive process is a major unsolved question. To address this issue, we have devised a high-throughput, computer-automated procedure to efficiently train rats to perform a task requiring flexible, context-dependent selection and integration of sensory information (adapted from Mante et al., Nature, 2013). In our task, rats are presented with a 1.3s-long train of 5ms, randomly-timed auditory pulses. Each pulse is played either from a speaker to the animal's left or from a speaker to their right, and each pulse is either low-frequency (6.5 KHz) or high frequency (14 KHz). In blocks of "location" trials, rats are rewarded if they turn, at the end of the stimulus, towards the side that had played the greater total number of pulses, ignoring the frequency of the pulses. In blocks of "frequency" trials, rats are rewarded for orienting left if the total number of low frequency pulses was higher than the total number of high frequency pulses, and orienting right otherwise, ignoring the location of the pulses. For any given pulse train, correct performance thus requires selecting the relevant feature, depending on task context. Our preliminary behavioral data suggest that rats can learn to perform this behavior after

approximately 4 to 5 months of training. Because information is delivered in randomized, yet precisely-known pulses, statistical methods can be applied to precisely characterize the animals' behavior. Preliminary data suggest that the rate of accumulation of both context-relevant and context-irrelevant sensory information is approximately constant throughout the stimulus presentation. In summary, our results demonstrate that rats are a viable model to study context-dependent feature selection for decision-making, and open the door to the use of the rich experimental tools available in rodents to dissect the neural mechanisms underlying flexible feature selection.

Title: Trial history vs. sensory memory - a causal study of the contribution of rat Posterior Parietal Cortex (PPC) to history-dependent effects in working memory

Authors: *A. AKRAMI[1,2], C. D. KOPEC[1], C. D. BRODY[1,2];
[1]Princeton Neurosci. Inst. (PNI), Princeton, NJ; [2]Howard Hughes Med. Inst., Princeton, NJ

Abstract: Behavior in various tasks cannot be seen as an isolated phenomenon out of the context, that is, the brain is constantly engaged in storing new memories and executing actions while integrating incoming sensory input with past memories and subject's internal model of the task. Working memory (WM), the ability to store and manipulate information for short periods of time, is an example where contextual information, given specifics of the past history, becomes an integral part of perception and memory. A particular type of WM task, called Parametric Working Memory (PWM), is delayed comparison, the sequential comparison of two graded stimuli separated by a delay period of a few seconds, which forces the subject to maintain an analog value in memory. We have developed an auditory delayed comparison task in rats, adapted from a tactile task (Fassihi and Akrami et. al 2014, Akrami et al 2015). On average, rats show a remarkable ability to hold information about the first stimulus in their memory for up to 10s. A salient feature of PWM is that it is adaptive to various factors in the task, e.g the saliency of the stimuli, the delay duration, and interestingly, task history. Using a regression model to quantify the animals' behavior, we show how performance on each trial depends on the reward history (Busse et al 2011), as well as the stimulus history. These biases are similarly observed in human subjects performing a similar PWM task. For the first time we carry out local optogenetic

inactivations of Posterior Parietal Cortex (PPC) in rats which is assumed to be involved in working memory. We found that, surprisingly, some PPC inactivations improve performance. Quantitative analyses suggest that this may be due to a reduction in the biases caused by the history of recent trial rewards and punishments, as well as sensory stimuli. Furthermore, electrophysiological recordings from PPC does not show its involvement during the delay period but rather show neurons carry significant amount of information about the subject's recent experience of sensory stimuli as well as their recent choices and rewards. These results suggest a crucial history-dependent contribution of PPC to working memory behaviors and specifically to longer scale memory of past sensory inputs that span over several trials.

Title: Systematic optogenetic mapping of cortical regions required for sensory-evidence accumulation in the mouse

Authors: ***L. PINTO**[1], S. KOAY[1], S. Y. THIBERGE[1,2], D. W. TANK[1,2], C. D. BRODY[1,3]; [1]Princeton Neurosci. Inst., [2]Bezos Ctr. for Neural Dynamics, [3]Howard Hughes Med. Inst., Princeton Univ., Princeton, NJ

Abstract: The accumulation of sensory evidence is a crucial aspect of perceptual decision-making, and it involves complex neural computations requiring sensory processing, weighing of sensory evidence for or against a decision, as well as short-term memory of accrued evidence. Given this complexity, it is likely that many cortical areas are causally involved in evidence

accumulation. However, little is known about which areas are necessary for this crucial cognitive function. To tackle this question, we implanted VGAT-ChR2-EYFP mice with a transparent skull preparation, allowing optical access to the entire dorsal surface of the cortex, and inactivation of discrete cortical patches by activating ChR2-expressing GABAergic neurons (Guo et al., 2014, Neuron). Head-fixed mice were trained on a novel virtual navigation-based visual accumulation task (Koay et al., SFN Abstracts 2015; see also Koay et al., SFN 2016), wherein they navigate a T-maze to retrieve water rewards from one of the two arms. While the animals run up the central stem of the virtual T salient visual stimuli (vertical columns, or towers) appear on either side, distributed as a spatial Poisson process of different rates (cue region, 200 cm). After a memory region without any stimuli (100 cm), the animal then makes a right or left to turn to indicate which side had the highest total number of towers. The visual stimuli thus need to be incrementally accumulated towards a decision. Mice achieved high overall performance (~ 80% correct), were sensitive to the difference in right and left towers, and incrementally accrued evidence, as revealed by psychometric functions and a psychophysical reverse correlation analysis (Brunton et al., 2013, Science). We then used a blue laser coupled to a 2D scanning galvanometer system to comprehensively and systematically inactivate discrete cortical patches while mice performed the task. Whole-trial inactivation of several visual cortical regions and association cortex resulted in decreases in performance, observed in VGAT-ChR2-EYFP mice but not in control mice. We are currently carrying out finer temporal inactivation, e.g. only during the cue or memory periods, to allow us to tease apart the individual contributions of these areas to specific computations in the task. Identifying these regions will be crucial to guide future cellular-resolution studies to understand the neural circuit computations underlying evidence accumulation for decision-making.

Title: Recurrent network models of evidence accumulation.

Authors: *K. RAJAN, B. B. SCOTT, C. M. CONSTANTINOPLE, D. W. TANK;
Princeton Univ., Princeton, NJ

Abstract: Behavioral experiments have raised a number of quantitative, testable hypotheses about how the brain encodes accumulated evidence in favor of a decision, in both rodents [Brunton, Botvinick & Brody, 2013; Scott et al, 2015], and primate studies [Gold & Shadlen, 2007]. Experimental advances now support recordings and imaging in the frontal orienting field, secondary visual cortex and posterior parietal cortex during accumulation of evidence tasks, [Scott et al, in prep; Hanks et al, 2015]. Here, we combine analysis of the resulting population data with neural network modeling of both the behavioral process and the neuronal dynamics to identify mechanisms in cortical circuits that provide the type of working memory involved in evidence accumulation [Pereira & Wang, 2014; Wang, 2012]. In most models, memories are stored over short periods of time by persistent neural activity, particularly through fixed points [Hopfield & Tank, 1985; Hopfield, 2015; Amit & Brunel, 1995; Hansel & Mato, 2001]. Recently, an alternative mechanism has been suggested involving richer patterns of population activity - neural sequences [Rajan, Harvey & Tank, 2016]. We have studied the role of neural sequences in mediating memory for evidence accumulation and discrimination tasks. The main hypothesis is that diverse and transient sensory responses distributed across a neural population encode accumulated evidence in working memory during these tasks.
To test this hypothesis, we trained recurrent networks of model neurons to perform evidence accumulation tasks based on comparison of stimuli of two different magnitudes. The trained networks produce sequential activity to support short-term memory and contain both partially structured connectivity for stimulus integration and evidence accumulation, combined with random connectivity to stabilize other functions within a reservoir computing framework. We evaluate these networks based on the degree to which they match the observed trial-by-trial variability and scaling of the estimation errors in modeling the behavioral data [Nieder & Miller, 2003; Brunton, Botvinick & Brody, 2013; Scott et al, 2015]. In addition, networks built in this manner capture the behavioral performance of the rats, matching measured psychometric functions. By incorporating both reward-incentivized exploration in the training process and inattention/distraction inputs, the model can also be used to investigate the neural mechanisms underlying “lapse rates” observed experimentally during these and similar tasks.

Title: A head-fixed somatosensory task in mice for the study of neural mechanisms of evidence accumulation

Authors: *B. DEVERETT[1,2,3,4], S. KOAY[1,2], S. S.-H. WANG[1,2,3];

Abstract: Working memory is a core cognitive process that supports perception, decision making, and problem solving. In animal models, neural and behavioral dynamics of working memory can be probed through the gradual presentation of sensory evidence over time. For example, rodents can be trained to accumulate evidence in the form of pulsatile visual or auditory stimuli presented on their left and right sides (Brunton et al. 2013, Science 340.6128:95-8; Scott et al. 2015, eLife 4.e11308, Koay et al., Soc. Neurosci. Abstr. 2015, 442.15/BB47). In these tasks, rodents indicate the side with the greater amount of evidence by orienting or navigating, both of which involve a specific motor action.
We established a head-fixed mouse paradigm for working memory that deviates from these tasks in two ways: the modality of sensory stimuli and the mode of decision readout. In this new task, head-fixed mice are presented with sensory evidence in the form of brief puffs of air to the whisker pad regions of the face, with onset times distributed randomly according to a Poisson process with different rates for left- and right-sided stimuli. Mice are taught to suppress licking while evidence is presented during a period that varies in duration from trial to trial. After an additional delay period, a visual “go” cue is presented, and mice report their choice by licking one of two liquid reward delivery tubes positioned to their left and right. Mice learned to perform this task at levels comparable to head-orienting and virtual reality-based paradigms. After approximately twenty one-hour sessions, mice successfully performed trials ranging from 10-16 seconds in duration, with stimulus rate differences ranging from 9:1 to 3:2. Psychometric, chronometric, and reverse correlation analyses suggest that mice integrated information across the whole cue presentation period. In comparison to a virtual reality-based visual evidence accumulation task, mice exhibited lower lapse rates and higher consistency. This task may help disambiguate higher-level cognitive features from movement-specific and sensory modality-

specific effects. In particular, we are using this evidence accumulation task to explore contributions of cerebellar regions that have strong connectivity with nonmotor neocortical regions involved in working memory (Wang, Kloth, & Badura 2014, Neuron 83:518, Strick et al. 2009, Annu. Rev. Neurosci. 32.1:413-34).

Title: Neural dynamics in a mouse navigation and accumulation of visual evidence task

Authors: *S. KOAY[1], B. ENGELHARD[1], L. PINTO[1], B. DEVERETT[1,2,3], S. Y. THIBERGE[1,4], C. D. BRODY[1,5], D. W. TANK[1,4,2];

Abstract: Decision-making tasks involving accumulation of sensory evidence provide a flexible framework in which to study neural mechanisms of working memory. Extending work in human and non-human primates (Gold et al., Annu Rev of Neuroscience 2007) and rats (Brunton et al., Science 2013; Scott et al., eLife 2015), we demonstrated that mice can perform a combined virtual reality navigation and accumulation of visual evidence decision-making task (Koay et al., SFN 2015). Transgenic mice expressing the genetically encoded calcium sensor GCaMP6f in excitatory neurons were trained in a head-fixed virtual reality system (Harvey et al., Nature 2009) to navigate in a T-shaped maze. As mice ran down the main corridor, visually salient "towers" appeared along the left and right walls of the cue region. Tower positions were randomly distributed per trial as spatial Poisson processes with a different mean count for each side. Mice then traversed a memory region where no towers appeared. Upon reaching the T-intersection they had to run down the left or right arm (turn region), and were given a liquid reward for selecting the side that had more towers. Mice achieved performances of 70%-80% correct trials, with trial durations of 10-20s. Each mouse was implanted with a 5mm diameter

cranial imaging window centered over the anterior-medial border of primary visual cortex, permitting two-photon cellular resolution imaging of calcium dynamics of neurons in layers 2/3 and 5 across a wide region of cortex. Neural activity underlying calcium dynamics was estimated using a demixing and deconvolution algorithm (Pnevmatikakis et al., Neuron 2015). Recording locations (AM, retrosplenial cortex, etc.) were defined relative to primary and secondary visual areas whose borders were estimated using wide-field functional mapping (Garrett et al., J. Neuroscience 2014). In most regions we observed neurons with task-modulated activity; cells typically had Ca^{2+} transients for only short time intervals (hundreds of ms to seconds) that within a trial were staggered in time across the population (Harvey et al., Nature 2012). Regional differences were seen in the frequency of cells active in the cue, memory, and turn regions. Of particular interest to evidence accumulation models, some neurons exhibited transient responses to the presentation of individual towers, predominantly for towers on a preferred side. Response amplitudes were highly variable and often had different overall modulations which depended on position in the cue region. These experiments yield a rich dataset for examining neural coding and dynamics underlying evidence accumulation and decision-making.

Title: Heterogeneous dynamics in frontoparietal cortex encode sensory memories during accumulation of evidence tasks

Authors: ***B. B. SCOTT**[1,2,3], C. M. CONSTANTINOPLE[1,2,3], C. D. BRODY[1,2,3,4], D. W. TANK[1,2,3];
[1]Mol. Biol., [2]Princeton Neurosci. Inst., [3]Bezos Ctr. for Neural Circuit Dynamics, [4]Howard Hughes Med. Inst., Princeton Univ., Princeton, NJ

Abstract: Behavioral studies suggest that animals accumulate sensory evidence over time to make perceptual decisions. In mammals this accumulation process is thought to involve the activity of neurons in frontal and parietal neocortex, however the precise circuit mechanisms of evidence accumulation are not known. Using two-photon imaging in voluntarily head restrained rats (Scott et al., Neuron, 2013), we examined calcium dynamics of GCaMP6f-expressing layer 2/3 cortical neurons during a pulse-based accumulation of evidence task, which we recently developed (Scott, Constantinople et al., eLife, 2015). In this task rats viewed two simultaneous streams of light pulses, presented from a left and a right LED. After the end of the streams, rats were rewarded for orienting to the side that had the greater number of pulses. A linear encoding model was used to characterize the responses of neurons to task events including individual quanta (flashes) of evidence, and to distinguish sensory responses from premotor activity. Consistent with previous studies, a population of neurons distributed across frontal and parietal cortex exhibited strong responses that reflected both the timing and the magnitude of the accumulated sensory evidence. However, contrary to leading models of evidence accumulation, these neurons displayed extensive heterogeneity in the dynamics of responses to pulses. Responses of individual neurons were transient, typically shorter than the duration of the trial, with different neurons active at different times following a pulse. Inspired by network models of working memory in which transient and heterogeneous responses combine linearly to produce persistent activity (Goldman, Neuron, 2009), we found that the temporal diversity of responses was sufficiently rich to form a basis set for a wide range of exponential decay functions, including those with long time constants. These results suggest that diverse, time varying sensory responses distributed across frontoparietal cortex may support the parametric visual working memory necessary for evidence accumulation on behavioral timescales.

Title: Stable contingencies drive orbitofrontal predictions

Authors: *J. S. RICEBERG[1], M. SHAPIRO[2];
[1]Neurosci., Mount Sinai Sch. of Med., New York, NY; [2]Icahn Sch. of Med. of Mount Sinai, New York, NY

Abstract: Memory can inform goal-directed behavior by linking current opportunities to past outcomes. The orbitofrontal cortex (OFC) may guide value-based responses by integrating the history of stimulus-reward associations and computing expected outcomes: representations of predicted hedonic value and quality. We compared OFC coding in identical tasks controlled by contingencies that varied reward history. Under stable contingencies the OFC signaled integrated reward history with anticorrelated population codes that distinguished goals and predicted task performance. The firing rates of single neurons distinguished identical behaviors guided by different outcomes in predictive, retrospective, and goal location coding. When contingencies were unstable, however, the OFC signaled different outcomes with uncorrelated population codes that did not predict performance, and though retrospective and goal coding were maintained, predictive coding declined. The OFC distinguishes recent actions and actual outcomes independent of reward stability, but predicts expected outcomes only when stable contingencies promote the integration of reward history.

Title: Distinct contributions of hippocampal and prefrontal afferents to nucleus reuniens during spatial working memory

Authors: B. A. EMANUEL, H. L. HALLOCK, E. C. MYHRE, *A. L. GRIFFIN;
Univ. Delaware, Newark, DE

Abstract: Spatial working memory, the ability to acquire, maintain, and use spatially relevant information over a temporal gap, has been demonstrated to depend on functional interactions between the hippocampus and medial prefrontal cortex (mPFC). Recently, our lab has demonstrated that the nucleus reuniens (Re), part of the ventral midline thalamus that is reciprocally connected to both hippocampus and mPFC, plays a crucial role in coordinating

interactions within the hippocampal-mPFC circuit during spatial working memory (SWM). However, the specific circuitry that governs this coordination has not yet been explored. Therefore, we investigated the functional involvement of Re and its afferents in SWM using a projection-targeting optogenetic silencing approach. We infused an adeno-associated virus vector engineered to express fluorescently labelled archaerhodopsin (pAAV5-CAG-ArchT-GFP) into the dorsal subiculum, mPFC, or Re in separate groups of rats. After virus injection, all rats were implanted with an optical fiber targeting the Re. Rats were then allowed to recover for at least 6 weeks to allow for opsin expression. We then trained rats to perform a delayed nonmatch to position (DNMP) task in a T-maze. The advantage of using a DNMP task is that its design effectively teases apart the encoding and retrieval portions of SWM into two separate traversals of the maze: sample (encoding) and choice (retrieval) phases, separated by a delay period over which information must be maintained. After rats reached criterion on the DNMP task, data collection began. Optical stimulation was driven via a compact LED module emitting 550-nm light through a patch cable. Choice accuracy was recorded from four distinct experimental conditions given in pseudorandom order across days that varied according to which task phase the rat was performing when the LED was turned on: the sample phase, the choice phase, the delay period and the entire trial. The Re group showed impaired choice accuracy on all four conditions. Terminal suppression of the dorsal subicular input to Re caused a selective deficit on the sample-only light condition, suggesting that dorsal subiculum-Re projections are critical for the encoding of task-relevant spatial cues. Conversely, terminal suppression of mPFC input to Re caused a selective deficit on the delay-only light condition, suggesting that medial prefrontal-Re projections support the maintenance of these spatial representations. These findings implicate Re in all aspects of spatial working memory, and indicate pathway-specific roles for Re afferents during the encoding and maintenance of spatial information necessary for successful SWM.

Title: Investigating the role of the nucleus reuniens in spatial working memory

Authors: *A. C. GARCIA, A. L. GRIFFIN;
Univ. of Delaware, Newark, DE

Abstract: Spatial working memory (SWM) has been shown to rely on the functional integrity and connectivity of the hippocampus and medial prefrontal cortex (mPFC). However, it remains to be determined how task-relevant information is organized within this circuit to guide SWM behavior. In the rat, direct connections between the hippocampus and mPFC are restricted to a monosynaptic projection extending from the ventral portion of hippocampus to mPFC. However, the nucleus reuniens (RE) of ventral-midline thalamus has been shown to share afferents and efferents with both dorsal and ventral hippocampus and mPFC. Recent work from our lab using *in vivo* recordings of RE in the awake, behaving rat has shown that disruption of RE activity not only impairs SWM performance, but concomitantly disrupts hippocampal-mPFC synchrony and the direction of information flow within the hippocampal-mPFC circuit. Thus, RE could play a role in coordinating hippocampal-mPFC interactions during SWM. Consistent with this notion, a recent study demonstrated that suppression of RE activity decreased trajectory-dependent firing in hippocampal CA1 during a continuous alternation (CA) task (Ito et al., 2015). However, compared to other SWM tasks, both the SWM demand of the CA task and its ability to dissociate between the processes of encoding and retrieval are relatively low. Moreover, experimental evidence shows that the CA task does not require the functional integrity of the hippocampus for successful performance. Therefore, we set out to investigate the role of RE in SWM using a hippocampus-dependent task with a high SWM demand that allows dissociation between the processes of encoding and retrieval: the delayed non-match to position (DNMP) task in a T-maze. This task requires cue-based encoding on the sample run, maintenance of the information during a 20-second delay period, and memory-dependent retrieval on the choice run. In line with previous reports, a subset of RE units showed trajectory-dependent firing, while a separate subset showed differential firing between sample and choice runs, reminiscent of CA1 single units recorded during a DNMP task (Griffin, Eichenbaum, & Hasselmo, 2007). These results suggest that distinct subsets of RE units differentially contribute to encoding and retrieval processes. Therefore, RE may function as a hub for integrating information from multiple brain regions and dynamically directing task-relevant information within the hippocampal-mPFC circuit to support SWM-guided decision making.

Title: Neural ensemble dynamics of the medial prefrontal cortex underlying shifts in cognitive strategy

Authors: *F. WANG, T. H. KIM, H. INAN, A. WILLIAMS, S. GANGULI, M. J. SCHNITZER;
Stanford Univ., Stanford, CA

Abstract: During shifts in cognitive strategy, the medial prefrontal cortex (mPFC) is thought to exert a crucial role by coordinating the functions of multiple brain systems. Inactivation of the mPFC impairs the ability to shift between different cognitive strategies[1-3], and electrophysiological recordings in behaving rodents have revealed evidence of mPFC neural activity that is temporally linked to strategy shifts[4,5]. To examine the neural ensemble dynamics underlying strategy shifts, we used a miniature fluorescence microscope to image the calcium dynamics of hundreds of individual mPFC neurons in the prelimbic cortex (PrL) of mice performing a strategy-switching navigation task.
In this task, mice switched between a hippocampus-dependent, allocentric (spatial) navigation strategy and a striatum-dependent, egocentric strategy (or vice versa) to earn a water reward. We identified distinct subsets of PrL neurons with either contemporaneous or anticipatory coding for various task parameters and phases, including the mouse's spatial location and the anticipated receipt of reward. We also found neural ensemble activity patterns in PrL related to the two different strategies, and we are presently studying how these patterns and their dynamics might underlie the representations and shifts between different strategies. Overall, our work reveals the large-scale dynamics of frontal cortical neural ensembles in mice performing our specific cognitive task, and paves the way to future studies of the neural ensemble codes underlying other modes of cognitive control.

Title: Outcome selective recall of neural ensembles in prefrontal cortex of rule-learning rats

Authors: *S. MAGGI[1], A. PEYRACHE[2,3], M. D. HUMPHRIES[1];
[1]Fac. of Life Sci., Univ. of Manchester, Manchester, United Kingdom; [2]NYU Med. Ctr., New York, NY; [3]McGill Univ., Montreal, QC, Canada

Abstract: The medial prefrontal cortex (mPFC) contributes to diverse aspects of memory-driven cognition, including working memory during tasks, and replay of task-related activity during sleep. Unclear is how mPFC population dynamics underlie working memory contributions to learning. One possibility is that mPFC populations support learning using cell assemblies that appear in order to sustain relevant items in working memory.
To address these issues, we analysed population activity from the mPFC of rats learning rules in a Y-maze. Spike-train data (tetrode recordings) and behavioural data were from the study of Peyrache et al (2009; Nat Neurosci, 12, 916-926). Rats were required to learn one of three rules on the Y-maze: go left; go right; or go to the lit arm. Reward was obtained by reaching the end of the goal arm corresponding to the current rule. After reward delivery or absence, rats made a self-paced return to the starting position during the inter-trial interval (ITI), which was examined for signatures of learning-specific working memory. We analysed data from 46 sessions, in 10 of which the rats met the learning criterion mid-session.
To test for signatures of task-specific working memory, we quantified the functional network of pairwise correlations between simultaneously recorded neurons in the ITI. In every session, we found the functional network was comprised of statistically robust neural ensembles. Within each session, ensembles were present in every ITI and formed a remarkably stable proportion of the population across all ITIs. Having detected potential cell assemblies, comparing learning and non-learning sessions allowed us to test for their role in working memory for learning. Remarkably, we found that the same ensembles were recalled after each correct trial, but not error trials. This outcome-selective recall only occurred during learning sessions. Moreover, within each learning session, the appearance of outcome selective ensembles preceded stable behavioural performance. Our results show that mPFC populations form true cell assemblies during learning, which retrospectively code for rewarding outcomes. These assemblies could provide the dynamical basis for maintaining a specific task-related item in working memory when triggered by reward.

Title: Evaluating the role of GABA interneurons in the medial prefrontal cortex during working memory in mice

Authors: ***R. NGUYEN**[1], J. C. KIM[2];
[1]Psychology, [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Working memory involves coordinated timing and synchrony of network activity in the medial prefrontal cortex (mPFC) by GABA interneurons. GABA interneurons are a diverse population with distinct cell types differentially contributing to cognition and behaviour. Two major non-overlapping GABA interneuron populations in the mPFC are the parvalbumin (PV)- and cholecystokinin (CCK)- GABA interneurons. We examined the requirement of PV and CCK-GABA interneurons in working memory by optogenetically silencing their activity in the mPFC of mice performing an olfactory delayed-nonmatch-to-sample test. The inhibitory opsin ArchT was expressed in CCK-GABA interneurons using dual recombinase intersectional genetic labeling, and in PV interneurons using AAV-mediated gene delivery. PV and CCK-GABA interneurons were inhibited either during the sample, delay, or response phase of the task by light illumination timed to these events. CCK-GABA interneuron inhibition selectively during the response phase impaired working memory performance. These results support the function of CCK-GABA interneurons in working memory retrieval or expression.

Title: Performance of the odour span task is not disrupted by inactivations of the posterior parietal cortex in rats

Authors: *G. A. SCOTT, N. K. ZABDER, Q. GREBA, J. G. HOWLAND;
Dept. of Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Working memory, the ability to temporarily store information for use and manipulation, is thought to depend on a distributed set of brain areas. These include higher cortical areas involved in executive function and attention, such as the prefrontal and parietal cortices, which maintain attention on the items stored in working memory. However, relatively little research has been conducted in rodents to elucidate the exact roles each of these areas plays in working memory, particularly in relation to the construct of working memory capacity. Previous work in our lab has demonstrated that performance of the odour span task (OST), a behavioural task that tests the ability of rats to remember an increasingly large, trial unique set of odours in order to obtain a food reward, in rats is disrupted by the temporary inactivation of the medial prefrontal cortex and striatum. However, the effects of deactivating the parietal cortex on the OST has not been studied. Therefore, the present experiment assessed the effects of inactivating the posterior parietal cortex on performance of the OST. Rats (n = 12) were food restricted and, after being shaped to perform the basic rules of the task, underwent training in the OST over a period of 1.5-3 weeks. Four guide cannulae were then surgically implanted aimed at the posterior parietal cortex (AP -3.8 mm; ML ±2.2 mm and 3.4 mm; DV -0.2 mm from brain surface). After recovery and retraining, rats were tested after intra-parietal infusions of a mixture of muscimol and baclofen (GABA-A and GABA-B agonists, respectively) or saline (control). The infusions took place over two days using a crossover design in which each rat received muscimol/baclofen and saline in a counterbalanced order. Interestingly, infusions of muscimol/baclofen did not disrupt working memory performance, assessed by the mean number of odours each rat could remember before making an error on each day of training. A subset of rats (n = 4) was also tested in crossmodal object recognition (CMOR; a test that depends on the parietal cortex) as a positive control, and exhibited a memory impairment after muscimol/baclofen, but not saline, infusions. These results suggest that performance of the odour span task does not depend on the parietal cortex. The result is surprising given the past research

demonstrating the importance of the parietal cortex for attentional processes and working memory in other tasks. Current work to expand the sample size in CMOR is ongoing.

Title: The role of the medial prefrontal cortex in working memory capacity

Authors: ***L. AN**[1], N. SUN[1], J. CATTON[1], A. TSENGER[1], Q. GREBA[1], C. LAPISH[2], J. HOWLAND[1];
[1]Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]Indiana Univ., Indianapolis, IN

Abstract: Working memory is a psychological construct encompassing executive functions responsible for the manipulation and maintenance of information over short intervals. The amount of information that can be held is referred to as working memory capacity. In rodents, the medial prefrontal cortex (mPFC) plays a key role in organizing and processing cognitive functions, including working memory capacity. To better understand how mPFC neurons contribute to working memory capacity, 13 male Long-Evans rats were trained on the odor span task (OST), a non-spatial task that assesses the capacity of working memory. Following implantation of electrode arrays, ensemble extracellular recordings of single units were obtained from the mPFC of freely moving rats during the OST. Neurons (n=394) with a mean baseline firing rate of 4.7±1.1 Hz were collected. Approximately 80% of the units were classified as regular-spiking (RS) cells and about 8% of them were fast-spiking (FS) interneurons. We explored the roles of mPFC neurons during sequential events of a given trial (trial start, odor approach, and reward) and the delay period under different spans (low, 2-6 odors; medium, 8-11 odors; high, 13-17 odors). Firing rate of RS cells increased during trial start, before novel and familiar odor approach, and after obtaining reward. Interestingly, firing rates significantly changed when correct, but not incorrect, choices were made. About 60% of event-related units significantly changed their activity to more than one event, and this proportion tended to increase with increasing span. No obvious event-related changes were found in the firing pattern among

low, medium, and high spans. During the delay, RS neurons were detected that increased activity during the start of the delay, end of the delay, or throughout the delay period. Delay cells that increased firing rate before trial start changed their firing pattern in the late period of the high span trials with greater activity 1 s before trial start. These preliminary data provide insight into the neural dynamics of working memory, specifically during correct choices.

Title: Holeboard discrimination learning in S100 calcium-binding protein B knockout mice

Authors: K. HAGEBOUTROS[1], H. WU[2], V. VENKATARAMAN[2], *B. D. FISCHER[1]; [1]Cooper Med. Sch. of Rowan Univ., Camden, NJ; [2]Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: The holeboard learning test is a well-established measure of spatial learning, which has been used in both genetic and pharmacological mouse models. The apparatus is an open field chamber with 16 holes in the floorboard. The task requires mice to discriminate between baited vs. non-baited holes over successive trials. The holeboard test assesses spatial working memory and reference memory. S100β is a calcium-binding astroglial protein whose gene is found on chromosome 21. The overexpression of S100β is implicated in Alzheimer's disease and Down syndrome. The present study used the holeboard test to assess learning and memory expression in mice deficient in S100β (S100β KO mice). Our working hypothesis is that lacking S100β serves as a protective mechanism in regards to memory. After a habituation phase, food-deprived mice were trained for three consecutive days. Each day consisted of 6 consecutive 3-minute trials. A delay recall test was conducted three weeks later with the same baited holes. Working memory errors (entering a hole that was already visited) and reference memory errors (visiting a hole that is not baited) were recorded. The S100β KO mice readily acquired the task and both

working- and reference-memory errors were reduced by day two. There was no significant difference between 3 month old and 9 month old mice in terms of number of reference and working memory errors made across trials. Overall, the low average number of memory errors made and lack of statistical significance between 3 month old and 9 month old mice in the present study raise the possibility that lacking S100β can serve as a protective mechanism against memory decline.

Title: Role of toll-like receptor 4 in diesel exhaust origin secondary organic aerosol-induced impaired spatial learning ability in neonatal mice

Authors: *T. WIN SHWE, Y. FUJITANI, H. WATANABE, S. HIRANO;
Natl. Inst. Envir, Tsukuba, Japan

Abstract: *Background:* Recently, we have reported that diesel exhaust origin secondary organic aerosol (DE-SOA) exposure during developmental period may affect the olfactory-based spatial learning behavior in preweaning mice. Toll-like receptor (TLR)-4, a pathogen-associated molecular pattern receptor plays a role in inflammatory cascade in response to certain stimuli in the brain. Little is known about the role of TLR4 in learning and memory functions. *Objectives:* The present study was designed to examine the involvement of TLR4 in olfactory-based spatial learning disability induced by exposure of environmental pollutants during the developmental period in neonatal mice. *Methods:* Pregnant C3H/HeN (TLR4 intact) and C3H/HeJ (TLR4 deficient) mice were purchased from Charles River Japan Inc. (Yokohama, Japan) and exposed to clean air, DE ($100 \pm 25 \mu g/m^3$) and DE-SOA ($120 \pm 25 \mu g/m^3$) from gestational day 14 to postnatal day (PND) 10 (5 h/day for 5 days) in exposure chambers. We have generated DE-SOA by oxidation of diesel exhaust particle with ozone. In the olfactory-based learning behavior, the time to reach the target goal cage was recorded for each PND 11 neonatal mouse using a video-assisted computer and Any-maze software (Muromachi Kikai, Tokyo, Japan). After completion of the spatial learning test, the hippocampus from each mouse was removed and examined for

the expressions of memory function-related genes and TLR4 signaling pathway genes using real-time RT-PCR. *Results:* Regarding the olfactory-based spatial learning test, both C3H/HeN and C3H/HeJ mice exposed to DE or DE-SOA took a longer time to reach the target as compared to respective control mice, but memory impairment was found greater in C3H/HeN mice compared to the C3H/HeJ mice. The expression levels of memory function-related genes such as the N-methyl-D aspartate (NMDA) receptor subunits NR1 and NR2B, and of TLR4 signaling pathway genes such as NFκB, TNF-α, COX2 and Iba1 were significantly increased in the hippocampi of the DE-SOA-exposed C3H/HeN newborn mice as compared to the control mice, but not in C3H/HeJ mice. *Conclusion:* We suggest that the potential toxic substances contained in DE-SOA may reach the brain via the systemic circulation or the olfactory nerve route to induce olfactory-based learning deficits in neonatal mice. Our results indicate that TLR4 may play an important role in environmental pollutant-induced neuroinflammation and spatial learning impairment by modulating the expressions of memory function-related genes and TLR4 signaling pathway genes in neonatal mice.

Human High Performance

Global Initiative for Sports Neuroscience

Title: Astaxanthin-enriched diet potentiates the effects of mild exercise on hippocampal-dependent memory and neurogenesis in adult mice

Authors: ***J. YOOK**, H. SOYA;
Advanced Res. Initiative For Human High Performace, University of Tukuba, Japan

Abstract: Recent studies have revealed that some dietary supplements, such as epicatechin and DHA, and exercise have similar roles in enhancing spatial memory and adult hippocampal neurogenesis (AHN). Their synergistic effects, however, have been shown only for memory, leaving some issues to be addressed before their clinical use. We recently reported that chronic mild exercise (ME) is sufficient to enhance both spatial memory and AHN (Inoue *et al*., PLoS

One, 2015), and that chronic administration of astaxanthin (ASX, 0.5%), a marine-organism-derived natural carotenoid, has the same effect on the hippocampus (Yook *et al*., Mol Nutr Food Res, 2016). Here, with the aim of developing clinically applicable methods, we postulated that ASX-enriched diets would improve memory by increasing AHN with special molecular mechanisms in adult mice. Male C57BL/6J mice (12 weeks old) were housed individually, and received ASX-enriched diets (0.5% ASX) with or without treadmill exercise (an intensity of below ventilatory threshold: 7 m/min) for 4 weeks. To evaluate spatial memory, the Morris water maze (MWM), including four days of acquisition and one day of probe tests, was performed in the final week of the intervention. To label newborn cells, all mice were intraperitoneally injected with 5-bromo-2'-deoxyuridine (BrdU, 100 mg/kg) for 3 consecutive days before the intervention. Immunohistochemistry was performed on coronal sections of the brain to examine AHN. The potential molecules underlying ME and/or ASX-induced AHN were analyzed using DNA microarray and Ingenuity Pathway Analysis database for genes identified in the hippocampus. The results of the MWM revealed that both ME and ASX produced significant increases in spatial learning and memory. The effects of ME on increased spatial memory were further enhanced when combined with ASX-enriched diets. The results of AHN analysis demonstrated that ME and ASX individually increased proliferation cells ($Ki67^+$) and newborn mature neurons ($BrdU^+/NeuN^+$), and their combination induced a greater increase in AHN than their respective individual effects. Using an omics approach, upregulation of genes associated with AHN, such as *Lep* and *Cxcr4*, was commonly observed in ME and ME+ASX. Interestingly, *Igf1r* was upregulated with the combination of ME and ASX, but not with ME alone. These results, which show that an ASX diet synergistically potentiates the ME effects on spatial memory associated with AHN with novelly identified molecular insights, support our hypothesis and intimate a powerful intervention strategy of combining ME and ASX for cognitive failure based on hippocampal structure and function. Thus we have begun clinical trials.

Title: Experience dependent epigenomic reorganization

Authors: *C. G. DUKE[1], A. KENNEDY[2], D. SWEATT[2], J. DAY[2];
[1]Sch. of Med., [2]Neurobio., UAB, Birmingham, AL

Abstract: The formation and maintenance of new memories requires transcription and translation of genetic material, and epigenetic mechanisms such as DNA methylation and demethylation serve as powerful regulators of this gene expression that is crucial to these processes. Moreover, aberrant DNA methylation has been identified in neurological and psychiatric disease states associated with impaired cognition, such as Alzheimer's disease, autism-spectrum disorders, schizophrenia, and drug addiction. Despite the clear necessity for epigenetic and transcriptional changes in memory formation, the precise nature of these phenomena has not been comprehensively explored. To illuminate this area, we harnessed whole-genome sequencing tools to systematically characterize memory-related changes in gene expression and DNA methylation status following memory acquisition. Using a hippocampus-dependent memory task (contextual threat learning), we report widespread and coordinated DNA methylation changes in the hippocampus (CA1) of Sprague-Dawley rats that are specific to threat learning and target genes involved in synaptic transmission and neuronal communication. We observed thousands of significant gene expression and epigenomic changes that are experience dependent, and these modifications were evident as early as one hour following the learning experience, becoming more marked and pronounced after twenty-four hours. Gene ontology term analysis showed that significantly hypomethylated genes were enriched for functional categories related to synaptic transmission. Additionally, we integrated these datasets with previously characterized epigenetic and transcriptional changes in brain disease states to provide a comprehensive resource to aid in the identification of memory-relevant therapeutic targets. Our results shed new light on the gene expression and methylation changes involved in memory formation suggesting that this process is dynamic and experience dependent, in addition to providing a roadmap for future work to identify therapeutic targets.

Title: Interleukin-1 has a brain region- and memory task-specific role in heroin-conditioned contextual memory

Authors: *C. LEBONVILLE[1], L. HUTSON[1], M. JONES[1], J. PANICCIA[1], L. COOPER[1], R. FUCHS[2], D. LYSLE[1];
[1]Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC;
[2]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Interleukin-1 (IL-1), a pro-inflammatory cytokine, has been linked to learning and memory. Specifically, this cytokine is thought to be involved in the maintenance of long term potentiation (LTP), a proposed mechanism of learning-related neuroplasticity. Studies also suggest that IL-1 is involved in hippocampal dependent, yet not hippocampal independent, memory. Previous studies in our lab have implicated IL-1 as having a role in a contextual immune conditioning paradigm using heroin. Like many other opiates, heroin suppresses the immune system. Similarly, exposure to contexts associated with heroin use can produce immunosuppression through Pavlovian conditioning. This learned effect relies on the learned association between a novel context and the immunosuppressive properties of opiates. The functional integrities of the dorsal hippocampus (DH), the basolateral amygdala (BLA), and the nucleus accumbens shell (NAcS) are necessary for this conditioned effect. Our laboratory demonstrated that siRNA-mediated IL-1β gene silencing in the DH prevents the *expression* of heroin-conditioned immunosuppression. Here, we expanded on this finding by 1) investigating the role of IL-1 in other brain regions shown to have a role in heroin conditioned immunosuppression and 2) expanding on its role within the DH using another context-heroin associative learning task. For the first goal, rats were conditioned to associate heroin with a distinct context. After training and 30 min before a test session, rats received bilateral microinfusions of the endogenous IL-1 receptor antagonist (IL-1RA) or saline into either the BLA, NAcS, or the caudate putamen (CPu) as a control region. Rats were then either re-exposed to the heroin-paired context (tested for expression of conditioned immunosuppression) or remained in their home cages (control) and their immune system was challenged using

lipopolysaccharide (LPS). Splenic iNOS and plasma nitrate/nitrite levels were assessed 6 h later. Disruption of IL-1 signaling in the BLA, but not the NAcS nor CPu, blocked the expression of heroin-conditioned immunosuppression. For goal two, rats were trained using a conditioned place preference (CPP) paradigm where one side of an apparatus was paired with heroin. After training and 30 min before testing, IL-1RA was infused into the DH yet this manipulation did not disrupt expression of CPP. Collectively, these studies demonstrate that the role of IL-1 in memory depends on the specific contextual memory task and which brain regions are under investigation.

Title: Analysis of topographical memory and hippocampal neurogenesis in mice using the hamlet test

Authors: *L. CROUZIER, D. GILABERT, M. ROSSEL, F. TROUSSE, T. MAURICE; Inserm U1198, Montpellier, France

Abstract: The Hamlet test is an innovative behavioral analysis appliance that provides a complex environment following a resolutely anthropomorphic approach for testing topographical memory and spatio-temporal disorientation in mice. The apparatus mimics a small village with a central agora and streets expanding from it, leading to functionalized houses (Drink, Eat, Play, Run, Interact). Animals are habituated in groups of 6/8 individuals during 4 h a day, for several weeks. Memory can be tested by depriving mice from water (or food) during 20 h and testing, in a 10-min session, their ability to locate the Drink (or Eat) house. We analyzed the exploration pattern and topographical memory in different mouse strains (Swiss, C57BL/6, AKR) and gender. Habituated mice were compared to a control group of mice kept in room stabling. Significant differences in exploration patterns and memorization of the streets were observed between the strains and gender. The contribution of the hippocampus, which plays a central role in memory and topographical and spatial navigation, was investigated in C57BL/6 mice. Neurogenesis was analyzed in terms of proliferation, maturation and survival processes. First, we

observed an increase in proliferative and immature neuron markers, such as the increase in the number of Ki67 and doublecortin (DCX) positive cells in the subgranular zone of the dentate gyrus in the habituated group. Using 3D fluorescence imaging, longer and highly branched DCX positive neurons were visualized in the habituated group compared to non-habituated. In addition, newborn neurons were labeled using BrdU injection in the two groups and BrdU were revealed after 24 h to label newborn neurons or after 2 weeks to measure cell survival. The data obtained so far suggest that orientation and memorization in the Hamlet test promotes differentiation and maturation of adult neural progenitors and boosts neuroplasticity. Besides, neuroanatomical structures activated by habituation in the Hamlet were labeled using cFos and FosB and expression levels of memory-related immediate early genes are currently analyzed. Therefore, the Hamlet test allows the study of topographical memory in mice based on complex environment habituation and could provide an innovative tool to many research needs in various scientific fields.

Title: Systemic inflammation induces persistent dysregulation of memory and gene expression

Authors: ***D. TCHESSALOVA**[1], K. M. COLLETTE[2], A. A. KEISER[2], L. M. TURNBULL[2], A. E. WEHBE[2], N. C. TRONSON[2];
[2]Dept. of Psychology, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Systemic immune activation occurring during illness or surgery results in cognitive and memory deficits that last for years after recovery. To better understand how acute inflammatory signaling induces persistent alterations in memory, we used subchronic systemic immune challenge and examined long-lasting changes in memory, epigenetic modifications, and gene expression. There are sex differences in immune responses and susceptibility to persistent memory deficits, therefore we compared male and female mice throughout this study. Our paradigm consisted of intermittent systemic injections of one of two immune-inducing agents: the bacterial endotoxin lipopolysaccharide (LPS: 250ug/kg) or the viral analog polyI:C (6

mg/kg). Persistent changes in hippocampal-dependent memory were assessed either one week or eight weeks after the last injection using contextual fear conditioning and novel-object recognition. No alterations in hippocampal-dependent memory were observed at one week. In contrast, there was significant, sex-specific dysregulation of memory in both tasks eight weeks after the last injection. Notably, females, but not males, showed altered context fear conditioning. These findings demonstrate that alterations in memory emerge long after immune signaling has resolved, in a sex-dependent manner. Enduring changes in histone modifications and gene expression in the hippocampus were detected using western blotting and RNAseq, respectively. Of particular interest, were histone acetylation and methylation (eg. H3K9ac, H3K27me3) marks together with expression of neuroimmune proteins, neurotrophins, and stress-associated signaling pathways. Collectively, these data demonstrate that a systemic immune challenge induces sustained dysregulation of hippocampal-dependent memory and enduring differences in gene expression that may underlie the changes in memory. Systemic inflammatory events, such as major illness, cause long term alterations in epigenetic regulation and gene expression that contribute to the development of sex-specific memory impairments, cognitive alterations, and mood disorders.

Title: The impact of neurogenesis on flexible maze training: effects on hippocampal volume, depression, and cognition

Authors: *T. J. SCHOENFELD, D. RHEE, H. A. CAMERON;
NIMH/NIH, Bethesda, MD

Abstract: Hippocampal volume loss is a biomarker for depression and is correlated with cognitive defects. Volume recovery is suggested to mediate symptom improvement, however little is known about the cellular changes responsible for hippocampal volume change. Research shows that ablation of neurogenesis in adult rats reduces hippocampal volume and blocks behavioral effects of antidepressants. Taxi drivers have larger hippocampi than non-drivers,

suggesting that spatial training induces hippocampal growth. Therefore, we were interested in devising a rat model of spatial training-induced hippocampal growth and exploring the role of neurogenesis in that growth. To do this, we created a novel maze, called the flex maze, with interchangeable walls that enables us to create multiple mazes within the same arena. We treated GFAP-TK transgenic rats (TKs) and WT littermates with valganciclovir for 8 weeks to specifically ablate adult neurogenesis. Rats were then trained on three different mazes, each with unique olfactory and visual cues, over the course of 4 weeks. Control rats also had daily access to the arena, but with only a fixed route towards reward not requiring any maze solving. After training, rats were tested on novelty suppressed feeding (NSF) to measure depressive-like behavior or an object location test to assess hippocampal-dependent memory. Brains were perfused and extracted to measure volume using a 14.1T MR scanner. Both WTs and TKs learned mazes at the same rate, showed spatial knowledge in probe trials, and retrieved mazes well after training. Only the maze scented with peppermint, an aversive odor for rats, showed a genotype difference, as WTs were slower to solve this maze and did not retain it in retrieval trials. Flex maze-trained WTs had larger hippocampi than controls, which was fully explained by increases in ventral CA1. TKs did not show this volume increase, but had smaller hippocampi than WTs, with significant volume decreases in the dentate gyrus and CA3. Both flex maze-trained WTs and TKs had less depressive-like behavior in NSF, but only flex maze-trained WTs showed increased learning in the object location test. The data suggest only 4 weeks of flex maze-training is sufficient to increase CA1 volume in ventral sections, however this is dependent on the presence of adult-born neurons in the hippocampus.

Title: Chemogenetic modulation of the medial habenula during cocaine action.

Authors: *A. J. LOPEZ, M. E. ESPINOZA, K. M. SAKATA, A. O. WHITE, J. L. KWAPIS, A. AL-KACHAK, Y. ALAGHBAND, D. P. MATHEOS, M. A. WOOD, 92697;

Abstract: The medial habenula is an epithalamic region characterized by a dense projection to the interpeduncular nucleus. This projection is known as a hub for nicotinic acetylcholine receptors and cholinergic signaling. As such, addiction research has focused on the MHb with regard to nicotine, specifically nicotine withdrawal and self-administration. Yet, the role of the MHb in response to other drugs of abuse, such as cocaine, remains relatively uncharacterized and unclear. We use Designer Receptors Exclusively Activated by Designer Drug (DREADDs) to assess the role of the MHb in cocaine-associated memory. DREADDs are a novel tool that can be applied to drive changes at the cellular, circuit and, ultimately, behavioral levels. Their unique sensitivity to clozapine-n-oxide (CNO) paired with specific viral approaches allow for DREADDs to target particular brain regions, and more importantly, specific cell-types. Here, we demonstrate that the MHb is sensitive to specific cocaine treatments and is engaged by reinstatement of cocaine-induced conditioned place preference. We assessed the role of acetylcholine neurons in the MHb in relapse-like behavior using a conditioned place preference paradigm. ChAT-IRES-Cre mice received bilateral infusions of Cre-dependent excitatory (DIO-HM3D) or inhibitory DREADD (DIO-HM4D) into the MHb (0.5uL, M/L: +/- 0.33; A/P: -1.55; D/V: -3.0). Following conditioning and extinction, animals were primed with 3 mg/kg CNO (0.5% DMSO, 0.9% saline; I.P.) or vehicle (equal w/v) 40 minutes prior to being reinstated. For DIO-HM3D experiments, animals were reinstated with saline. For DIO-HM4D experiments, animals were reinstated with 5 mg/kg of cocaine-HCl. We demonstrate that DREADD-induced activation of MHb acetylcholine neurons can induce reinstatement of cocaine-induced CPP in the absence of cocaine. Conversely, DREADD-induced inhibition is capable of blocking cocaine-primed reinstatement of CPP. These experiments support previous work demonstrating the MHb is engaged following cocaine re-exposure. Moreover, in demonstrating the MHb is necessary and sufficient for reinstatement of cocaine-induced CPP, we provide evidence for its unique role in associative memory and other drugs of abuse.

Title: Fatty acid amide hydrolase overexpression in the basolateral nucleus of the amygdala paradoxically decreases anxiety and reduces fear expression in rats

Authors: *M. MORENA[1], K. D. LEITL[2], A. RASHID[3], S. A. JOSSELYN[3], M. N. HILL[2]; [1]Cell Biol. & Anat. and Psychiatry, [2]Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: The endocannabinoid (eCB) system is well known to play an important role in the regulation of emotional states and cognitive processes. A growing amount of evidence has demonstrated that elevations in the eCB anandamide (AEA) signaling within the basolateral complex of the amygdala (BLA) attenuate stress responses such as anxiety and fear expression. Specifically, inhibition of AEA hydrolysis by the enzyme fatty acid amide hydrolase (FAAH) within the BLA has been shown to reduce anxiety, neuroendocrine responses to stress and promote fear extinction. To determine if impairments in AEA signaling within the BLA would produce the opposite effects, and induce a stress-like state characterized by heightened anxiety and sustained fear, we examined the effects of overexpression of FAAH locally within the BLA on behavioural indices of anxiety and fear memory dynamics. Male adult Sprague Dawley rats were bilaterally infused in the BLA with an Herpes simplex virus type 1 vector, which preferentially infects principal neurons, containing FAAH and green fluorescent protein (HSV-FAAH-GFP) or a control vector containing only GFP (HSV-GFP). 72 h following HSV administration, a time point in which protein transfection is maximal, we found increased FAAH-mediated AEA hydrolysis together with decreased AEA levels within the BLA, confirming that the virus did successfully increase FAAH expression. At this same time point, a separate cohort of rats was tested for anxiety behaviour in an elevated plus maze, a light/dark box and an open field task. Quite surprisingly, we found that the overexpression of FAAH induced consistent anxiolytic effects in all three behavioural tasks we performed, relative to HSV-GFP rats. An additional cohort of animals was tested for fear memory extinction in an auditory fear conditioning paradigm. To prevent any effects of FAAH overexpression on the initial fear memory consolidation, animals were first fear conditioned and 24 h after conditioning, the animals were injected with HSV-FAAH-GFP or its control vector. 72 h following HSV administration rats were re-exposed to the tone alone for 4 consecutive days to examine fear extinction dynamics. Unexpectedly, rats infused with the HSV-FAAH-GFP vector exhibited a dramatic reduction in fear expression when exposed to the tone after conditioning, particularly on the first day of extinction training as compared to their HSV-GFP control rats.

These findings suggest that the exact modes of action of AEA within the amygdala in the regulation of emotional states and memory are still far from being clear, thus, opening the avenue to investigate new potential mechanisms by which these processes may occur.

Title: Nuclear receptor Nr4a mutant mice have impaired hippocampus dependent memory formation

Authors: ***S. CHATTERJEE**[1], W. O'BRIEN[2], M. BRIDI[3], J. HAWK[3], T. ABEL[1]; [1]Biol., [2]Dept. of Neuroscience,, [3]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA

Abstract: New experiences are initially encoded as labile short-term memories, which are converted into stable long-term memory by gene transcription-dependent processes. Gene expression after learning involves a transient wave of transcription that is critical for memory consolidation. Following early transcriptional activity, learning also induces persistent long-lasting transcriptional changes that are reported to be involved in the storage of long-term memory. Increased transcript levels of 13 nuclear receptors, including all 3 members of the Nr4a subfamily, have been identified after learning. Interestingly, after learning, the promoters of Nr4a1, Nr4a2 and Nr4a3 show higher occupancies of histone H3.3, a mark for active transcription. In the present study, we show that transgenic expression of a dominant-negative form of NR4A (Nr4aDN) in forebrain neurons impairs long-term memory consolidation in spatial object recognition and Barnes maze. Importantly, the Nr4aDN mice do not show anxiety related behaviors in elevated zero maze. Golgi staining showed reduced dendritic spine density from CA1 pyramidal neurons of Nr4aDN mice. Quantification of the active components of AMPA and NMDA receptors at the synapses of Nr4aDN mice are being performed. We also identified Bdnf and Fosl2 as major targets of Nr4a dependent transcription. Chromatin Immuno-precipitation confirmed the binding of Nr4aDN to the promoters of Bdnf and Fosl2. Therefore,

the present study further underscores the importance of Nr4a function during hippocampus dependent memory storage.

Title: Comparative metallo- and element-omics profiling reveals aberrant copper contents in the brain of Ts1Cje, a mouse model for Down syndrome

Authors: ***K. ISHIHARA**[1,2], E. KAWASHITA[1], K. YAMAKAWA[2], H. SAGO[3], S. AKIBA[1]; [1]Kyoto Pharmaceut. Univ., Kyoto-Shi, Japan; [2]Lab. for Neurogenetics, RIKEN Brain Sci. Inst., Wako-shi, Japan; [3]Ctr. of Maternal-Fetal, Neonatal and Reproductive Med., Natl. Ctr. for Child Hlth. and Develop., Tokyo, Japan

Abstract: It is poorly understood the dyshomeostasis of elements including trace metals in the brain with Down syndrome (DS), although trace metals such as zinc, manganese, copper and iron are necessary for the growth and function of the brain. Since the Ts1Cje mouse is widely used as an animal model of DS, we examined here the brain levels of biogenic trace elements including biogenic metals in the brain of Ts1Cje mice. The levels of ultra-trace, trace, and major elements in the hippocampus, striatum, cerebral cortex, and cerebellum of Ts1Cje mice and wild-type littermates were assessed by inductively coupled plasma mass spectrometry (ICP-MS). Semi-quantification analysis revealed that the levels of some elements were disturbed in the cerebral cortex, hippocampus, striatum and cerebellum of Ts1Cje mice at 3 months of age (n = 7) compared with wild-type mice (n = 10). Especially, the concentration of copper ion in the brain of Ts1Cje mice was significantly increased in the three brain regions, cerebral cortex, hippocampus, and cerebellum. Furthermore, 1.5-2-fold increase in the concentration of copper ion in the Ts1Cje brain (n = 7) compared with wild-type mice (n = 6) was confirmed by a punctual quantitative analysis of ICP-MS. To explain the mechanisms of excess accumulation of copper ion in the brain of Ts1Cje, we assessed the expression of copper transporting proteins, Ctr1, Atp7a, and Atp7b. The P-type ATPases, Atp7a and Atp7b, both transport copper out of cells or into the trans-Golgi network, whereas Ctr1 is a plasma membrane protein that functions

as a high-affinity cellular copper uptake transporter. Immunoblot analysis revealed that the expression of Ctr1 was significantly decreased in the cerebral cortex, hippocampus, and cerebellum, but not in the striatum of Ts1Cje mice at 3 months of age (n = 3) compared with wild-type mice (n = 3). In contrast, Atp7a and Atp7b were expressed at a similar level in the brain regions of both genotypes. Our findings suggest that the dysregulated accumulation of copper ion may contribute a cognitive impairment in Ts1Cje mice.

Title: Maternal behaviour effects on atrx expression, genome stability and longterm neurobehavioral development in the adult offspring

Authors: *I. C. WEAVER, K. LEE, A. KORGAN, E. WAUGH, A. HUNDERT, E. MACRAE, D. GOGUEN;
Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Mounting evidence indicates that the maintenance of chromatin architecture is essential for normal human development and cognitive function. The ATRX gene, which is essential for normal growth and cognitive development, encodes a chromatinremodeling protein that is expressed in developing neural structures, including newlyborn cortical and hippocampal neurons in mice. Employing a new model of gestational psychological stress, in combination with wellestablished models of physical prenatal stress, we have shown that maternal behavior mediates the effects of gestational psychological stress on neural ATRX gene expression in the offspring, which is associated with alterations in DNA methylation, DNA damage signaling and stable individual differences in learning and memory and anxietyrelated and social behavior, as well as cortical and hippocampal function in the adult animal. These results and those from crossfostering studies support the possible involvement of ATRX in the sensitization of neurons to stress hormones and the programming of somatic behavior in response to maternal care. Since

disruption of ATRX impairs cognition and motor functions, inhibits learning in mouse pups, and contributes to developmental silencing of imprinted genes that shape somatic growth and brain, we hypothesize that the effects of motheroffspring interactions during the first week of postnatal life on ATRX expression and function influences both genome integrity and gene expression programs that underlie normal cognitive and emotional development. The elucidation of the mechanisms involved in the impact of neonatal nurturing addresses perhaps the most challenging question in development: How are experiences occurring in early life rendered permanent? In the case of genome stability and sustained changes in gene expression in brain cells, we can begin to understand the neurobiological basis for individual differences in personality and cognition as well as related risk for learning and behavioural disorders (e.g., Autism Spectrum, ADHD).

Title: Modelling episodic memory deficit in depression

Authors: *J. FANG, S. CHENG;
Ruhr-University Bochum, Bochum, Germany

Abstract: Major depressive disorder (MDD) is a common and costly disorder associated with considerable morbidity, disability, and risk for suicide. MDD is characterized by a constellation of behavioral, emotional and cognitive symptoms especially in the domain of memory. In particular, many studies find an impairment of episodic memory in MDD patients, some observing an almost linear correlation between episodic memory performance and scores on a depression rating scale. Although the mechanisms underlying this memory dysfunction remain unclear, diverse animal models of depression find impaired adult neurogenesis (AN) in dentate gyrus. These newborn cells synaptically integrate into the hippocampal circuit and provide the potential substrates for new learning and memory. Both psychophysiological and computational studies suggest that dentate gyrus AN plays a critical role in minimizing interference between

overlapping memories by pattern separation, by which similar, but not identical, inputs are made less similar at the output stage. Therefore, we propose that inhibition of AN related to depression would prevent pattern separation so that the ambiguity between stored memories further impairs the accuracy of episodic memory retrieval. Here, we adapt a computational model of the semantic and episodic memory system, which we developed in previous work. In this model, a semantic representation is learned as a low dimensional representation of high-dimensional sensory input. During encoding of an episode, sequences of semantic representation patterns are stored as episodic memory. We model the impact of AN on episodic memory via its effect on pattern separation. In this model, AN adds additional noisy components to the original memory patterns. These components are unique to each memory sequence, i.e., patterns in the same sequences share the same noisy components, but they differ between different sequences. Hence, our model implements pattern integration between patterns within a sequence and facilitates discrimination between similar memory patterns in different sequences. This feature distinguishes our model from previous approaches, which assume that pattern separation operates on individual patterns. Our results show that retrieval performance is significantly better for the memories stored and retrieved during an asymptomatic phase, as compared to those memories stored and retrieved during a depressive episode. We also observe a retrograde effect for memories stored during an earlier asymptomatic phase, but retrieved during a later depressive episode.

Title: Dimorphic modulation of the membrane-associated progesterone receptor neudesin in adult hippocampal neurogenesis

Authors: *A. NOVAIS[1,2], C. FERREIRA[2], F. MARQUES[2], N. SOUSA[2], J. PALHA[2], J. C. SOUSA[2];
[1]Life and Hlth. Sci. Res. Inst. (ICVS), Braga/Guimarães, Portugal; [2]Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Hlth. Sciences, Univ. of Minho and ICVS/3B's - PT Government Associate Laboratory,, Braga/Guimarães, Portugal

Abstract: Neudesin, also known as neuron derived neurotrophic factor (NENF), is a heme/steroid binding protein. *In vitro* it has been shown to be a potent stimulator of embryonic

neuronal precursors proliferation and differentiation, as well as a survival factor for neurons. Surprisingly, *in vivo* NENF's putative neurotrophic action has only been reported to be novel anorexigenic neurotrophic factor. Since NENF presents a cytochrome b5-like heme/steroid binding domain in it's primary structure, it is classified as a member of the membrane associated progesterone receptor family similarly to PGRMC1, a protein that binds progesterone to induce rapid non-genomic effects independent of nuclear receptors. Although NENF's binding to progesterone has not been proven yet, NENF protein structure has 39% of structural homology to PGRMC1 and has been hypothesized to participate in these cascades. In the brain, progesterone and its metabolites are reported to influence, with gender-specificity, cellular plasticity and neurogenesis particularly at the hippocampus. Another important characteristic of progesterone is its anxiolytic effect revealed to act through non-genomic actions. In this study, we used neudesin-null mice and performed a global characterization adult behavior, as well as, assessed the proliferation status of both adult neurogenic niches (hippocampus and sub ventricular zone). In adulthood neudesin-null males show an anxious-like phenotype in novel contextual exposure paradigms, as the elevated plus maze (EPM), light-dark box and the novelty suppress feeding tests. These gender differences were also present in the neurogenic niche of the hippocampus (sub granular zone) but not in the sub ventricular zone. Additionally neudesin-null males show an impaired freezing behavior in the contextual fear conditioning protocol, a task dependent on adult newly born neurons in the dentate gyrus. Neudesin-null mice gender differences together with the possible involvement of neudesin in the non-genomic actions of progesterone made us hypothesized if neudesin might be involved in this phenomenon. Our data might support a mechanistic link between progesterone, neudesin and hippocampal neurogenesis in the modulation of contextual dependent tasks.

Title: Proteomic analysis of intracellular signaling pathways underlying visual recognition memory in monkey

Authors: *B. A. CORGIAT[1,2], C. MUELLER[2], J. N. TURCHI[4], J. L. OLDS[3], R. C. SAUNDERS[4], L. A. LIOTTA[2], M. MISHKIN[5];

[1]NIMH/NIH, Bethesda, MD; [2]George Mason Univ., Manassas, VA; [3]George Mason Univ., Fairfax, VA; [4]NIMH, Bethesda, MD; [5]NIMH, Bethesda, VA

Abstract: Visual recognition memory is critically dependent upon the perirhinal cortex. More specifically, visual memory formation requires cholinergic activation of perirhinal M1 receptors and is characterized by enhanced multiunit activity in the upper middle and deep layers of perirhinal cortex. However, the M1 muscarinic-dependent intracellular signaling profiles underlying the critical synaptic changes induced during visual memory formation are unknown. Since the M1 receptor activates numerous intracellular pathways, we attempted a proteomic approach that allows for a multiplexed analysis of signaling proteins from numerous brain regions. Using reverse phase protein microarrays (RPPA), preliminary data from our group indicated (1) highly variable phosphorylation levels of M1-dependent proteins in perirhinal cortices and other medial temporal lobe structures when sampled across three monkeys, and (2) a time-dependent decrease in phosphorylation levels of M1 proteins after tissue extraction. As a result we modified our tissue harvesting protocol to include (i) freezing the tissue more rapidly, (ii) freezing bilateral areas simultaneously, and (iii) increasing the amount of tissue sampled per brain region. These modifications, plus a within animal interhemispheric comparisons, improve our ability to see protein changes related to memory function in future behavioral experiments.

Title: Olfactory memory is enhanced via Wnt/β-catenin signaling in the subventricular zone of mice exposed to extremely low-frequency electromagnetic fields

Authors: *A. MASTRODONATO[1], S. BARBATI[1], L. LEONE[1], C. COLUSSI[2], K. GIRONI[1], C. GRASSI[1];
[1]Inst. of Human Physiol., Univ. Cattolica Med. Sch., Rome, Italy; [2]Inst. of Cell Biol. and Neurobiology, CNR, Monterotondo (RM), Italy

Abstract: We recently reported that exposure to extremely low-frequency electromagnetic fields (ELFEF) enhances hippocampal-dependent spatial learning and memory by increasing hippocampal neurogenesis. The present study was aimed to investigate whether ELFEF stimulation also affects olfactory memory by modulating neurogenesis in the subventricular zone (SVZ) of the lateral ventricle, and to identify the underlying molecular mechanisms.
We found that 30 days after the completion of ELFEF stimulation protocol (1 mT; 50 Hz; 3.5 h/day for 12 days) ELFEF-exposed mice showed a higher discrimination index between a familiar and a novel odor than controls (82.8 ± 3.8 vs 64.2 ± 3.9%, respectively; n=8; $p<0.01$). Sixty minutes after the first trial, animals were exposed again to the same odor for 5 min: ELFEF-exposed mice showed a significant decrease in the time of exploration on the second presentation compared to controls (4.9 ± 0.5 [n=7] vs 9.9 ± 1.1 s [n=8], respectively; $p<0.001$) and an increased digging time near the odor that was previously associated to a reward (19.0 ± 1.4 vs 9.9 ± 0.9 s respectively; n=8; $p<0.001$).
Immunohistochemical analyses performed in ELFEF-exposed mice revealed increased NSC proliferation in the SVZ, as assessed by the number of $BrdU^+/Nestin^+$ cells (833.7 ± 0.9 vs 532.6 ± 0.1 in controls; n=3; $p<0.01$). Newborn NSCs differentiating towards the neuronal phenotype (i.e., $BrdU^+/DCX^+$ cells) were similarly increased in the rostral migratory stream of ELFEF-exposed mice (408.2 ± 1.1 vs 118.6 ± 0.7 cells in controls; n=3; $p<0.001$). This difference was retained when we counted the number of new cells that had become mature neurons in the olfactory bulb (i.e., $BrdU^+/NeuN^+$ cells) 30 days after the end of ELFEF stimulation protocol (560.2 ± 14.3 vs. 262.2 ± 14.0 in controls; n= 3; $p<0.001$). These effects were associated with upregulated expression of mRNAs encoding for critical regulators of adult neurogenesis, including Wnt3, and with an increased nuclear localization of the transcription factor β-catenin. *In vivo* injection of the Wnt3 inhibitor Dkk-1 (200 ng /0.5 µl) into the SVZ of ELFEF-exposed mice reverted ELFEF's effect on olfactory memory. Dkk-1 treatments of cultured NSCs inhibited the expression of neurogenic genes suggesting that the ELFEF-induced increase of olfactory memory relies on SVZ neurogenesis modulation.
Collectively, our findings unveil a new molecular mechanism regulating olfactory memory in mammals that relies on Wnt/β-catenin pathway and open the way to novel treatments of brain disorders associated with impaired adult neurogenesis and olfactory memory including neurodegenerative diseases and mood disorders.

Title: The impact of phospholipase D1 and D2 genetic ablation in hippocampal functioning

Authors: *T. G. OLIVEIRA[1], I. CASTANHO[1], L. S. MARINHA[1], R. R. SILVA[1], A. M. MIRANDA[1,2], F. V. BRAVO[1], G. DI PAOLO[2], V. PINTO[1];
[1]ICVS/3Bs, Univ. of Minho, Braga, Braga, Portugal; [2]Columbia Univ., New York, NY

Abstract: Over the past years increasing amount of attention has been given to signaling lipids as well as to its modulating enzymes, such as phospholipases. Specifically, phospholipase D (PLD), that converts phosphatidylcholine to phosphatidic acid, has been shown to exhibit a role in neurological development and physiology. Several studies have been associating PLD1 and PLD2, the two main mammalian PLD isozymes, to neurological processes, including neurotransmitter release, dendritic branching, cognition, and brain development. Also, the hippocampus has been suggested as one of the brain regions showing the highest PLD activity and neurodegenerative conditions such as Alzheimer's disease associated pathways have been shown to be modulated by PLD signaling. Thus, the aim of this project is to better understand the potential role of PLD in hippocampal function in adult mice upon Pld1 or Pld2 genetic ablation. We performed a hippocampal related behavioral characterization of these animals and a structural analysis regarding dendritic morphology. Our behavioral data, specifically considering motor and exploratory activity, anxiety and memory, showed that PLD2 knockout mice behavior is not altered when compared to their wild type littermates. Although most of this was also observed in the animals lacking PLD1, the results indicate an object recognition-dependent short-term memory deficit. Regarding hippocampal dendritic arborization, the ablation of either PLD1 or PLD2 led to an increase in dendritic morphology, although with a different impact of each isozyme in the dorsal and ventral hippocampus. Our results suggest the separate ablation of PLD1 and PLD2 leads to different effects in the dorsal and ventral hippocampus.

Title: Variations in intersession habituation behavior and genetic background within two cohorts of the same Il7r knockout mouse

Authors: *G. W. BOTHE[1], A. F. EISENER-DORMAN[1,2,3], D. J. SYMULA[1], V. J. BOLIVAR[1,2];

Abstract: Targeted ablation, one of the most commonly used tools in mouse genetics, plays an important role in elucidating the complexities of gene function. However, it is critical to remember that conventional gene ablation methodology has limitations that could lead to erroneous conclusions about the actual role of the targeted gene. Although a phenotype can be due to the absence of the targeted gene, it may instead be the result of residual embryonic stem cell-derived genetic material, either in the flanking region immediately surrounding the ablated gene or in the rest of the genetic background. The use of different strains/substrains for subsequent breeding can also introduce genetic variation that may contribute to an observed phenotype. To illustrate this point, we investigated the genetic underpinnings of a habituation behavior deficit using two cohorts of the same Il7r-/- knockout mouse obtained from The Jackson Laboratory. Using our published breeding scheme and whole-genome genotyping, we determined that the genetic background was responsible for the habituation deficit: the Il7r-/- cohort with a mixed C57BL/6J (B6J) and C57BL/6TB6/N (B6N) background and a greater amount of residual 129S7-derived genetic material exhibited poor habituation, whereas the Il7r-/- congenic cohort with a primarily B6/J genetic background had habituation levels similar to those of B6J controls. Further testing is necessary to determine whether the behavioral differences are due to residual 129S7-derived genetic material or genetic differences between the two B6 substrains; however, our findings underscore the importance of investigating the genetic background of knockout mice to avoid misinterpretation of results.

Title: Optogenetic interrogration of the role of dorsal and ventral hippocampal adult-born neurons in contextual fear conditioning

Authors: *K. A. HUCKLEBERRY[1], T. COPELAND[1], F. SHUE[1], W. YIN[2], R. A. CHITWOOD[1], M. R. DREW[1];

Abstract: The hippocampus contains one of the few neurogenic niches within the adult brain—the subgranular zone of the dentate gyrus (DG)—and exhibits significant functional heterogeneity along its dorsoventral axis. Although adult-born neurons within the DG have been implicated in many hippocampus-dependent behaviors, little is known about how the function of the adult- born neurons varies along this axis. We used a highly specific Nestin-CreER(T2) mouse line (Lagace et al., 2007; Sun et al., 2014) to induce expression of the light-activated neural silencer archaerhodopsin in neural progenitor cells and their progeny. Optical fibers were implanted into the dorsal or ventral DG to selectively silence adult-born neurons in these regions. We then tested the contribution of ≤6-week-old adult-born granule cells to acquisition of context fear memory by delivering laser illumination during training. Neither dorsal nor ventral silencing affected the activity burst during the shock, indicating that silencing did not alter shock sensitivity. Silencing dorsal but not ventral adult-born neurons significantly decreased postshock freezing, a measure of short-term memory (Fanselow, 1980, 1982). Context memory expression was tested twenty-four hours after acquisition without laser illumination. Both dorsal and ventral silencing during acquisition were associated with reduced freezing in the context test. The data confirm earlier reports that adult hippocampal neurogenesis is required for acquisition of contextual fear (Saxe et al., 2006; Drew et al., 2010; Denny et al., 2012). However, the results conflict with other recent reports suggesting that ventral DG is not necessary for contextual fear conditioning (Khierbek et al., 2013; Danielson et al., 2016). Experiments in progress are assessing how inhibiting dorsal and ventral adult-born neurons alters local neural activity and the generalization of context fear. In summary, silencing dorsal adult-born neurons impaired both short- and long-term memory for context fear, whereas silencing the ventral adult-born neurons impaired only long-term memory. The data suggest that dorsal and ventral hippocampal adult-

born neurons make distinct contributions to context fear memory. We hypothesize that the dorsal adult-born neurons support context memory while the ventral adult-born neurons support the context-shock association.

Title: Inflammatory signaling and epigenetic modifications in persistent memory deficits after myocardial infarction

Authors: *K. COLLETTE[1], R. E. GARCÍA-HERNÁNDEZ[1], A. A. KEISER[1], D. TCHESSALOVA[2], L. M. TURNBULL[1], G. LU[1], N. C. TRONSON[1];
[1]Psychology, [2]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Cognitive impairment after an inflammatory event, such as myocardial infarction (MI) or major surgery, persists in many patients long after inflammation has abated. These cognitive deficits correlate with a higher rate of morbidity and mortality as well as reduced quality of life. Here we examined the mechanisms by which short-term inflammatory signaling causes persistent changes in neural function contributing to disruptions of memory. Prior results from our laboratory demonstrated that memory deficits and depression-like behavior occur 8 weeks after a cryo-injury model of MI in mice. In contrast, 2 weeks after MI, no memory impairments were evident. These findings suggest that the initial inflammatory event triggers ongoing molecular dysregulation that mediates persistent changes in affective processing and memory. To determine the interactions between neuroimmune signaling, intracellular signaling pathways, and epigenetic modifications leading to impaired memory, we examined specific changes in these factors over a time-course of 3 hours to 8 weeks following MI. We used MI, sham, and non-operated mice at each time-point. Cytokines (serum and hippocampus), MAPK signaling pathways, and histone acetylation in the hippocampus were examined shortly after surgery. At 1 and 8 weeks post-MI, we assessed memory and quantified levels of histone acetylation and methylation. After 8 weeks, we observed ongoing epigenetic changes including increased acetylation in male (H3K9) and female (H3-phosphoS10-acK14) hippocampus in a sex-specific

manner. Determining the mechanisms of persistent cognitive impairments after MI will identify novel targets for their treatment and prevention.

Title: Extra-coding RNAs regulate dynamic DNA methylation and gene expression

Authors: *N. GALLUS, K. E. SAVELL, F. A. SULTAN, R. C. SIMON, J. S. REVANNA, J. J. DAY;
Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Epigenetic mechanisms in neurons are central regulators of neuronal function, experience-dependent gene expression, and adaptive behavior. DNA methylation is a well-studied epigenetic mechanism that exerts potent control over transcription and is critical for synaptic plasticity and long-term memory in multiple brain circuits. Although DNA methylation at specific sites in the genome is actively modified by neuronal activity and behavioral experience, it is presently unclear how methylation status at individual genes or even individual cytosine nucleotides can be targeted for modification. Extra-coding RNAs (ecRNAs) are non-coding, non-polyadenylated RNA species that arise from protein coding genes and regulate DNA methylation via direct interactions with DNA methyltransferases (DNMTs). Here, we used cortical neuronal culture systems to investigate the regulation, binding, and localization of a specific ecRNA transcript from the Fos gene locus. We find that this ecRNA is sensitive to multiple forms of neuronal activity, binds to both de novo and maintenance DNA methyltransferases with high affinity, and blocks DNA methylation at the Fos locus. To investigate the localization of ecRNA on a single cell basis, we employed single-molecule RNA FISH with multiplexed probes to separately identify mRNA and ecRNA transcripts. This technique confirmed activity-dependence of ecRNA induction and revealed a correlation between ecRNA and mRNA expression on a single cell level. Consistent with this observation,

anti-sense based knockdown of the Fos ecRNA selectively reduced Fos mRNA. Ongoing experiments are investigating the ability of targeted ecRNA delivery to specific gene loci to alter DNA methylation patterns and gene expression. Overall, these results suggest that ecRNAs are fundamental regulators of the establishment and perpetuation of DNA methylation patterns in neuronal systems, and reveal a promising avenue for epigenetic targeting in neurological and cognitive disease states.

Title: CREB is not necessary for increases in hippocampal volume induced by environmental enrichment

Authors: ***D. A. VOUSDEN**, R. ALLEMANG GRAND, J. SCHOLZ, S. JOSSELYN, P. FRANKLAND, J. P. LERCH;
Neurosci. & Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Human imaging studies show that experience leaves a lasting impact on brain structure. For instance, learning to juggle or navigate an environment alters the volume of specific brain regions (Zatorre 2012). However, the cellular mechanisms and signaling pathways underlying these volume changes remain poorly understood. Mouse imaging studies are ideal for probing the cellular bases of these changes. In rodents, environmental enrichment is a well-established paradigm to study the effect of experience on the brain (Diamond 1964). Environmental enrichment refers to housing conditions that provide more stimulation than standard cages, and can include toys, running wheels and social interaction. Enrichment is associated with many responses, including increases in dendritic branching, cell genesis and behavioural changes (van Praag 2000). Moreover, enrichment increases hippocampal volume at a scale detectable with mouse MRI (Scholz 2015). However the link between cellular and volume changes is unknown.
One hypothesis is that the enrichment effects are due to learning to navigate a novel, spatially complex environment, and are mediated by the same cellular mechanisms underlying learning

and long-term memory (LTM). Consistent with this, spatial maze-training also increases hippocampal volume in mice, but this effect is reduced in mice with impaired LTM. Given this, we hypothesized that enrichment-induced changes in hippocampal volume could be blocked by targeting the signaling pathways implicated in learning/LTM.
The transcription factor CREB is critical for LTM and modulates many processes stimulated by enrichment including dendritic growth. We used CREB deficient mice to ask whether volume changes induced by enrichment require CREB-dependent processes.
Methods: In vivo manganese-enhanced MRI was used to image adult CREB mutant mice (CREB+/+, CREB+/- & CREB-/-) at baseline, and then 48 hours, 1 week and 2 weeks after mice were placed into an enriched or standard environment. The enriched cage consisted of 3 storeys with tunnels and a running wheel. Automated image processing algorithms were used to detect volume changes associated with enrichment.
Results: Surprisingly, our preliminary results suggest that enrichment increases hippocampal volume regardless of CREB genotype. This implies that contrary to our hypothesis, the volume changes are mediated by CREB-independent pathways or that only residual CREB function is required. Future experiments will test our revised hypothesis that hippocampal volume changes induced by enrichment are mediated by CREB-independent effects of exercise, while those induced by spatial learning require CREB.

Title: Mapping emerging neocortical active ensembles during retrieval of remote memory via functional bioluminescence imaging of Arc promoter activity

Authors: *N. YAGISHITA-KYO[1], H. OKUNO[1,2], S. KAMIJO[1], T. KAWASHIMA[1], Y. UEMURA[3], S. TAKEMOTO-KIMURA[1,4], H. BITO[1];

Abstract: Activity-dependent gene expression is critical for the persistence of long-term memory. However, it has been challenging to identify, map and longitudinally compare active forebrain domains within the same animals *in vivo*, based on memory-related gene expression location during memory encoding and retrieval of remote memory. Previously, neurons activated after various cognitive tasks were determined *ex vivo*, based on immediate early gene (IEG) expression measured by means of *in situ* hybridization or serial two-photon tomography. To permit functional IEG imaging *in vivo*, we here developed a transcranial bioluminescence imaging system to enable widefield cortical recording of *Arc* promoter activity. First, we generated a transgenic mouse line in which an optimized luciferase reporter was driven under the control of the characterized full-length promoter of the *Arc* gene. We adopted a brighter version of luciferase (Emerald luciferase) as a reporter protein and further shortened its half-life using PEST sequence to minimize background and reliably measure *Arc* activation profile. In order to establish functional imaging from awake, head-fixed, intact-skull reporter mice, we further built an *in vivo* luminescence imaging system equipped with an EM-CCD, a head-fixed instrument, a light-proof box, and a continuous luciferin infusion port for long-term imaging. Using this imaging system, repeated transcranial imaging sessions were performed in the same animals over a couple of weeks, before, during and after an odor-reward association task, which initially required, but later became independent of, hippocampal activity. Based on image-based statistical analyses, we identified emerging, task-dependent, or memory retention period-dependent, increases in *Arc* promoter activity in several cortical areas associated with retrieval of remote memory of an odor-reward association task. These results shed new lights on the spatial spread and temporal dynamics of systems consolidation *in vivo*.

Title: BDNF rescues BAF53b-dependent synaptic plasticity and cocaine-associated memory in the nucleus accumbens

Authors: *A. O. WHITE, E. KRAMÁR, A. LÓPEZ, J. KWAPIS, J. DOAN, D. SALDANA, F. DAVATOLHAGH, Y. ALAGHBAND, M. BLURTON-JONES, D. MATHEOS, M. WOOD; Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Recent evidence implicates epigenetic mechanisms in drug-associated memory processes. However, a possible role for one major epigenetic mechanism, nucleosome remodeling, in drug-associated memories remains largely unexplored. Here we examine mice with genetic manipulations targeting a neuron-specific nucleosome remodeling complex subunit, BAF53b. These mice display deficits in cocaine-associated memory that are more severe in BAF53b transgenic mice compared to BAF53b heterozygous mice. Similar to the memory deficits, theta-induced long-term potentiation (theta-LTP) in the nucleus accumbens (NAc) is significantly impaired in slices taken from BAF53b transgenic mice but not heterozygous mice. Further experiments indicate that theta-LTP in the NAc is dependent on TrkB receptor activation, and that BDNF rescues theta-LTP and cocaine-associated memory deficits in BAF53b transgenic mice. Together, these results suggest a role for BAF53b in NAc neuronal function required for cocaine-associated memories, and also that BDNF/TrkB activation in the NAc may overcome memory and plasticity deficits linked to BAF53b mutations.

Title: The role of HDAC3 in object location memory formation and the acquisition and extinction of cocaine-associated memory

Authors: *Y. ALAGHBAND, J. L. KWAPIS, R. DANG, O. V. AIMIUWU, A. AL-KACHAK, A. O. WHITE, A. J. LOPEZ, K. M. LATTAL, D. P. MATHEOS, M. A. WOOD; Neurobio. and Behavior and Ctr. for the Neurobio. of Learning & Memory, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Chromatin modification is a molecular mechanism for both long-term memory formation and cocaine-induced neuroplasticity. Histone deacetylases (HDACs) are chromatin modifying enzymes that have been implicated as powerful negative regulators of memory processes. In these experiments, we investigate the role of HDAC3 (the most highly expressed Class I HDAC in the brain) in object-location memory as well as the acquisition and extinction of cocaine-associated memories using a genetic and viral approach. To investigate the role of HDAC3 in the dorsal hippocampus during object-location memory formation, C57BL/6J male mice received infusions of viruses which either overexpressed the *Hdac3* gene or had a dominant negative mutation of the gene. We demonstrate that impairing the enzymatic activity of HDAC3 in the dorsal hippocampus enhances object-location memory. Manipulating HDAC3 in the dorsal hippocampus also affects gene expression during the consolidation of object-location memory. Further, discrete stimuli or contexts previously associated with drugs of abuse are a major contributor to relapse among addicts. Conditioned place preference (CPP) is used to study cue-elicited context preference. Previous work from our laboratory has shown that inhibition of HDAC3 not only facilitates the acquisition of cocaine-CPP, but also modulates the extinction of drug-associated behavior in a manner that is subsequently resistant to reinstatement. The specific neural loci where HDAC3 plays this critical role in the acquisition and extinction of cocaine-cue memories is yet to be determined. In these experiments, we also explored the role of HDAC3 within the dorsal hippocampus and infralimbic cortex in cocaine-cue memories. Our findings demonstrate a critical role for HDAC3 in the molecular mechanisms underlying object-location and cocaine-cue memories.

Title: Do adult-born granule cells "retire"?

Authors: *W. C. ABRAHAM[1,4,5,2], S. M. OHLINE[2,5,4], R. U. HEGEMANN[2,5,4], K. L. WAKE[2,5,4], M. F. DINNUNHAN[2,5,4], L. SCHWEITZER[2,5,4,3], S. M. HUGHES[3,5,4]; [2]Psychology, [3]Biochem., [1]Univ. of Otago, Dunedin, New Zealand; [4]Brain Res. New Zealand, Dunedin, New Zealand; [5]Brain Hlth. Res. Ctr., Dunedin, New Zealand

Abstract: Neurogenesis in the dentate gyrus occurs throughout adulthood in mammals. However, there is controversy whether adult-born neurons decline in their activity levels and eventually "retire" as recently born neurons functionally take their place in neural circuitry. To address this issue, we birth-dated neurons in the dentate gyrus of Sprague-Dawley rats at 35, 12, 6 and 4 wk prior to study at 10 months of animal age, using the thymidine analogues chloro-deoxyuridine and iodo-deoxyuridine. We used immunofluorescence to identify active neurons, defined as those showing co-localization of the thymidine analogue and the immediate early gene Zif268, as well as a neuronal marker, either calbindin or NeuN. We found that, as predicted, cells born at 12 and 6 wk before study were significantly less active (i.e. showed less Zif268 expression) than cells born 4 wk prior ($p = 0.002$ and $p = 0.01$, respectively). Surprisingly, the cells born 35 wk prior to study, when the animals were 2 months old, expressed Zif268 just as frequently as 4 wk old cells. We then asked whether the relatively young animal age (2 months) when these 35 wk cells were born was the reason for the retained activity level across time. Cells birth-dated at this animal age and studied 12 wk later (animal age 5 months) showed the same high level of Zif268 expression as cells that were 4 wk old in the same animals. This contrasted with the low activity reported above for cells born at 7 months and studied 12 wk later at 10 months, suggesting that the animal age at cell birth is a critical factor. To further test whether the 35 wk cell age was in some way special, we birth-dated cells at 35 wk and 12 wk (when the animal was 7 months and 12 months old, respectively) prior to study at 15 months. The levels of activity at these two time points were not significantly different from each other, but significantly lower than the activity of the 35 wk old cells born at 2 months of animal age at studied at 10 months ($p = 0.0037$). Thus the 35 wk cell age is not itself a determinant of cell activity. Instead, these results indicate that neurons born when a rat is young (2 months of age) continue to be highly active in neuronal circuitry throughout adulthood. If "retirement" does occur, it may be specific to cells born during an animal's middle-age.

Title: Cholinergic Modulation of pyramidal neurons in the ventral Subiculum

Authors: *S. WANG[1,2], D. TALMAGE[2,3], L. ROLE[1,2];
[1]Program In Neuroscience, SUNY At Stony Brook, Stonybrook, NY; [2]Neurobio. and Behavior, [3]Pharmacol. Sci., SUNY at Stony Brook, Stony Brook, NY

Abstract: The ventral Subiculum (vSub) is a major output area of the hippocampus with projections to multiple brain region related to the acquisition and retention of memories associated with emotionally salient experience. The vSub receives cholinergic input from the medial septum and diagonal band of Broca (MS-DBB) complex. Previous studies show that altering the cholinergic input to the vSub changes the output to other areas (e.g. basolateral amygdala, BLA; Calandreau et al., 2006), and can profoundly vSub involved acquisition and recall of fear memory (Kenny et al., 2012; Cox et al., 2013). However, the circuits that mediate these changes within the vSub are less well described and the mechanism by which acetylcholine (ACh) regulates the circuit remains unclear. This current study is to determine how ACh modulates the activity within the vSub circuit and to determine how ACh regulates the output of vSub pyramidal projection neurons (PYNs). To begin to assess the effect of ACh on regulating vSub PYN excitability in acute vSub slice preparations, we deliver ACh with or without the presence of ACh antagonists and monitor the membrane potential and evoked currents in individual PYN via patch-clamp. ACh (1mM or 10uM) increases the overall firing rate of vSub PYNs. Lower concentrations of ACh also elicit a transient decrease in the frequency of tetrodotoxin (TTX)-resistant inhibitory synaptic transmission (mIPSC) onto PYNs. The cholinergic modulation of mIPSCs is blocked by submicromolar atropine, consistent with a muscarinic ACh receptor (mAChR) mediated mechanism. ACh also elicits a transient increase in the frequency of TTX resistant excitatory synaptic transmission (mEPSC) onto PYNs, which may involve nAChRs as removal of nAChR antagonists also elicits a transient increase in mEPSC frequency. To examine the effects of cholinergic signaling in vSub circuit dynamics we have used genetically encoded calcium indicators to monitor the calcium level within vSub PYNs. ACh (1mM) induces a dramatic increase in calcium signaling in over 80% of neurons, as

well as a change in the extent of synchronization of calcium waves among neighboring neurons. These data are consistent with the idea that ACh can increase the excitability of PYN network in vSub, possibly via both mAChRs and nAChRs.

Title: Alterations in the novel object recognition circuit following MeCP2 deletion from cholinergic neurons

Authors: *E. C. BALLINGER[1], C. P. SCHAAF[2], D. A. TALMAGE[1], H. ZOGHBI[2], L. W. ROLE[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Baylor Col. of Med., Houston, TX

Abstract: Rett Syndrome (RTT) is an autism spectrum disorder that affects approximately 1 in 20,000 girls and is caused by mutations in the gene encoding methyl CpG binding protein 2 (*MeCP2*). The cholinergic system appears to be particularly important in RTT, as decreases in cholinergic markers have been correlated with increased clinical severity in patients with RTT. Schaaf and Zoghbi have developed a powerful transgenic mouse model, whereby *MeCP2* is selectively deleted in cholinergic neurons only, to facilitate study of the contribution of this cholinergic lesion to the overall phenotype of RTT. Interestingly, this model exhibits a selective deficit in recognition memory, a form of declarative memory that has been shown by lesion and electrophysiological studies to be dependent upon cholinergic signaling in the perirhinal cortex (PRH). This memory deficit may map onto the intellectual disability seen in patients with RTT, however, its circuit level electrophysiological underpinnings are unknown. We use *in vivo* electrophysiology to compare baseline firing characteristics of PRH neurons in both mice in whom *MeCP2* has been selectively deleted in cholinergic neurons (*MeCP2* sKO) and control. We also use optogenetics to selectively activate cholinergic neurons in the Nucleus Basalis of Meynert, the cholinergic source nucleus that innervates the PRH, while simultaneously recording the effects of this selective activation to evaluate the cholinergic response profile of the PRH in each genetic condition. The network consequences of this altered responsiveness are evaluated using genetic markers of activity to map the recognition memory engram in both controls and

MeCP2 sKO. We have shown that PRH units of control are much more variable than PRH units from *MeCP2* sKO mice, perhaps indicating a loss of cholinergic modulation of firing. Additionally, the response of PRH units from *MeCP2* sKO to stimulation of cholinergic input is greatly reduced. Recognition memory engram mapping shows that while control mice show differential activation of the PRH when exposed to either a novel or a familiar object, *MeCP2* sKO mice show no such differential activation. The deficient cholinergic modulation of PRH unit firing that we have observed among *MeCP2* sKO mice may thereby impair encoding of the recognition memory engram and lead to the observed behavioral deficits. These results will further understanding of the role of ACh in encoding recognition memory and of the circuit level perturbations that may underlie cognitive phenotypes seen in patients with RTT.

Title: Cholinergic dysfunction of the entorhinal cortex in a mouse model of aging

Authors: *M. ANANTH[1], D. TALMAGE[2,3], L. ROLE[2];
[1]Program in Neurosci., [2]Dept. of Neurobio. and Behavior, [3]Dept. of Pharmacol. Sci., Stony Brook Univ., Stony Brook, NY

Abstract: Age-related cognitive decline is a growing problem; by the year 2050 over 80 million people in the United States will be aged 65 and older. As such, our understanding of the pathophysiology and progression of age-related cognitive decline is of the utmost importance. The cholinergic system has long been implicated in cognitive decline, and perhaps more specifically, severe pathological cognitive decline as observed in Alzheimer's disease. What remains unknown is the role of acetylcholine (ACh) in the temporal dynamics of age-related cognitive decline. The entorhinal cortex (EC) is an important relay station to the hippocampus, as well as a number of cortical areas. Importantly, it has been found to be particularly vulnerable in aging. The EC gets a major cholinergic projection from the basal forebrain (BF) cholinergic nuclei - a group of cholinergic nuclei that provide ACh to many cortical and subcortical structures. As the EC is affected early in aging, the circuit between the BF and the EC is of particular importance, and can give valuable information about how altered cholinergic system integrity in aging can alter cortical function. We have to our advantage a mouse model that

recapitulates aging pathology of both amyloid beta plaque and neurofibrillary tangle accumulation at an earlier physical age. Using this model, we use optogenetic stimulation and *in-vivo* electrophysiology to investigate the responsiveness of EC units to increased endogenous ACh.
Preliminarily, we have found that the health and integrity of the BF cholinergic nuclei are compromised in the aging model. When examining the extent of cholinergic innervation to the EC, we find that the aging model has less cholinergic terminals, and those that remain appear fragmented. Using *in-vivo* electrophysiology to understand the implications of these changes, we found that EC opto-stimulation differentially modulates EC units in the aging model as compared to controls. In response to increased ACh in the EC, control animals have an increase in firing rate, while aging animals have a change in the firing pattern with no increase in firing rate. Interestingly, at baseline, EC units in the aging model have elevated firing rate as compared to controls. These preliminary findings suggest that impaired cholinergic innervation of the EC may result in an elevated EC firing rate, which renders EC units unable to respond normally to endogenous ACh release. These studies can provide explanations as to the early ACh dependent vulnerabilities in EC function in aging. Additionally, these experiments provide key information regarding the circuit level implications that result from altered responsiveness to ACh.

Title: Amino acid metabolizing enzyme, l-amino acid oxidase, controls the contextual memory through modulating acetylcholine level

Authors: *K. USUDA, G. WATANABE, K. NAGAOKA;
Vet. Sci., United Grad. Sch. of Vet. Science, Gifu, Tokyo, Japan

Abstract: Amino acids participate directly and indirectly in a variety of important biochemical functions in brain. Recently, we identified that one of amino acid metabolic enzyme, L-amino acid oxidase (LAO), expressd in mice hippocampus. It has been known that LAO converts particular l-amino acids, phenylalanine, methionine and leucine etc. into keto acids, ammonia and hydrogen peroxide. In this study, we investigated the importance of LAO in brain function using by LAO knockout (KO) mice.
Firstly, we observed the presence of LAO protein in hippocampus of wild-type (WT) but not in

LAO KO mice by immunofluorescence analysis. In addition, we measured the concentration of free amino acids in the hippocampus using mass spectrometry analysis. It was found that some free amino acids such as phenylalanine significantly increased in the hippocampus of LAO KO mice compared to that of WT mice. Next, we conducted several behavior test, open field test, elevated plus maze test and passive avoidance test, and found that LAO KO mice showed higher anxiety and weaker short and long term contextual memory compared to WT mice. To understand the change of major neurotransmitter concentrations in the hippocampus, we also measured acetylcholine, noradrenaline, serotonin and dopamine by mass spectrometry analysis. Interestingly, acetylcholine concentration in LAO KO hippocampus was significantly lower than in WT. Thus, we administered donepezil, inhibitor of acetylcholinesterase, to LAO KO mice and conducted passive avoidance test. It should be noted that administration of donepezil clearly improved contextual memory in LAO KO mice. We also confirmed that the concentration of acetylcholine in LAO KO hippocampus after donepezil administration was recovered to same level in WT mice.
In conclusion, we revealed first evidence that LAO plays an important role in brain function, especially contextual memory through modulating acetylcholine level in hippocampus. Although we did not show exact mechanism how LAO modulates acetylcholine level, we provided one possibility that accumulation of phenylalanine might be related to decrease of acetylcholine level in LAO KO hippocampus.

Title: Role of the cholinergic midbrain in long-term habituation

Authors: A. LOUTTIT, N6G 1R3, E. AZZOPARDI, T. ZAMAN, *S. SCHMID;
Univ. of Western Ontario, London, ON, Canada

Abstract: Sensory filtering refers to the processes that allow us to pre-attentively filter out redundant or unnecessary sensory information and consists of one of the most basic forms of learning, habituation. Habituation is a progressive decrease in response following repeated exposure to a stimulus and can be studied using the acoustic startle response (ASR) and

exploratory behaviour in an open field as behavioural models. Habituation can be a either a transient process occurring within a single test session or long lasting when a decrease in response is observed across several sessions. The traditional view of cholinergic modulation of habituation is that acetylcholine is involved in habituation of motivated behaviour, such as exploratory behaviour, but is not involved in habituation of reflexive behaviour, such as the ASR. However, a recent study suggests that acetylcholine may be involved in long-term habituation of ASR. A potential cholinergic structure that has been previously implicated in modulating the startle response and locomotor behaviour is the pedunculopontine tegmental nucleus (PPT). We hypothesized that cholinergic PPT neurons modulate long-term habituation of the ASR and exploratory behaviour. To test the role of cholinergic PPT neurons in habituation, transgenic (CreChAT) rats were injected with an inhibitory DREADD (rAAV8-hSyn-DIO-hM4Di-mCherry) or control (rAAV8-hSyn-DIO-mCherry) viral construct. Long-term habituation of the ASR and exploratory behaviour was tested over five consecutive days in which a systemic injection of the DREADD activator clozapine-*N*-oxide (CNO) was delivered prior to the test session. Preliminary findings suggest that cholinergic PPT neurons are not involved in long-term habituation of the ASR, but may be involved in long-term habituation of exploratory behaviour. In addition to behavioural experiments, *in vitro* electrophysiology was performed to confirm neuronal silencing following CNO application.

Title: Reversal of scopolamine impairment by a type II nAChR alpha7 positive allosteric modulator in the NHP CANTAB paired associates learning task

Authors: ***M. R. WEED**[1], J. POLINO[1], D. POST-MUNSON[1], M. BOOKBINDER[1], L. KISS[2], J. HERRINGTON[1], L. J. BRISTOW[1];
[1]Genetically Defined Dis. and Genomics, [2]Leads Discovery & Optimization, Bristol-Myers Squibb Res., Wallingford, CT

Abstract: Performance on the human CANTAB paired associates learning (PAL) task is impaired in patients with mild cognitive impairment (MCI) and further impaired in Alzheimer's disease (AD). Indeed, worsening of PAL performance in MCI patients reliably predicts conversion to AD. Previous studies have demonstrated that scopolamine impairs performance on

a nonhuman primate (NHP) version of the CANTAB PAL task. Agonists at the nicotinic alpha 7 receptor subtype (nAChRa7) have been shown to significantly reverse scopolamine's impairment of the NHP CANTAB PAL task, and the present study investigated whether a positive allosteric modulator (PAM) selective for nAChRa7's would have a similar effect. nAChRa7 PAMs have been described as type I (where current is increased without changing receptor kinetics) and type II (receptor desensitization is slowed leading to a longer and larger charge transfer). Compound 1 potentiated peak ACh-induced currents 1-fold relative to a maximal ACh concentration 3 mM and slowed channel desensitization, resulting in a 52-fold increase in charge transfer, consistent with a type II nAChRa7 PAM. Cynomolgus monkeys (N=7) were trained to perform the CANTAB NHP PAL task, including multiple levels of task difficulty. Similar to previous reports, scopolamine pretreatment impaired NHP PAL performance in a difficulty-dependent fashion. Scopolamine-induced impairments were significantly ameliorated by Compound 1 at 0.1 mg/kg. These results are the first demonstrating scopolamine reversal by an nAChRa7 PAM in NHPs and are consistent with previous results where donepezil and nAChRa7 agonists significantly reversed scopolamine impairment of the NHP PAL task. Efficacy of nAChRa7 PAM in reversing scopolamine impairment is consistent with their development as therapeutics for cognitive decline in MCI or AD. In addition, the high degree of similarity of the NHP CANTAB PAL task and the human CANTAB PAL task provides a unique opportunity to perform highly translational research.

Univ., Seoul, Korea, Republic of

Abstract: *Terminalia chebula* extract (TCE) has been widely used for cardiotonic, diuretic, and homeostatic treatments in many Asian countries. The major components of TCE such as tannic acid and chebulagic acid have anti-oxidant, anti-mutagenic, and anti-inflammatory properties. Although several *in vitro* studies have examined acetylcholinesterase (AChE) inhibitory activities of TCE, its neuropharmacological effects on memory function remain to be examined. The present study, therefore, investigated the anti-amnesic effects of TCE using scopolamine model of memory impairments. Mice was orally administered with TCE (200 mg/kg) or donepezil (5 mg/kg) for 14 days (days 1-14), and scopolamine (1 mg/kg) was injected intraperitoneally for 7 days (days 8-14), 30 min before the Morris water maze task (MWM) which was used to examine cognitive status. The brain of animals was dissected to measure expression levels of AChE and choline acetyltransferase (ChAT) in the hippocampus. Animals with administration of scopolamine alone showed impairments in acquisition and retention in MWM and increased hippocampal AChE expression levels. TCE treatments significantly attenuated scopolamine-induced memory impairment and restored hippocampal AChE expression levels. In addition, TCE treatments increased hippocampal ChAT expression levels. These findings suggest that TCE might be cognitive enhancer associated with modulation of cholinergic neurons. Supported by the National Research Council of Science & Technology (NST) grant by the Korean government (MSIP) (No. G15120 and CRC-15-04-KIST).

Title: Neuromodulatory effects on acetylcholine on alpha rhythm generation and how it relates to cognitive functioning

Authors: *R. SHARMA[1], P. RAMAKRISHNA[2], S. NADKARNI[2];
[1]Biol., IISER-PUNE, Pune, India; [2]IISER-Pune, Pune, India

Abstract: Oscillations are said to play a vital role in organizing neuronal computations across various anatomical regions of the brain. These well characterized; wide range of brain rhythms are typically coordinated based on the intrinsic electrical properties of the neurons, network motifs, synaptic properties and neuromodulatory influences.
Acetylcholine(Ach) functions as a neurotransmitter, as well as a neuromodulator in the extra-cellular-matrix(ECM) driving activity in entire populations of neurons. In the thalamo-cortical circuit, the neuromodulatory effects of Ach can crucially change network excitability leading to activity in the alpha spectrum (one of the dominant oscillations of the brain).
In a biophysically detailed neuronal network model of the thalamo-cortical circuit, we explore the generation of alpha-rhythms and its mechanism of disruption in Alzheimer's Disease(AD). We quantify the detailed current dynamics of the thalamo-cortical circuit involved in alpha that leads to emergence of the rhythm via enhanced acetylcholine activity. We show how heterogeneity in gap-junctional coupling strength between high-threshold thalamocortical cells (HTCs) can produce rich dynamics wherein cells can fire in and out of phase in agreement with experiments and influence the alpha-rhythm activity. Further, we show how shifting alpha band to lower frequencies contributes to enhanced inhibitory drive to the HTC cells and can be the causal link to diminished power in the alpha spectrum seen in Alzheimer's patients. We also investigate how changes in intracellular calcium signaling related to AD can disrupt Alpha.

Title: Regulation of the temporoammonic pathway in the hippocampus by acetylcholine

Authors: *J. PALACIOS[1,2], J. R. MELLOR[1,2];
[1]Physiology, Pharmacol. and Neurosci., [2]Ctr. for Synaptic Plasticity, Sch. of Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: The release of acetylcholine in the hippocampus during awake behavior is important for encoding memory. Within the hippocampal network, acetylcholine has diverse effects which are not ubiquitous and instead are exhibited at individual neurons and synapses. The Temporoammonic (TA) pathway carries spatial information from grid cells in entorhinal cortex layer III (EC LIII) to CA1 hippocampal place cells synapsing onto the distal dendrites. It is not currently known how acetylcholine regulates synaptic transmission in the temporoammonic pathway or which acetylcholine receptors mediate this regulation. To determine how acetylcholine regulates the temporoammonic pathway we made whole cell patch clamp recordings from CA1 pyramidal neurons in acute hippocampal slices from adult mice. Electrical stimulation in the Stratum Lacunosum Moleculare was used to isolate excitatory postsynaptic currents (EPSC) in the presence of Picrotoxin and recording at -70 mV or disynaptic inhibitory postsynaptic currents (IPSC) recording at 0 mV. The acetylcholine receptor agonist carbachol (CCh 10 μM) reduced both excitatory and inhibitory synaptic responses and increased paired-pulse ratio for excitatory responses, indicating a presynaptic locus of action. Specific pharmacological intervention showed that neither M1 agonist was able to reproduce CCh induced synaptic currents reduction, nor M1 antagonist blocked the effect. In contrast, M3 receptor antagonist occluded CCh induced reduction of synaptic probability of release to the same extent for EPSC and IPSC. The reduction in synaptic response for excitatory and inhibitory responses was similar for both but the increase in paired pulse ratio for excitatory responses produced a facilitation of excitatory-inhibitory balance in response to repetitive stimulation. In addition, CCh produced an increase in the number of spikes in the CA1 pyramidal neurons when TA synapses were repeatedly stimulated over a range of frequencies. This increase was principally mediated by a membrane potential depolarization, rather than a synaptic effect. We conclude that acetylcholine modulates the temporoammonic pathway onto CA1 pyramidal neurons by presynaptically located M3 muscarinic receptors.

Title: Microanalytical system for neural response to neurotransmitter using voltage imaging and electrochemical micropump

Authors: *K. HARADA, Y. YOSHIMI;
Shibaura Inst. of Thechnology, Tokyo, Japan

Abstract: “Brain-on-chip (BOC)” devises, where neurons are incubated in microchips simulating internal condition of brain, are feasible for study of the mechanism of disease or chemotherapy of brains or neurons. Response of neurons to neurotransmitters is an important factor to evaluate activity of neurons in disease or therapy. Then we developed a new BOC devise which uses an electrochemically driven diaphragm micropump for neurotransmitter administration and voltage imaging for detecting neural response which is less invasive to the chip than traditional electrophysiological method. The micropump was fabricated by attaching polydimethylsiloxane (PDMS) sheets using plasma-etching. Electrolysis of the electrolyte pushed diaphragm to jet out the neurotransmitter solution in the pump. Then neurons isolated from abdominal ganglion of *Aplysia californica* were allowed to adhere on poly-L-lysine coated PDMS sheet to incubate for 3-4 days. The neurons were stained with Di-4-ANEPPS as a voltage sensitive dye (VSD). The dyed neuron was placed facing to the nozzle of the pump. Neural response was detected by the fluorescent intensity of the VSD. The VSD imaging of the neurons detected the action potentials 481 ± 64 ms later than the voltage application to the pump in order to administrate 1 mM acetylcholine solution. But the administration of 3 M potassium chloride solution by the micropump, the action potential was detected with latency of 277 ± 26 ms after the voltage application to the pump. The difference of response time is consistent with the fact that high concentration of potassium ion changes membrane potential directly but acetylcholine induces the potential change through acetylcholine receptor on the membrane. The result indicates that the administration of neurotransmitter by the micropump is effective for measurement of neural response latency. Neural signal can be detected less than one second, this system may monitor the neural function in the presence of therapeutic drugs or toxins. In this new system, neurons are not attached to the electrode and can be stimulated by plural neurotransmitters. The micropump has a very simple structure, and then many micropumps can be integrated in a small chip, which is promising to elucidate mechanism of neuron in abnormal condition.

Title: Presynaptic control of glutamatergic transmission by serotonin and acetylcholine in the prefrontal cortex

Authors: *A. L. BAKER, A. T. GULLEDGE;
Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: Neocortical pyramidal neurons comprise two broad classes of projection neurons: commissural/callosal (COM) neurons that provide interhemispheric connectivity, and corticofugal neurons that project to many subcortical targets, including, in the case of corticopontine (CPn) neurons, the pontine nuclei. COM and CPn neurons have distinct morphological and physiological characteristics, including divergent postsynaptic responses to the neuromodulators acetylcholine (ACh) and serotonin (5-HT). Despite the well-characterized selectivity of postsynaptic regulation of COM and CPn neurons by ACh and 5-HT, little is known about the presynaptic selectivity of these transmitters on glutamatergic transmission in the cortex. To examine this, we are expressing channelrhodopsin-2 (ChR2) in select afferent pathways to the medial prefrontal cortex, and testing presynaptic effects of ACh and 5-HT on light-evoked synaptic events in pairs of physiologically-identified COM and CPn neurons. We first characterized the synaptic connectivity of ChR2-expressing COM afferents in one hemisphere onto pairs of COM and CPn neurons in the contralateral hemisphere. Interhemispheric COM afferents targeted COM and CPn neurons with equal probability, and generated excitatory postsynaptic potentials (EPSPs) of similar magnitude in both neuron types across a range of light intensities (n = 19 pairs). However, across all light intensities, COM inputs to CPn neurons were more likely to initiate action potentials than were COM inputs to simultaneously recorded COM neurons ($p < 0.05$). Bath application of 5-HT (40 μM, in the presence of blockers of postsynaptic 5-HT_{1A} and 5-HT_{2A} receptors) reduced the amplitude of COM-evoked EPSPs in both COM (from 8.9 ± 1.1 to 4.5 ± 0.7 mV) and CPn (from 8.7 ± 1.0 to 3.5 ± 0.6 mV) target neurons (n=19 pairs; $p < 0.05$). Although reductions in EPSP amplitudes were somewhat larger in CPn neurons (-62 ± 3%; n = 25) compared to COM neurons (-49 ± 4%; n = 23; $p < 0.05$), this may reflect a decrease in input resistance (-6.3 ± 2.3%; $p < 0.05$) observed selectively in CPn neurons, which may result from insufficient blockade of 5-HT_{1A} receptors, or from the expression of additional postsynaptic 5-HT receptors in CPn neurons. Preliminary results suggest that endogenous ACh also potently reduces glutamate release from COM afferents onto contralateral COM and CPn target neurons. These results contribute to our understanding of the connectivity and neuromodulatory control of cortical circuits.

Title: Characterization of [^{3}H]PT-0921, a novel muscarinic acetylcholine receptor positive allosteric modulator radioligand selective for the M_4 subtype

Authors: *D. L. SMITH[1], C. R. BUTLER[2], R. E. O'CONNOR[3], M. POPIOLEK[1], L. ZHANG[2]; [1]Neurosci., Pfizer Inc, Cambridge, MA; [2]Neurosci. Medicinal Chem., Pfizer Inc., Cambridge, MA; [3]Pharmacokinetics, Dynamics, and Metabolism, Pfizer Inc., Groton, CT

Abstract: The availability of a potent and selective radioligand that binds to the M_4 muscarinic acetylcholine receptor (mAChR) allosteric site will facilitate the understanding of M_4 positive allosteric modulator (PAM) pharmacology. Herein, we profile a M_4 selective PAM radioligand, [^{3}H]PT-0921, in rat and human M_4 stable cell lines and native tissue assays. PT-0921 is a novel M_4 mAChR PAM shown to decrease cAMP production with an EC_{50} of 6.09 ± 1.46 nM (human) and 1.81 ± 0.13 nM (rat) for stably expressing M_4 HEK293 cells, measured using a potentiation assay in the presence of an EC_{20} concentration of acetylcholine (ACh). This receptor-selective ligand showed no functional PAM response at the M_1, M_2, M_3, and M_5 mAChR subtypes when tested up to 10 μM. Also, the effects on the affinity of ACh at the [^{3}H]NMS orthosteric binding site was examined in M_4 stable cell lines and PT-0921 reduced the concentration of ACh required to inhibit [^{3}H]NMS binding to the M_4 mAChR, left-shifting the EC_{50} of ACh by 35-fold (rat) and 65-fold (human) at 10 μM. Binding of [^{3}H]PT-0921 to coronal sections of the rat brain in autoradiographic localization studies showed distribution in the cortex, nucleus accumbens, caudate putamen, and olfactory tubercle, while being displaced by 10 μM of the M_4 PAM, Compound A. One limitation of PT-0921 is that it is a Pgp/BCRP substrate and though it gets into the brain, it is actively transported out. This liability made a [^{3}H]PT-0921 in vivo receptor occupancy assay unfeasible. To overcome this challenge, we took advantage of the Pgp/BCRB triple knockout mouse. In these transgenic mice we were able to utilize [^{3}H]PT-0921 for quantification of in vivo occupancy of another M_4 PAM, Compound B, which showed 92% receptor occupancy in the striatum when administered at 10 mg/kg. Taken together, these data show PT-0921 to be a selective M_4 PAM and [^{3}H]PT-0921 is shown to be a useful tool in the investigation of M_4 PAMs both in vitro and in vivo.

Title: Muscarinic modulation of GABAergic neurotransmission in the basolateral amygdala.

Authors: *A. FAJARDO SERRANO, L. LIU, D. D. MOTT, A. J. MCDONALD;
Dept. of Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: The density of the cholinergic innervation of the basolateral nucleus of the amygdala (BL) by the basal forebrain is much greater than that of the neocortex or hippocampus. Activation of muscarinic receptors in BL is critical for the consolidation of many types of memory including inhibitory avoidance and fear conditioning. Since suppression of GABAergic inhibition is important for synaptic plasticity in the BL, it is essential to determine which, if any, interneuronal (IN) subpopulations are modulated by activation of distinct presynaptic muscarinic receptors. To investigate this question we performed paired recordings from presynaptic INs and postsynaptic PNs using whole-cell patch-clamp techniques in rat amygdalar slices. Putative INs and PNs were initially identified on the basis of differences in perikaryal size and shape, and electrophysiological properties. Application of muscarine (10 μm) suppressed the IPSCs evoked by presynaptic INs in the paired PNs by 80%, but left spontaneous IPSCs intact. In other studies, in both rats and mice, evoked monosynaptic IPSCs in PNs were inhibited by 50% by muscarine. This suppression was almost entirely reversed by the M2R antagonist AF-DX 116 (1 μm). The inability of muscarine to completely inhibit the IPSCs at saturating concentration suggests that M2Rs are present on only a subpopulation of inhibitory axon terminals. As in the cortex there are two main types of INs in the BL. INs expressing parvalbumin (PV) provide most of the perisomatic innervation of PNs, but also innervate PN dendrites. INs expressing somatostatin (SOM) mainly innervate distal dendrites and spines of PNs. Dual-labeling electron microscopic studies using immunoperoxidase and silver-enhanced immunogold procedures are now in progress to determine whether M2Rs are expressed in the axon terminals of PV+ and/or SOM+ INs. In addition, structures that are postsynaptic to these terminals are identified on the basis of morphological criteria. Limited preliminary data from M2R/PV preparations suggest that some PV+ terminals forming synapses with dendritic shafts may express M2Rs. Further analysis is required to confirm these findings, to gather data on PV inputs to PN perikarya, and to investigate expression of M2Rs in SOM+ axon terminals. In conclusion, electrophysiological and neuroanatomical findings to date suggest that activation of M2Rs in axon terminals of one or

more subpopulations of BL INs is critical for the disinhibition of PNs by ACh. This disinhibition could contribute to the consolidation of emotional memory by the BL.

Title: Cholinergic signaling in fear extinction

Authors: ***G. C. JONES**, J. R. MCELROY, S. C. TRYON, A. C. SHARKO, M. A. WILSON, D. D. MOTT;
Dept. of Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Post-Traumatic Stress Disorder (PTSD) is a mental health disorder that can occur following a traumatic event such as being in combat, witnessing or being assaulted, or experiencing a natural disaster. Individuals with PTSD are unable or impaired in their ability to extinguish fear memories, resulting in disabilities preventing them from living normal, healthy lives. However, it remains unclear why some individuals exposed to traumatic events develop PTSD while others are more resilient and do not. Acetylcholine is known to play a critical role in fear learning, but its role in fear extinction is not as well understood. This study utilized a rat model of fear extinction to determine if individual differences in extinction learning are correlated with markers of cholinergic signaling. Cholinergic markers include M1 muscarinic acetylcholine receptor (M1 mAChR) and vesicular acetylcholine transporter (vAChT). These cholinergic markers are strongly expressed in brain regions, such as the amygdala and prefrontal cortex (PFC), which function in the fear extinction circuit. The goal of the present study was to determine whether individual differences in cholinergic signaling in these brain regions underlie the differences observed in fear extinction. Expression levels of cholinergic markers were measured in the amygdala and PFC of male Long-Evans rats after undergoing a Pavlovian fear conditioning and extinction paradigm. We found that rats exhibited individual differences in

extinction of freezing behavior following twenty presentations of a conditioned auditory stimulus. When M1 mAChR expression in these animals was assessed, a significant correlation was evident between expression level of M1 mAChR in the amygdala and the freezing behavior during the extinction trials. Expression of M1 mAChRs in the amygdala of animals showing good extinction learning was significantly higher than that in animals resistant to extinction. In contrast, there was no significant correlation between vAChT expression and freezing in either amygdala or PFC. These results suggest that low expression of M1 mAChRs in the amygdala is correlated with deficits in fear extinction. These results are in agreement with the role of muscarinic receptors in other aversive learning paradigms, and suggest that therapeutic strategies aimed at enhancing muscarinic signaling in the amygdala may enhance fear extinction in animals and perhaps patients with PTSD.

Title: Muscarinic receptors differentially regulate glutamatergic pathways in the basolateral amygdala

Authors: ***S. C. TRYON**, L. LIU, A. J. MCDONALD, D. D. MOTT;
Dept. of Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: The basolateral amygdala (BL) is essential for emotional memory and fear learning. The BL receives strong recurrent excitation as well as afferent glutamatergic inputs from a variety of brain regions, including midline thalamic nuclei (Thal), prelimbic area (PL) of the medial prefrontal cortex and the lateral nucleus of the amygdala (LA). The BL is also the target of extensive cholinergic innervation from the basal forebrain. Acetylcholine acting in the BL plays a critical role in consolidation of fear memory, although exactly how it modulates synaptic transmission to BL is relatively unknown. To investigate this question we examined muscarinic acetylcholine receptor (mAChR) modulation of synaptic transmission at different glutamatergic inputs to the BL. Using optogenetics and whole cell electrophysiology in rodent amygdalar

slices, we compared the effects of mAChR activation with muscarine (10 μM) on synaptic transmission at recurrent and afferent inputs to BL pyramidal neurons (PNs). Bath application of muscarine strongly suppressed evoked EPSCs at PL inputs, while EPSCs at Thal inputs were only partially inhibited and input from LA was not inhibited. Muscarine also failed to inhibit recurrent excitation in BL. At cortical inputs muscarine-evoked inhibition was partially blocked by the M1 mAChR antagonist, telenzepine, and fully blocked by the M3 antagonist 4-DAMP, indicating that the inhibition was produced by activation of M1 and/or M3 mAChRs. Interestingly, while muscarine suppressed cortical input to BL PNs during a single stimulus, it increased the reliability of excitatory transmission during a stimulus train by reducing synaptic depression. This effect was greatest at stimulus frequencies in the gamma band (30-90 Hz). These findings suggest that during periods of high cholinergic tone mAChRs would filter cortical and thalamic input to BL, while leaving inputs from LA and recurrent inputs from BL unchanged. This may increase the signal to noise ratio for LA input to BL, allowing the LA to more strongly influence BL PNs at frequencies below gamma band. However, at gamma frequencies cortical inputs would be strengthened. This frequency dependent regulation could protect the BL from asynchronous afferent input, while increasing functional coupling and synaptic plasticity between BL and PL cortex.

Title: The atypical antipsychotic olanzapine disturbs depotentiation and reversal learning by modulating mAChRs

Authors: W. SONG, J.-H. CHA, S. YOON, *M.-H. KIM;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Olanzapine (Olz), one of the most frequently prescribed atypical antipsychotics, is generally considered a first-line drug for treating schizophrenia. In contrast to psychotic symptoms, the effects of Olz on cognitive symptoms of schizophrenia are still unclear. In addition, the mechanisms by which Olz affects the neural circuits associated with cognitive function are unknown. Here we investigated the effects and mechanisms of Olz on synaptic plasticity and the cognitive behavior of mice. Olz interrupts depotentiation without disturbing *de novo* LTP and LTD. At hippocampal SC-CA1 synapses, co-activation of NMDARs (N-methyl-

D-aspartate receptor), mGluRs (metabotropic glutamate receptors), and mAChRs (muscarinic acetylcholine receptors) is necessary and sufficient to reverse stably expressed LTP. Olz inhibits the activation of mAChRs, which amplifies glutamate signaling. Behaviorally, Olz impairs spatial reversal learning of mice in the Morris water maze test. Our results uncover a novel mechanism underpinning the cognitive modulation of Olz and show that the anticholinergic property of Olz affects glutamate signaling and synaptic plasticity.

Title: Bursting cholinergic neurons of the basal forebrain show synchronous activity in an auditory detection task

Authors: *T. LASZLOVSZKY[1], A. KEPECS[2], B. HANGYA[1,2];
[1]Lendulet Lab. of Systems Neuroscience, IEM H, Budapest, Hungary; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The cholinergic basal forebrain (CBF) has been implicated in diverse cognitive functions through its influence on cortical information processing. Earlier studies differentiated tonic and phasic effects of the CBF based on the varying timescales of cortical acetylcholine release (Parikh et al., 2007). In accordance, *in vitro* experiments described an early- and a late firing cholinergic group, likely corresponding to bursting and non-bursting neurons (Unal et al., 2012), proposing that bursting neurons convey phasic information while non-bursting neurons set tonic levels of cortical acetylcholine. However, this theory has not been tested *in vivo*, therefore it remains unclear how bursting and non-bursting groups of CBF contribute to

cholinergic effects at different time scales (Hangya et al., 2015).
To address this question we analyzed optogenetically identified and putative cholinergic neurons in the nucleus basalis (NB) (n = 44) and in the horizontal limb of the diagonal band of broca (HDB) (n=12) in mice performing an auditory detection task requiring sustained attention. Our analysis of autocorrelations (Royer et al., 2012) uncovered three types of cholinergic neurons: 'tonic' neurons showing long refractory periods, 'phasic bursting' neurons showing classical bursting phenotype and 'phasic non-bursting' neurons exhibiting short refractory but no prominent burst shoulders. By analyzing cross-correlations of concurrently recorded pairs of NB neurons (n = 16) we discovered that the bursting ones were synchronously active at a short timescale, unlike the tonically active cholinergic neurons. However, all three cell types were capable of fast and precise responses to behaviorally salient events, which clearly distinguished them from tonically active cholinergic interneurons of the striatum. Thus, bursts of cholinergic neurons likely reflect strong bottom-up excitatory drive that, with the added synchrony, leads to stronger and more wide-spread cortical activation.

Title: Smoking-like nicotine levels increase excitatory synaptic response in the prefrontal cortex of the mouse

Authors: *R. D. CUEVAS OLGUIN[1], F. VAZQUEZ-PONCE[1], E. ESQUIVEL-RENDON[1], J. VARGAS-MIRELES[1], I. GONZALEZ-NATERAS[1], M. MIRANDA-MORALES[1], H. ARIAS[2], M. ATZORI[1];
[1]UASLP, San Luis Potosi, Mexico; [2]Med. Educ., California Northstate Univ. Col. of Med., Elk Grove, CA

Abstract: The legal addictive drug nicotine produces multiple biological effects. Central effects of nicotine are still scarcely understood. Nicotine users report an emotional relief during the first several minutes following the intake of the drug by smoking. This phenomenon has been correlated with the co-release of several neurotransmitters, mainly dopamine, throughout the limbic system. In the present work we investigated the possibility that nicotine directly affects

synaptic transmission in the limbic system. We did so by determining the effect of a dose of nicotine equivalent to smoking one cigarette (300 nM) on the excitatory synaptic transmission of the prefrontal cortex - a brain region involved in the perception of pleasure and relief - in a murine model (C57BL/6). In order to determine the effect of nicotine on excitatory synaptic transmission, we performed patch-clamp recording on layer 5 visually-identified neurons of the medial prefrontal cortex, measuring electrically evoked pharmacologically isolated post-synaptic currents (eEPSC) in the presence of the blocker of γ-amino butyric acid (GABA) type A receptor ($GABA_AR$) blocker bicuculline meth-chloride. α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic receptor ($AMPA_R$)-mediated synaptic signals were recorded at the holding voltage V_h = -70 mV and measured as peak amplitude of the corresponding synaptic inward current, while N-methyl-D-aspartate receptor (NMDAR)-mediated currents were recorded at the holding voltage V_h = +40 mV and measured as the late current at a fixed interval of 180 ms after the stimulation artefact (in order to minimize the AMPAR-mediated contribution), both of them using a paired pulse protocol at 180 ms interpulse interval, every 12 s. Nicotine increased both AMPAR-mediated as well as NMDAR-mediated eEPSCs (120 ± 33 %, n = 8; 41 ± 22 %, n = 6, respectively), without changing the pair pulse ratio (ratio between the second response, A_2 and the first response A_1, PPR = A_2/ A_1) for either AMPAR-mediated eEPSC (0.95± 0.02 in control, vs. 0.83 ± 0.96) or NMDAR-mediated eEPSCs (0.79 ± 0.06 in control vs 0.73 ± 0.07 in nicotine, same samples). Our results show that the presence of nicotine acutely enhances glutamatergic synaptic transmission. The simultaneous increase of AMPAR-mediated and NMDAR-mediated signal, together with the lack of change in PPR, suggest that nicotine may increase excitatory synaptic response through a presynaptic mechanism, possibly through the increase in glutamate release. The identification of the type of nicotinic receptors involved in the enhancement of glutamatergic response and its physiological significance still require further investigation.

Title: Cholinergic modulation of striatal projection neurons activity *In vivo*

Authors: *S. ZUCCA, A. ZUCCA, J. WICKENS;
Neurobio. Res. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: The striatum is the main input nucleus of basal ganglia. The principal output neurons of the striatum (striatal projection neurons, SPNs) transform the input to the striatum, originating from all areas of the cerebral cortex, into output activity that is transmitted to other basal ganglia structures. This transformation involves interactions of glutamatergic inputs from the cortex, with local input from other SPNs, extrinsic modulation by dopaminergic afferents, and local interneurons. Acetylcholine is released in high concentrations by a population of cholinergic interneurons (CINs), but the function of acetylcholine in the striatum remains enigmatic. We have recently shown that loss of cholinergic function in the striatum is associated with a significant impairment in learning of new behavioral strategies (Aoki et al., J Neurosci, 2015). However, how CINs firing pattern contribute to local striatal activity *in vivo* remains to be elucidated. To investigate this question, we made electrophysiological recordings in anesthetized mice from SPNs while optogenetically controlling CINs firing. CINs were identified *in vivo* by juxtacellular recordings and showed typical spontaneous firing with regular, irregular, and bursting patterns. SPNs exhibited low spontaneous firing frequency. We found that optogenetic activation or inactivation of CINs did not produce significant increase or decrease of their firing rates. We hypothesize that CINs may have a state-dependent modulatory effect on slow membrane oscillations of SPNs. To test this hypothesis, we will obtain whole-cell recordings from SPNs and compare the effect of CINs pause burst firing patterns on spontaneous membrane potential fluctuations and in responses to glutamatergic synaptic input.

Title: Identifying novel genes required for synaptic function among human 21st chromosome orthologs

Authors: *S. K. NORDQUIST[1], J. PIERCE-SHIMOMURA[2];
[1]Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Trisomy of the 21st chromosome results in Down syndrome, one of the most common congenital disorders with an underlying genetic basis. Though Down syndrome is associated with many phenotypes, those that affect the nervous system present the greatest obstacles to achieving high quality of life. To better understand the genetic basis of neurological phenotypes in Down syndrome, we systematically screened all putative human 21st chromosome orthologs in *Caenorhabditis elegans* using both RNA interference (RNAi) and loss-of-function mutant analysis. In addition to screening for superficial neuronally dependent behaviors (e.g. locomotion), we also assessed neuromuscular synaptic function using the acetylcholinesterase inhibitor aldicarb. We identified several genes with decreased cholinergic secretion, including *mtq-2*, a highly conserved ortholog of the human 21st chromosome gene *N6AMT1*. Further, we determined a preliminary neuronal expression pattern for *mtq-2* in *C. elegans*. These data suggest a potential role of *mtq-2* in mediating nervous system function in worm and provide a platform on which mammalian researchers may build.

Title: Oleanolic acid ameliorates scopolamine-induced cognitive impairment in mice

Authors: S. JEON, J. ZHANG, Y. GWON, *J. RYU;
Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Oleanolic acid is a naturally occurring triterpenoid that is widely present in food and medicinal plants. To examine the effect of oleanolic acid on memory deficits, we employed a scopolamine-induced cognitive deficit mouse model. A single administration of oleanolic acid significantly increased the latency on the passive avoidance task and affected the alternation behavior on the Y-maze task and the exploration time on the novel object recognition task, indicating a recovery of the cognitive impairment induced by scopolamine. In accordance with previous reports, oleanolic acid enhanced ERK1/2 and CREB phosphorylation and BDNF expression in the hippocampus. Together, these results imply that oleanolic acid ameliorates scopolamine-induced memory impairment by modulating the ERK1/2-CREB-BDNF pathway in mice, suggesting that oleanolic acid would be a potential therapeutic agent for the treatment of cognitive deficits.

Title: Paradoxical effects of alpha 7 nicotinic acetylcholine receptor antagonists on memory formation and receptor functioning

Authors: ***N. P. VAN GOETHEM**[1], E. FEDELE[2], D. PUZZO[3], C. REBOSIO[2], W. GULISANO[3], A. PALMERI[3], D. PAES[1], L. WENNOGLE[4], Y. PENG[4,5], D. BERTRAND[6], J. PRICKAERTS[1];
[1]Maastricht Univ., Maastricht, Netherlands; [2]Univ. of Genoa, Genoa, Italy; [3]Univ. of Catania, Catania, Italy; [4]Intra-Cellular Therapies Inc, New York City, NY; [5]Rutgers Cancer Inst. of New Jersey, Rutgers Univ., New Brunswick, NJ; [6]HiQScreen Sàrl, Geneva, Switzerland

Abstract: α7 nicotinic acetylcholine receptors (α7nAChRs) are ligand-gated ion channels that have been implicated in modulating cognitive functions like episodic memory and attention. Hence, α7nAChR agonists/modulators have been investigated as potential drug candidates to improve cognition in Alzheimer's disease (AD) and schizophrenia, with the partial agonist EVP-6124 (Encenicline) recently terminated in Phase III clinical trials. Upon repeated activation the α7nAChR quickly desensitizes, possibly limiting the effects of (partial) agonists. In the current study, the cognition enhancing properties of low dose administration of selective α7nAChR antagonists were investigated in rats as low doses of methyllycaconitine (MLA) have been reported to improve cognition in animals. Memory acquisition and consolidation processes were assessed separately with the object recognition task (ORT). The compounds used for these studies were MLA and Compound 7i. Interestingly, it was found that low doses of either MLA or Compound 7i improved the acquisition, but not the consolidation processes of object recognition memory at a 24 h retention interval. Conversely, higher doses impaired the memory performance at a shorter 1 h retention interval. In addition, the same compounds were studied in a model of neuronal plasticity, long-term potentiation (LTP). In accordance to the behavioral studies, it was demonstrated that pre-tetanus low-dose administration of MLA or Compound 7i produced a longer lasting potentiation, whereas post-tetanus administration had no effect. Microdialysis studies showed that MLA administration substantially increased hippocampal glutamate efflux which has been found to be related to object memory processes. To further elucidate the mechanism by which these α7nAChR antagonists exerted this paradoxical effect,

electrophysiological studies in oocytes expressing human α7nAChRs were performed. These studies will be outlined and have led to novel a mechanistic model. The proposed model is an extension of the minimal allosteric model of ion channels in which low concentrations of α7nAChR antagonists re-sensitize the receptor channel by reversing the desensitized state to the resting state, which is again susceptible to agonist binding and subsequent channel opening. In summary, blocking α7nAChRs with low doses of selective antagonists improves specifically the memory acquisition process. While the main focus of the α7nAChR as a target for cognition enhancement has been on agonists and positive modulators, antagonism of these receptors at low doses might actually prove to be a valuable approach for cognition enhancement in AD or schizophrenia.

Title: Cognitive deficits in a rat model of Parkinson's disease are reversed by low dose acetylcholinesterase inhibition and serotonin 5-HT_{2A} inverse agonism

Authors: *D. T. HUBBARD, E. S. BURSTEIN, C. BELLIZZI, K. MCFARLAND; Biosci., ACADIA Pharmaceuticals, San Diego, CA

Abstract: Parkinson’s disease (PD) is primarily associated with motor impairment, yet non-motor symptoms, including behavioral and cognitive disturbances, are prevalent and greatly impact daily functioning and quality of life. Current treatments for PD dementia include administration of acetylcholinesterase inhibitors (AChEIs) which can be accompanied by undesirable side effects. Lowering the effective dose of AChEI could reduce the prevalence or severity of these side effects. The current work examined the potential of using low-doses of donepezil or rivastigmine in conjunction with a selective 5-HT_{2A} antagonist/inverse agonist called M100,907 to improve cognition in a rat model of PD. Sprague Dawley rats received bilateral sham or 6-hydroxydopamine (6-OHDA) lesions of the substantia nigra (SN)[1]. Following recovery, rats were administered M100,907, either donepezil or rivastigmine, or combinations of M100,907 with either donepezil or rivastigmine prior to assessment of novel object recognition (NOR) or working memory performance in the radial arm maze (RAM). 6-OHDA lesion

impaired the cognitive performance of rats in the NOR and RAM tests. Treatment with either rivastigmine or donepezil attenuated the cognitive deficits of 6-OHDA lesion rats, while M100,907 was ineffective. In addition, sub-effective doses of rivastigmine or donepezil combined with M100,907 reversed the deficits of lesioned rats in the NOR and RAM tasks. Pharmacokinetic studies suggest that the increased potency of either rivastigmine or donepezil cannot be explained by changes in their bioavailability as a consequence of co-administration with M100,907. This work suggests that rats with 6-OHDA lesion of the SN display cognitive deficits. Further, combined administration of low doses of AChEIs and selective 5-HT_{2A} inverse agonists, while ineffective alone, could be effective treatments of cognitive deficits associated with dopaminergic cell death, potentially with fewer side effects.

Title: Effect of a new benzoazocine on learning, spatial memory, and oxidative stress on acetylcholinesterase activity in rats.

Authors: *I. LIMON PEREZ DE LEON[1], A. PATRICIO-MARTINEZ[1], N. MUÑOZ-MORENO[1], R. LOPEZ-GONZALEZ[2], J. TERAN-VAZQUEZ[2], B. LEON-CHAVEZ[3]; [1]Benemerita Univ. Autonoma De Puebla FCQ Lab. Neurofarma, Puebla, Mexico; [2]Ctr. de Quimica, BUAP, Puebla, Mexico; [3]Lab. de pruebas preclinicas, BUAP, Puebla,Pue, Mexico

Abstract: It have been reported that the Benzoazocines are structures azocines and that may have inhibitory activity on acetylcholinesterase (AChE). Drugs that enhance cholinergic activity through by reversible inhibition of the enzyme acetylcholinesterase and increase synaptic levels of acetylcholine is plausible that improves attention, learning and the memory process. If these

new benzoazocines produce these effects, it would be candidates to improve cognitive processes in neurodegenerative diseases such as Alzheimer's disease. Some acetylcholinesterase inhibitors such as galantamine reversibly inhibit AChE only up to 60%, increasing acetylcholine levels, resulting in an improvement in learning and memory processes. The aim of this study was to evaluate the effect of administration of a novel compound benzoazocines on learning and spatial memory. Also we investigated the effect on AChE activity in intact rats. Male Wistar rats were used. The animals were divided into control group (n = 7) and problem group (n = 7) and were administered subcutaneously [DMSO 0.5%] and 1.5 mg / kg of benzoazocines respectively, for 19 days. Spatial learning was assessed in the radial maze 10 days after administration. Memory was assessed on 21 day in the 8-arm radial maze. After the memory test, the animals were euthanized and extracted: frontal and temporal cortex, amygdala and hippocampus. Using spectrophotometer test the lipid peroxidation and nitrite determinations were made. The AChE activity was determined by the Ellman assay. The Benzoazocines (1.5 mg / kg) administration resulted in no change in the learning test. However there was an increase by 20% correct responses in the test of spatial memory compared to the control group. This dose caused no harmful effects on the system, with no induction of lipid peroxidation, or oxidative stress or nitrosative stress, compared to their respective control group. The administered dose (1.5mg / kg) produced an increase of 30% in the inhibition of AChE activity hippocampus and temporal cortex. There were not changes in amygdala and frontal cortex. The results provide the basis of study on that new structures are benzoazocines as compounds with anticholinesterase function and plausible effect on improving memory.

Title: Does nicotine exposure potentiate the neurotoxic effects of prenatal alcohol-induced cognitive impairment?

Authors: ***M. A. MAJRASHI**, D. BHATTACHARYA, S. BHATTACHARYA, J. BLOEMER, M. BUABEID, M. ESCOBAR, P. DAS PINKY, V. SUPPIRAMANIAM, M.

DHANASEKARAN;
Harrison Sch. of Pharm. /auburn Univ., Auburn, AL

Abstract: Women (10-20%) have been found to consume large amount of alcohol (ethanol) during pregnancy. Prenatal alcohol exposure has been correlated to multitude of dose dependent effect on the structure and functions of the central nervous system in the humans and animals. During the pregnancy, in addition to alcohol consumption, smoking (nicotine exposure) is also observed. Thus, alcohol (ethanol) and smoking (nicotine) exposure during pregnancy can have substantial neurotoxic effects on the offspring. Therefore, in our study, we used a Sprague Dawley rat model exposed to alcohol (mixed with water) and nicotine (subcutaneous-mini osmotic pump) during gestation. We assessed the effects of alcohol and nicotine exposure on the behavioral and neurological changes. Y-maze was used to study the effect on cognitive impairment. Long-term potentiation (LTP) and expression of ILK & PSD-95 was studied to correlate the effects with cognition. Significant deficits in spatial memory task were observed in the alcohol only treated group as compared to the control. Interestingly, the offspring exposed to prenatal nicotine and alcohol showed significant improvement in the spatial task as compared to the alcohol treatment. However, the improvement in spatial learning deficit is not supported by the LTP in these animals. Alcohol and nicotine exposed animals showed significant deficit in LTP as compared to the control. There was an increase in the hippocampal PSD-95 expression and no change in ILK expression in the alcohol and nicotine treated group as compared to alcohol alone or the control. Thus, nicotine and alcohol exposure during pregnancy may have a mixed and detrimental effect in the central nervous system.

Title: The role of hippocampal to medial prefrontal cortex projections, and effects of acetylcholine manipulation in these regions, during an associative recognition memory task

Authors: *K. E. GILROY, P. J. BANKS, G. R. I. BARKER, E. C. WARBURTON, Z. I. BASHIR;
Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: A series of experiments were conducted in a cross-maze using a behavioural design based on the Object-in-Place (OiP) test of associative recognition memory. An intact tripartite network between the hippocampus, perirhinal cortex and prefrontal cortex has previously been demonstrated to be critical for successful performance during the OiP task. Optogentic manipulations were used to determine the nature of the interactions between the hippocampus and medial prefrontal cortex at various stages of the task and pharmacological manipulation of acetylcholine was used to determine the possible role of neuroplasticity in these two regions. The results are discussed in relation to the tripartite network and the formation of associative recognition memory.

Title: Electromagnetic forced stimulation alters differentially spatial learning processes depending on the time of the day.

Authors: *M. E. ARIAS-GARCÍA, D. BUSTAMANTE-VALDEZ, M. VÁZQUEZ-SUMANO, N. ORTEGA-VILLEGAS, P. DURAN;
LBAE, Facultad de Ciencias, Univ. Nacional Autonoma De México, Ciudad de México, Mexico

Abstract: Currently the exposure to electromagnetic waves is increasing due to the presence of household appliances related to the electric current and the emission of low-frequency waves, as well as radio stations, TV antennas, telecommunication signals, Wi-Fi, smartphones, etc. Damages to the health have been linked to them, however, transcranial electromagnetic stimulation has been used has therapy for epilepsy, depression, PTSD with positive results in humans, in animal models there is experimental evidence that at an particular intensity, magnetic stimulations normalize corticosterone levels in stressed animals, as well as when the organism is

exposed to non-ionizing radiation neurogénesis in the hippocampal dentate gyrus turns out to be favored. Also, there is experimental evidence about how magnetic stimulation can alter the learning and memory processes, in here, there is controversy, since some authors refer a positive meanwhile others found deleterial effects. Magnetic stimulation at 8mT, has been found to decrease consolidation in the reference memory using the Morris maze. The aim of this study was to determine if the forced exposure to electromagnetic waves of low frequency (0.2mT) in a particular moment of the day generates positive results in learning processes of learning and reference memory in adult rats. Sprague-Dawley adult male rats, were randomly divide in 6 groups (n=10), maintained under a 12/12 light cycle, water and food ad libitum, temp 22-24°C in polycarbonate cages. All groups were confined to a faradized chamber for 15 minutes every day for 3 weeks. Control (Co) was confined but not stimulated, meanwhile 2 groups were confined and stimulated (0.2mT) at ZT2 (means 2hrs after lights on), and 2 other groups were confined and stimulated at ZT14 (2hr after lights off). After 3 weeks all groups were tested using the Morris water maze, as follows ZT2 group was subdivide in ZT2/ZT3 and ZT"/ZT15, meaning animals were tested at ZT3 or ZT15. ZT14 groups were under similar treatment, ZT14/ZT3 andZT14/ZT15. Controls were tested at ZT3 and ZT15. Our results shows that total acquisition latency improved in all stimulated groups, those were faster learners as well. Consolidation latencies were improved in ZT2/ZT3 and ZT14/ZT3, but worsened in ZT2/ZT15 and ZT14/ZT15 groups. For reference memory Probe immediately afterwards, we found no significant differences, but after 8 days memory was poorer than control. We conclude that although 0.2mT appears to be positive for learning, there is a temporal component may be linked to the circadian attention processes that affect the memory consolidation and long term retrival.

Nacional de Pediatría, Mexico, Mexico; [8]Facultad Ciencias, UNAM, México, Mexico

Abstract: The cadmium (Cd) is a highly toxic heavy metal and have been determined that Cd affects some organs such as the liver and kidney. Apparently, the brain is also affected and interferes with the cognition function. However, for the time there are few studies dealing with the effects of the Cd over the learning and the spatial memory and his correlation with the concentration of the Cd in the hippocampus, and the blood serum. To carry out this study, pregnant female rats, where used and monitored until parturition. The eight male pups were assigned by one mother. They were kept in a light-dark 12:00 to 12:00, the pups were injected ip with cadmium chloride at doses of 1 mg/kg /600 µl injection and control group were injected with saline. The injections were daily up to 56 days of life. The learning test was performed at 120 days of age, per six consecutive days, and the spatial memory in the 7th day using the aquatic maze of Morris (AMM). Finally after the last register (day 7), the subjects (Ss) were sacrificed by decapitation with anesthesia for obtaining serum and hippocampus, it was also determined the concentrations of Cd by atomic absorbance spectrophotometry. The results on the learning and especial memory in the AMM showed that the treated group with Cd his learning decreased significantly compared with the control group. On day seven, the Ss of control group showed a persistent searching on the platform, while Ss of control group with Cd weren´t persistent in the searching of the platform and Cd concentration in hippocampus and serum blood were increased in the experimental group. These data suggest that Cd chronic administration was accumulated in hippocampus, and may provoke alterations in this structure altering the learning and spatial memory processes.

Title: Acute E14 Cadmium administration alters water intake circadian rhythm, visual perception, anxiety and stress responses in the rat

Authors: J. S. GONZALEZ-RUANO, E. MORENO-SÁENZ, M. E. ARIAS-GARCÍA, D. J. BUSTAMANTE-VALDEZ, *P. DURAN;
Facultad De Ciencias, UNAM, Ciudad de Mexico, Mexico

Abstract: Cadmium (Cd) is a heavy metal profusely distributed in the environment as a pollute from human industrial activities It is known to be potentially teratogenic even lethal during the development. Its teratogenic effects are mainly found in neural tube formation, renal, skeletal, heart and immune system. In mice there is evidence that a single dose of Cd administrate during the retinal ganglion cells (RGC) proliferative critical period induce the dead of RGC in the offspring. Intrinsically photosensitive Retinal Ganglion Cells (ipRGCs) are known to participate in the circadian synchronization, in rats the proliferative critical period of those cells has been found at E14. The aim of this study was to determine if the acute administration of Cd at E14 produce postnatal alterations in the water intake circadian rhythm. We followed the early postnatal development markers, and performed a visual perception task at a juvenile postnatal age. We found not differences in synchronization when compared with controls, but an increase in the rhythm amplitude, and delay of 2 or 3 days in development markers, as well we found the acute Cd administration had an effect in the anxiety and stress behavioral markers in the open field of visual cliff task. Those results suggest the acute E14 Cd administration is enough to produce behavioral and physiological effects on those structures developing during that particular period.

Title: Prenatal nicotine exposure alters stress- anxiety circadian rhythm in female mice

Authors: *M. FUENTES-CANO, L. G. MENDOZA-MORENO, P. DURAN;
Facultad De Ciencias, UNAM, Mexico City, Mexico

Abstract: Smoking and nicotine use during pregnancy has been associated with several adverse effects of growth and perinatal development. Abortion, low weight at birth, delayed postnatal development and changes in cognitive performance are among those detrimental effects. Acetylcholine is one of the most important signalling brain developmental processes which can be interfered by nicotine interaction with nicotinic cholinergic receptors (nAChr). There is also evidence that nicotine itself can disturb sex hormones patterns in both female and male adults, as well as in offspring exposed to nicotine during pregnancy and lactation. Nicotine consumption may be affecting critical periods during which certain neural circuits are formed, resulting in modifications in behavioural sexual dimorphism. The aim of the present study was to evaluate the effect of perinatal nicotine administration on the daily rhythm of stress and anxiety-like response in the juvenile mice. BALB/c female mice were given perinatal nicotine diluted in water (6 mg/kg/day -Slotkin, 1995-). After offspring delivery, litters were weighted and developmental markers were taken in order to assess the model (Ajarem, 1998). Only female offspring between 30-40 days old was used in the behavioural tests. The marble burying task was used as a model to measure stress and anxiety-like behaviour, during six temporal windows for three consecutive days. Ten nicotine-exposed females and ten control females were used in each temporal window. Mice were held on 12:12 LD conditions, with access to water and food *ad libitum*. Nicotine offspring showed a 2 to 3 days delay regarding developmental markers such as whiskers, eye opening, mobility, etc. After the behavioural test results suggest that control female mice exhibit a bimodal stress and anxiety response daily rhythm, with the highest levels peaking at the light phase, and a low response level between them, in the middle of the light phase. On the other hand, perinatal exposure to nicotine appears to produce modifications to this daily rhythm, elevating stress response levels during the middle of the light phase.

Title: Extradimensional attentional set-shifting related changes in prefrontal and striatal neuronal activity.

Authors: V. OBERTO, H. GAO, M. ZUGARO, *S. I. WIENER;
Col. De France CIRB, Paris, France

Abstract: Cortical connectivity with the striatum (Str) involves parallel yet overlapping anatomical 'loops'. Prefrontal (Pfc)-Str loops are implicated in goal directed learning processes and flexible attentional set-shifting. Here we examine changes in neural activity during set-shifting via simultaneous recordings of multiple single neuronal activity and local field potentials in 7 rats from areas including dorsomedial and ventral Str and cingulate, prelimbic and infralimbic areas of Pfc. The rats switched between two different reward-response contingencies in an automated T-maze with return arms. First they performed a brightness discrimination task (*VC)* where the rewarded arm was cued by video displays behind the reward arms, varying pseudorandomly between trials. Upon reaching criterion they were challenged with a spatial orientation task (*T*, reward always on the animal's non-preferred side: left or right) while (inconsequential) visual cues were still present. Extradimensional task switches continued whenever criterion performance was reached. Note that the only cue indicating the current rule was the presence or absence of the liquid reward. Here we focus analyses on sessions where rats successively reached criterion in VC (called 'VC1'), then T, and then VC again (called 'VC2'). We analysed 469 Str and 231 Pfc neurons with a bootstrap Monte Carlo method to detect increases or decreases in firing rate among the criterion performance trial epochs: VC1, T and VC2. Activity in these three conditions was compared separately for each of 15 bins along the central arm of the maze. The sampling of subregions of Pfc or of Str showed no differences for the three epochs. About 20% of the neurons in both Str and Pfc showed location-specific activity level increases or decreases in pair-wise comparisons among VC1, T or VC2 epochs. Surprisingly, both in Str and Pfc the highest incidences of these activity shifts were for VC1 vs. VC2 comparisons. In Str, the numbers of cells with activity shifts were: 37 for VC1 vs T; 29 for T vs VC2 and 51 for VC1 vs VC2. In Pfc the numbers of responsive cells were: 11 for VC1 vs T; 18 for T vs VC2 and 22 for VC1 vs VC2. The high incidence of VC1 vs VC2 activity shifts indicates that the firing rates of the neurons do not simply consistently code for a particular task but rather might be sensitive to other factors such as the history of recent behavioral challenges, possibly impacting on the level of motivation or fatigue of the animal. Furthermore the distribution of incidences of shifts for the three comparisons appears be different in Pfc vs Str. If confirmed this could reflect differences in executive and decisional processing in the two structures.

Title: Locus coeruleus task-related activity in an attentional-set shift task.

Authors: L. XIANG[1], A. HAREL[1], S. I. WIENER[1], *S. J. SARA[2];
[1]CIRB, [2]Collège de France, Paris, France

Abstract: The noradrenergic nucleus locus coeruleus (LC) plays a role in cognitive function, controlling vigilance states, orienting attention, modulating responses in sensory pathways and promoting long term memory consolidation. Recent fMRI studies in humans lend support to the hypothesis derived from rodent studies, that LC activation promotes rapid shifts in cortical attentional networks in response to a change in environmental contingencies. To further examine this hypothesis we designed a set-shift task in an automated T maze with video displays behind the reward arms and liquid rewards. Rats initially were required to learn a brightness discrimination task. Each trial was initiated by the rat when it left the start area and crossed a photocell that turned on the discriminanda. After criterion performance of 8 successive rewarded trials was reached, a spatial response-reward contingency was instated with brightness cues still present in the same pseudorandom sequence - the rat had to learn to ignore them and acquire the spatial rule for rewards. Well-trained rats underwent successive task shifts within a single session. The aim here was to determine the relevant task-related stimuli that elicited a response in the LC. After reaching criterion on the brightness discrimination, rats were anesthetized and implanted with a moveable microelectrode in LC, a tetrode in hippocampus and in the prelimbic area of prefrontal cortex. After recovery, rats were retrained to criterion on the brightness task, and then the response-reward contingency was switched to a non-preferred side turning task in the same session. Results indicate that LC neurons are engaged as the rat initiates the trial, with peak firing 500-200 ms *before* the onset of the visual cue. This activation occurred across all trials and contingency conditions and is reminiscent of previous reports that LC neurons respond preferentially to a preparatory stimulus in a formal conditioning protocol. However in this case, the preparatory stimulus would be internally generated. Other task-related LC responses observed consistently through different recording sessions include phasic activation just before crossing the reward arm photocell and almost total inhibition at reward consumption sites

(inhibition both in rewarded and non-rewarded trials). After this inhibition, LC cells were again phasically activated in the return arm, from 1 s before until crossing a photocell triggering the extinction of the visual cue, which signaled the end of the trial. These task-related responses of LC neurons will instruct future experiments using optogenetically-elicited gain or loss of LC function to study its role in cognition.

Title: Effects of insulin on excitatory transmission in the nucleus accumbens of non-obese and obese rats

Authors: ***M. F. OGINSKY**, C. R. FERRARIO;
Univ. of Michigan, Ann Arbor, MI

Abstract: Excitatory transmission in the nucleus accumbens (NAc) mediates motivation for food. Infusion of insulin in the NAc increases motivation for food, but the mechanisms underlying this effect are poorly understood. Insulin decreases excitatory transmission in the cortex and ventral tegmental area and increases dopamine release in the NAc. Here, we determined the effects of insulin on excitatory transmission in the NAc core of non-obese and obese adult rats. Whole cell patch clamp recordings of evoked AMPAR mediated excitatory postsynaptic currents (eEPSCs) were made in NAc medium spiny neurons from rats fed lab chow (Lab Diet 5001) or 60% high-fat diet (Open Source Diets D12492; 8 wks). Bath application of insulin increased eEPSC amplitude at low concentrations (30 nM), but reduced eEPSC amplitude at higher concentrations (50, 100 or 500 nM). Because insulin has a high affinity for the insulin receptor (IR) and lower affinity for the insulin-like growth factor-1 receptor (IGF-1R) we hypothesized that increases in eEPSC amplitude at 30 nM were due to activation of IRs, while decreases at higher concentrations were due to activation of IGF-1Rs. To test this, we included the insulin receptor inhibitor, HNMPA (300 μM), in the recording pipette

or the IGF-1R antagonist, picropodophyllotoxin (PPP; 500 nM), in the bath before applying insulin. Consistent with our hypothesis, HNMPA blocked the ability of 30 nM insulin to increase eEPSC amplitude. In addition, when 100 nM insulin was applied in the presence of PPP, there was an *increase* in eEPSC amplitude. Together these data show that activation of IRs and IGF-1Rs produce opposing effects on excitatory transmission, with IR activation increasing and IGF-1R activation decreasing excitatory transmission. When recordings were made from obese rats, increases in excitatory transmission after 30 nM insulin were completely absent, while decreases after 100 nM insulin were comparable to those seen in chow fed controls. These data suggest that IR-mediated effects may be reduced after high-fat diet consumption, while IGF-1R-mediated effects remain intact. In addition, data from high-fat fed rats suggest that peripheral alterations induced by consumption of high-fat diet may significantly impact the ability of insulin to modulate neuronal function. In sum, our data show that in non-obese rats insulin bi-directionally influences excitatory transmission via dissociable actions on IRs and IGF-1Rs, and suggest that consumption of high-fat food selectively blocks IR-mediated increases in NAc excitatory transmission. These data shed light on potential mechanisms by which insulin may regulate motivational processes.

Title: Dissecting the neuromodulatory landscape of the PVN

Authors: *L. XIAO[1], J. NASENBENY[1], M. PRIEST[1], T. LU[2], Y. KOZOROVITSKIY[1]; [1]Dept. of Neurobio., [2]Dept. of Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: Oxytocin is a hormone and neuromodulator that regulates central nervous system to control social behavior. Oxytocin neurons are primarily concentrated in two areas of the hypothalamus: paraventricular nucleus (PVN) and supraoptic nucleus (SON). Oxytocin neurons in the PVN, but not the SON, are responsible for the majority of central oxytocin projections. However, in addition to oxytocinergic neurons, the PVN contains many distinct neurotransmitter-expressing populations (*e.g.*, vasopressin, corticotripin-releasing factor, *etc*). Here, relying on several Cre recombinase-expressing mouse lines, as well as immunohistochemical and *in situ* hybridization techniques, we profile the neuromodulatory populations of PVN, together with their fast neurotransmitter content (*e.g.*, GABA), and begin to characterize the functional impact of neural activity with in specific PVN projections.

Title: Chronic SSRI treatment promotes inhibitory serotonergic signaling in rat prefrontal cortex

Authors: *E. K. STEPHENS[1], D. AVESAR[1], T. P. TODD[3], D. J. BUCCI[3], S. GERBER[2], A. T. GULLEDGE[1];
[1]Physiol. & Neurobio., [2]Genesis and Biochem., Geisel Sch. of Med. At Dartmouth, Lebanon, NH; [3]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The selective serotonin reuptake inhibitor (SSRI) fluoxetine is one of the most widely prescribed drugs for the treatment of depression and anxiety. SSRIs directly and immediately increase the amount of serotonin (5-HT) in the brain by blocking 5-HT transporters, yet little is known about how elevated 5-HT levels contribute to the delayed therapeutic efficacy of SSRIs, which develops slowly over several weeks. Here we demonstrate that chronic treatment with fluoxetine alters the physiological impact of 5-HT on pyramidal neurons in the rat prefrontal cortex (PFC). Unlike in the mouse PFC, where serotonergic responses are strictly segregated among callosal/commissural projection (COM) and corticopontine (CPn) neurons, serotonergic signaling in the rat PFC is more variable among projection neuron subtypes. Similar to the mouse, COM neurons in rat (94%; n = 49/52) exhibited excitatory responses to 5-HT via

activation of 5-HT_{2A} (2A) receptors, either alone (n = 32/52), or as part of biphasic responses involving an initial 5-HT_{1A} (1A) receptor-mediated inhibition (n = 17/52). A few rat COM neurons (6%; n = 3/52) exhibited purely inhibitory responses to 5-HT. More surprisingly, whereas almost all CPn neurons in the mouse PFC are inhibited by 5-HT, most CPn neurons in the rat PFC exhibited 2A-dependent excitatory (68%; n = 40/59) or biphasic (3%; n = 2/59) responses. Only 19% (n = 11/59) of rat CPn neurons exhibited pure 1A-dependent inhibition. The proportions of CPn neurons excited by 5-HT did not differ with sex or across animal strains, including Long Evans, Kyoto/Wistar, and Sprague Dawley. Additionally, manipulations such as enriched environments, or housing in a different facility, did not affect 5-HT responsivity in rat CPn neurons. However, chronic treatment with the SSRI fluoxetine (7 mg/kg/day) for 21 days via a subcutaneous osmotic pump, shifted serotonergic responsiveness in rat CPn neurons, such that 5-HT inhibited the majority (56%; n = 44/79) of neurons, while only 38% (n = 30/79) of CPn neurons exhibited excitatory (n = 27) or biphasic (n = 3) responses ($p < 0.01$; Fisher's Exact Test). The impact of chronic fluoxetine was selective for CPn neurons, as 5-HT responses in COM neurons remained qualitatively unchanged following fluoxetine-treatment, with 61% (n = 36/59) excited, 34% (n = 20/59) biphasic, and 3% (n = 2/59) inhibited by 5-HT. Serum analyses confirmed that fluoxetine-treated animals had 9.4 ng/mL fluoxetine, a level significantly above that detected in vehicle-treated animals (1.4 ng/mL; $p < 0.05$; Student's t-test). These data reveal a novel form of modulatory plasticity in rat PFC that may contribute to the delayed therapeutic action of SSRIs.

Title: Corticotrophin releasing factor dose-dependently modulates excitatory synaptic transmission in the noradrenergic nucleus locus coeruleus

Authors: *B. D. WATERHOUSE[1], D. J. CHANDLER[2];
[2]Neurobio. and Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The noradrenergic nucleus locus coeruleus (LC) is a critical node in the stress response and receives afferent input from a number of corticotrophin releasing factor (CRF) containing structures. Several *in vivo* and *in vitro* studies have shown that CRF robustly increases the firing rate of LC neurons in a dose-dependent manner. While it is known that these increases are dependent on CRF receptor subtype 1 and mediated by effects of the protein kinase A/cAMP intracellular signaling cascades on potassium conductance, the impact of CRF on synaptic transmission within LC has not been clarified. In the present study, we used whole-cell patch clamp electrophysiology in horizontal brainstem slices to assess how varying concentrations of bath-applied CRF affected AMPA-receptor dependent spontaneous EPSCs. Compared to vehicle, 10nM and 25nM CRF had no significant effects on any sEPSC parameters. 50nM CRF, however, significantly increased sEPSC amplitude, width, and charge transfer, while amplitude and charge transfer were significantly decreased by 200nM CRF. While 100nM CRF did not affect the mean change as compared to vehicle, it did significantly increase the variability of the response, such that approximately half of the neurons exposed to this dose displayed increased sEPSC amplitudes, while the other half showed decreased amplitudes. These observations suggest that stress may differentially affect ongoing excitatory synaptic transmission in LC depending on how much CRF is released from presynaptic terminals. Specifically, mild or moderate stressors may potentiate excitatory synaptic transmission, thereby increasing phasic LC responses to salient stimuli, whereas intense stressors might dampen these responses. Combined with the well-documented effects of CRF on membrane properties and spontaneous LC discharge, these observations may help explain how stress and CRF release are able to simultaneously increase tonic LC discharge and decrease sensory-driven phasic discharges. These findings have implications for how stress affects the fidelity of signal transmission and information flow through LC and how norepinephrine release in cognitive, sensory, and motor circuitries and ensuing behaviors might be impacted.

Title: Pharmacological inhibition of diacylglycerol lipase α, but not diacylglycerol lipase β, blocks endocannabinoid-mediated retrograde synaptic depression

Authors: *X. LIU[1], J. TONG[1], C. VICKSTROM[1], D. OGASAWARA[2], H. DENG[3], M. STELT[3], B. F. CRAVATT[2], Q.-S. LIU[1];
[1]Med. Col. of Wisconsin, Milwaukee, WI; [2]the Scripps Res. Inst., La Jolla, CA; [3]Leiden Univ., CC Leiden, Netherlands

Abstract: The endocannabinoid 2-arachidonoylglycerol (2-AG) mediates multiple forms of retrograde synaptic depression including depolarization-induced suppression of excitation (DSE), inhibition (DSI) and synaptically evoked suppression of excitation (SSE) induced by activation of group I metabotropic glutamate receptors (mGluRs). Diacylglycerol lipases (DAGLα and DAGLβ) are biosynthetic enzymes for 2-AG. However, previously known DAGL inhibitors cannot distinguish between DAGLα and DAGLβ, and conflicting results have been reported regarding whether DAGL inhibitors block DSE and DSI. Here, using the recently-developed selective DAGLβ inhibitor KT109 and dual DAGLα/β inhibitors DO34 and DH376, we investigated the effects of acute, selective pharmacological inhibition of DAGLα and DAGLβ on DSE, DSI and SSE in Purkinje cells in mouse cerebellar slices. We report that dual DAGLα/β inhibitors DO34 and DH376 blocked DSE, DSI and SSE in Purkinje cells of the cerebellum, whereas selective DAGLβ inhibitor KT109 did not have significant effects. This pharmacological profile could also be extended to DSI in CA1 pyramidal neurons in the hippocampus and medium spiny neurons in the dorsal striatum. Taken together, these results provide pharmacological evidence that 2-AG synthesized by DAGLα, but not DAGLβ, is required for endocannabinoid-mediated retrograde synaptic depression.

Title: Shifting the mineralocorticoid and glucocorticoid receptor balance affects early life stress related effects on hippocampal glutamatergic transmission

Authors: *H. KARST[1], M. LOI[2], S. KANATSOU[2], H. J. KRUGERS[2], M. JOELS[1]; [1]Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]SILS-Center for Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Stressful events early in life can increase the risk to develop psychiatric disorders. In several models for early life stress (ELS) in rodents, it was shown that hippocampal learning tasks during adulthood were impaired. In these ELS animals also long term potentiation (LTP) in slices of the hippocampus was affected. Recent studies indicate that the functionality of the corticosteroid receptors may be important for the risk to develop ELS related disorders. Here we studied which of the two corticosteroid receptors, the glucocorticoid (GR) or mineralocorticoid receptor (MR), could be responsible for changes in the glutamatergic transmission, induced by ELS in rodents. In 3 months' old rats which were maternally deprived for 24 hours at postnatal day (PND) 3, we recorded in vitro miniature excitatory postsynaptic currents (mEPSCs) in hippocampal CA1 neurons. ELS dramatically decreased the frequency of the mEPSCs , by almost 70% . The amplitude of the mEPSCs was not affected. To study the role of the GRs, we treated rats with Mifepristone for three days at PND 26-28. The treatment with this GR antagonist completely rescued the effect of ELS, measured in the adult rats. To study the role of the MRs after ELS, we used mice with an overexpression of the MR (MRtg). In these experiments we induced ELS in MRtg and control mice with the limited bedding/nesting model. With this ELS model we also detected a reduction in the mEPSC frequency in the hippocampus (dentate gyrus) in control mice. In the MRtg mice, however, ELS did not affect the mEPSC frequency anymore. In none of the tested animals, the amplitude of the mEPSCs was affected. We conclude that when the GRs are suppressed or the MRs are brought to overexpression, the effect of ELS on hippocampal glutamatergic transmission is reduced. These results indicate that the balance between GR and MR may predict vulnerability to stress.

Title: Uncovering the effects of agonism at postsynaptic α_{2A}-adrenergic receptors on neuronal activity within the bed nucleus of the stria terminalis

Authors: *N. A. HARRIS[1,2,3,4,5], A. T. ISAAC[2], S. A. FLAVIN[3], D. G. WINDER[1,2,3,4,5];
[2]Mol. Physiol. and Biophysics, [3]Vanderbilt Brain Inst., [4]Neurosci. Program in Substance Abuse, [5]Kennedy Ctr., [1]Vanderbilt Univ., Nashville, TN

Abstract: Stress is a major risk factor for relapse to drug-seeking behavior. The bed nucleus of the stria terminalis (BNST) receives an extensive noradrenergic input and has been shown to be critical in stress-induced reinstatement of drug-seeking behavior. In rodents, systemic or intra-BNST treatment with α_2-adrenergic receptor agonists decreases stress-induced reinstatement behaviors. Clinical studies report that guanfacine, an α_{2A}-AR agonist, curbs cravings for a variety of substances of abuse. We have previously shown that α_{2A}-ARs are heavily expressed in the BNST, and that noradrenergic signaling in the region is dramatically altered in α_{2A}-AR knockout mice. Data suggests that competing inhibitory and excitatory actions of this drug in the BNST could reflect carefully coordinated control of BNST activity. Our lab has shown inhibitory effects of guanfacine in the BNST on electrically evoked EPSCs and optically evoked EPSCs derived from parabrachial nucleus (PBN) afferents, consistent with canonical presynaptic G_i signaling. In contrast, in a Thy1-COP4 transgenic mouse line, bath application of guanfacine enhances optically evoked field potentials. In addition, systemic guanfacine is known to initiate c-fos expression in BNST neurons. These findings led us to pursue mechanistic studies of this effect. Using RNAscope *in situ* hybridization, we show that systemic guanfacine leads to expression of cfos transcripts in 90% of cells that express *adra2a* (α_{2A}-AR) mRNA, as compared to 10% of cells after saline. Interestingly, ~50% of cells that express cfos do not co-express *adra2a* mRNA, suggesting potential involvement of an underlying BNST microcircuit in this effect. We hypothesized that this novel excitatory effect occurs via activation of postsynaptic α_{2A}-ARs leading to decreased cAMP-dependent opening of hyperpolarization-activated cyclic nucleotide-gated nonselective cation (HCN) channels. This hypothesis is based on our observations that ~80% in cfos+ cells after systemic guanfacine in a cfos-eGFP mouse line exhibited a hyperpolarization-dependent sag consistent with Ih, as well as enhanced excitatory field potential responses in Thy1-COP4 BNST slices after HCN inhibition by ZD7288. However, RNAscope experiments show little co-localization of *adra2a* and *hcn1* mRNA, suggesting either *hcn2* involvement or independent mechanisms of activity enhancement. In addition, whole cell recordings show that guanfacine preincubation does not affect the amplitude of I_h in cfos+ BNST neurons after systemic guanfacine. Future studies will test the involvement of HCN2 channels and other candidates in guanfacine enhancement of BNST activity.

Title: Differential modulation of synapses by neuropeptides with convergent actions on intrinsic excitability

Authors: *X. LI, D. BUCHER, F. NADIM;
Dept Biol. Sci., Rutgers/Njit, Newark, NJ

Abstract: Neuronal excitability and synaptic function depend on neuromodulators, and different modulators shape neural circuit activity into different patterns. However, circuits are likely under control of more than one modulator at all times. Therefore, understanding co-modulation is important for the study of circuit dynamics. Modulators can converge onto the same subcellular targets in a neuron, or affect different targets. In the case of true convergence, i.e. different modulator receptors sharing the same signaling pathway and subcellular target, the effects of two modulators should be simply additive until they occlude each other. In all other cases, interactions between two modulators can be complex and highly nonlinear. In the pyloric circuit of the crab stomatogastric ganglion (STG), several neuropeptides are converging onto the same voltage-gated current, occluding each other's effects. Different effects on circuit activity are attributed to the fact that each circuit neuron only responds to a subset of these peptides, i.e. each peptide activates a different subset of neurons. In addition, concentration-dependence and magnitude of the effect can be different between two neuropeptides. More recently, it has been shown that some peptides can also affect synapses. If both synaptic partners express receptors to the same peptide, the effects can potentially be mediated through both presynaptic and postsynaptic mechanisms. We studied the effect of proctolin and crustacean cardioactive peptide (CCAP) on the synaptic connections between the pyloric dilator (PD) and lateral pyloric (LP) neurons in the STG. Both PD and LP express receptors to proctolin, but only LP expresses receptors to CCAP. The effects of proctolin and CCAP on the voltage-gated current in LP are consistent with convergence and occlusion. However, the effects on synapses are more complex. PD and LP make reciprocal graded inhibitory connections, and we show that both synapses are strengthened by each neuromodulator, albeit in different fashion. At the PD to LP synapse, CCAP enhances the synaptic current amplitude while proctolin modulates its dependence on presynaptic voltage. At the LP to PD synapse, either modulator increases the amplitude of the synaptic current and changes dependence on presynaptic voltage. At both synapses, sequential

application shows that CCAP completely occludes the effect of proctolin. In contrast, CCAP application additionally increases synaptic current after application of proctolin. These results suggest that co-modulation of synaptic effects is more complex than simple convergence, with potential consequences for circuit modulation.

Title: High-fat diet causes hippocampal resistance to leptin-driven modulation of synaptic transmission

Authors: *M. MAINARDI, M. SPINELLI, F. SCALA, S. FUSCO, A. MATTERA, M. D'ASCENZO, C. GRASSI;
Inst. of Human Physiol., Catholic Univ. Sch. of Med., Rome, Italy

Abstract: Leptin plays an essential role in metabolic homeostasis, by signaling to the brain the level of long-term energy stores (i.e., white adipose tissue depots). Strikingly, abundant expression of ObRb - the functional isoform of the leptin receptor - can be detected also in the hippocampus, a structure not primarily involved in metabolic homeostasis, but central to learning and memory processes. Indeed, leptin has been shown to modulate hippocampal synaptic transmission and plasticity. Moreover, at the behavioral level, leptin is able to affect performance in hippocampus-dependent tasks. Taken together, these effects have led to postulating a neurotrophin-like role for leptin.
Since it is becoming increasingly clear that altered diet composition affects brain functioning, we asked whether a high-fat diet since weaning can lead in adulthood to altered response to the action of leptin on the hippocampus.
We first performed patch-clamp recordings on brain slices comprising the CA3 to CA1 circuit obtained from adult (age 3-4 months) mice fed a high-fat diet (HFD group) or a standard diet (SD group). We found that, in SD mice, bath application of leptin (50 nM) increased the frequency of spontaneous excitatory postsynaptic currents (sEPSCs), and that this effect was lost in HFD mice (SD = 144.25 ± 21.45%, HFD 98.44 ± 4.52% of baseline value; ANOVA-1, $p = 0.003$). Analysis of glutamatergic, AMPA receptor-mediated evoked currents revealed that leptin

increased amplitude in SD mice, whereas no significant difference was observed in HFD mice (SD = 166.11 ± 13.03%, HFD = 102.81 ± 9.85% of baseline value, ANOVA-1, $p < 0.001$). Moreover, a similar effect was observed on paired-pulse facilitation, which we evaluated over a wide range of inter-stimulus intervals: 200 ms (SD = 117.20 ± 6.58%, HFD = 104.37 ± 8.15%), 100 ms (SD = 114.19 ± 5.54%, HFD = 100.56 ± 4.42%), 50 ms (SD = 131.47 ± 9.46%, HFD = 99.88 ± 8.59%), 20 ms (SD = 136.10 ± 11.64%, HFD = 101.03 ± 7.19%; % of baseline values, ANOVA-3, $p < 0.001$).
In search of a molecular correlate of these functional phenomena, we checked the integrity of the STAT3 cascade, a key transducer of leptin action on neurons. In line with electrophysiological data, intraperitoneal injection of leptin (3 mg/kg) caused strong phosphorylation of STAT3 in SD mice, a response that was significantly blunted in HFD mice (SD = 382.77 ± 37.05%, HFD = 208.19 ± 49.32% of baseline value, ANOVA-2, $p = 0.003$).
These results indicate the development of hippocampal leptin resistance in mice fed a high-fat diet, and highlight the general role of this hormone in modulating neuronal activity well beyond areas involved in metabolic homeostasis.

Title: Actions of the tryptophan metabolites 3-hydroxy-kynurenine (3HK) and Xanthurenic Acid (XA), on gamma oscillations in the rat hippocampus

Authors: ***T. E. SALT**[1], F. WEISZ[1], R. SCHWARCZ[2], S. A. NEALE[1,3];
[1]UCL Inst. Ophthalmology, London, United Kingdom; [2]Dept. of Psychiatry, Maryland Psychiatric Res. Ctr., Baltimore, MD; [3]Neurexpert Ltd, London, United Kingdom

Abstract: The kynurenine pathway is a major route of tryptophan metabolism, and this pathway may be disturbed in several psychiatric and neurodegenerative disorders (Schwarcz *et al* 2012). 3-Hydroxy-kynurenine (3HK), a molecule arising from tryptophan, is a precursor for several kynurenines, including xanthurenic acid (XA). Interestingly, XA serum levels are reduced in patients with schizophrenia (Fazio *et al* 2015). We have previously shown that both 3HK and XA can reduce hippocampal synaptic transmission, and it is probable that some of the effect of 3HK is attributable to the conversion of 3HK to XA (Neale *et al* 2013; Ngomba *et al* 2015).

Gamma oscillations are thought to be an important biomarker of cognitive functions. We have thus investigated the actions of 3HK and XA on hippocampal *gamma* oscillations in an effort to shed light on the role of these kynurenines in cognitive disorders.
Horizontal *in vitro* slice preparations were made from the brains of adult male Sprague-Dawley rats. Extracellular field recordings were made from the CA3 area of the hippocampus in an interface bath at ~33C. Addition of carbachol (5μM) to the bathing medium resulted in the generation of stable *gamma* oscillations with peak power in the 32-42Hz region. Further addition of XA (0.3-3mM) resulted in a reversible concentration-dependent reduction of the *gamma* power by up to 91±3% (3mM). Addition of 3HK (1mM) also reduced the *gamma* power (by 61±9%) whereas 1mM XA reduced the *gamma* power by only 29±4%. There did not appear to be any significant change in the frequency of the *gamma* power peak under these conditions.
In summary, we have shown that 3HK, the direct metabolic precursor of XA, has similar effects to XA in reducing the power of *gamma* oscillations in the hippocampus. This finding is consistent with the idea that changes in 3HK levels could drive XA levels and thus produce effects on neuronal circuit function, although it does not exclude the possibility that 3HK has direct effects. This may be important in our understanding of how malfunction of the kynurenine pathway can cause changes in circuit function that may be related to pathological changes in cognitive processes.

Title: Synaptic effects of social defeat stress: interleukin-6-dependent contribution

Authors: ***E. ESQUIVEL RENDON**[1], J. VARGAS-MIRELES[1], F. MEDINA-GARCIA[1], A. MALDONADO-HERNANDEZ[1], P. ACOSTA-MARES[1], R. CUEVAS-OLGUIN[1], I. GONZALEZ-NATERAS[1], M. MIRANDA-MORALES[1], S. ROSE-JOHN[2], M. ATZORI[1];

[1]Facultad de Ciencias, UASLP, San Luis Potosi, Mexico; [2]Biochem., Christian Albrechts Univ., Kiel, Germany

Abstract: Social stress potentially undermines well-being in humans as well as in many mammalian species. The biological correlates of social stress are not yet completely understood. Recent investigation has underscored the importance of pro-inflammatory cytokines, particularly interleukin-6 (IL-6), as mediators of the effects of stress in the central nervous system (CNS). We considered the possibility that social stress triggers synaptic changes in stress-vulnerable CNS regions in an IL-6-dependent fashion. To test this hypothesis we used GFAP-sgp130Fc (transgenic, TG) mice, a murine model in which IL-6 trans-signaling -a critical mechanism of action IL-6 in the CNS - was blocked. As a model of social stress we determined the effects of Social Defeat Stress protocol (SDS) on wild type (WT, C57BL/6) or TG animals. SDS animals were submitted to a 10-day stress protocol consisting in a 15 min-long sessions in which they were put in contact with a CD1 white mouse, whose aggressive behavior had been determined in previous separate tests. At the end of the protocol we evaluated whether or not experimental animals responded to stress, by comparing the time spent in an area in the proximity of the CD1 mouse vs. the time spent in the same area in the absence of the CD1 mouse. Preliminary experiments showed that while WT stressed animals - as expected - spend considerably less time in the CD1-interaction area, compared to non-stressed animals. Stressed TG animals fail to substantially decrease the time spent in the CD1-interaction area, suggesting that TG mice respond to stress differently from WT mice. We further studied synaptic function of the same animals in their prefrontal cortex, a CNS area that has been shown to be particularly vulnerable to social stress. The synaptic parameters studied were the ratio between α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid-receptor (AMPAR)-, the γ-amino butyric acid type A ($GABA_AR$)-, and the N-methyl-D aspartate-(NMDAR)-mediated component of electrically evoked synaptic currents from visually identified neurons in cortical layer 5 medial prefrontal cortex. Our results showed that SDS decreases the ratio I_{AMPA}/I_{GABA} (0.57 ± 0.11 in non-stressed vs. 0.32 ± 0.02, unpaired Student t-test, d.o.f. = 15) in WT mice but not in TG mice (0.60 ± 0.09 in non-stressed vs. 0.56 ± 0.12, d.o.f. = 18). On the contrary, the ratio between I_{AMPA}/I_{NMDA} remained unchanged regardless of group (WT vs. TG) or treatment (non-stressed vs. stressed). These data suggest that at least part of the behavioral and central effects of social stress are mediated by IL-6 -dependent central trans-signaling.

Title: Pro-bumetanide treatment reduces long-lasting learning and memory deficits induced by repeated administration of ketamine in neonatal rats

Authors: *B. D. BUTLER[1], M. KHAN[1], R. A. STEVENS[1], S. MUQUEET[1], S. KOKANE[2], P. THAPA[3], F. W. FOSS[3], Q. LIN[2];
[1]Biol., [2]Psychology, [3]Chem., Univ. of Texas At Arlington, Arlington, TX

Abstract: Ketamine (KET), a non-competitive N-methyl-D-aspartate receptor (NMDAR) antagonist is commonly used as a pediatric anesthetic. However, several experimental studies have indicated its involvement in inducing widespread neurotoxicity in the neonatal brain, subsequently leading to long-lasting cognitive and memory deficits that persist into adulthood. Previous studies from our group demonstrated that bumetanide – an Na^+-K^+-$2Cl^-$ cotransporter (NKCC1) antagonist – has the ability to reduce these KET-induced deficits. However, bumetanide does not cross the blood-brain barrier (BBB) efficiently upon systemic injection. Therefore, in this study, we used a derivative form of bumetanide, known as pro-bumetanide (PBUM) which crosses the BBB more efficiently upon systemic administration. In order to investigate the potential neuroprotective effects of PBUM, we co-administered PBUM at varying doses with ketamine or vehicle (VEH). Male and female rat pups, at postnatal day 9, were randomly assigned to the following drug-treatment groups: 6 mg/kg PBUM (6-PBUM)+KET, 12 mg/kg PBUM (12-PBUM)+KET, 18 mg/kg PBUM (18-PBUM)+KET, VEH+KET, and VEH+VEH. About four weeks following drug administration, all groups were tested for spatial learning and memory abilities using the Morris Water Maze (MWM) and Object Location Memory (OLM) task. Consistent with our previous results, the ketamine-only group (VEH+KET) exhibited an increase in time to perform these tests, indicting deficiencies in spatial learning and memory as compared to the control (VEH+VEH). In contrast, the co-treatment groups (n-PBUM+KET) exhibited behavior similar to the control, and outperformed the VEH+KET group, providing evidence that PBUM does demonstrate lasting neuroprotection upon systemic co-administration with ketamine at neonatal ages. This was further corroborated by the OLM results. The n-PBUM+KET groups spent more time in the zone in which the object's location was changed (similar to the VEH+VEH group) while the VEH+KET group spent relatively equal amounts of time in both zones. This indicates that while the n-

PBUM+KET and VEH+VEH groups identified the novel position of the object, the VEH+KET group could not. In conclusion, this study provided evidence that PBUM was effective in preventing cognitive and memory deficits induced by neonatal administration of ketamine. To the best of our knowledge no other research has been performed using a ketamine model to test forms of pro-bumetanide. Thus, these results set precedence for the need to further investigate the potential therapeutic effects of bumetanide derivatives and their underlying biomolecular mechanisms involved.

Med. Ctr., Nijmegen, Netherlands; [5]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Glucocorticoids, released during arousing experiences, enhance the consolidation of memory processing. Recent findings indicated that glucocorticoids interact with the endocannabinoid system of the hippocampus or the amygdala in modulating memory consolidation. Previously, we have shown that corticosterone administration into the dorsal striatum also enhances memory of inhibitory avoidance training. In the striatum, the cannabinoid

receptor type 1 (CB1R) is highly expressed but it remains unknown if endocannabinoids cooperate with glucocorticoids to enhance striatal-dependent memory. Our objective was to evaluate if there is a striatal glucocorticoid-endocannabinoid interaction that modulates memory consolidation of an aversive experience. Male Wistar rats, with bilateral cannulae in the anterodorsal striatum, were trained on an inhibitory avoidance task and had a retention test 48 h later. We found that the CB1R antagonist AM251 (0.28 or 0.56 ng/µl) administered into the striatum immediately after the inhibitory avoidance training impaired memory consolidation. In contrast, the CB1R agonist WIN55-212 (50 or 100 ng/µl) enhanced memory consolidation, and this effect was blocked by systemic administration of the corticosterone-synthesis inhibitor metyrapone (50 mg/kg, ip) given 90 min before training. Additionally, a low dose of AM251 (0.28 ng/µl) administered immediately posttraining blocked the memory-enhancing effect of posttraining corticosterone administered systemically (3 mg/kg, ip) or of corticosterone (20 ng/0.5 µl) infused directly into the dorsal striatum. Our findings provide evidence on the broad interaction of endocannabinoids with glucocorticoids that modulate memory, now assessed in the striatum; suggesting that the endocannabinoid system is recruited by glucocorticoids to enhance memory consolidation of an emotional aversive training experience. Title: Trichostatin A prevents stress-induced spatial memory impairment

Authors: V. VARGAS-LÓPEZ[1], *A. MÚNERA[2];
[1]Physiol., Univ. Nacional de Colombia, Bogotá D.C., Colombia; [2]Univ. Nacional De Colombia, Bogotá, Colombia

Abstract: Acute stress induced before spatial training impairs long-term memory and it is related to decreased dendritic spine density, diminished kinase activity, and reduced expression neural cell adhesion molecule (NCAM), brain-derived neurotrophic factor (BDNF), and activity-regulated cytoskeleton-associated protein (Arc) in the hippocampus. Epigenetic mechanisms involved in such effect has not been yet study; but, since spatial training and intense stress have opposite effects on histone acetylation balance, it is conceivable that disruption of such balance may underlie acute stress-induced spatial memory consolidation impairment. In this study, we tested the effectivity of the histone deacetylase inhibitor Trichostatin A (TSA) to prevent the deleterious effect of acute restrain stress on long-term spatial memory in adult male Wistar rats. We found that animals stressed before training in the Barnes maze showed impaired long-term memory, in association with increased plasma corticosterone levels, and decreased histone H3 acetylation levels in the dentate gyrus of the hippocampus and the prelimbic cortex, as compared to non-stressed animals. Remarkably, these effects were prevented by intraperitoneal administration of TSA (1mg/kg) immediately after the spatial training. The aforementioned results are consistent with reports showing that histone deacetylases inhibition can prevent stress-induced anxiety, somatic hypersensitivity, and visceral pain, and supports the hypothesis that deleterious effects of stress on memory involve altered histone acetylation balance.

Title: The endocannabinoid 2-AG mediates a novel form of presynaptic plasticity at a critical relay in hippocampal circuitry

Authors: *W. WANG[1], B. H. TRIEU[1], Y. JIA[1], K.-M. JUNG[1], C. A. KARSTEN[1], C. B. MERRILL[1], K. MACKIE[2], C. M. GALL[1,3], D. PIOMELLI[1,4,5,6], G. LYNCH[1,7];

Abstract: The endocannabinoid 2-arachidonoyl-sn-glycerol (2-AG) modulates synaptic function at many loci throughout the brain with effects generally mediating a dampening of transmission. There is good evidence that 2-AG is produced, on demand in dendritic spines by metabotropic glutamate receptor (mGluR)-mediated activation of the synthetic enzyme diacylglycerol lipase-α (DGL) and acts upon presynaptic CB_1 receptors to depress release. The present studies re-evaluated endocannabinoid actions at lateral perforant path (LPP) innervation the dentate gyrus and identified a novel form of 2-AG-dependent signaling that mediates an enduring enhancement of transmission that entails increases in neurotransmitter release. In studies of hippocampal slices from rats and mice, we found that high frequency stimulation of the LPP induces long term potentiation (LTP) that is blocked by CB_1 receptor antagonism and absent in CB_1 knockouts; the same manipulations had no effect on the magnitude of LTP in the adjacent medial perforant path or in field CA1. Results indicate that 2-AG mediates the endocannabinoid-dependent LTP (ecLTP) in the LPP: It is blocked by DGL inhibition but enhanced by antagonism of 2-AG degradation whereas manipulation of anadamide degradation had no effect. Mechanisms of ecLTP include activities in both pre- and postsynaptic compartments. Induction relies upon mGluR and NMDA receptors, and changes in postsynaptic calcium, whereas expression entails a depression of paired pulse facilitation indicating increased neurotransmitter release. Evidence for ecLTP in the LPP suggests that memory encoding that relies upon this system is also endocannabinoid, and 2-AG, dependent. We tested this using an odor discrimination task known to rely upon the lateral entorhinal to dentate projection. In rats, odor discrimination learning was impaired by CB_1 antagonism but facilitated by treatments that increase 2-AG content. Together these results demonstrate that the encoding of information carried by a principal hippocampal afferent involves a novel, endocannabinoid-dependent form of synaptic plasticity.

Title: Interactions between progesterone & tropisetron in the modulation of cognitive behavior in female rats.

Authors: J. HASSELL, M. MAZENKO, *S. S. MASWOOD;
Biol., Millersville Univ., Millersville, PA

Abstract: The neurotransmitter serotonin (5-HT) is involved in the modulation of cognitive functions. The precise mechanism of action of the 5-HT system in the facilitation of cognitive functions has not been clearly identified. However, compounds such as tropisetron that act as an antagonist at the 5-HT_3 receptor enhance cognition. Similarly in female rodents, priming with estrogen and/or progesterone enhances cognition in several behavioral models including the object recognition task. The object recognition task is a model of cognition in rodents in which the natural tendency of rats to explore novel aspects of the environment is utilized. Rats spend more time exploring the novel object, suggesting that rats recognize previously explored objects. Earlier we reported that the 5-HT_3 receptor antagonist, tropisetron, enhances object recognition in regularly cycling intact female rats. Interestingly, both estrogen and progesterone also modulate the functioning of 5-HT_3 receptors by acting as antagonists at this receptor. Since estrogen, progesterone and tropisetron all act as antagonists at the 5-HT_3 receptor, we hypothesized that the cognitive enhancing effects of tropisetron would be further accentuated in ovariectomized female rats primed with either estrogen or progesterone.
Contrary to expectation, we did not find a synergistic effect between estrogen and tropisetron in the object exploration task. Our preliminary data however, show that progesterone and tropisetron may act synergistically to enhance cognition. Since we looked at a single dose of progesterone and tropisetron, we are currently evaluating multiple doses of progesterone and tropisetron in ovariectomized Sprague-Dawley female rats using the object recognition task as a model of cognition. Findings from this study will help us further understand the interaction between the serotonergic system and female hormones in the modulation of cognition.

Title: Neurotoxic and cognitive effects of neonatal (+)-methamphetamine: Role of reactive oxygen species (ROS)

Authors: ***S. A. JABLONSKI**[1], K. LASANCE[2], L. LEMEN[2], S. J. THOMAS[3], S. C. SANCHEZ[3], M. ASCHNER[4], M. T. WILLIAMS[1], C. V. VORHEES[1];
[1]Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Radiology, Univ. of Cincinnati Col. of Med., Cincinnati, OH; [3]Clin. Pharmacol., Vanderbilt University, Sch. of Med., Nashville, TN; [4]Mol. Pharmacol., Albert Einstein Col. of Med., New York, NY

Abstract: Rats treated with (+)-methamphetamine (MA) during neonatal development (equivalent to third trimester brain development in humans) results in deficits in allocentric learning and memory (L&M) in the Morris water maze (MWM), egocentric learning in the Cincinnati water maze (CWM), working and reference memory impairments in the radial water maze, and in contextual fear conditioning. These L&M deficits are substantial, stable, and larger than in adult animals (Vorhees et al., 2007). However, it remains to be elucidated what mechanisms mediate the developmental MA-induced cognitive deficits in the absence of dopamine-related effects that are found in adult rodents after MA exposure. Neonatal MA-exposed rats also exhibit exaggerated hyperactivity in response to the D_1 agonist SKF-82958, reduced hyperactivity to the NMDA antagonist MK-801, and mild under-response to D_2 autoreceptor agonist, quinpirole, but no changes in response to serotonergic agonists. Because prenatal exposure to MA increases reactive oxygen species (ROS) in adult rats, we tested the involvement of ROS after neonatal MA exposure in two ways: by measuring F_2 isoprostanes (F_2-IsoPs) and by pretreatment with the spin trapping agent alpha-phenyl-N-tert-butyl nitrone (PBN) prior to each dose of MA. There was no change in F_2-IsoPs in striatum or hippocampus after the first dose on P6 or last dose on P15. Nor did PBN attenuate MA-induced L&M deficits. We investigated striatal D_1 receptors using micro PET/CT imaging and the D_1 ligand, TISCH, after treated rats were adults. We found no effects of treatment. We also examined brain oxygen

activity using 2-fluoro-2-deoxyglucose (FDG) and found no change after challenge with the D_1 agonist SKF-82958. In sum, third trimester-equivalent MA exposure (P11-20 or P6-15) in rats leads to long lasting L&M impairments and changes in dopaminergic and glutamatergic receptor function, but not in ROS production, or changes in D_1 receptor binding or metabolic activity. Hence, the exact mechanism of MA-induced developmental effects remains to be elucidated.

Title: Gonadal hormones modulate ethanol induced memory deficit in adolescent female rats

Authors: J. A. TRAVIS[1], K. ISHIWARI[2], ***R. SIRCAR**[1,3];
[1]The City Col. of New York, New York, NY; [2]Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY; [3]Psychiatry & Behavioral Sci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Earlier, our lab has reported that ethanol treatment in pre-pubertal adolescent male and female rats causes hippocampus-associated memory deficit. Whether ethanol affects hippocampus related memory function in post-pubertal rats is not known. In this study, we investigated the effects of ethanol on hippocampus-associated and amygdala-related cognitive functioning in post-pubertal adolescent male and female rats. Post-pubertal rats were administered a single injection of ethanol (2 g/kg) intraperitoneally or equivalent volumes of deionized water. Some female rats were ovariectomized and given hormonal supplementation (estrogen and/or progesterone). Additional controls included sham-operated vehicle-treated animals. All rats were trained in the fear conditioning paradigm. Twenty-four hours later, all experimental animals were tested for: (i) contextual fear conditioning in the same training chamber, and (ii) cued fear memory in a modified test chamber. For each rat, freezing during contextual and cued fear conditioning tasks were recorded. Acute ethanol-treatment in intact post-pubertal female rats showed significant disruptions in hippocampus-related contextual memory but not amygdala-associated cued fear memory. Post-pubertal male rats did not show any ethanol-induced memory deficit. There was significant effect of estrous cyclicity on ethanol-induced behavior in intact female rats. Exogenously administered estrogen with or without

progesterone altered the sensitivity of ethanol-induced memory impairment in ovariectomized post-pubertal female rats. Together, these data suggest that female gonadal hormones play an important role in modulating ethanol-induced memory impairment in post-pubertal animals.

Title: Cannabinoid receptor antagonist AM251 reduces radiation-induced cognitive decrements

Authors: ***V. K. PARIHAR**, A. LILAGAN, A. SYAGE, S. F. KWOK, N. N. CHMIELEWSKI, M. M. ACHARYA, J. E. BAULCH, C. L. LIMOLI;
Dept. of Radiation Oncology, Univ. of California, Irvine, CA

Abstract: There are now more than 10 million cancer survivors in the United States. With these numbers, chronic sequelae that result from cancer therapy have become a major health care problem. Although radiation therapy of the brain has improved cancer cure rates, learning disorders and memory deficits are a common consequence of this therapy. As exposure to ionizing radiation results in enhanced depressive- and anxiety-like behaviors and memory dysfunction, it is believed that the inhibition of hippocampal neurogenesis represents an underlying mechanism. Here, we investigated the effects of the cannabinoid receptor antagonist AM251 on radiation-induced cognitive decrements and reduced neurogenesis 1 and 3 months following exposure. To validate the functional significance of CB1 receptor blockade, 6 month old mice were first subjected to head only irradiation (9 Gy) then given 4 consecutive daily doses of AM251 (1 mg/kg) every month for 3 months. Learning and memory was assessed by novel object recognition (NOR) and Object in Place (OiP) memory tasks, while the Elevated Plus Maze Test (EPM) was used to quantify anxiety-like behavior. Preliminary studies have indicated a potential neurocognitive benefit of AM251 treatment in irradiated mice. Interestingly, quantification of BrdU+ cells and the number of doublecortin (DCX) positive newly born neurons in the subgranular zone-granule cell layer has revealed that AM251 enhances neurogenesis and cell proliferation compared to the control group ($p<0.05$). Our findings suggest that certain radiation-induced sequelae can be reduced by AM251 treatment, possibly through a mechanism involving enhanced neurogenesis.

Title: Sex differences in the metabolic and cognitive effects of ghrelin signalin

Authors: ***I. KADISH**[1], M. SHARPE[1], T. VAN GROEN[1], A. PATKI[2], T. R. NAGY[3], D. B. ALLISON[4];
[1]Dept Cell, Developmental and Integrative Bio, [2]Dept Biostatistics, [3]Dept Nutr. Sci., [4]Sch. of Publ. Health, Nutr. Obesity Res. Ctr., Univ. of Alabama Birmingham, Birmingham, AL

Abstract: Environmental interventions that affect rate of aging and life span tend to have a greater effect in one sex than the other. Whereas studies have been done on the effects of sex differences in many neurological diseases, e.g., Alzheimer's disease and autism, the role that gender plays in metabolic diseases is much less clear. Ghrelin (a gut hormone), via hypothalamic circuits, is involved in hunger and meal initiation causing *perceived* negative energy balance even in eucaloric conditions. Interoceptive cues caused by ghrelin are likely similar to those produced by caloric restriction. In previous studies we have shown that long term treatment with ghrelin agonist improves cognition and glucose handling in aging male mice. In the current study we tested the hypothesis that ghrelin agonist treatment in female mice will have more pronounced positive effects on metabolism and cognition than in male mice. Female C57BL/6J mice at two months of age were randomly assigned into 4 groups (n=20/group) on the basis of weight matching. One group (control) received *ad libitum* access to food while the other group (ghrelin) received the same amount of diet consumed by the control group and 30 mg/kg of synthetic ghrelin agonist (LY444771) daily, the third and fourth groups underwent ovariectomy (OVX control and OVX-ghrelin). Food consumption and body weights were measured weekly. At 10 months of age an oral glucose tolerance test was performed. At 12 months of age all

groups were submitted to a battery of cognitive and behavioral tests, followed by an imaging procedure (QMR) and indirect calorimetry. Biochemistry and immunohistochemistry analysis were carried out to assess the changes in brain tissue and plasma. Ghrelin agonist treatment improved glucose tolerance in both ghrelin agonist treatment groups to compare with the control groups. There was significant ($p<0.0001$) increase in energy efficiency in ghrelin treated animals. Cognition was improved ($p<0.04$) in OVX ghrelin treated group to compare with OVX control, but did not significantly influence the cognitive outcome of 12 month old intact mice. Insulin signaling was improved in hippocampus and inflammation was attenuated in white matter and hypothalamus in ghrelin agonist treated mice. In conclusion, to compare with male mice, long term ghrelin agonist treatment in female mice significantly increased energy efficiency in intact and OVX and improved cognition in middle age OVX mice.

Title: Nogo receptor 1 overexpression in forbrain neurons alters dopamine release kinetics

Authors: *E. S. ARVIDSSON, T. E. KARLSSON, A. T. BRODIN, K. WELLFELDT, A. JOSEPHSSON, L. OLSON;
Karolinska Institute, Dept. of Neurosci. (, Stockholm, Sweden

Abstract: The ability to learn from experience and to store memories is fundamental to life. Losing these abilities, as in Alzheimer's disease, is devastating. To implement the required structural synaptic re-organizations needed to permanently embed novel memories in the brain, a complex and precisely organized molecular machinery consisting of plasticity-enhancing and plasticity-inhibiting systems needs to be activated. We previously discovered that increased neural activity is linked to rapid down-regulation of Nogo receptor 1 (NgR1). To test if such regulation is important for the formation of lasting memories, we generated MemoFlex mice, with inducible overexpression of NgR1 in forebrain neurons. While these mice have normal LTP and, under undemanding circumstances, normal 24 hr memory, formation of lasting memories is severely impaired. However, when transgenic NgR1 expression is turned off in these mice (by doxycycline), the ability to form lasting memories is restored. We also found that the presumed structural synaptic reorganization needed to form permanent engrams occurs during the first week after experiencing a memory-causing event. The aim of this study is to further investigate how Nogo-signaling affects neurotransmitter release. Because dopamine signaling has been implicated in regulating plasticity and memory, we used electrochemical measurements with amperometry to allow *in vivo* quantification of dopamine with a very high temporal and spatial resolution in NgR1 overexpressing mice. Initial results revealed severe impairment of KCl-induced dopamine release in dorsal striatum in overexpressing, compared to littermate controls. Ongoing work focuses on the mechanisms behind this effect. We will determine if turning off the NgR1 transgene might result in normalization of DA kinetics and if DA release kinetics are altered in mice lacking NgR1.

Title: Aging decreases intrinsic excitability within layer II/III principal cells of the lateral entorhinal cortex

Authors: *C. LIN, M. OH, J. DISTERHOFT;
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Aging is often associated with a decline in hippocampus-dependent learning and memory. Numerous studies have investigated the neurobiological mechanisms that underlie aging-related learning and memory impairments. Previous research has shown that within the CA1 region of the hippocampus, a decrease in intrinsic excitability within pyramidal neurons underlies learning deficits within aged animals. The current project focuses on determining whether intrinsic excitability within the principal neurons of the entorhinal cortex also decreases with age and whether these changes may also contribute to age-associated learning deficits observed. The entorhinal cortex relays information from cortical regions to the hippocampus and is highly susceptible to aging-related changes. Specifically, the lateral portion of the entorhinal cortex (LEC) been suggested to support hippocampus-dependent temporal associative learning. Therefore, whole cell current clamp recordings were performed on the principal neurons of layer II/III of the LEC from young adult (3-6 month old) and aged (29-32 month old) F1 F344xBN hybrid rats. Within layer II, these are the fan cells and within layer III, the recordings were made from pyramidal neurons. Measures of intrinsic excitability include accommodation and postburst afterhyperpolarization (AHP). Our preliminary results indicate that fan and pyramidal neurons from aged animals are less excitable relative to their younger counterparts. This decrease in excitability manifests as an increase in accommodation and an increase in the postburst AHP. The results are similar to previous data from the CA1 region of the hippocampus and suggest LEC intrinsic excitability may also be a measure and mechanism supporting learning. Identification of these changes in aging will point to a potential target for future therapeutics in alleviating aging-related learning and memory deficits.

Title: Age as a risk factor for the disruption of cognitive performance by exposure to the types of radiation encountered on exploratory class missions to other planets

Authors: *B. M. RABIN[1], B. SHUKITT-HALE[2], K. L. CARRIHILL-KNOLL[1], M. G. MILLER[2], K. A. BARTON[1];
[1]Univ. Maryland Baltimore County, Baltimore, MD; [2]Human Nutr. Res. Ctr. on Aging, USDA-ARS, Boston, MA

Abstract: Exposure to the types of radiation encountered in space (particles of high energy and charge [HZE particles]) produces changes in neurocognitive performance similar to those observed in the aged organism. As such, it is possible that there would be an interaction between the effects of exposure to HZE particles and the effects of aging. Previous research using ^{56}Fe particles has shown an interaction between age of irradiation and the dose needed to produce a deficit in cognitive performance, such that doses of HZE particles that did not affect the performance of younger subjects affected the performance of older ones. The present experiments were designed to evaluate the generality of the relationship between age of irradiation and the dose needed to disrupt cognitive performance as a function of the characteristics of the specific particle. Male F-344 rats between 2 and 16 months of age were exposed to ^{48}Ti, ^{16}O, and ^{4}He particles at the NASA Space Radiation Laboratory at Brookhaven National Lab. Cognitive performance was evaluated by testing performance on an ascending fixed-ratio operant task. In this task the subject must make an increasing number of responses in order to obtain a reward (food pellet). This task measures the motivation of the organism to work for reinforcement and the responsiveness of the organism to changes in environmental contingencies, including changes in reinforcement contingencies. Overall, the results indicated that for the higher linear energy transfer (LET) particles (^{56}Fe and ^{48}Ti; which produce greater tissue destruction along the particle track) a lower dose was needed to disrupt cognitive performance in the older subjects. Conversely, the available results suggest that a similar relationship may not be observed for the lower LET particles (^{16}O and ^{4}He) which produce less tissue destruction along the particle track). These results suggest that the effectiveness of specific particles in disrupting cognitive performance may, under some conditions, vary as a function of the age of the organism at the time of irradiation and the LET of the specific particle.

Title: The effects of cognitive enrichment and exercise on age-related cognitive decline in rats

Authors: *M. E. BASHAM;
Neurosci. Program, Regis Univ., Denver, CO

Abstract: A decline in cognitive abilities is an inevitable part of aging. However, cognitive activity during one's lifetime can create a cognitive reserve that partially mitigates this cognitive decline. Thus, cognitive enrichment programs aimed at older adults have been developed in an attempt to delay, or even reverse, normal, age-related cognitive decline. Overwhelmingly, the animal research into mitigating age-related cognitive decline using cognitive interventions involves cognitive enrichment beginning early in life and often persisting into adulthood. These animal models are analogous to the human experience of education beginning early in life. Very few animal models present cognitive enrichment later in life, analogous to the brain training programs currently offered to older adults. Moreover, many of the animal models confound cognitive enrichment and exercise, making it difficult to attribute cognitive gains to cognitive activity rather than physical activity. Therefore, the present study administered either cognitive enrichment or exercise to already aged rats and then compared their cognitive performance to aged controls. In a water maze task, exercised aged rats swam faster and shorter distances to a hidden platform than control rats, but rats exposed to cognitive enrichment late in life did not perform better than controls. Surprisingly, exercised aged rats spent less time searching in the appropriate quadrant during probe trials than either control rats or rats exposed to cognitive enrichment late in life. These findings suggest that cognitive enrichment presented exclusively later in life will not mitigate normal age-related cognitive decline.

Title: The effects of a combination dietary intervention of caloric restriction and curcumin on normally aged C57BL/6 mice

Authors: *M. SARKER[1], S. FRANKS[2], N. SUMIEN[2], M. J. FORSTER[2];
[1]UNT Hlth. Sci. Ctr., Fort Worth, TX; [2]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Our main hypothesis was that a combination treatment of dietary curcumin and CR will improve age associated neurobehavioral dysfunction better than either treatment alone via anti-inflammatory and antioxidant mechanisms. To determine whether or not combining these two interventions would result in additive or synergistic benefits, dietary curcumin and caloric restriction were tested for functional end points, either alone or in combination, in late middle age (MAG) (15 months) and early senescent (AG) (20 months) C57BL/6J male and female mice. Mice were assigned in groups to receive: (i) base diet ad libitum (AL), (ii) weight stable caloric restriction (CR), (iii) curcumin in the base diet (7200 mg/kg diet) (CURAL) or (iv) curcumin plus CR (CURCR). After 8 weeks of treatment, mice underwent a behavioral battery that tested for cognitive and psychomotor function. The final blood draw for assessment of inflammation and oxidative stress was at 16 weeks of dietary treatment. Curcumin overall improved visual acuity for both MAG males and females as well as AG males compared to their age matched control. There was no effect of dietary treatment on bridge walking for females, which is indicative of cerebellum functioning, compared to their age-matched control. CURCR and CR MAG and AG males however outperformed their age matched control on the bridge walking test. All three dietary interventions had significant effects on pro and anti-inflammatory cytokines, KC-GRO concentration was significantly decreased in CR and CURCR in the middle aged males and females group and was correlated to body weight; TNF-α concentration was significantly decreased in both CURAL and CURCR in middle aged males and there was a significant decrease in C-reactive protein in aged females under CURCR. MAG CURAL and AG CR males had lower levels of oxidative stress compared to baseline measures. Based on results from the motor tests and blood based biomarkers and earlier data on cognitive and other psychomotor function, dietary curcumin can be used as a CR mimetic for certain components of healthy functional aging but the benefits may not entirely be related to its anti-inflammatory and anti-oxidant effects. Future studies should include different doses and a tapered down caloric restriction regimen.

Title: Sex differences in cognition, emotional reactivity, and motor ability in gonadally-intact middle-aged marmosets (Callithrix jacchus)

Authors: *N. GERVAIS[1], K. P. WORKMAN[1], M. LACLAIR[2], A. LACREUSE[1];
[1]Psychological and Brain Sci., [2]Neurosci. and Behavior, Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Sex differences in cognition are well documented. Women outperform men on measures of perceptual speed and verbal abilities, while men outperform women on tests of spatial processing. Robust sex differences also exist in stress responses. However, it is unclear how these sex differences change over time and whether males and females follow different trajectories of age-related cognitive decline. Studies in nonhuman primate models can help resolve this issue. The common marmoset (*Callithrix jacchus*) is a New World primate with a short lifespan that can perform complex cognitive tasks in computerized settings that are comparable to those used with humans. The present study is part of a longitudinal project aimed at determining whether males and females follow different trajectories of cognitive aging. This report focuses on sex differences at study entry. Thirteen marmosets (7 females), aged 4-6 years were tested on a comprehensive battery of tasks assessing cognitive function, motor skills and emotional reactivity. For cognition, monkeys were initially trained on a simple visual discrimination problem, followed by reversal learning using the Cambridge Neuropsychological Test Automated Battery (CANTAB). They also performed the Hill-and-Valley task as a measure of fine motor skills. To assess emotional reactivity, each marmoset was separated from their colony for 7 hours. Behavioral assessments, which involved recording the occurrence of approximately 25 behaviors, occurred a total of 6 times: immediately before separation, 3 times during separation, immediately after separation, and 24-hr later. No sex difference was found for simple discrimination, but males tended to perform better than females on the reversal learning task. No sex difference was observed in motor skills. During separation from the colony, females were more reactive than males, as indicated by more agitated locomotion, and vocalizations. Together, these findings expand upon previous studies and demonstrate sex differences in reversal learning and emotional reactivity in gonadally-intact middle-aged marmosets. As the study progresses, we should be able to determine the neural correlates of these sex differences and how they may change with aging.

Title: Novel object recognition in aging mice - a critical evaluation of analytical methods in the comparison of C57BL/6 WT and NLRP3 knockout mice.

Authors: *A. TRASCHUETZ, S. SCHWARTZ, M. T. HENEKA;
AG Klinische Neurowissenschaften, Universitätsklinikum Bonn, Bonn, Germany

Abstract: Beside the assessment of spatial learning in various mazes, novel object recognition tasks have become the most widely applied behavioral tests of learning in both rats and mice. With ample evidence that they probe hippocampus-dependent memory formation, these tests have become gold standards in experiments investigating mechanisms or interventions in rodent models of neurodegeneration. For example, novel object tasks have been used to show that the development of Alzheimer's disease-like pathology and cognitive impairment in APP/PS1 mice depends on the NLPR3 inflammasome (Heneka et al, Nature, 2013).
Here, we investigated the value of a novel object recognition task with a 24h intersession interval in probing the impairment of hippocampal memory functions in aging C57BL/6 Wildtype and NLRP3ko mice. Suprisingly, we discovered that even when established protocols are applied, the results of a novel object task can be manipulated by an arbitrary selection of analytical parameters. Young mice (3 months) maintain their novel object preference during the whole 10-minute-probe session. Older mice (9 and 12 months), however, demonstrate a significant preference for the novel object only within the first 1-2 minutes of the test session. This indicates that the behavioral phenotype of older mice not only depends on memory function, but also on altered novel object preference per se. Despite the use of a cutoff for the total exploration time to account for differences in exploratory activity (Leger et al., Nature Protocols, 2013), memory performance of older mice appears to be severely impaired for total exploration times longer than 5 seconds.
Developping an unbiased analytical approach, we show that object recognition memory in aging mice is only mildly impaired in aging. However, we demonstrate that this impairment nevertheless occurs at the age of just 9 months and is mediated by NLRP3-dependent inflammation. Caution should be applied when using or interpreting results of novel object recognition tasks in aging mice.

Title: Delivery of osteocalcin in the dentate gyrus enhances cognitive functions and ameliorates age relate memory loss

Authors: *S. KOSMIDIS[1], A. POLYZOS[3], L. KHRIMIAN[2], G. KARSENTY[1], E. KANDEL[1]; [1]Neurosci., [2]Genet. and Develop., Columbia Med. Ctr., New York, NY; [3]Mol. Biol. Div., Biomed. Res. Fndn. of the Acad. of Athens (BRFAA), Athens, Greece

Abstract: The interplay between brain and body metabolism is now beginning to be studied at the molecular level. Recent findings pinpoint osteocalcin (Ocn) as a hormone produced by bone that affects cognitive functions. However, the precise molecular and functional consequences of osteocalcin in the brain, are largely unknown. Here we perform local injection of recombinant osteocalcin in the hippocampal areas that accumulate Ocn and assess its cognitive effects. We identify an osteocalcin-dependent molecular pathway associated with memory, and pinpoint its mechanism of action through the RbAp48 protein. Rbap48 deficiency has been previously described as a key component of Age Related memory loss. We present evidence that OCN acts to ameliorate cognitive symptoms of normal aging and to restore age related memory loss by increasing the RbAp48 /CREB protein levels in the dentate gyrus.

Title: A multiple microinfarction based model for vascular dementia in aged rats

Authors: *P. VENKAT, M. CHOPP, J. CHEN;
Neurol. Res., Henry Ford Hosp., Detroit, MI

Abstract: Background and purpose: Vascular Dementia (VaD) affects cognition and memory. VaD accounts for nearly 20% of all dementia patients and is prevalent among the older population. In this study, we investigated a multiple microinfarction (MMI) model in aged male Wistar rats (16-18months), and assessed the consequent cognitive decline and white matter (WM) damage. **Materials and methods:** Male aged Wistar rats (16-18 months) were subjected to MMI (500, 70-100μm cholesterol crystals injected into the internal carotid artery, n=6/group) and cognitive deficits were evaluated 4 weeks later. Rats were sacrificed 4 weeks after MMI for immunohistochemical analysis. **Results:** The MMI model in aged rats induces vascular dementia with significant ($p<0.05$) short term memory loss (novel object recognition test), long term memory loss (odor test), anxiety-like behavior (open field evaluation), and impaired spatial learning and memory (Morris water maze test) at 4 weeks after MMI compared to aged control rats. MMI induces significant sensorimotor deficits that persist until at least 4 weeks after MMI. Compared to aged control rats, MMI significantly ($p<0.05$) decreases axon and myelin density, oligodendrocyte progenitor cells and oligodendrocytes numbers, and decreases synaptic protein expression in the WM tracts of the corpus callosum and striatal WM bundles. Golgi staining indicates that in comparison to aged control rats, aged-MMI rats have significantly ($p<0.05$) decreased neurite branching and cortical and hippocampal spine density. MMI in aged rats significantly damages hippocampal neurons. MMI in aged rats significantly induces water channel dysfunction indicated by decreased Aquaporin-4 (AQP-4) expression around blood vessels in the striatum. This AQP-4 loss around vessel significantly ($p<0.05$) correlates with cognitive deficits. **Conclusions:** The MMI model in aged rats induces significant cognitive impairment and WM/axonal damage primarily in the WM tracts of the corpus callosum and

striatal WM bundles and neurons of the hippocampus. MMI significantly decreases axon and myelin density, promotes demyelination, impairs synaptic plasticity, and decreases neurite branching and dendritic spine density in the cortex and hippocampus. Water channel dysfunction may contribute to cognitive deficits and WM damage induced by the MMI model.

Title: Characterization of cognition in aging immunocompromised mice

Authors: S. REGE[1], T. HEIKKINEN[2], H. HACKBART[1], *E. CZIRR[1], I. GALLAGER[1], R. HODGSON[2], S. BRAITHWAITE[1], S. MINAMI[1];
[1]Alkahest, San Carlos, CA; [2]Charles River Labs., Kuopio, Finland

Abstract: Assessing cognitive behaviors and their modulation by therapeutics in mouse models is important in the development of treatments for a range of neurodegenerative disorders and other indications associated with cognitive decline. Potential off-target effects generated by experimental therapies could confound behavioral outcomes, which highlights the importance of identifying the appropriate animal model. An example is the testing of human-derived reagents and proteins that could make for attractive therapeutic candidates, but their use in a heterologous species would generate deleterious immune responses. To circumvent this problem immunocompromised mice can be used, however the characterization of their cognitive function as it relates to aging has not been well explored. We studied the effect of aging on two strains of immunocompromised animals, NOD.CB17-*Prkdc*^{scid}/NcrCrl (NOD scid) and NOD.Cg-*Prkdc*^{scid}*Il2rg*^{tm1Wjl}/SzJ (NSG) mice. Animals were compared at 3 months and 12 months of age in assays including open field, Y-maze and contextual fear conditioning. To address variability in performance in behavioral assays between different laboratories, we have conducted studies at two independent sites with independent researchers. Immunocompromised animals show age-related reductions in motor function and cognitive decline within 1 year of age, indicating accelerated aging compared to wild-type animals. These results confirm that immunocompromised animals can be used as a platform to test changes in age-related cognitive processes and other functions, and their modulation by a range of therapeutic agents.

Title: Drug targeting of rev-erb improves cognition in alzheimer's disease mouse model

Authors: ***D. ROBY**[1], F. RUIZ[1], B. KERMATH[1], J. E. MORLEY[2], T. BURRIS[1], S. A. FARR[1]; [1]Pharmacol. and Physiological Sci., [2]Intrnl. Medicine/Geriatrics/Endocrinology, St. Louis Univ., Saint Louis, MO

Abstract: Alzheimer's disease (AD) has a plethora of possible risk factors, but the most certain risk factor is aging. Hallmarks of AD are aggregates of hyper-phosphorylated tau and amyloid-β (Aβ), and impediments in learning and memory are among the most common initial symptoms of the disease. The onset of perturbed sleep patterns suggests that circadian rhythm in AD patients is disrupted, indicating that the central clock is involved in the onset of AD. The central clock is

regulated mainly by nuclear receptors (NR). A key NR, REV-ERB, inhibits and regulates transcription of clock genes and genes involved in long-term potentiation (LTP). REV-ERB's expression is fairly ubiquitous in the brain. Recent studies have shown the correlation between REV-ERB-associated behavior and proteins involved in AD's onset. Aβ accumulation is associated with the disruption of the sleep/wake cycle and impairs the rhythmic fluctuation of Aβ interstitial fluid levels in a transgenic mouse model. Furthermore, Aβ disrupts both the circadian sleep/wake cycle and hippocampal learning formation, suggesting that alterations in REV-ERB expression may be part of Aβ's pathology. Here, we examined the effects of the REV-ERB agonist SR9009 on learning and memory in the SAMP8 mouse model of AD. We studied the effects of SR9009, a specific REV-ERB agonist, in a SAMP8 mouse model. This is an accelerated aging model that exhibits consistent age-related increase in Aβ, hyper-phosphorylated tau, oxidative stress, impaired efflux of Aβ from the brain as well as learning and memory deficits beginning around 8 months and fully developed at 12 months. We treated male SAMP8 mice with SR9009 (100 mg/kg body weight i.p.) beginning at 11 months of age. After 4 weeks of treatment, they exhibited improved learning and memory behavior phenotypes compared to aged SAMP8 mice treated with vehicle. Aged SAMP8 mice treated with SR9009 had learning and memory comparable to that of young SAMP8 mice (4 months) treated with vehicle in novel object recognition and T-maze retention. SR9009 was given post-onset of cognitive deficits, showing that increased REV-ERB activity is able to rescue the cognitive deficits associated with Aβ and tau. This study presents REV-ERB as a potential target in the treatment of AD.

Title: Molecular correlates of altered neural communication in ofc layer 2-3 during human aging

Authors: *M. PABBA[1], E. SCIFO[1], F. KAPADIA[1], Y. NIKOLOVA[1], C. MA[2], N. MECHAWAR[3], G. C. TSENG[2], E. SIBILLE[1];

[1]Psychiatry, Pharmacol. and Toxicology, Univ. of Toronto, Campbell Family Mental Hlth. Res. Inst., Toronto, ON, Canada; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]McGill Univ., Montréal, QC, Canada

Abstract: *Background*: Multidisciplinary studies have demonstrated a decline in orbitofrontal cortex (OFC) cognitive functions, grey matter volume, loss of spines/synapses at layer 3 as well as gene expression changes related to neural communication during the course of normal aging. Recently, the gene expression changes that occur during the course of normal aging have been classified into nine hallmarks of aging based on peripheral tissue. However, the extent to which these hallmarks apply to brain tissue comprised largely of non-dividing cells has not been evaluated. Gene array and functional imaging studies have provided large-scale information on brain aging; however, to date no unbiased high-throughput proteomic studies have been performed on the OFC during human aging. Cortical layers 2/3 have a prominent role in processing feedforward and feedback information within local circuitry and with other regions of the brain. Accordingly, we performed proteomic profiling of the OFC layer 2/3 during human aging. *Prediction*: Proteomic analysis of OFC layer 2/3 during human aging will reveal changes in biological hallmarks of aging, specifically affecting levels of glutamate/GABA/glia-signaling components (i.e., altered neural communication). *Methods and Results*: MS-based proteomics was performed on laser-captured layer 2/3 of postmortem OFC from 15 young and 18 old male subjects. Label free quantification and random-intercept modeling revealed 131 differently expressed proteins (p value ≤ 0.05 and a minimum of 20% effect size), including 66 up- (e.g., GFAP, AQP4) and 65 (e.g., GRM2, 3, CALB1) down-regulated proteins, respectively. Most age-associated proteins were related to altered neural communication. Functional and network analyses on differentially expressed proteins showed enrichment for glutamate-related signaling and processes, for example, learning and memory among many other hallmarks of aging such as deregulated nutrient sensing and loss of proteostasis. Interestingly, age-altered layer 2/3 proteins showed association with many neurological and psychological disorders. *Summary*: Our study identified qualitative and quantitative proteomic changes in the OFC layer 2/3 during the course of aging. Results from this study also confirmed previously identified age-associated molecular changes (hallmarks of aging) from transcriptomic, morphological and imaging studies on the OFC. Changes in neural communication at layer 2/3 may contribute to age-associated decline in OFC related cognitive functions. Overlap between age-altered and disease associated proteins suggests that aging may contribute to acceleration of disease progression.

Title: Oral administration of a brain penetrating ghrelin receptor agonist (hm01) inhibits age-dependent memory loss in mice.

Authors: *R. G. SMITH[1], S. P. MAHAL[2];
[1]Metabolism & Aging, Scripps Florida, Jupiter, FL; [2]Metabolism and Aging, Scripps Res. Inst., Jupiter, FL

Abstract: Declining levels of the growth hormone secretagogue/ghrelin receptor (GHSR1a) are associated with age-dependent functional deficits. The lowest levels were found in brains from sporadic Alzheimer's disease patients. Previously we reported that administration of an orally active agonist of GHS-R1a to elderly subjects restored the young adult phenotype.[1] Furthermore, we recently showed in mice that GHSR1a and dopamine receptor-1 (D1R) form heterodimers in hippocampal neurons that are essential for initiation of synaptic plasticity and hippocampal memory.[2] We now report that oral gavage of the GHS-R1a agonist, HMO1, prevents age-dependent memory loss in 10-18 month old mice. HMO1-treated mice show significant improvements in both spatial and contextual memory. In the water maze test remote memory improved significantly (p=0.008) 1 week after acquisition. In fear conditioning, improvements in memory (p=0.011) were detectable (mice at age 18 months), up to 3 months after the initial foot shock.
In summary, our studies show that while aging reduces the concentration of ghrelin receptors in the brain, oral administration of the brain penetrating ghrelin receptor agonist, HM01, augments GHSR1a:DRD1 heteromer signaling and prevents/restores age-related memory loss in mice, most likely via DRD1 mediated hippocampal memory. 1. Title: Aged animals appear cognitively and behaviorally hyporesponsive to chronic restraint (psychosocial stress) compared to young animals

Authors: *K. STAGGS, J. POPOVIC, S. QUTUBUDDIN, E. M. BLALOCK;
Pharmacol., Univ. of Kentucky, Lexington, KY

Abstract: It is established that aging has detrimental consequences including a change in sleep architecture, a blunted circadian rhythm, and a decrease in cognition. Psychosocial stress (PS) is a non-painful stimulus associated in humans with major life changes including job loss, death of a spouse, and social isolation. It strongly influences multiple systems (e.g., corticosterone level, body temperature regulation, sleep and cognition). In prior work, we showed that acute PS resulted in typical cognitive deficit and hyperthermia responses in young animals, but that aged animals were hyporesponsive to this acute PS challenge. However, PS in humans is normally chronic, not acute, and the likelihood of experiencing PS increases with age. Nevertheless, little work has investigated the response of chronic PS in aged subjects. We hypothesized that aged animals will continue to be hyporesponsive to chronic PS. To test this, young (3mos) and aged (19mos) male Fischer344 rats were assigned to control or PS groups and implanted with wireless telemetry from Data Sciences International to monitor sleep and body temperature. Chronic PS (restraint, 3 h/day, 4 days/week, 4 weeks) effects on distress response, Morris water maze (MWM), body temperature, and corticosterone levels were collected. Chronic PS did not affect spatial MWM training, deep sleep duration, body temperature, or corticosterone levels at any age. PS resulted in decreased active period wake in aged animals. Conversely, aged animals were hyporesponsive to PS effects on the distress response and MWM probe trial. Taken together, the aged animals appear cognitively and behaviorally hyporesponsive to chronic PS.

Sci., Federal Univ. of Ouro Preto, Ouro Preto, Brazil; [4]AgroParisTech, Paris, France; [5]Biol., Halmos Col. of Natural Sci. and Oceanography, Nova Southeastern Univ., Fort Lauderdale, FL; [6]Dept. of Pharmaceut. Sciences, Col. of Pharm., Nova Southeastern Univ., Davie, FL

Abstract: Previous studies have shown that ovariectomy (OVX) impairs cognitive function in Sprague Dawley rats using the 12-arm radial arm maze. **AIM**: In this study, we investigated if OVX impairs cognitive function in a hypertensive vs. normotensive animal model. **METHODS**: Dahl salt-sensitive (DS) and salt-resistant (DR) female rats underwent OVX or sham-operation (Sham) at 6 weeks of age. Six months later, the animals were evaluated with the Novel Object Recognition Test (NORT). **RESULTS**: Between 8 & 9 months of age, three DS-OVX rats died, presumably due to stroke as a result of the hypertension, as previously we found that OVX accelerated the age-associated increase in arterial pressure in these rats. When we compared the NORT results in the animals that later died with the animals that survived, we found the time spent with the novel object was significantly less [(time spent with novel object / total time spent with novel object and familiar object): DS-OVX-survived, 0.82 ± 0.06 (n=5) vs. DS-OVX-died, 0.60 ± 0.1 (n=3); p = 0.04]. DS-Ovx-survived scores were significantly higher than what would have been expected by chance (p=0.008), but the DS-Ovx-died scores were not, indicating that the DS-Ovx-survived rats recognized the novel object as new, but the DS-Ovx-died rats may not have. Furthermore, the hypertensive DS rats tended to do poorer on the NORT compared to the normotensive DR rats [(time spent with novel object / total time spent with novel object and familiar object): DS, 0.77 ± 0.04 (n=16) vs. DR, 0.85 ± 0.03 (n=15); p = 0.056]. In contrast, no DR rats died and there was no difference detected in the proportion of time spent with the novel object between the DR-OVX and DR-Sham. **CONCLUSION**: This study is consistent with the hypothesis that the hypertension exacerbated by OVX impairs cognitive function in the DS rat.

Title: The effect of a lifespan-extending drug, acarbose, on cognitive healthspan in a mouse model of Alzheimer's disease

Authors: ***S. J. MOORE**[1], R. C. PARENT[1], R. A. MILLER[2], G. G. MURPHY[3];
[1]Mol. & Behavioral Neurosci Inst., [2]Dept. of Pathology and Geriatrics Ctr., [3]Mol. & Behavioral Neurosci Inst. and Dept. of Mol. and Integrative Physiol., Univ. of Michigan, Ann Arbor, MI

Abstract: As the aged population continues to grow, there is increased interest in discovering and exploiting interventions that can prolong lifespan. The National Institute on Aging's Interventions Testing Program has shown that acarbose, a drug which is already used in the treatment of diabetes because it blunts the post-meal spike in blood sugar, significantly extends lifespan in a genetically heterogeneous mouse line, UM-HET3. However, the question of whether acarbose can also preserve or extend cognitive function in mice as they age has not been explored. In addition, advancing age remains the largest risk factor for developing neurodegenerative diseases like Alzheimer's disease (AD); thus, acarbose treatment may also be effective in preserving or rescuing cognitive function in mouse models of neurodegenerative disease.
To address these questions, we are treating mice with acarbose (delivered ad libitum in their chow) starting at 4 months of age and evaluating the cognitive function of separate cohorts of mice at several different time points throughout the lifespan. Our preliminary data show that in wild-type UM-HET3 mice, even as early as 9 months of age, acarbose improves cognitive function, as assayed by the Morris water maze, compared to mice maintained on control chow. Additionally, in a mouse model of AD (the 5xFAD model, which has five familial AD mutations, including 3 separate mutations in the amyloid precursor protein, APP, and 2 distinct mutations in presenilin-1, PS-1) that has been bred on the UM-HET3 genetic background, acarbose treatment was sufficient to rescue cognitive deficits observed in the Morris water maze at 9 months of age.

Because acarbose is already used in a clinical capacity in humans and is known to be safe and well-tolerated, it has the potential for rapid translation into clinical studies. Together with our results, this suggests that acarbose treatment may be useful in a therapeutic setting to extend lifespan and to improve cognitive outcomes in both healthy aged populations as well as in those impacted by neurodegenerative diseases.

Title: The role of HDAC3 in age-related plasticity and memory dysfunction

Authors: *J. L. KWAPIS, Y. ALAGHBAND, E. A. KRAMÁR, A. J. LÓPEZ, A. O. WHITE, D. RHEE, C. M. MICHAEL, G. SHU, D. P. MATHEOS, M. A. WOOD;

Abstract: Aging is accompanied by cognitive impairments, including difficulty forming long-term memories. Long-term memory formation requires gene expression, a process that may be disrupted with age (Rowe et al., 2007; Berchtold et al., 2008). Epigenetic alterations (changes in gene expression that occur through alterations in chromatin structure) may therefore contribute to age-related impairments in gene expression and long-term memory. One major epigenetic mechanism important for memory is histone acetylation, in which acetyl groups are added or removed from histone tails by acetyltransferases (HATs) or histone deacetylases (HDACs), respectively. Increasing histone acetylation by blocking HDAC activity generally enhances both gene expression and long-term memory. In particular, histone deacetylase 3 (HDAC3) appears to

be a key negative regulator of long-term memory formation, as blocking HDAC3 produces persistent object location memory following subthreshold training. Here, we tested whether HDAC3 activity also contributes to age-related impairments in synaptic plasticity and long-term memory. We hypothesized that dysregulated HDAC3 activity in the aging brain contributes to an unusually repressive chromatin structure that limits synaptic plasticity and memory formation. To test this, we disrupted HDAC3 in the dorsal hippocampus of 18-month-old mice with two different manipulations: focal genetic deletion with HDAC3$^{flox/flox}$ mice and activity-specific blockade with a dominant negative point mutant virus (AAV-HDAC3(Y298H)-V5). We found that HDAC3 disruption ameliorated age-related impairments in both long-term memory and synaptic plasticity. To determine the mechanism through which HDAC3 deletion ameliorates memory impairments, we measured gene expression in the dorsal hippocampus of young and aging mice. We found that phosphorylation of HDAC3 was aberrantly increased in the aged brain after learning, even though total HDAC3 levels were similar in young and old brains. We also identified Nr4a1 and Nr4a2 as key downstream mechanisms through which HDAC3 dysfunction may contribute to age-related memory impairments. Together, these results support the hypothesis that HDAC3 is dysregulated with age, leading to age-related impairments in gene expression, long-term memory formation, and synaptic plasticity.

Title: Prefrontal cortex interneuron vulnerability in behaviorally characterized aged monkeys

Authors: K. H. SCHULZE[1], A. M. SPIEGEL[1], *J. M. LONG[1], E. J. PEREZ[1], M. T. ROBERTS[2], P. R. RAPP[1];
[1]Natl. Inst. On Aging-NIH, Baltimore, MD; [2]California Natl. Primate Res. Ctr., Davis, CA

Abstract: Aging is associated with a decline in working memory, a cognitive capacity dependent on area 46 of the dorsolateral prefrontal cortex (PFC) in both humans and animal models. These deficits occur in the absence of dramatic PFC neuron loss, suggesting more subtle changes in circuitry integrity underlie the impairment. The GABAergic network, including parvalbumin immunoreactive (PV-IR) interneurons maintains appropriate network dynamics by regulating activity among excitatory neurons and has been demonstrated to be vulnerable to the negative effects of aging in rodents. The effect of age on PV-IR cell number in the primate PFC, however, is unknown.

Here, PFC PV-IR interneuron number was assessed in 7 young adult (8-13 yrs.) and 15 aged (27-38 yrs.) rhesus monkeys (*Macaca mulatta*) of both sexes. Animals were previously tested on a delayed response test of spatial working memory known to be sensitive to aging and PFC damage. Aged subjects performed poorly relative to a large population of young animals, and comparable to aged monkeys in many previous experiments. For post-mortem histological analysis, animals were perfused with cold fixatives, and the brains were frozen and sectioned in the coronal plane at 40 microns in an evenly spaced 1 in 10 series. For each brain, a single series spanning the rostro-caudal length of area 46 was processed for the immunocytochemical visualization of PV (Sigma, cat#P3088), using diaminobenzidine as the chromagen. Design-based stereological techniques were employed to estimate the total number of PV-IR neurons in both the dorsal and ventral banks of area 46.

The estimated number of PV-IR interneurons in the ventral bank of area 46 was comparable in young and aged monkeys, averaging a total of 639,398 and 559,774, respectively. In contrast, aged monkeys displayed roughly 40% more PV-IR neurons in the dorsal bank relative to young adults (totals = 853,755 vs. 608,609, p=0.05). These results add to a growing body of evidence on interneuron vulnerability in aging, suggesting that disrupted inhibitory circuitry in the PFC is a prominent feature of neurocognitive aging across species.

Title: Quantifying changes in medial prefrontal cortex immediate early gene expression as a function of aging related cognitive decline

Authors: *V. L. EHLERS, M. SEHGAL, B. K. FULLEYLOVE-KRAUSE, J. R. MOYER, Jr; Psychology, Univ. of Wisconsin Milwaukee Dept. of Psychology, Milwaukee, WI

Abstract: The world's population of individuals aged 85 and over is projected to increase by 350% by the year 2050. It is important for research on aging to assess changes in brain function throughout the aging process in order to combat aging-related cognitive decline and to improve the quality of living for the elderly. One way to understand how aging alters the neuronal circuitry that underlies aging-related cognitive decline is to study extinction of fear conditioning. Previous data from our lab suggest that aged rats exhibit impaired fear extinction. Thus the current experiments were designed to assess how immediate early gene (IEG) expression of Zif-268 and c-fos was altered in brain regions implicated in associative learning in order to better understand how overt behavioral deficits might be linked to aging-related changes in the brain. Young, middle-aged, and aged rats were separated into four experimental groups: naïve, pseudo-conditioned (PSEUDO), trace fear conditioned (TRACE), and fear extinction (EXT). On day 1, TRACE and EXT rats underwent trace fear conditioning (10 trials of 15 s tone, 30 s trace interval, 1 s footshock), while PSEUDO rats underwent pseudo conditioning (10 tones and 10 shocks that were explicitly unpaired). On days 2 and 3, EXT and PSEUDO rats were given 10 tone-alone presentations. On day 4, TRACE, EXT, and PSEUDO rats were presented with 2 tone presentations to assess trace fear memory. Brain slices were collected 1-hr after testing to assess IEG expression in various brain regions of interest (e.g., mPFC, hippocampus, amygdala, retrosplenial cortex). Our initial studies did not observe any statistically significant behavioral differences between age groups, however, analysis of mPFC indicated that in adult rats IEG expression was elevated within the prelimbic and infralimbic subregions within the PSEUDO, TRACE, and EXT groups ($p < .05$). Although learning occurred in the aged animals, this learning did not involve significant changes in IEG expression within mPFC, suggesting that aging may result in circuit-level changes in molecular signaling that supports acquisition and extinction of trace fear conditioning.

Title: The extreme memory challenge: A search for the heritable foundation of exceptional memory

Authors: ***M. A. PYC**[1], E. GIRON[2], P. CHEUNG[1], S. DE BELLE[1], T. TULLY[1];
[1]Cognitive Sci., Dart NeuroScience LLC, San Diego, CA; [2]Dart NeuroScience, San Diego, CA

Abstract: We are interested in discovering new candidate targets for drug therapies to enhance cognitive vitality in humans throughout life, and to remediate memory deficits associated with brain injury and brain-related diseases such as Alzheimer's and Parkinson's. To achieve our goal we need a comprehensive and objective understanding of the human genome contribution to variation in memory performance in healthy individuals. We are implementing a Genome-Wide Association Study (GWAS) to identify genetic loci varying among individuals who possess exceptional and normal memory abilities. These genes and those in associated networks will inform drug discovery and development. Our first step is to identify exceptional members of the population. Thus, we have created an online memory test - the Extreme Memory Challenge (EMC) - to conveniently screen through an unlimited number of subjects to find individuals with exceptional memory consolidation abilities. Identified subjects are (1) validated by a battery of secondary memory tasks, and (2) providing saliva samples from which we can isolate DNA for GWAS. Ten pilot experiments were conducted to parameterize the EMC screen. Participants learned face-name pairs for a delayed recall test. After initial study, each name was presented and participants were asked to select the correct face among four (distracters were other faces paired with different names). One day later participants completed a final test trial. We are primarily interested in forgetting across sessions, as this provides an estimate of consolidation across a 24-hour time interval. Pilot studies indicated the optimal protocol should include 30 face-name pairs, presented at a 4 second rate. To date, 14,010 participants from 173 nations have been screened in the EMC. Of these, 9,189 have completed both sessions. Individuals in our sample are most frequently Caucasians (56%), US citizens (40%), native English language speakers (45%), post-secondary school-educated (63%), reported being most alert in the morning (52%), with good vision (70%), and right handed (89%). The gender distribution was split evenly. Performance in the EMC decreased across sessions by 8% (from 60% to 52%). We identified 22 subjects scoring 3+ standard deviations from the forgetting mean, and 23 scoring perfectly during both sessions. For both of these exceptional groups, performance is being validated by our memory battery prior to the genomics portion of the project, now underway.

Title: Stressed management women increase memory task efficiency after a 8-week mindfulness-based positive emotions cultivating program

Authors: *D. F. SANTAELLA[1], J. B. BALARDIN[1], B. PORTES[1], P. TOBO[2], C. BARRICHELLO[2], S. S. LACERDA[1], J. R. SATO[3], E. AMARO JR.[1], E. H. KOZASA[1]; [1]Brain Inst., Hosp. Israelita Albert Einstein, Sao Paulo, Brazil; [2]Natura Inovação, São Paulo, Brazil; [3]Univ. Federal do ABC, São Paulo, Brazil

Abstract: Default mode network (DMN) is a connectivity system involved in different resting state functions, such as autobiographical information; self-referenced memories; referring to descriptions and emotions of one's self; moral reasoning; social evaluations; thinking about other one's thoughts; remembering the past, imagining the future and episodic memory, present during mind wandering processes. Conectivity studies have demonstrated that DMN and working memory may not have opposite functions and that DMN and WMN (working memory network) may both be active during a memory task. Corporative environments have a great stress load on managers, specially women (with double shifts, facing home duties) and are prone to burnout. Objective: To investigate the effects of a 8-week mindfulness-based program of cultivating positive emotions, ethics and healthy interpersonal attitudes (Florescer) on brain functional activation during a memory task (n-back) in stressed management women. Methods: sixty workers from Natura Cosmetics S.A. were invited; 59 were included, 24 finished the 8-week program. After giving written consent, participants were evaluated for: class presence, home practice, age, and were submitted both to a resting state and to a memory task (N-Back) inside a functional magnetic resonance 3T device. During the memory task, subjects were instructed whether to find a specific letter, or to remember if it had been presented one or two positions behind. Significance was set at $p<0.05$, with $Z>2.3$. Data was processed using FSL software. Results: Both groups were equal at study entry for correct responses and reaction time in the "find" task: Florescer vs. Control (correct responses 6.9±2.8 vs. 6.6±2.6 p=0.963 and reaction time 591±113 vs. 678±145 ms p=0.405). Florescer program did not change these parameters and groups remained equal at 8 weeks: (7.7±1.3 vs. 7.1±2.1 p=0.350 and 580±97 vs. 598±93 ms p=0.783). Regarding functional activations, groups demonstrated different activation patterns when submitted to the memory task after training: Florescer increased and Control decreased activation on DMN structures such as: posterior cingulate gyrus, precuneus, hippocampus, frontal medial cortex, posterior cingulate gyrus, frontal pole, anterior cingulate gyrus, lingual gyrus; besides those, corpus callosum also showed greater activation pattern. Conclusion:

Florescer program increased DMN engagement during a memory task in corporative environment distressed women, possibly indicating that this program allowed participants to perform the task in a more relaxed inner attitude; a smaller attentional engagement and with increased efficiency.

Title: Is transcranial alternating current stimulation an effective tool for cognitive research?

Authors: *V. BRAUN, S. HANSLMAYR;
Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Transcranial alternating current stimulation (tACS) is widely used to entrain or modulate brain oscillations and shed light onto the relationship between oscillatory activity and cognitive processes. tACS could be an effective tool for cognitive research if it was able to modulate brain oscillations in a time critical manner. During cognitive tasks, brain oscillations show a highly dynamic behaviour. For instance beta oscillations decrease in power within a couple of milliseconds during memory processing followed by a subsequent increase in amplitude. If tACS should be useful for asking causal questions about these dynamics it must influence brain oscillatory behaviour in a similar time range. In a series of experiments we addressed the question whether event-related, transient tACS in the beta frequency range can be used to modulate 2 different processes: episodic memory formation and motor cortex excitability. Experiments 1 and 2 aimed at replicating and extending findings from a recently published TMS study. By using rTMS it has been shown that entrainment of left prefrontal beta oscillations leads to impaired memory encoding of verbal material. In order to replicate and extend these findings, 72 healthy human participants engaged in an incidental encoding task of verbal and non-verbal material while receiving tACS to the left and right inferior frontal gyrus (IFG) at 6.8Hz, 10.7Hz, 18.5Hz, 30Hz, 48Hz and sham stimulation for 2s during stimulus presentation. Experiment 3 addressed the question whether 10s of beta tACS is sufficient to

entrain brain oscillations in the primary motor cortex (M1). By administering tACS to M1 at the individual motor beta frequency of 8 subjects, we investigated the relationship between the size of TMS induced MEPs and tACS phase. The present results indicate that applying tACS over a short period of time (2s; 10s) did not entrain brain oscillations and did not affect behaviour. In experiments 1 and 2, findings from a TMS study could not be replicated. Beta tACS did not affect memory performance. Likewise, no entrainment effects could be found in experiment 3. MEP size was not modulated by the tACS phase, indicating that our stimulation protocol did not entrain beta oscillations in M1. Taken together these findings suggest that using tACS in an event-related manner and applying the stimulation for short periods of time is not effective in modulating brain oscillatory activity. These failures of event-related tACS to modulate cognition or cortical excitability cast doubt on whether tACS could be an alternative to rTMS in unravelling the causal relationship between brain oscillatory activity and cognitive processes.

Title: Environmental encoding and brain structure

Authors: *H. R. EVENSMOEN, L. RIMOL, T. HANSEN, A. HÅBERG;
NTNU, Trondheim, Norway

Abstract: The relationship between encoding of the different associations that our environmental representations consist of and cortical area and thickness, and the size of different structures in the brain, is to a large extent unknown. In this study, the participants had to learn either 20 or 35 small virtual environments. The environments consisted of five objects that formed a unique positional pattern within the environments. Each environment was enclosed by one of 10 differently shaped outer walls. The participants had to complete several runs. Each run involved five environments. After each run, the participants' ability to associate the objects together, associate the objects with the outer wall, recreate the objects positional pattern, place the objects positional pattern relative to the outer wall, place the objects in their position within the positional pattern, were tested for each environment. The association between the different environmental measures and cortical thickness and area, and subcortical volumes, were investigated in Freesurfer. The relationship between the environmental measures and the size of

the different subregions along the anterior-posterior axis of the hippocampus were also investigated, using a high resolution T2 image and ASHS.

Title: Comparison of the ERP correlates of encoding item-item and item-context associations

Authors: ***J. X. WONG**, J. D. KOEN, L. J. LEWIS, M. D. RUGG;
Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX

Abstract: A key feature in forming episodic memories is the establishment of associations between different components that comprise the memory episode. In order to investigate the neural correlates underlying memory formation, we can contrast neural activity during study for items that are remembered or forgotten on a subsequent memory test, with the assumption that the processes indexed by this contrast contribute to whether an item subsequently receives an accurate memory judgment. In a previous fMRI study, we had participants perform an incidental encoding task where they studied both item-item ('associative') and item-context ('source') information in each trial. We found that successful encoding of associative information was accompanied by 'subsequent memory effects' in cortical brain regions distinct from those for successful source encoding. Here, we employed EEG/ERP to the study/test procedure used in our fMRI study in order to characterize the temporal correlates of encoding the same two types of memory associations. We recorded EEG during the incidental encoding task, where participants studied both associative (picture-word pair) and source information (left/right picture location). At test (not recorded), participants saw both studied and new pictures, and the requirement was always to judge whether a picture was old/new, and then to judge either its studied location (left/right), or its studied associate (out of two previously studied words). We formed ERPs separately for study trials later tested for location (source) and associative memory, and further segregated these according to the accuracy of the respective memory judgments. We found a polarity reversal in the subsequent memory ERPs, in which more positive-going ERPs were found for successful associative encoding, whereas more negative-going ERPs were found for successful encoding of source information. This polarity reversal suggests that successful

associative and source memory encoding are supported by qualitatively distinct encoding operations. These findings correspond with prior ERP studies that found greater positivity for encoding semantic information, and greater negativity for encoding non-semantic information. We also found a temporal dissociation, in which the more negative-going source subsequent memory effects emerged at picture onset, and were sustained until word presentation, whereas the more positive-going associative subsequent memory effects emerged only after word onset. The current data are consistent with our prior fMRI findings that distinct encoding processes contribute to the subsequent memorability of different types of associations.

Title: Consolidation modulates learning following prediction errors

Authors: ***O. BEIN**, L. DAVACHI;
Psychology, New York Univ., New York, NY

Abstract: Prediction errors (PEs) are thought to play a critical role in learning. Recent work has focused on the role of the hippocampus in the detection of memory-based PEs. However, our understanding of how new learning and previous memories are affected by prediction violation is scarce. Furthermore, it is unclear how memory PEs might differ and invoke different kinds of learning for old compared to newly acquired prior memories. Prominent theoretical frameworks propose that PEs should lead to the initial creation of a separated memory trace in the hippocampus (Love, Medin and Gureckis, 2004; McClelland, McNaughton and O'Reilly, 1995) that is later integrated into our knowledge stores. However, this may differ for old and new memories. More consolidated memories may be represented in cortex and thus this may reduce interference within newly learning hippocampal associations. Thus to examine learning following PEs, we presented participants with a stream of objects. Unbeknownst to the participants, the stream was composed of repeating sequences of objects (A-B-C), as well as single objects (D) interspersed between the triads. After initial learning, we induced PEs by presenting the stream of objects again, but replacing the last object in each sequential triad (C-items) with another equally familiar objects (D-items). Critically, for half of the triads, the initial learning occurred immediately before the PE induction, while for the other half, learning occurred the previous day, thus allowing for some consolidation of learned sequences. Memory

integration was assessed by an associative priming test. Our initial results show evidence for integration of old C items with new PE D items, however this was only seen for the more consolidated triads. Specifically, we see that D-items primed the C-items of the initially learned triads, only when prior knowledge was consolidated, but not when it was recent. The results suggest that consolidation may promote new learning by facilitating the integration of novel associations into knowledge. Preliminary imaging analysis will focus on the role of the medial temporal lobe in mediating learning following prediction errors.

Title: An Investigation of tDCS-induced modulations of episodic memory encoding

Authors: *G. GALLI, V. NEACSU, F. J. NEWTON;
Dept. of Psychology, Kingston Univ., Kingston Upon Thames, United Kingdom

Abstract: A typical observation in memory research is that items learned using semantic or "deep" operations, such as attending to the meaning of the item, are better remembered than items encoded using "shallow" operations, such as attending to its structural features. Neuroimaging and brain stimulation studies have consistently demonstrated that effective deep encoding is associated with the engagement of the left ventrolateral prefrontal cortex (VLPFC). It is not clear however whether effective shallow encoding engages the same brain region, or more posterior areas such as the parietal cortex. Whether or not episodic encoding relies on a single neural system irrespective of encoding task is therefore still unknown. In the present study we attempted to address this question using anodal transcranial direct current stimulation (tDCS). Thirty-two participants received anodal tDCS while they encoded lists of words using deep and shallow encoding strategies. Half of the participants received the stimulation over the left VLPFC, the other half over the left parietal cortex. Memory for the words was then assessed with a recognition memory test. As typically observed, we showed that items encoded with a deep encoding strategy were better remembered than items encoded using a shallow encoding strategy. This effect however was not modulated by anodal tDCS in either group. Overall, anodal stimulation did not induce any significant change in memory performance compared to sham. These results contribute to the existing debate regarding the effectiveness of electrical current stimulation in modulating higher cognitive functions by showing a lack of behavioural effects of

tDCS, at least in the context of the present stimulation protocol and memory task. Further studies are needed to understand under which condition, if any, tDSC induces changes in memory abilities.

Title: Dynamic default network engagement as a function of stimulus familiarity and task performance

Authors: ***J. LAM**[1], G. TURNER[1], N. SPRENG[2];
[1]Psychology, York Univ., North York, ON, Canada; [2]Human Ecology, Cornell Univ., Ithaca, NY

Abstract: Numerous studies have demonstrated that default network activation precedes and predicts subsequent errors in goal-directed tasks. A consistent attribute of these tasks is that the stimuli are devoid of personal knowledge or significance. Recently, we devised an N-back task for faces, which included both unknown and famous individuals. Famous faces spontaneously elicited default network activity, which persisted through a 2-back match interval, and was associated with better task performance. Here we extend this line of research by examining dynamics of default network activity during successful and unsuccessful trials on a 3-back working memory task with famous faces as targets (with intervening anonymous face distractors) or distractors (during anonymous face target trials). Young adult participants (N = 20) underwent fMRI scanning while completing a 3-back working memory task with two core conditions: Fame relevant/Anonymous irrelevant (FAAF) and Anonymous relevant/Fame irrelevant (AFFA). This study served to identify dynamic default network engagement as a function of stimulus familiarity and task performance. Consistent with prediction, successful FAAF performance was associated with activation of the default network (posterior cingulate cortex (PCC), anterior and lateral temporal lobes, ventromedial prefrontal cortex, and angular gyrus) and attentional control (inferior and superior parietal lobule, and insula), and visual association areas (fusiform face area). Successful AFFA trials were associated with a pattern of activity including attentional control (superior and inferior parietal lobule, frontal eye fields, insula and MT+) and visual association brain regions (fusiform face area). In contrast, unsuccessful AFFA trials were

associated with co-activation of default regions (hippocampus, angular gyrus, ventromedial prefrontal cortex, PCC) and attentional control areas brain regions (dACC, insula). FAAF errors were associated with a more circumscribed pattern of default and attentional control network activity (PCC, inferior parietal lobule right dorsolateral prefrontal cortex, frontal eye fields, insula). These data provide strong support for the dynamic role of the default network in goal-directed processing. Flexible activation of default network brain regions with attentional control areas and higher order perceptual brain regions can both support or disrupt external goal-direct processing, depending on the task relevance of stored representations.

Title: Human hippocampal recording and stimulation: Validation of depth electrode placement through combined high-resolution imaging and electrophysiologic recordings

Authors: R. WICKS[1], M. WITCHER[1], D. COUTURE[1], A. LAXTON[1], G. POPLI[1], M. SOLLMAN[1], D. SONG[2], V. MARMARELIS[2], T. BERGER[2], S. DEADWYLER[1], *R. E. HAMPSON[1];
[1]Wake Forest Sch. of Med., Winston Salem, NC; [2]USC, Los Angeles, CA

Abstract: Accurate localization of depth electrodes within the CA3 and CA1 subfields in the human hippocampus is critical for the detailed analysis of the neuronal circuitry and potential future applications in memory restoration. To date clinical studies of hippocampal function in humans has been based on imaging with depth electrode localization, a method limited for functional anatomic resolution. Likewise, electrophysiological recordings in human hippocampus have had non-precise anatomic localization.
Eleven adult human patients with medically refractory epilepsy underwent implantation of multiple, stereotaxically-placed, electrodes for seizure localization. Each patient had at least one multisite cellular-recording electrode placed within the largest (head) region of hippocampus which was confirmed using post-operative, high-resolution 3T MRI. Cognitive tasks were then

administered to 8 patients, consisting of sample image presentation within a visual Delayed-Match-to-Sample (DMS) paradigm. Accuracy of electrode placement within the CA3 and CA1 subfields of these patients was assessed via analyses of single unit neuronal firing patterns of 'pairwise' CA3-to-CA1 correlograms during sample and match response phases of the DMS task.
Comparison of pre- and post-operative MRI confirmed that at least one multi-site electrode in each patient was localized with recording sites positioned in both the CA1 and CA3 subfields. Electrode locations that were putatively identified (on the basis of probe morphology and post-operative MRI) as CA3 vs. CA1 were confirmed to exhibit electrophysiological correlates of the well-performed DMS task. Pairwise cross-correlations between putative CA3/CA1 cell pairs revealed that 16% exhibited feedforward activation, while 64% exhibited simultaneous activation consistent with synchronous activation of the CA3 and CA1 cell layers via perforant path during the DMS task. Only 3% of cell pairs exhibited negative cross correlation lag and feedback activation associated with mis-identification of either the CA3 or CA1 neuron within the pairs. Nonlinear modeling of CA3-to-CA1 encoding confirmed the functional connectivity during the task and will be used to validate behavioral relevance during testing of a related neural prosthetic designed to facilitate patient memory within the task.

Title: Differential responsivity of left and right rostrolateral prefrontal cortex to temporal order violations during the retrieval of real world memories

Authors: *T. E. CHOW, A. J. WESTPHAL, J. RISSMAN;
Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Rostrolateral prefrontal cortex (RLPFC) critically supports a range of higher cognitive processes, including the control and monitoring of episodic retrieval. Here we aimed to better characterize the contribution of distinct left and right lateralized RLPFC regions during the retrieval of contextually-rich real world autobiographical memories. Using short sequences of photographs as probe stimuli, we examined the degree to which RLPFC activity was modulated as a function of whether the photos of the event were novel or familiar and whether the temporal sequence of the event unfolded in the proper order. Eighteen subjects wore necklace-mounted digital cameras to photograph their daily lives over the course of 3 consecutive weeks. A total of 120 photographic sequences, each consisting of 8 unique images, were selected to represent distinctive events in participants' lives. Participants underwent fMRI scanning while making mnemonic judgments about these events, half of which had been previously encountered during a laboratory session that occurred the day before. Furthermore, half of all events in the fMRI scan session were also presented in a temporally scrambled manner, where the last 4 images within a photo sequence were shown in a different order than what originally occurred. Brain activity was interrogated as a function of photo pre-exposure status (previewed vs. non-previewed) and temporal order (intact vs. scrambled). Our analyses demonstrated a striking dissociation in the activation profile of left and right hemisphere RLPFC regions. Left RLPFC showed greater activity for temporally scrambled photo sequences relative to intact event sequences, but only when the photo sequences were being experienced for the first time. Since temporal order violations in such sequences could not be detected based on comparison with one's memory-derived expectations, this result suggests that left RLPFC may play a role in evaluating whether each successive photo is consistent with one's schema for how events of the type depicted tend to unfold. Interestingly, right RLPFC also showed greater activation for scrambled than intact photo sequences, but only when the sequences had been pre-exposed. This suggests a role in monitoring for a memory-based prediction error (i.e., detecting when the photo sequence was inconsistent with the way it was experienced the prior day). Taken together, this dissociation provides evidence that left and right RLPFC may be sensitive to distinct facets of temporal order violations and may contribute in different ways during autobiographical memory retrieval.

Title: Neural correlates of working memory following the practice of meditation - a high-density EEG study

Authors: *S. DEEPESHWAR[1], S. VINCHURKAR[2], K. NAVEEN[2];
[1]Swami Vivekananda Yoga Res. Fndn., Bangalore, India; [2]Swami Vivekananda Yoga Anusandhana Samsthana (SVYASA), Bangalore, India

Abstract: Background: Meditation has been described as training in awareness, which produces definite changes in perception, attention and cognition. This study aimed at mapping the neural correlates of working memory before and after the practice of meditation.
Materials and Methods: Fifty healthy male participants with age ranging from 18 to 35 years were recruited for this study (mean age ± SD was 27.1 ± 5.8 years). Participants with at least one year of meditation experience were enrolled for the study. This study was conducted at a residential yoga university where subjects were assessed in a self as control pre-post design and were randomly tested for meditation (Cyclic meditation) and control sessions (supine rest) on two separate days.
Electroencephalography (EEG) was recorded using a standard 128 Channel EEG system while performing a Visual N back task. Event related potentials (ERP) were derived and source estimates were mapped using standard protocols. Accuracy of the responses and reaction times were included for analysis.
Results: Reaction times were significantly lower and accuracy on the task was significantly higher following the practice of meditation. Subjects exhibited shorter latencies and significantly higher N100 and P300 amplitudes following the practice of meditation. sLORETA constraint was used for source estimation. The regions of highest activation were Fusiform gyrus, parahippocampal gyrus, middle occipital gyrus and the Uncus.
Conclusion: These findings suggest the role of meditation practice in facilitating sustained attention, visuo-spatial processing and executive functions.
Keywords: Meditation, Visual N back, N100, P300, working memory

Title: Predicting involuntary memories

Authors: ***S. A. HALL**[1], K. H. ZHU[1], K. E. BRODAR[2], M. HONG[3], P. A. KRAGEL[4], D. LI[1], D. BERNTSEN[5], D. C. RUBIN[1];

Abstract: Memories that arise without retrieval effort, or involuntary memories, are an important and frequent form of autobiographical memory and when disrupted, can be an important symptom of mental disorders like post-traumatic stress disorder. Previous work has shown increased activity in the medial temporal lobes and frontoparietal regions during the encoding of items that are later remembered voluntarily compared to those that are not. These effects are referred to as difference due to memory effects (DM). Further, it has been shown that during the encoding of emotionally negative film clips, there is increased activity in regions typically associated with emotion processing, like the amygdala and the rostral anterior cingulate cortex, during the viewing of scenes that are later recalled involuntarily compared to those that are not. However, the majority of involuntary memories experienced in people without mental disorders are emotionally neutral or even positive. An analyses of DM effects that predict the occurrence of involuntary memories across a range of emotional valence levels would allow us to predict these vital memories. To do this, during encoding in the MR scanner, sounds were paired with pictures from the IAPS dataset with emotional valence ratings ranging from neutral to negative. During retrieval in the MR scanner, participants heard the sounds and did an unrelated sound laterality judgment. After the retrieval scan, participants heard the sounds and determined whether its associated picture had been involuntarily recalled during the retrieval scan. As a control condition, unpaired sounds were also presented during encoding and retrieval. Only paired sounds that elicited an involuntary memory during the retrieval scan and unpaired sounds that did not elicit a memory were analyzed. A whole-brain searchlight MVPA was performed on the encoding data. A classifier was trained to differentiate between remembered paired sounds and not-remembered unpaired sounds. The classifier correctly differentiated

between remembered and not remembered trials 65% of the time. Pattern differences between these two conditions were in the supramarginal gyrus, thalamus, insula, caudate, posterior cingulate cortices, bilateral somatosensory cortex, and cerebellum. The involvement of the supramarginal gyrus, thalamus, and insula is consistent with previous work that has shown DM effects in these regions for voluntary memories. Differences in these regions may suggest that items that are associated with more elaborative encoding are more likely to be remembered involuntarily than those that are not.

Title: Saccadic eye movements are phase-locked to posterior alpha oscillations during successful memory formation - evidence from MEG, fMRI and intracranial data

Authors: *T. STAUDIGL[1], E. HARTL[2], S. NOACHTAR[2], I. C. WAGNER[1,3], C. F. DOELLER[1], O. JENSEN[1];
[1]Donders Ctr. for Cognitive Neuroimaging, Radboud Univ., Nijmegen, Netherlands; [2]Epilepsy Center, Dept. of Neurol., Univ. of Munich, Munich, Germany; [3]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands

Abstract: The sampling of visual information is assumed to be discrete rather than continuous (VanRullen & Koch, 2003). Empirical work suggests that the visual system samples the environment at 7-12 Hz, possibly clocked by alpha oscillations (VanRullen et al., 2011). This relatively slow sampling period at 80-140 ms seems at odds with the remarkably fast processing speed of the visual system. For instance, it has been demonstrated that the visual system can distill meaning from images presented for only 13 ms (Potter et al., 2014). This conundrum could partly be resolved if saccades are locked to the phase of ongoing visual oscillations, as investigated in this study.
We simultaneously recorded MEG and eye tracking data from 36 healthy participants during a free viewing encoding task of natural pictures. Memory was subsequently tested in order to classify the encoding trials as ‘later remembered’ versus ‘later forgotten’. MEG data were

aligned to the onset of saccades. Analyses of inter-trial coherence revealed significantly higher phase-locking in the alpha (8-12 Hz) band prior to saccades for later remembered vs. later forgotten pictures. The source of this effect was localized to the parieto-occipital cortex. Intracranial data recorded directly from the occipital and parietal cortex of epilepsy patients provided converging results. Additionally, fMRI data was collected to investigate saccade-related, hippocampal activation and connectivity with the parieto-occipital cortex during successful memory formation.
The study provides evidence that saccadic eye-movements and brain oscillations are coordinated, and demonstrates that this coordination determines what the brain encodes. Specifically, our results suggest that saccades are timed to the dynamic state of the brain, such that the new retinal inputs are temporally aligned to the 'optimal' phase of the alpha rhythm. Concurrent connectivity analyses of source-level MEG and fMRI data will provide first insights into the communication between the visual system and the hippocampus during memory formation, and how this communication is modulated by saccadic eye movements.

Title: Effects of aging on activations in the dorsomedial prefrontal cortex and hippocampus during encoding with autobiographical reasoning

Authors: ***T. TSUKIURA**[1], K. NORIMOTO[1], R. YAMAWAKI[1,2,3], Y. SHIGEMUNE[1,4]; [1]Cognitive & Behavioral Sci., [2]Human Hlth. Sci., Kyoto Univ., Kyoto, Japan; [3]Rehabil. Unit, Kyoto Univ. Hosp., Kyoto, Japan; [4]Cognitive Neurol. and Dementia Res., Otto-von-Guericke Univ. Magdeburg, Magdeburg, Germany

Abstract: Autobiographical reasoning is important in constructing stories about the self and one's life. Previous studies have demonstrated that the self-referential processing such as

autobiographical reasoning enhances the memory encoding (SRE: self-reference effect). However, little is known about the age-dependent changes of neural mechanisms underlying SRE by autobiographical reasoning. The current fMRI study investigated this issue. In this study, we employed 25 healthy young (10 females, mean age: 21.4) and 22 healthy older adults (12 females, mean age: 65.8). During encoding with fMRI, participants were presented with pictures selected from IAPS, and were required to view them in two conditions. One condition was the self-related reasoning (Self), in which participants viewed pictures by projecting themselves onto the pictures, whereas in the other condition, participants viewed target pictures by a third person's view such as TV shows or newspapers (Other: other-related reasoning). During retrieval without fMRI, participants recognized whether the pictures were old or new with high and low confidence. All encoding trials were categorized into Hit including subsequent hits with high confidence, and Miss including subsequent hits with low confidence and misses with high and low confidence in each of Self and Other. In behavioral data, both young and older adults remembered targets more accurately in Self than in Other, but the enhancing effect was larger in young adults than in older adults. In fMRI data, successful encoding activations (Hit vs. Miss) in the hippocampus were significantly decreased by the effect of aging. In addition, the dorsomedial prefrontal cortices (dmPFC) showed age-related decrease of activations in Self-Hit vs. Other-Hit, but no age-related difference of dmPFC activations was found in Self-Miss vs. Other-Miss. In the gPPI analyses for young adults, functional connectivity between the dmPFC and hippocampus in Self-Hit was correlated with individual scores of Hit rates, whereas older adults did not show the correlation. These findings suggest that SRE by autobiographical reasoning could be reduced by aging, and the age-related declines of SRE could reflect lower functional connectivity between the dmPFC and hippocampus in older adults.

Title: Serial dependence in spatial working memory: attraction not swaps

Authors: *D. BLISS, M. D'ESPOSITO;
Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA

Abstract: Since 2009, the swap model has been the prevailing account of inter-item interference in continuous-report tests of working memory. A "swap" is defined as a misbinding of item features that causes a subject to report the feature value for the wrong item when probed. An alternative account proposes that instead of inducing swaps, non-target items exert a more subtle pull of the target feature value in the direction of the non-target value, with a magnitude dependent on the distance between the target and non-target values. This effect has been termed "attraction." For the first time in humans, we find evidence of a serial dependence in responses on a test of spatial working memory (the classic oculomotor delayed-response task), consistent with the attraction account. Specifically, the response on each trial is pulled a few degrees in the direction of the previous trial's stimulus (now a non-target) as a function of the distance between the two stimuli. This serial dependence is clearly present in each of our three subjects. The magnitude of the effect grows with memory delay up to about six seconds. We develop a novel formal model to account for the attraction effect and demonstrate that it provides a far better fit to the data than the swap model. Furthermore, the attraction model fully accounts for what has been considered the smoking gun of the swap phenomenon: a central tendency in the deviation of responses from non-target values. As the second stage of our modeling effort, we review evidence that speaks to the neural basis of the identified attractive serial dependence, and formulate a framework for moving from an abstract mathematical model to a concrete neural one.

Title: Blast from the past: Episodic memory supports working memory maintenance

Authors: ***A. NOVICK**, A. M. BORNSTEIN, K. A. NORMAN, J. D. COHEN;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Humans rely on multiple types of memory to make decisions. In particular, when an item must be remembered, it can be committed to working memory (WM) for active maintenance or episodic memory (EM) for later retrieval. Traditionally these have been considered in isolation of one another. For example, short term retention in the absence of distraction is often assumed to rely on WM function. However, it is possible periodic retrievals from EM also contribute to retention. In addition to being an important strategy in normal function, this has the potential to complicate interpretations of mechanisms underlying behavior in WM tasks. Here, we provide evidence that EM affects behavior in simple WM tasks, even when WM is not disrupted.

To establish a marker for EM retrieval, 94 subjects studied multiple word lists, with each list associated with its own unique "context" picture. These words were later used as targets in a simple WM task: subjects first saw a target set composed of 4 words drawn from one of the lists; after an 18 second retention interval, a probe word appeared and subjects were asked whether the probe was not a member of the target set.

Given the short interval and the absence of overt distractions, it would ordinarily be assumed subjects perform the task by actively maintaining targets in WM, without reliance on EM. To test this, we investigated if presenting target words from a list triggers retrieval of the context (from EM) in which the list was studied, thus impacting performance. If context is not retrieved from EM, there should be no difference in responses to lures from the same context and distractors from other contexts. In contrast, if context is retrieved, it could assist in identifying targets and rejecting words from inconsistent contexts, and interfere with rejection of "lure" words from the same context as the targets.

We found same-context lures significantly slowed RT relative to different-context probes. This behavioral result suggests information retrieved from EM can affect participants' WM task performance.

To further test this hypothesis, we used MVPA on fMRI data to track reinstatement of the individual context images during retention intervals of the WM task. Reinstatement of target context correlated with RT to probes. On lure trials, this correlation was positive, indicating context information shared between targets and lures was distracting; on different context trials, this correlation was negative, indicating inconsistent context information between targets and different context words facilitated rejection. These fMRI results also support the hypothesis that EM retrievals occur during WM maintenance and impact performance in WM tasks.

Title: Gluing memories via oscillations: Theta phase synchrony drives associative memory formation in humans

Authors: *A. CLOUTER, K. SHAPIRO, S. HANSLMAYR;
Univ. of Birmingham, Edgbaston, United Kingdom

Abstract: The objective of our experiments was to investigate the effects causal role of neural synchrony between visual and auditory processing regions on associative memory formation for multi sensory events.
Multisensory episodic memories rely on successfully binding elements that are processed in separate, specialised brain regions. The formation of episodic memories is thought to rely on the synchronization between distant brain regions in the theta frequency band. However, causal evidence for this idea from humans is missing. To provide such evidence we developed a novel multisensory memory paradigm where participants encode sound-movie associations. Modulating the luminance and amplitude of the videos and sounds independently allowed us to control the degree of phase synchrony between the auditory and visual cortex. We then further show in two experiments that memory for the sound-movie associations differs drastically depending on the degree of inter-sensory phase synchrony.
In the first experiment, in the encoding phase, all participants were shown short (3-second) videos that were luminance modified with a 4 Hz sine wave, with an accompanying audio clip that had been amplitude modulated with a 4 Hz sine wave. The phase offset (i.e., synchrony) between the audio clip and the video was 0, 90, 180, or 270 degrees. In a second experiment, the videos and sounds were modulated at 4 Hz, 1.7 Hz (delta), and 10.5 Hz (alpha). On each trial, participants rated how well the audio clip suited the contents of the video clip. Each of six blocks contained 16 audio-video pairings (four at each phase angle), and was followed by a brief distractor task and an associative recognition test.
Associations were better remembered in the synchronous compared to the asynchronous condition. This effect was specific to theta (i.e. 4Hz) and did not occur in a faster (10.5 Hz) or slower frequency (1.7 Hz). These findings suggest that episodic memory formation in humans relies on a theta specific synchronization mechanism.

Title: Intersubject correlation analysis of students' brain activity during listening to teacher's explanation.

Authors: *Y. HIRAKO[1,2], T. KOIDE[2], T. ITO[3], S. SHIMADA[4];
[1]Meiji Univ., Tokyo, Japan; [2]Electrical Engin., Meiji graduate school, Science and technology, Japan; [3]Meiji university, School of Arts and Letters, Japan; [4]Electronics and Bioinformatics, Meiji university, Science and technology, Japan

Abstract: In this study, we investigated the mechanism of comprehending teacher's explanation by utilizing intersubject correlation (ISC) analysis of students' brain activity. ISC is calculated by utilizing general linear model (GLM) with one subject's brain activity as a model to see how similar the other subject's brain activity was.
Twenty-four right handed subjects participated in the experiment (one female, aged 21.3 ± 0.17 years, mean ± SD). Half of the subjects (N=12) listened to the explanation of a teacher about basic probability statistics in the recorded video. Another half listened to the equivalent explanation performed by another teacher in the recorded video. The hemodynamic responses in the bilateral cortical areas (9 x 9 square cm area each) were recorded by using 48-ch functional near-infrared spectroscopy (fNIRS) during explanation. The sampling frequency was 10 Hz. After the recording, the subject continuously (10 Hz) scored the rating of comprehensibility of the explanation by watching the movie again (0 - 100). The measured brain activity was analyzed by ISC analysis between two subjects who listened to the same teacher or different teachers. We also calculated Pearson's correlation between the ISC and the subjective rating of comprehensibility.
The ISC analysis showed significant ISCs in the right dorsolateral prefrontal cortex (DLPFC) (ch-38, BA9: $t(24) = 1.83$), the middle temporal gyrus (ch-46, BA21: $t(24)=3.70$), and the frontal eye field (ch-31, BA8: $t(24) = 1.71$). Among those, the right DLPFC showed a significant difference in ISCs between the subjects who listened to the same teacher and the subjects who listened to the different teachers (ch-38: $t(24) = 1.78$, $p<0.05$). The correlation analysis between the ISC and the subjective rating showed significant correlations at the left premotor cortex (ch-6, BA6: $r=0.24$, $p<0.05$) and the left angular gyrus (ch-21, BA39: $r=0.17$, $p<0.05$).
These results suggest that DLPFC is involved in comprehending teacher's explanation, by playing a role as working memory to translate verbal information into abstract numerical

representation, which likely covariates among students who listened to the same teacher's explanation.

Title: Reward and salience determine the precision of working memory encoding with different time-courses

Authors: ***P. C. KLINK**[1,2], D. JEURISSEN[1,3], J. THEEUWES[4], D. DENYS[2,1], P. ROELFSEMA[1,2,4];
[1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands; [2]Academic Med. Center, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Columbia Univ., New York, NY; [4]VU Univ., Amsterdam, Netherlands

Abstract: The general abundance of sensory information requires the brain to prioritize and select subsets of information for further processing and storage in working memory. Stimulus salience and reward expectations influence this prioritization but the underlying mechanisms are not well understood. We hypothesized that selective attention might act as a gating mechanism at the interface between sensory codes and memory storage. When multiple stimuli compete for representation in working memory, selective attention could bias this competition and affect the quality of memory encoding. Such a gating mechanism would furthermore have little effect on working memory during memory maintenance or retrieval. We tested the selective attentional gating hypothesis by investigating how stimulus saliency (contrast) and reward expectancy determine the precision of visual working-memory representations. Participants remembered the

orientation of three Gabor patches shown for 3s, and reproduced the orientation of one of them after a 2s memory interval. Reward expectancy was manipulated with color cues that indicated the amount of potential reward but had no predictive value about which stimulus would be probed. Bottom-up salience was modulated by changing stimulus contrast. Reward cues only affected memory precision when they were presented during the encoding phase of the task, not during maintenance or retrieval. Previously learned non-predictive color-reward associations had a similar effect on memory precision, but it gradually weakened over time. These reward-based priority effects required relatively long stimulus presentations as they disappeared when we shortened the encoding phase from 3s to 300ms. Interestingly, the influence of stimulus contrast on memory precision was oppositely related to encoding duration, with memory precision being affected with short but not with longer stimulus presentations. Our results provide new insight into how memory resources are flexibly distributed over potential memory targets, with selective attention acting as a dynamic gating mechanism at the interface between sensory and memory systems.

Title: Reward prediction errors enhance episodic memory

Authors: *N. ROUHANI[1], K. A. NORMAN[2], Y. NIV[2];
[1]Psychology, Princeton Univ., Princeton, NJ; [2]Psychology and the Princeton Neurosci. Inst., Princeton, Princeton, NJ

Abstract: Phasic dopaminergic signals are thought to track the degree to which actual outcomes are different from what was expected (a “reward prediction error” signal). These signals are critical for trial-and-error learning in the striatum. However, similar dopaminergic signals project to the hippocampus (Shohamy & Adcock, 2010), suggesting that prediction errors might influence the formation of episodic memories as well. Recent theoretical work has suggested that large prediction errors may serve to fractionate the stream of experience into separate memory traces (Gershman, Radulescu, Norman & Niv, 2014). Here we test the ensuing prediction that

more distinct traces will be formed in environments with higher risk (and therefore, larger prediction errors), leading to better memory fidelity. N=200 participants learned from trial and error which of two types of pictures, indoor or outdoor scenes, leads to higher rewards. Pictures were presented within two different contexts ('rooms'), with each room associated with a different degree of reward variance (risk) but matched in mean value, such that the rewards associated with pictures in one room gave rise to higher prediction errors than in the other room. On each trial, participants were shown an image, entered an estimate of how much that type of scene (indoor or outdoor) is worth on average, and were then re-presented with the image along with its reward. Participants learned the values for the scenes better in the low-risk than in the high-risk room, although they optimally reduced their learning rate in the high-risk environment. Conversely, a recognition test revealed that memory for high-risk scenes was better than that for low-risk, and that this effect was largely driven by better memory for images for which there was a greater absolute (or unsigned) prediction error at reward outcome. This finding suggests that enhanced memory for extreme outcomes (Ludvig et al., *J Beh Dec Making*, 2014) may actually be modulated by an absolute prediction error signal during learning. Current work is assessing whether reactivation of memories encoded at reward outcome (and within different 'risk' contexts) differentially biases decisions.

Title: A common, fine-grained code for object meaning in perirhinal cortex

Authors: ***A. R. PRICE**[1], M. BONNER[1], J. PEELLE[2], M. GROSSMAN[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Washington Univ. in St. Louis, St. Louis, MO

Abstract: Many studies have examined object knowledge by studying the neural representation of object categories (e.g., tools versus animals), which often broadly differ on coarse features, such as shape, size, and texture. However, little is known about the neural mechanisms for encoding the fine-grained semantic attributes of specific objects within a semantic category. For

example, how do we know that a red apple is conceptually more similar to a green apple than to a blue apple? Here, we address this question by using a novel stimulus set that allowed us to leverage the natural statistics of object color information to investigate a neural code for object meaning. In an fMRI experiment, 16 subjects viewed images of objects that were systematically manipulated in color while performing an unrelated object detection task. The stimuli included three sets of specific objects (apples, leaves, and roses). The objects were each presented in five different colors (red, pink, blue, green, and yellow). For each object set, we created a semantic-similarity model based on the co-occurrence frequencies of color-object combinations from a large lexical corpus. This model predicts that "red apple" and "green apple" would have more similar neural representations than "red apple" and "pink apple" in brain regions that code high-level semantic information about objects. The semantic-similarity models were unique for each object category, and were orthogonal to perceptual models for shape or color similarity alone. Using representational similarity analysis of the multi-voxel patterns, we found that perirhinal cortex was the only region that significantly correlated with the semantic-similarity model ($p<0.01$). Next, we proposed that a key function of the semantic codes in this region is to provide a common understanding of object meaning across individuals. This predicts a specific functional architecture: neural codes in this region should be structured to provide a common ground between observers of the visual world. For example, a typical object like "red apple" should have a more similar neural instantiation across individuals than a less typical object like "blue apple." To test this hypothesis, we hyper-aligned each subject's data to a common, high-dimensional space (Haxby et al., 2011). Indeed, we found that perirhinal cortex was unique in containing population codes for which inter-subject similarity correlated with object typicality ($p<0.01$). Our results suggest that perirhinal cortex encodes high-level object knowledge and may instantiate a neural "common ground" for object meaning across individuals.

Title: Goal-directed episodic memory decisions are reflected in the functional connectivity patterns

Authors: *Y. NAH[1], S. A. HUETTEL[2], I. G. DOBBINS[3], S. HAN[1];
[1]Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of; [2]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC; [3]Dept. of Psychology, Washington Univ. in St. Louis, St. Louis, MO

Abstract: Numerous functional magnetic resonance imaging (fMRI) episodic memory studies demonstrate that contrasting correctly recognized studied items (HIT) against correctly rejected novel items (CR), known as "Retrieval success effect", yields activation in distributed brain regions, including prefrontal, parietal, striatal and other regions. However, whether the interactivity of these distributed networks solely reflects retrieval judgment or goal-related decision has not been investigated thoroughly. We conducted fMRI studies using episodic Old/New recognition tasks to investigate the functional connectivity patterns within the 'retrieval success' networks during different recognition processes (HIT vs. CR) and manipulated the motivational significance of episodic memory decisions (i.e., performance-linked monetary reward and feedback). Nineteen participants judged whether each serially presented word is old (studied in encoding sessions) or new (never seen before) during retrieval. For the initial two runs, there was neither monetary reward nor performance feedback. For the last two runs, on the other hand, either correct "Old" or "New" responses were potentially rewarded in HIT-Incentive or CR-Incentive runs, respectively. Non-directional *F* test across the factors (Incentive condition × Feedback presence) revealed significant activations in several brain regions, including prefrontal, caudate, parietal and other regions, from which the task-dependent time-series were extracted. Pairwise cross-correlation coefficients of the extracted time-series across the networks were analyzed using functional connectivity multivariate pattern analyses (fcMVPA) with a linear support vector machine algorithm. The classification between HIT vs. CR iterated as a function of number of features included, and the peak accuracy (95%) was achieved. In addition, to explore how the connectivity patterns within retrieval success networks differ as a function of goal-dependent response type, fcMVPA were again applied in run 3 and 4, which showed peak accuracies of 95 to 100%. More importantly, connectivity patterns obtained during Incentive conditions in both runs (HIT-Incentive in run 3, CR-Incentive in run 4) showed similarly greater connectivity across the networks compared to standard responses in No-Incentive runs. These findings demonstrate that patterns of functional connectivity across nodes, previously known as retrieval success networks, reflect goal-congruent interactivity independent of the status of memory probes and suggest that participants preferentially construe HIT as intrinsically potential reward.

Title: Beyond slots and resources: an integrative approach to visual working memory

Authors: *R. SENGUPTA, J. K. TSOTSOS, S.-A. YOO, C. WLOKA, T. KUNIC;
Dept. of Electrical Engin. and Computer Sci., York Univ., Toronto, ON, Canada

Abstract: In recent years, research in the area of visual working memory has followed a few fixed avenues. One of the most influential formulations focuses on the capacity of visual working memory (VWM), an area which has been dominated by slot based frameworks (e.g., fixed slots, dynamic resource allocation with variable precision, etc.) (Luck et al., 1997; Ma et al., 2014). Interestingly, the debate has largely been within this paradigm. Research on capacity has largely progressed without a firm model of the actual content of working memory, relying rather on vague ideas of representation. Although it is widely held that attention acts as a gate to working memory, the actual mechanism of such a function largely remains elusive. In the current work we have developed an integrative account of visual working memory and attention. We have placed our model within the larger context of the selective tuning model of visual processing (Tsotsos et al., 2014) due to its comprehensive, biologically plausible, and computationally extensible framework. The content of VWM is the attentional sample collected by the visual processing hierarchy, and the capacity is determined by the resolution of the attentional sample and the computational constraints which apply to its subsequent maintenance in VWM (for instance during serial recall). Our model makes a number of predictions, including that the variability of working memory capacity in change detection experiments is determined by the physical size of the visual display. We have confirmed this prediction with a psychophysical experiment in which subjects performed a change detection task on a display which varied between 10x10 degrees to 12x12 degrees, and set sizes of objects varied between 2, 4 and 6. The idea of a fixed number of slots, and thus capacity, was originally supported by the poor performance at set sizes higher than 4 in working memory tasks (Cowan et. al., 2001). Our results show that for the larger display, change detection accuracy for 6 items was 15% greater than what was reported in Luck et. al. (1997), which is clearly outside what was traditionally considered the working memory capacity limit (Cowan et. al., 2001). Thus, we demonstrate that there is a display size dependency of performance which a classic slot view of working memory capacity cannot account for. Overall, we posit that the current framework provides a way to

break out of the slot based idea for working memory and move towards a more integrative approach to visual processing in general.

Title: Comparing fear conditioning using immersive virtual reality versus computer display

Authors: ***J. ROSÉN**, G. KASTRATI, F. AHS;
Dept. of Psychology, Uppsala, Sweden

Abstract: Fear conditioning in lab environments has proven to be an effective method when studying autonomic responses to threat. However the role of immersion has not been extensively researched in fear conditioning and extinction. Here we tested whether fear conditioning of virtual characters in an immersive virtual reality environment using head mounted display (HMD) was enhanced relative to fear conditioning in a lab environment using a traditional computer monitor. In both settings, one virtual character was displayed at a proximal and another character at a distant egocentric location, while being followed by the delivery of a mild electric shock (CS+). Two distance matched control stimuli were never paired with shock (CS-). Skin conductance responses (SCRs) were used as conditioning index. Results showed that proximal characters elicited greater SCRs than distant characters both when using immersive virtual reality and when using computer display. However, proximity enhancement of SCRs was greater in the virtual reality setting than in the lab setting. During fear conditioning CS differentiation was reduced at proximal location due to enhanced responding to the CS-, indicating slowed safety learning at proximal location. This effect was observed using either of the two display settings. Fear was extinguished to a similar degree when using immersive virtual reality and computer display. Results suggest that cued fear learning is similar when cues are displayed in immersed virtual reality as when cues are displayed at a computer monitor, but that distance manipulations have a greater effect on autonomic responses in immersive virtual reality.

Title: Disentangling remembered and perceived information in the full correlation matrix of human brain activity

Authors: *J. HUTCHINSON, Y. WANG, N. TURK-BROWNE;
Princeton Univ., Princeton, NJ

Abstract: Bringing to mind details from the past is often associated with the re-engagement of the same cortical regions that were involved when those details were initially perceived. Given this common substrate, how are we nonetheless able to distinguish internally and externally generated information? Here we explore the hypothesis that even if retrieval and perception share content, the neural sources of these representations differ, and thus measuring network engagement for these two processes might allow us to properly attribute our experience. To identify these divergent networks, we used full correlation matrix analysis (FCMA) — an unbiased, optimized technique for computing and decoding all pairwise correlations in the brain. In our study, 24 participants were trained to associate unique pairs of images (one face with one scene per pair) and were then presented with blocks of either face or scene images during fMRI. In the Perceive condition, they performed a male/female judgment on face images or a building/nature judgment on scene images. In the Retrieve condition, they performed the same set of judgments on the same sequences of images, but rather than judging the presented images, they judged the associated images from the other category based on memory. This design allowed us to hold visual stimulation constant while varying demands on internal vs. external processing. Applying a machine learning classifier to the full correlation matrix from each block, we were able to robustly decode with greater than 80% accuracy whether the block was from the Perceive or Retrieve condition. FCMA could also be used to identify voxels and regions whose connectivity with other regions was particularly informative. Moreover, the decoding and localization results could be compared with more traditional, activity-based multivariate pattern analysis (MVPA) approaches, and with behavior in the different tasks. The results provide insight into how the same representational space can be used by both internally and externally driven processes without necessarily leading to failures of reality monitoring. More generally, they highlight the value of quantifying cognitive processes in terms of connectivity patterns, in

addition to activity patterns and overall activity, when seeking to understand brain mechanisms and dynamics.

Title: Online measures of perceptual integration predict statistical learning

Authors: *L. BATTERINK, K. A. PALLER;
Northwestern Univ., Evanston, IL

Abstract: Statistical learning allows learners to discover structure in the environment, as occurs during speech segmentation. Statistical learning may be divided into at least two dissociable components, perceptual binding of individual stimulus units (e.g., syllables) into integrated items (e.g., words), and encoding of these extracted items into long-term memory. Previous studies have generally focused on the outcome of statistical learning by assessing performance on post-learning tasks, and thus have not dissociated these two components. The goal of the present study was to characterize the perceptual component of statistical learning, examining whether differences in learners' online perception of input predicts performance on post-exposure learning tasks. Participants were exposed to streams of repeating trisyllabic nonsense words ("structured" condition) and of randomly concatenated syllables ("random" condition). Online learning was indexed by an EEG-based measure that quantified neural entrainment at the frequency of the repeating words, reflecting whether learners subjectively experienced individual elements or integrated items as the basic perceptual units of the speech stream. After exposure, statistical learning was assessed offline using both an explicit rating task and a reaction-time task. In the structured condition, neural entrainment to the trisyllabic words (1) was higher than in the random condition, (2) increased as a function of exposure and, (3) predicted performance on the post-exposure reaction time task. Unexpectedly, neural entrainment to trisyllables in the random condition also predicted post-exposure task performance. These results suggest that neural measures are sensitive to an individual's ability to seek out underlying patterns in the environment, which is a key predictor of statistical learning success. Our findings also provide evidence that the perceptual binding of individual stimuli into integrated items is a critical

component of statistical learning and an important source of variability in statistical learning performance.

Title: Parietal memory reactivation and retrieval-induced modification of long-term memories

Authors: ***H. LEE**[1], R. SAMIDE[2], F. R. RICHTER[3], B. A. KUHL[2];
[1]Dept. of Psychology, New York Univ., New York, NY; [2]Dept. of Psychology, Univ. of Oregon, Eugene, OR; [3]Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Lateral parietal cortex, specifically angular gyrus (ANG), has consistently been implicated in long-term memory retrieval: activity in ANG increases with vivid remembering, and the contents of reactivated memories can be decoded from ANG activity patterns. However, understanding the functional significance and nature of memory reactivation within ANG remains an important objective. For example, does reactivation within ANG functionally differ from reactivation in occipito-temporal cortex (OTC)? Here, we addressed this issue by asking whether reactivation in ANG and OTC predicts retrieval-induced strengthening or modification of memories. We conducted a three-phase fMRI experiment. In phase 1 (learning phase), subjects studied associations between words and pictures of faces, scenes, or objects. During phase 2 (retrieval practice), half of the previously learned words were presented alone and subjects retrieved the picture associated with each word. Words were presented three times each and subjects rated the vividness of the retrieved memory on each trial. In the final phase (test phase), which took place outside of the scanner, subjects were tested on their recognition memory for pictures. There were three types of test pictures: novel, studied, and critical 'lure' pictures that were perceptually similar and conceptually identical to the studied pictures. For each picture, subjects indicated whether it was 'old' or 'new' and how confident they were. Behavioral results indicated that retrieval practice increased recognition accuracy for the pictures, but that higher accuracy occurred via an increase in hit rate and false alarms (with the increase in hit rate being larger). This effect was particularly evident when subjects reported high vividness during retrieval practice. Consistent with prior findings, vivid remembering (during

retrieval practice) was associated with higher univariate activation and pattern-based reactivation in ANG and OTC. However, reactivation in ANG vs. OTC differentially predicted performance on the post-test: reactivation in OTC—but not ANG—was associated with a reduced rate of false alarms to critical lures. Thus, while activation and pattern-based information in ANG strongly scaled with vivid remembering, ANG reactivation did not protect against the increased false alarm rate that was associated with retrieval practice. These findings suggest that ANG representations are more likely to be gist-based or semantic in nature than representations in OTC and that by separately considering reactivation in each region, predictions can be made about how the act of retrieval influences a memory.

Title: Computational model and erp enabled prediction of single trial behavior on a numerical comparison task

Authors: *R. W. PRATHER, S. HEVERLY-FITT;
Human Develop. & Quantitative Methology, Univ. of Maryland, College Park, MD

Abstract: We demonstrate how a computational model can predict single-trial behavior for individual participants completing a numerical comparison task. Participants performed a non-symbolic numerical comparison task while reaction time, response, and electrophysiological (EEG) data were recorded. Mean ERP amplitude within the time window of 280-380ms was extracted for each trial. Consistent with existing literature on numerical processing we find a distance effect with both behavioral and neural measures. Participant accuracy correlated positively with the proportional distance between the two values being compared. We also found a significant correlation between parietal ERP amplitude (P3 and P7 channels) and the distance between the comparisons being made. We then used a multilayered dynamical systems model with evolutionary algorithm updating to predict behavior for each participants performance on a trial-by-trial basis. Each participant's data was modeled with an independent instantiation of the model. The initial model training included the first two thirds of each participant's data. Model input included trial response, reaction time and average ERP amplitudes for parietal channels.

The training comprised of multiple generations of an evolutionary algorithm in which model specifications were adjusted to best fit the individual participant's data. Accuracy in initial model fit to individual participant responses ranged from 82% to 95%. Accuracy for reaction time fit ranged from a mean deviation of 150ms to 400ms. The best fit model specifications for each participant were then used to predict novel data, the remaining 1/3 of trials. The computational models were able to generalize to novel data as well as data used for the initial optimization. We discuss leveraging individualized prediction of on number comparison performance to symbolic arithmetic tasks, an important educational and developmental outcome.

Title: Characterizing parietal memory network responses under incidental memory task conditions in highly-sampled individual subjects using fMRI

Authors: *A. W. GILMORE[1], S. M. NELSON[7,8,9], T. O. LAUMANN[2], J. J. BERG[1], D. J. GREENE[3,4], E. M. GORDON[7,8], A. L. NGUYEN[2], M. ORTEGA[2], R. S. COALSON[3,2], B. L. SCHLAGGAR[3,2,5,4,6], S. E. PETERSEN[1,3,2,5], N. U. F. DOSENBACH[2], K. B. MCDERMOTT[1,3]; [1]Psychological and Brain Sci., Washington Univ., Saint Louis, MO; [2]Neurol., [3]Radiology, [4]Psychiatry, [5]Anat. and Neurobio., [6]Pediatrics, Washington Univ., St. Louis, MO; [7]VISN 17 Ctr. of Excellence for Res. on Returning War Veterans, Waco, TX; [8]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [9]Psychology and Neurosci., Baylor Univ., Waco, TX

Abstract: Recently, a sparse network of regions in parietal cortex has been associated with encoding and retrieval processes in human long-term memory. Activity within this "parietal memory network" (PMN) appears to follow three main response patterns depending on one's history with a given stimulus (Gilmore et al., 2015): 1) PMN regions deactivate relative to a resting baseline for newly-encountered stimuli (as during a typical study phase); 2) PMN regions show repetition enhancement effects (i.e., increase in activity) across item repetitions; 3) PMN regions activate above resting baseline levels for stimuli that have been observed multiple times (as during a typical retrieval phase). BOLD responses in PMN regions are thought to reflect the degree to which a stimulus is perceived to be novel or familiar, though the relative contributions of familiarity per se and of attention to that familiarity are not yet well understood. In part, this is because our understanding of the PMN is based on explicit memory experiments, in which subjects are required to either intentionally encode information in preparation for a later test, or are explicitly directed to orient to their history with a given item. The degree to which the PMN responds similarly under incidental memory conditions—in which no direct test of memory is conducted—is unknown, and may be helpful in understanding how different processes affect PMN activity. This was explored in the present work.

Ten highly-sampled subjects underwent fMRI scanning across ten different days. Each day, subjects performed an incidental memory task, in which they were instructed to make semantic decisions about stimuli that appeared multiple times in the course of a single session (e.g., whether a word referred to an abstract or concrete concept). Sufficient data were collected to conduct analyses on the level of individual subjects. Whole brain voxelwise analyses of BOLD activity associated with different stimulus presentations revealed regions exhibiting both repetition enhancement and repetition priming. Targeted interrogation of PMN regions revealed that they deactivated as predicted during initial stimulus presentations, and also showed repetition enhancement across subsequent presentations. However, PMN regions did not activate above baseline for familiar stimuli, and instead remained near baseline activity levels.

The current data suggest that processes related to stimulus salience or attentional capture may account for repetition enhancement above baseline in PMN regions, whereas processes driven by novelty or familiarity can produce deactivation and lesser degrees of repetition enhancement.

Title: Individual representation of large scale brain network related to creative insight: Voxel-Based Morphometry <and> resting-state functional connectivity analyses

Authors: *T. OGAWA[1], T. AIHARA[2], T. SHIMOKAWA[2], O. YAMASHITA[2];
[1]ATR, [2]NIA, ATR, Kyoto, Japan

Abstract: Creative cognition is commonly agreed to play an essential role in the development of human civilization <and> cultural life. With use of recent neuroimaging techniques, neuroscientists of creative cognition have been studying on creative insight <and> domain-general/specific creative thoughts. However, an insight-specific network <and> its individual difference of broad-age ranged adults have been rarely investigated using both structural <and> functional neuroimaging techniques. Here, we focused on large-scale network associated with insight problem solving. We defined insight problem solving as including three characters: i) a solver needs to discover a single solution with convergent thinking, ii) a solver needs to change representation of a problem, iii) a solver suddenly moves from a state of not knowing a solution to a state of knowing a solution. We conducted an MRI experiment (T1-weighted image <and> 10-min resting-state fMRI scanning) <and> multimodal behavioral experiments to measure the cognitive function on 101 healthy subjects ranged in age from twenties to sixties. In the Voxel-Based Morphometry analysis of the T1-weighted images (76 participants), we identified seed brain regions where the gray-matter volume (GMV) were positively correlated with scores of insight. We applied the seed-based functional connectivity analysis of resting state fMRI to whole brain voxels. We found that the GMV in the bilateral precunei, the right middle cingulate cortex (*R*-MCC), the right superior parietal lobule (*R*-SPL) <and> the left middle temporal gyrus (*L*-MTG) were positively correlated with IPS score. According to the obtained seed regions, we extracted a task-positive network consisting of precunei, MCC, <and> superior frontal gyrus (SFG), <and> a task-negative network consisting of left MTG, superior temporal gyrus (STG), insula, right MTG, right fusiform, STG <and> bilateral precunei. This is the first study to identify the large-scale networks associated with creative insight. Our results support that individual creative insight ability was correlated with altered GMV involved in cognitive control regions, <and> that the insight score was associated with the strength of resting state functional

connectivity between the precunei <and> other brain regions related to default mode or language processing. These findings are comparable to the previously reported studies on the creative cognition such as domain-general creative thought.

Title: Effects of global signal regression (GSR) and motion scrubbing are essentially similar between and within subjects.

Authors: *B. ADEYEMO[1], B. SEITZMAN[1], S. E. PETERSEN[1,4,2,3];
[1]Dept. of Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Dept. of Radiology, [3]Dept. of Neurosci., Washington Univ. Sch. of Med., St. Louis, MO; [4]Dept. of Psychological and Brain Sci., Washington Univ. in St. Louis, St. Louis, MO

Abstract: Head motion is a pernicious problem for analyses involving resting state functional correlation (RSFC) data. Motion-related effects include motion outlier spikes directly associated with small motions and global artifacts found in greater abundance in scans with frequent movements. Because these artifacts produce systematic and spurious positive correlations, differences can arise when groups systematically differ with regard to these artifacts. While many have accepted the spiking artifact and have taken steps to address this (e.g. removal of affected frames, “scrubbing”), many still have yet to concede the importance of the global artifacts, in part because of potentially important global signal differences at the individual or group level.
In an attempt to address effects at a subject level we created two subgroups (N=25 each) from

the HCP database of RSFC data. All subjects had two separate sessions of resting state functional imaging (RSFC). For the LL group, both scans were associated with low amounts of motion. For the LH group, one scan had relatively low motion, the other had significant motion. The main assessment was the number of statistical differences between cells in the adjacency matrices sets of scans. We then assessed the effects, both across groups and within each of the two groups, when applying different combinations of scrubbing and global signal noise reduction algorithms. When comparing the lowest of the LL sessions with the high motion session of the LH group, thousands of differences were found. Removal of high motion frames (scrubbing), decreased the difference by about 29%, GSR by about 71%, and the combination about 77%. Similar measurements within the LH group were 28%, 87% and 90% respectively. Comparing the matrix effects for the between and within conditions showed considerable similarity: matrices correlate at 0.6.
Thus, the great bulk of the differences found in uncleaned data are due to artifact, and group and individual differences must be viewed with extreme caution when either or both GSR and motion scrubbing are not performed.

Title: Binaural beats for enhancing cognitive functions in healthy individuals

Authors: *G. B. PATRUDU;
Andhra Med. Col. & King George Hosp., Visakhapatnam, India

Abstract: Currently there is a surge in interest on research into the effect of binaural beats on cognitive functions. This review summarizes the results of studies on the effect of binaural beats on cognitive functions. Binaural beats have been shown to improve phase synchronization which is vital for cognitive processes. Binaural beats in the alpha (10 Hz) and theta (4 Hz) frequency range enhanced alpha-band oscillation synchrony between the auditory cortices during auditory stimulation (Solca et al., 2016). Also an increased temporo-lateral phase synchronization was observed due to 5Hz binaural-beat stimulation (Becher et al., 2015). Like wise, they have been shown to enhance attention.On a global local task listening to Gamma frequency binaural beats produced more attentional focussing(Colzato et al., 2015).In another study, Gamma frequency binaural beats eliminated the Attentional Blink, but only in individuals with low spontaneous

eye-blink rates (Reedijk et al., 2015). Similarly, individuals with low Eye Blink Rates mostly benefitted on task requiring creativity (Alternate uses task) from alpha binaural beat stimulation, while individuals with high Eye Blink Rates were unaffected or even impaired by both alpha and gamma binaural beats (Reedijk et al., 2013). Ultrashort duration of presentation (2 min)of steady state binaural beats were not sufficient to alter vigilance or entrain cortical frequencies at the two bands examined Theta (7 Hz) and Beta (16 Hz) in a study by Goodin et al. (2012).In a study by Kennel et al., (2010), listening to the binaural beats participants reported subjectively experiencing less problems associated with inattention during the study period. Auditory stimulation over a long time at a frequency of 5 Hz(theta) increased the capacity of immediate verbal memory(Ortiz et al., 2008). However with 7hz theta frequency for only a single session of 30 minutes showed decrease in immediate verbal memory recall (Wahbeh et al., 2007). In a study by Lane et al. (1998) listening to Binaural beta beats while performing visual vigilance task improved performance .Overall, the results of the studies on the effect of binaural beats on cognitive functions look positive. However , conflicting findings in some studies seem to be due to individual variations or predispositions of the study participants and the duration of application of binaural beats . More studies have to be done taking these factors into consideration to study effectively the influence of binaural beats on various cognitive functions.

Sch. of Med., St. Louis, MO; [9]Psychology and Neurosci., Baylor Univ., Waco, TX

Abstract: Lasting cognitive and behavioral effects of Traumatic Brain Injuries (TBI) are common among post-deployment military Veterans who have suffered head injuries. Such

symptoms are related to the presence of diffuse axonal injury resulting from shearing forces; this damage impairs normal communication between distant brain regions, effectively disrupting brain networks critical for cognitive function. However, studying how TBI disrupts brain networks has been challenging due to inter-individual variability in both the injuries sustained and the networks themselves. Recent work by Laumann et al. (2015) has demonstrated that the brain networks of individuals can be characterized with high fidelity if many hours of resting state functional connectivity MRI (rs-fcMRI) data are collected in each individual. This work found that the functional network organization of individual brains are significantly more complex than group-average networks. Here, we apply a similar high-data rs-fcMRI approach to study TBI-related effects on brain networks. We collected 2-3 hours of rs-fcMRI data from 5 US Military Veterans with a history of TBI (four with mild TBI only; one with moderate TBI) and from 2 Veterans with no TBI history. Functional connectivity analyses characterized both the spatial topographies of brain networks and the strength of functional connections within and between those networks. Similar to Laumann et al (2015), all subjects' individualized brain networks contained small network pieces that did not correspond to any network features present in group average data. Notably, network maps of TBI patients were not systematically different from those of either non-TBI Veterans or healthy non-Veteran individuals. However, the magnitudes of both positive and negative functional connections between and within networks were reduced in the TBI patients compared to the non-TBI participants. These results suggest that TBI-induced disruption of white matter may reduce absolute functional connectivity strength, but leave network shapes unchanged. More broadly, these results indicate the possibility that the individual-specific spatial topographies of functional brain networks may be relatively insensitive to damage that impairs connectivity within and between these networks.

Title: Deep dynamic phenotyping of the individual: tracking within-subject variability in social and emotional behavioral profiles using smartphones

Authors: *M. SHERMOHAMMED[1], I. J. BARNETT[2], M. V. KIANG[2], R. L. BUCKNER[1,3,4], J. T. BAKER[3,4,5], J.-P. ONNELA[2], L. H. SOMERVILLE[1];

Abstract: Extensive longitudinal phenotyping in the individual creates novel opportunities to measure physiology and brain states in relation to real world changes in social and emotional behavior. To explore this possibility, we tailored a custom smartphone research platform called Beiwe (Onnela & Rauch, 2016) to capture shifts in behavior and psychological state. Information about movement was passively captured using the phone's accelerometer, about location using GPS, bluetooth, and wifi, and about social interactions using text and call logs. In addition to these passive measures, participants completed 37 daily questions related to their physical, emotional, and social experiences that day. These combined measures allowed detailed monitoring of four individual participant's daily changes over a period of four months in mood, stress levels, energy, appetite, physical activity, and social engagement. Data-driven analysis techniques probed the relationships between measures within and across data types. Results revealed meaningful relationships between measures, such as the clustering of self-reported affect by valence and subject-specific relationships between affective states and social behaviors, suggesting that real daily changes in psychological state are captured. This information provides measurement of idiosyncratic psychological profiles. One of the primary purposes of this endeavor is to serve as a proof-of-concept of intensive daily behavioral probes. We found that subjects were able to maintain a high rate of compliance, supporting the feasibility of such a paradigm moving forward. Parallel work will integrate these behavioral and psychological measures with functional MRI data on the same individuals to examine day-to-day shifts in the organization of functional brain networks in healthy individuals, as well as individuals under stress, suffering from mood disorders, and at different points across the developmental course.

Title: Deep dynamic phenotyping of the individual: Circuit dynamics underlying longitudinal fluctuations in mood and cognition in patients with bipolar disorder

Authors: *J. T. BAKER[1,2,3], R. M. HUTCHISON[4], R. M. BRAGA[4,1,3,5], J. A. NIELSEN[4,1,3], L. FARFEL[4], M. E. MAROTTA[4], N. MUELLER[2], R. J. JUELICH[2], J.-P. ONNELA[6], D. ONGUR[1,2], R. L. BUCKNER[4,1,3];

Abstract: Longitudinal studies of neural circuit changes in individuals suffering from bipolar disorder are essential to advance our understanding of this inherently unstable condition, which has typically been studied in cross-sectional cohorts comparing groups with illness to controls. Until recently, longitudinal brain imaging coupled with dense behavioral characterization was not feasible due to the high burden of scanning and phenotyping instruments that depend on office visits. Smartphones are now ubiquitous devices for behavioral data acquisition in naturalistic settings, and together with the technological refinements in accelerated brain imaging, allow for these crucial studies to proceed. Here we describe a pilot study to collect behavioral, hormonal and anatomical / functional MRI changes at a time-scale during which significant fluctuations in mood and cognition are likely to occur in individuals with severe mental illness. Allostatic and homeostatic mechanisms at play within the medial frontal cortex, hippocampus, and related limbic structures could impinge upon the anatomy and functional

architecture of these systems, allowing us to characterize biological dynamics that underlie changes in mood and cognition. In four adults with a psychotic disorder (bipolar disorder with psychosis, schizoaffective disorder or schizophrenia), a brief core battery of functional tasks was acquired on separate days simultaneously with physiological measures (heart rate, respiration, GSR) and eyetracking (pupil size, position, eye closures). Visuomotor (120s), face matching (120s), rule switching (108s), 2-back (108s), mental rotation (108s) microtasks and a passive fixation "rest" (844s spread over two runs) task were collected. Simultaneous multi-slice sequences were used (Siemens 3T Prisma, SMS=5, TE=32.6ms, TR=1.0s, vox=2.4mm). Scanning was spaced over one year (up to 15 sessions per participants), with adaptive MRI sampling to more densely capture any changes in brain anatomy or function around periods of illness fluctuation. We found that patients remained compliant with daily surveys and monthly scan protocols even during periods of low mood and motivation. Relationships between smartphone-derived metrics of mood, energy, and cognition were examined in relation to menstrual cycle, periods of exogenous stress, and changes in treatments. These studies demonstrate proof-of-concept for applying a deep dynamic phenotyping approach in individuals with severe mental illness, suggesting a powerful novel paradigm for evaluating the effects of interventions on brain structure and function, and ultimately behavior.

Title: Allelic variations in PLP1 and CNTN1 modulate interhemispheric integration

Authors: *S. OCKLENBURG[1], W. M. GERDING[1], L. ARNING[1], E. GENÇ[1], J. T. EPPLEN[1], O. GÜNTÜRKÜN[1], C. BESTE[2];
[1]Ruhr-University of Bochum, Bochum, Germany; [2]Cognitive Neurophysiol., TU Dresden, Dresden, Germany

Abstract: Objective of the study:
The corpus callosum is the largest white matter tract in the human brain. Its main function is the integration of sensory, motor and cognitive information between the two hemispheres. Interestingly, interhemispheric communication during demanding cognitive tasks shows

pronounced inter-individual variation. The molecular mechanisms underlying these differences between individuals are largely unknown. Since the speed of axonal conduction depends on both the diameter of the axon and its myelination, genes involved in myelination are likely to influence the speed of interhemispheric integration. The aim of the present study was to investigate the role of allelic variations in myelin genes on interhemispheric integration.
Materials and Methods:
Overall, 453 healthy adults were genotyped for 18 single nucleotide polymorphisms (SNPs) in six myelin-related candidate genes (PLP1, GPM6A, MOG, MBP, CNTN1 and MOBP). To understand the possible genetic impact of these myelin genes on interhemispheric integration, the Banich-Belger Task, a widely used behavioral paradigm to assess interhemispheric integration, was used.
Results:
We replicated the typical pattern of results in the Banich-Belger Task, supporting the idea that performance on cognitively demanding tasks is enhanced when cognitive processing is distributed across the two hemispheres. Moreover, allelic variations in the proteolipid protein 1 gene PLP1 and the contactin 1 gene CNTN1 correlated with the extent to which individual performance was enhanced by interhemispheric integration.
Conclusion:
The results show that allelic variations in PLP1 and CNTN1 modulate the efficacy of transcallosal transmission. Genetic variation in myelin genes possibly affects the microstructure of the corpus callosum by altering oligodendrocyte structure, in turn modulating interhemispheric integration.

Title: Deep dynamic phenotyping of the individual: Dynamics associated with stress and transitions of college life

Authors: *G. COOMBS III[1], M. P. HIND[1], J. A. NIELSEN[1,2], J.-P. ONNELA[3], R. L. BUCKNER[1,2,4];
[1]Harvard Univ., Cambridge, MA; [2]Massachusetts Gen. Hosp., Charlestown, MA; [3]Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: Many questions about behavior and brain function focus on changes over time including responses to mood states and stress. Commonly occurring transitions during adolescence, in particular when starting college, are periods of high stress and increased risk for developing mental illness. 63% of college students say daily stress significantly interferes with their work. Thus, it is important to understand how college students adapt to increased academic and social pressures, and how brain and behavioral states change over time within individuals in response to real-world stressors. Sixteen healthy college students were deeply phenotyped over the course of 7 months (1 academic semester and breaks). Participants completed a daily 40 item survey about their physical, emotional, and social experiences, including individually tailored questions about specific stress-relief behaviors (e.g., eating, exercise, etc.). Objective measures of sleep, physical activity, and sociability were measured using an actigraphy monitor and a custom smartphone research platform (Beiwe; Onnela & Rauch, 2016). Finally, participants completed a brief battery of tasks selected to probe different cognitive domains, including face perception, reward, and executive function. To understand how stress-related states affect behavior and cognitive performance, participants completed the battery before and after real-world stressors, specifically the days immediately surrounding difficult exams for a total of 12 sessions throughout the semester. Results revealed meaningful relationships between measures, such as increases in self-reported stress and time spent cramming leading up to exams. Additionally, in some subjects, increases in stress and cramming were related to both subjective and objective measures of sleep quality, as well as other behaviors. This information provides measurement of idiosyncratic psychological profiles. Parallel work will integrate these behavioral and psychological measures with functional MRI data on individuals, including those enrolled in difficult courses and incoming freshmen as they transition to college, to examine stress-related shifts in the organization of functional brain networks and their relationship to real-world behaviors. Dense longitudinal study of the individual provides a foundation to better understand brain states and network interactions that change over time in response to life transitions and environmental stressors.

Abstract: The past era of human neuroscience has focused on group-averaged data acquired from temporarily isolated or sparse samples of the brain and behavior. Mobile aspects of the human condition have been underexplored including dynamic responses to transient life stressors, illness, administered pharmacology, childbirth and unexplained variation that is characteristic of adolescence and mental illness. Research focused on the group also emphasizes methods that may miss idiosyncratic features of the individual's brain and unique path through life. In addition to leaving major areas of human neuroscience uncharted, these emphases contribute to the challenge of translating functional neuroimaging approaches into clinical tools. Recent reports from Chen R et al (2012 Cell) and Poldrack RA et al. (2015 Nat Commun) provide proof-of-concept demonstrations that human biology, neuroimaging, and behavior can be intensely tracked over extended periods in the individual. Here we expand on these pioneering efforts by constructing and demonstrating a platform to extensively study individuals over time

using a combination of low-burden neuroimaging techniques that employ 'micro-tasks' and optimized brief acquisition sequences, real-world behavior and sleep tracking using active and passive features of smartphones and wearables, measures of hormones through saliva, and daily recorded voice diaries. Data and quality control procedures from three initial studies illustrate the potential of deep dynamic phenotyping as well as reveal new challenges. New challenges include constructing numerous versions of tasks that minimize habituation effects, keeping participants engaged, monitoring safety (including monitoring effects on hearing), and maintaining data security. We were particularly surprised by the variability in arousal across MRI sessions within a participant that may have contributed to miss-estimation of trait-attributed variance in prior studies. In addition to initial results, we also illustrate the neuroinformatics tools that have been constructed to handle these data which extend from the Brain Genomics Superstruct (GSP) project (Holmes et al., 2015 Sci Data) with refactoring to accommodate thousands of data entries from a small number of participants in contrast to a small number of data entries from thousands of participants.

Title: Left-ward structural asymmetry in visual word form area favors verbal Stroop performance

Authors: ***A. VALLESI**[1], I. MAZZONETTO[2], A. BERTOLDO[2];
[1]Neurosci., [2]Dept. of Information Engin., Univ. of Padova, Padova, Italy

Abstract: The Visual Word Form Area (VWFA) is thought to integrate feed forward visual processing with top-down influences from more anterior areas, such as those responsible for phonological and semantic processing during written word recognition. Intriguingly, activity in

the left VWFA is influenced by Stroop interference. In the light of these previous findings, we tested whether structural MRI asymmetries in the whole-brain, and in particular in the VWFA, would predict inter-individual differences in combatting Stroop interference. To check for the specificity of the results, we employed both a verbal Stroop task and a spatial one. Three groups (111 healthy young adults; F=80; mean age: 23 years, all right-handed) were scanned with 3T MRI at different sites. Surface area estimation and statistical analysis were carried out on T1-weighted images using an automated surface-based method in FreeSurfer. Participants' hemispheres were registered to a symmetric template (smoothing: 15 mm FWHM) and a Laterality Index (LI) for the area of each vertex was computed for each participant. The correlation of the cortical area LI with a Stroop interference measure (RT incongruent-congruent) was assessed at each vertex by means of a general linear model with a whole-brain non-parametric cluster-based multiple comparisons correction, after adding 3 covariates coding for the different sites. The results showed that an asymmetrically more pronounced surface area on the left hemisphere in a cluster including the VWFA was significantly correlated with lower Stroop interference in the verbal task only. These results confirm and extend previous functional MRI findings, by showing a role of the VWFA for higher-level processes based on word reading, including the suppression of word reading when this is required by the task. In particular the findings show that individuals with more left-lateralized VWFA have an advantage in combatting verbal Stroop interference suggesting, on the flip side, that a bigger VWFA on the right hemisphere may be detrimental for this process.

Abstract: Numerous investigations into resting state functional MRI (fMRI) have provided converging group-level descriptions of functional brain organization at the systems levels. Recent work from our lab has revealed that functional systems defined in one highly sampled individual contain distinct topological features that deviate from the group-level systems description (Laumann et al., 2015. Neuron). We describe these features as *topological variants*. Here, we extend our investigation of individual differences in functional brain organization to a new data set of 10 highly sampled young adults for whom 5 hours of resting state fMRI were collected (see Nelson et. al.). Analyzing 9 of the subjects with sufficient high-quality data we find that topological variants are present in all individuals. Further, we demonstrate that these variants are reliably observed in each subject across ten independent 30-minute fMRI sessions. Topological variants occur commonly in certain regions of cortex, for instance near the frontal operculum and the temporo-parietal junction, and rarely occur in other regions, such as primary sensorimotor, auditory, and posterior cingulate cortex. Moreover, we show that there are stereotypic patterns of topological variants, i.e. sets of variants that tend to co-occur across individuals. However, the functional systems to which variants are assigned appear to vary across individuals, even for variants that occur in the same anatomical location. Our preliminary findings suggest that topological variants are reliable components of adult functional brain organization at the individual-level. Future work in larger groups of subjects will help determine the full distribution of topological variants across healthy individuals.

Title: Network markers of individual variability in the human functional connectome.

Authors: C. PENA[1], A. AVENA-KOENIGSBERGER[1], J. SEPULCRE[3], *O. SPORNS[2]; [2]Psychological and Brain Sci., [1]Indiana Univ., Bloomington, IN; [3]Harvard Univ., Boston, MA

Abstract: A repertoire of individually variable patterns of functional connectivity (FC) underpins a broad set of individual patterns of human behavior and cognition. However, to date most neuroimaging studies have focused on consistent patterns in group-averaged functional connectivity (FC) and related graph measures. Lately, two new avenues have appeared in the field of functional connectomics. First, several studies have examined markers of individual variability using functional connectivity. Second, a different set of studies revealed significant dynamical variations within the same session challenging the static view of functional connectivity. In the present study we used both static and dynamical functional connectivity approaches to study the individual functional connectome. We aimed for two main goals. First, we set out to determine the minimal number of brain regions required to identify individual subjects (the minimal FC fingerprint). Second, we characterized different profiles of the intra-inter network functional connectivity the fingerprints across time. Forty subjects underwent two sessions of resting fMRI separated one month apart. Using standard preprocessing steps FC was measured for each subject as the Pearson pair-wise correlation of regional time series. Each matrix was reshaped into a vector containing the individual pattern of connectivity for each session. We then assessed the similarity across session computing the similarity amongst those vectors. These analyses were conducted under a wide range of parcellations (~48-2000 nodes) as well as different voxel resolution (2-4-8 mm). Finally, we implemented a simulated annealing optimization algorithm to determine the minimal FC fingerprint in seven resting state networks. In addition to static FC analysis, a temporal characterization was performed using windowed patterns. We found that the frontoparietal network contains network markers that allow identification of individuals with 100% accuracy, with lower levels of accuracy found in other networks. We also found that this fingerprint was expressed at different levels across time. Our study could be useful for characterizing individual differences in brain networks and in future applications in personalized connectomics.

Title: When the going gets tough, the low cholinergic stop going: Cholinergic genetic variation and right prefrontal activation, signal detection, and real-world distraction

Authors: ***A. CAPLE**[1], Z. LIN[1], A. BERRY[2], R. D. BLAKELY[3], M. SARTER[1], C. LUSTIG[1]; [1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Life Sci. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Dept. of Biomed. Sci., Florida Atlantic Univ., Jupiter, FL

Abstract: Right middle/inferior frontal gyrus activation has been linked to "attentional effort", the motivated recruitment of attention and cognitive control. Parallel rodent and human studies suggest that cholinergic inputs to right PFC make a critical contribution to the increased activation seen in human fMRI studies during demands on attention (see Lustig & Sarter, in press, for a recent view). We previously reported that a genetic polymorphism thought to reduce cholinergic efficiency (Ile89Val variant of the presynaptic choline transporter gene, rs1013940) was associated with reduced right PFC activation during a perceptual-attentional challenge (Berry et al., 2015). Here we report secondary analyses more closely examining the relationship of right PFC activation and connectivity to behavior. In contrast to controls, Ile89Val participants failed to activate right PFC in response to a perceptual-attentional challenge. Moreover, in a sizable proportion of participants (30%), the right PFC not only failed to activate but activity in this region decreased below levels observed in the absence of such a challenge. For Ile89Val participants, reduced or reversed right PFC activation was associated with reduced performance, specifically an increase in false alarms and in response-time variability during correct rejections. Reduced right PFC activation during the challenge condition also correlated with self-report measures of real-world distractibility. Together, these results suggest that reduced cholinergic function and right PFC activation lead to a decrease in attentional effort in challenging conditions, and instead an increased reliance on bottom-up salience.

Title: Individual variability and connectivity dynamics in modular organization of human cortical functional networks

Authors: *M. FUKUSHIMA[1], R. F. BETZEL[2,1], Y. HE[1,3], M. A. DE REUS[4], M. P. VAN DEN HEUVEL[4], X.-N. ZUO[3], O. SPORNS[1,5];

Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [5]Indiana Univ. Network Sci. Inst., Bloomington, IN

Abstract: There is growing evidence for modules in anatomical networks of neural populations and brain regions. Modular organization is also found in functional networks, in which connectivity is defined based on statistical dependencies between neuronal or regional activities. In such functional networks derived from human functional magnetic resonance imaging, individual variability in modularity exhibits possible relationships with variations in demographics and behavioral performance. In parallel, recent studies have demonstrated that functional networks during resting state vary on a time scale of tens of seconds. However, little is known about fluctuations of modularity in time-varying networks, as well as their relation to individual variations in modularity measured over longer time scales. In the present study, we relate individual variations and dynamic fluctuations of modularity and investigate connectivity patterns during periods of high and low modularity. Data were derived from a part of the

enhanced Nathan Kline Institute-Rockland Sample (NKI: n = 80, 18-30 years) and the Human Connectome Project (HCP: n = 84, 22-35 years). Time series were averaged within each cortical region in a functional (NKI: 113 regions) and an anatomical parcellation (HCP: 114 regions). The Pearson correlation was used as a metric of functional connectivity. Time-resolved functional connectivity was estimated using a sliding-window approach. Modularity was quantified using a quality function maximized by a community detection algorithm. Periods of high and low modularity were determined based on null distributions of fluctuations in modularity amplitude. We found that individual differences in modularity across subjects persisted across multiple resting-state sessions. In subjects exhibiting high modularity over longer time scales, time-resolved functional connectivity showed highly modular network structure more frequently. Time-resolved functional networks observed during periods of high modularity exhibited greater similarity to each other, compared to periods of low modularity. The high/low modular state centroid exhibited lower/higher similarity to structural connectivity, respectively, indicating that connectivity patterns averaged within periods of low modularity more closely reflect connectivity patterns of anatomical networks. Taken together, these results suggest that (long time scale) individual variations and (short time scale) fluctuations of modularity are interrelated, wherein the dynamics of modularity emerge from fluctuations around relatively uniform to structurally-based variable connectivity patterns.

Title: Deep dynamic phenotyping of the individual: Estimating within-subject cortical thickness to 10μm precision using cluster scanning

Authors: *J. A. NIELSEN[1,2], B. R. FISCHL[2,3], R. L. BUCKNER[1,2,3];
[1]Harvard Univ., Cambridge, MA; [2]Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Most studies of human brain anatomy have identified differences and patterns across groups of individuals. They have yielded important insights into the general properties of brain morphometry, trajectories through development, and group differences. However, changes that occur within individuals throughout development have not been studied and are typically considered too small to detect (e.g., developmental changes in cortical thickness are ~40μm/yr). The primary goal of the present work is to explore a method for detecting subtle changes in brain morphometry within an individual over a short period of time. The central idea is to take advantage of the extensive scanning we have recently conducted in four individuals to examine the limits of anatomical estimation. During each of 24 sessions per participant, a T1-weighted ME-MPRAGE image was acquired (Siemens 3T Prisma, TR=2.2s, TI=1.1s, TE=1.57ms to 7.03ms, FA=7°, vox=1.2mm, FOV=230mm). The structural images were analyzed using FreeSurfer 4.5.0. Error estimates were calculated by comparing estimates from independent data sets acquired within the same individual on separate days. Estimates of brain morphometry based on individual structural images resulted in typical error terms. As examples, the mean error in cortical thickness for a region of middle frontal gyrus was ~50μm (2.0%) and in volume for the thalamus was ~160mm^3 (2.0%). However, when we implemented cluster scanning (i.e., the acquisition of multiple images over a short period of time followed by averaging the estimates), the error decreased dramatically. The error in middle frontal gyrus decreased to ~12μm (0.5%) when averaging the estimates from 12 images (~30min total scanning); the error in thalamic volume decreased to ~40mm^3 (0.5%). Global cortical thickness could be estimated with a precision of ~5μm. We believe the high level of precision results from combining three factors: (1) sampling the cortical ribbon over thousands of voxels per image, (2) minimizing anatomical blurring by acquiring brief individual acquisitions, and (3) sqrt n signal averaging afforded by combing multiple estimates. Cluster scanning may be a fruitful method for detecting subtle changes in brain anatomy within an individual. The method may be particularly useful in the context of development (e.g., thinning of the cortical sheet during adolescence) or disease (e.g., accelerated atrophy due to dementia).

Title: Unique contributions of cortical brain characteristics to fluid intelligence

Authors: *C. FRAENZ, C. SCHLUTER, P. FRIEDRICH, O. GUNTURKUN, E. GENC; Dept. of Biopsychology, Ruhr-University, Bochum, Germany

Abstract: Previous research demonstrated that variations of diverse brain characteristics like gray and white matter volume predict differences in fluid intelligence. Studies employing graph theory to analyze the brain's structural and functional network connectivity found that individuals with pronounced fluid intelligence show higher values with regard to global efficiency. It is reasonable to assume that the aforementioned brain characteristics are correlated with each other. Therefore, we used an integrative approach to identify the unique contributions from each of the different brain characteristics in predicting fluid intelligence.
We measured fluid intelligence in a sample of 120 healthy participants by conducting a non-verbal intelligence test (BOMAT). In addition to that, we used MRI, DTI and resting-state fMRI measurements to examine the following brain characteristics: gray matter volume (GMV), white matter volume (WMV), structural and functional network connectivity (NET DTI & NET REST) as indexed by global efficiency, a measure yielded by graph theory. Using multiple regression analysis, we searched for unique contributions from each of the different brain characteristics in predicting fluid intelligence.
As expected, statistical analyses showed that GMV ($r = .34$, $p < .001$), WMV ($r = .19$, $p = .03$), NET DTI ($r = .23$, $p = .01$) and NET REST ($r = .28$, $p = .002$) are significantly correlated with fluid intelligence. Importantly, we found significant correlations between GMV and all other brain characteristics as well ($r = .27$ - $.78$, $p < .01$). Therefore, we performed a multiple regression analysis with GMV, WMV, NET DTI and NET REST as the independent variables and fluid intelligence as the dependent variable. Surprisingly, only GMV and NET REST provided unique contributions to the prediction of fluid intelligence (GMV, $ß = .36$, $p = .03$; NET REST, $ß = .20$, $p = .03$; other brain characteristics, $p > .31$). The pattern remained stable when controlling for the effects of age and gender.
In the past, brain characteristics predicting fluid intelligence were investigated independently of one another. Our work features an integrative approach that highlights the important interplay of such brain characteristics. Our results show that the influence of certain brain characteristics on fluid intelligence like WMV and NET DTI is scaled down heavily when examined in

combination with other brain characteristics like GMV and NET REST. Therefore, we conclude that gray matter volume and functional connectivity play major roles in the neural composition of fluid intelligence, whereas white matter volume and structural connectivity appear to have no unique contribution.

Abstract: Until recently, functional neuroimaging research has focused almost exclusively on studies of groups, not individuals, largely because the noise properties of the blood-oxygen level dependent (BOLD) signal require large amounts of data. Thus, the majority of functional neuroimaging studies have produced functional maps of an important research construct: the

group-average brain. While we have learned a great deal about the central tendencies of human brain organization from studies of group-averaged BOLD data, knowing more about the functional network organization of individual humans will be important in considering how neuroscience can contribute to the treatment of neuropsychiatric disorders. Laumann *et al.* (2015) produced the first high-fidelity individual functional network map by analyzing many hours of resting state functional connectivity MRI (rs-fcMRI) data collected on a single individual. They validated their single subject network map by annotating it with task-based fMRI data from the same individual and by comparing it to an existing group-averaged functional network map. This work provided a proof-of-principle for functional neuroimaging in individuals. Here, we present 10 subsequent high-fidelity individual network maps (5 F) based on 5 hours of rs-fcMRI, 10 hours of task-based fMRI and 5 hours of structural MRI data, per subject. This study verified and generalized the findings reported by Laumann et al. First, we found that the functional connectivity matrix of each individual was relatively stable across scanning sessions. We also observed that the functional organization of each individual brain was significantly more complex and detail-rich than the group-average map, even in our demographically homogenous sample of 10 healthy young adults (age 24-34). Using this subject-specific approach, we were able to identify new common network pieces, obscured in group-averaged data, most likely because of their smaller size. For example, in individuals we found that small regions in bilateral frontal cortex belong to the visual network. Although the focus here is on newly discovered network pieces common to all, similar analyses using the same set of data are investigating inter-individual variants in topology (see Seitzman *et al*.).High-fidelity functional network mapping will enable us to study single individuals with rare brain lesions, disorders or cognitive skills that might hold important clues about fundamental principles of human brain organization. Repeatedly scanning individuals also points out a straightforward path towards developing sensitive and specific functional neurodiagnostics.

Title: The relationship between axon density, myelination and microstructure in the human corpus callosum

Authors: *E. GENC, C. FRAENZ, P. FRIEDRICH, C. SCHLÜTER, S. OCKLENBURG, O. GUNTURKUN;
Ruhr Univ. Bochum, Bochum, Germany

Abstract: Signals from sensory half-fields are processed separately in the two hemispheres of our brain but give rise to a coherent percept due to interhemispheric integration. Previous research indicates that functional communication between the two hemispheres is modulated by the microstructure of the corpus callosum (CC). DTI fractional anisotropy (FA) can be considered as the most commonly used measure to describe the tissue microstructure of human white matter. However, physiological factors determining this anisotropy are not fully understood. Since CC fibers are strictly oriented in the left-right direction and do not show any crossings, this structure provides an excellent opportunity to study the influence of axon density and myelination on FA.
We acquired brain images from 218 healthy participants using four different MRI protocols. A high-resolution structural image was used to determine anatomical landmarks as seed regions for fiber-tractography. Further, a DTI measurement in combination with probabilistic fiber tracking was used to precisely define twelve different CC segments interconnecting homotopic regions of visual, parietal, temporal, somatomotor and frontal areas. Average FA values were computed for each segment. In addition to this, multi-shell NODDI and GRASE protocols were used in order to examine the axon density and myelination of the respective CC segments.
Statistical analyses showed a posterior-to-anterior gradient for axon density and myelination of callosal fibers. Further, we performed PCA analyses for each of the three white matter properties and found that the FA, axon density and myelination values of all CC segments could always be grouped into three components. Visual and parietal segments highly loaded on the first component, temporal and somatomotor segments on the second component and frontal segments on the third component. Additionally, we correlated the FA, axon density and myelination values of each CC segment with each other and found a constant positive association between the three white matter properties ($r = .17 - .51$, $p < .01$). Finally, we performed multiple-regression analyses to demonstrate that the average FA value of a given CC segment can be predicted more precisely by its axon density ($ß = .29 - .48$, $p < .01$) than its myelination ($ß = .01 - .21$, $p > .07$). Our study is the first to examine the *in vivo* distribution of axon density and myelination of human callosal fibers. Importantly, we demonstrated that in a highly coherent white matter structure like the CC axon density had a stronger contribution on anisotropic diffusion than myelination.

Title: Cognitive control network global connectivity is related to the mental health of healthy individuals

Authors: *D. H. SCHULTZ, T. ITO, L. I. SOLOMYAK, R. H. CHEN, R. D. MILL, K. R. KULKARNI, M. W. COLE;
CMBN, Rutgers-Newark, Newark, NJ

Abstract: We all vary in our mental health, even among "healthy" non-diagnosed individuals. To better understand the large-scale network mechanisms underlying this variability in mental health we examined the relationship between mental health symptoms and functional connectivity patterns in cognitive control systems. The frontoparietal cognitive control system consists of flexible hubs that can regulate distributed systems depending on current goals and dysfunction in the frontoparietal network (FPN) has been identified in a variety of psychiatric disorders. Alterations in FPN connectivity may influence mental health by disrupting the ability to regulate symptoms in a goal-directed manner. This suggests that the FPN may play an important role in the promotion and maintenance of mental health. We tested the hypothesis that disruptions in FPN connectivity are related to mental health symptoms. Previous studies have found differences in activity and connectivity of brain networks between healthy controls and individuals diagnosed with psychiatric disorders. Importantly, we examined this association in a non-medicated, non-diagnosed population of young adults. We collected data from 73 young adults, with participants completing the Center for Epidemiologic Studies Depression Scale Revised (CESD-R) and a resting-state fMRI scan. Functional connectivity (FC) was calculated between a standard set of functionally defined regions throughout the brain. Global brain connectivity (GBC) was calculated as the mean of FC values for each node (excluding nodes assigned to the same functional network). We found a significant negative correlation between GBC in the FPN and depression symptoms. This suggests that decreased connectivity between the FPN and the rest of the brain is related to increased symptoms of depression. In order to determine which specific connections were influenced we first used the Human Connectome Project as a discovery dataset. We correlated depression and anxiety symptoms with rest FC and identified FPN connections to probe in our independent data. Within these FPN connections of interest we found significant negative correlations between FPN-visual and FPN-sensorimotor connections and depression symptoms. Together these results suggest that decreased global FPN

connectivity is associated with increased mental health symptoms, and specific connections between the FPN and portions of the visual and sensorimotor networks contribute to this relationship. This data supports the hypothesis that global FPN connectivity contributes to the regulation of mental health symptoms.

Title: Deep dynamic phenotyping of the individual: Exploring brain state dynamics over multiple timescales

Authors: *R. HUTCHISON, III[1,2], R. M. BRAGA[2,3,4], J. T. BAKER[5,6,3], R. L. BUCKNER[2,3,6]; [1]Neurosci., [2]Harvard Univ., Cambridge, MA; [3]Massachusetts Gen. Hosp., Boston, MA; [4]Imperial Col. London, London, United Kingdom; [5]McLean Hosp., Belmont, MA; [6]Harvard Med. Sch., Boston, MA

Abstract: Most studies of human brain function have focused on trait estimates measured at one moment in time or a few longitudinal estimates spaced across extended delays. Dynamic fluctuations over days, weeks, and months have not been well studied despite a range of behavioral effects fluctuating over these timescales. The present work focuses on in-depth, longitudinal assessment of behavioral, physiological, and brain dynamics that are tailored to the specific network topography and temporal features of an individual. A primary goal is to explore the variability of evoked activity and functional coupling that occurs on multiple time scales -

spanning minutes to months - and their relationship to physiological and behavioral measures including autonomic arousal, mood, activity levels, and sleep quality. In 4 female young adults, a brief core battery of functional tasks was acquired on separate days simultaneously with physiological measures (heart rate, respiration, GSR) and eyetracking (pupil size, position, eye closures). Visuomotor (120s), face matching (120s), rule switching (108s), 2-back (108s), mental rotation (108s) microtasks and a passive fixation rest (422s) task were collected. Scanning was spaced over four months within two dense sampling periods (each period acquired 12 sessions spread across 28 days). Stimuli were not repeated across sessions. Across all tasks, simultaneous multi-slice sequences were used (Siemens Prisma, SMS=5, TE = 32.6ms, TR=1.0s, vox=2.4mm). Task-based and functional connectivity analyses revealed both stable and unstable features of brain activity patterns at a regional and network level within a task type across sessions. Dynamic functional connectivity analysis showed unique day-to-day signatures of state expression that were related to the differences in the static maps. The variability in magnitude estimates, frequency differences in functional configuration expression, and shifts in the temporal ordering of brain patterns will be linked to ongoing passive and active data collection. The focus on dense longitudinal study of the individual may provide a foundation to better understand brain states and network interactions that change over time including fluctuations in mood, addiction, and responses to stressful life events.

Title: Deep dynamic phenotyping of the individual: mapping idiosyncratic features of network and regional architecture

Authors: *R. M. BRAGA[1,2,3], R. HUTCHISON[1], H. LIU[3,4], R. L. BUCKNER[1,3,4];
[1]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA; [2]Imperial Col. London, London, United Kingdom; [3]Athinoula A. Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: There is growing interest in mapping the detailed functional architecture of individuals for clinical purposes (e.g., presurgical planning) as well as for discovery. In particular, while group-averaged data have been a tremendous engine for discovery of broad organizational properties, between-subject blurring and dependence on central tendencies may obscure organizational details. Here we analyzed the detailed organization of within-subject data collected over many sessions. In addition to 24 core sessions that collected a limited set of functional tasks, four extended sessions were acquired for in depth localization of functional regions. These sessions included many different tasks selected to probe domains that preferentially activate distinct brain regions including: motor topography, retinotopy, sentence reading, word classification, working memory (n-back), judgments of remembering, visuomotor response, emotional face perception, theory-of-mind, social movie viewing, mental rotation, and task switching. Extensive resting-state (passive fixation) data were also available for network estimation. The resulting maps were found to be reliable estimates of each individual's task active and resting-state networks. When individual participant maps were compared with group-averaged maps of the same task contrasts, differences in functional organization were clearly observed that could not be fully explained by registration or anatomical differences. In addition, large-scale intrinsic connectivity networks were found to contain heterogeneous subregions at the individual subject level, with some group-wise canonical networks being divisible into two or more networks based on functional connectivity. One prominent example occurs at or near the posterior cingulate. These results provide insight into how an individual's functional organization differs from that derived from group-average approaches to brain mapping. Parallel ongoing work is applying these insights to understand how an individual's functional organization varies day-to-day in healthy subjects, as well as individuals under stress and suffering from mood disorders.

Title: Distinct neural network dynamics are involved in three aspects of cognitive flexibility, determined at the trial level

Authors: *K. B. STEELE[1], S. MOLHOLM[1,2], J. J. FOXE[1,2,3];
[1]Neurosci., [2]Pediatrics, Albert Einstein Col. of Med., Bronx, NY; [3]Inst. for Neuromedicine and the Dept. of Neurosci., Univ. of Rochester, Rochester, NY

Abstract: An integral aspect of cognitive control is the ability to flexibility switch our attention between competing streams of information, and to do so seamlessly. This seemingly effortless skill belies the multitude of necessary processing steps along with the many brain regions involved. This results in a small but consistent switch cost, observable as delays in response time and as extra activity in the frontoparietal network. The switch cost is influenced by the presence of distracting, incongruent stimuli and whether the current task requires the same or a different motor response to the last. We sought - using high-density electroencephalography and blind source separation - to demonstrate that individuals are differentially affected by switching, incongruency, and response-switching, and that these differences are associated with functional variations in network processing. Ten neurologically-normal adults completed four separate task-switching sessions while being recorded with a 256-electrode EEG cap. Reaction time data demonstrated that faster responders were also more accurate, indicating there may be a spectrum of network efficiency. Surprisingly, not everyone exhibited a switch cost, some only had an incongruent cost and/or response-switch cost. This indicated there may be different aspects of the neural network causing the different types of behavioral delays. Independent component analysis (ICA) pulled out the activity arising from task-responsive neural sources. Across all individuals, frontoparietal regions were the majority of regions involved, such as the superior parietal cortex, inferior parietal cortex, middle frontal gyrus, superior temporal gyrus, and cingulate cortex. Using a causal inference algorithm to estimate the Markov equivalence class, which takes into account the network's activity as a whole, we determined that task-switching activity initiates in the middle frontal gyrus and left superior parietal cortex, passes it onto cingulate cortex, right superior parietal cortex, and finishes in middle frontal again as well as precentral (i.e. motor) cortex. Overall, switch costs were more strongly associated with parietal activity while incongruent delays were more associated with bilateral insular activity whereas response-switch costs were associated with less activity in the anterior cingulate. To conclude, individuals do not all have switch costs and are predisposed to be affected by different sources of conflict. This is most likely arising from differences in the temporal dynamics of the frontoparietal regions recruited for processing.

Title: Neural entrainment to the beat: The "missing pulse" phenomenon

Authors: *E. W. LARGE[1], E. M. ZION GOLUMBIC[2], C. E. SCHROEDER[3], D. POEPPEL[4]; [1]Dept. of Psychology, Univ. of Connecticut Dept. of Psychology, Storrs Mansfield, CT; [2]Gonda Brain Res. Ctr., Bar Ilan Univ., Tel Aviv, Israel; [3]Dept. of Psychiatry, Columbia Univ. Med. Ctr., New York, NY; [4]Dept. of Psychology, New York Univ., New York, NY

Abstract: Most humans have a near-automatic inclination to tap, clap or move to the beat of music. The perception of a periodic pulse in a highly complex musical rhythm is remarkable as it requires neural abstraction of the temporal structure of the stimulus. It has been suggested that nonlinear interactions in neural networks give rise to cortical oscillations at the beat frequency, and that entrained oscillation gives rise to the percept of pulse. Here we tested this "neural resonance theory" using MEG recordings as individuals listened to rhythmic stimuli. Participants listened to 30-second long sequences of complex syncopated drum sounds designed so that they contain no energy at the pulse frequency. We analyzed the spectrum of the neural activity while listening and compared it to the spectrum of the stimuli. We found neural resonance in auditory cortex at the pulse frequency, and showed phase locking to the missing pulse, despite the fact that this frequency was absent from the stimulus itself. Moreover, the strength of this response correlated with individuals' ability to tap the pulse of these stimuli, as tested in a follow-up session. These findings demonstrate that neural activity at the pulse-frequency in auditory cortex is internally generated rather than stimulus-driven, supporting the neural resonance theory. Critically, our results suggest that neural entrainment to the pulse is a fundamental dynamical mechanism underlying musical skill.

Title: The alpha-theta-gamma (ATG) switch - a neurophysiological and conceptual perspective

Authors: *U. RIBARY[1,2], S. M. DOESBURG[1], L. M. WARD[2];
[1]Simon Fraser Univ. (SFU), Burnaby, BC, Canada; [2]Univ. of British Columbia (UBC), Vancouver, BC, Canada

Abstract: Sensory, motor and cognitive functions are associated with oscillatory changes within task-relevant cortical regions, as well as alterations in functional and effective connectivity between those regions associated with neuronal synchronization. Magnetoencephalography (MEG) and Electroencephalography (EEG) have shown that brain dynamics within and between regions often differ markedly across frequencies, and that brain rhythms often interact across widely separated frequency ranges. It has further been reported that cross-frequency interactions may play an important role in local processing within thalamus and neocortex, as well as information transfer between subcortical and cortico-cortical brain regions. Strong commonalities in rhythmic network properties have been observed across recording techniques and task demands, but strong neuroscientific theories to situate such observations within a unified framework with direct relevance to explain neuropathologies remain scarce.
A comprehensive review into the animal and human literature indicates a further thinking beyond synchrony and connectivity and the readiness for more hypothesis-driven research and modeling toward unified principles of thalamo-cortical processing. We further introduced such a possible framework: "The ATG switch" *(Doesburg et al. 2015)*. We probed this neurophysiological framework to explain how coordinated cross-frequency and interregional oscillatory cortical dynamics may underlie typical and atypical brain activation, and the formation of distributed functional ensembles supporting cortical networks underpinning sensation and cognition. We also discussed evidence that alpha-theta-gamma dynamics emerging from thalamocortical interactions may be implicated and disrupted in numerous neurological and neuropsychiatric conditions.
We present a conceptual overview of this framework as a novel plausible mechanism to integrating local and large-scale thalamocortical brain networks and discuss its alterations in clinical pathologies.

Title: Hazard rate modulates reaction time to auditory and visual stimuli with complex probabilistic structure

Authors: *M. GRABENHORST, G. MICHALAREAS, C. ABEL, V. DEHMELT, D. POEPPEL;
Neurosci., Max Planck Inst. (MPIEA), Frankfurt, Germany

Abstract: Anticipating the timing of salient events is required for successful interaction with the environment. Temporal cues embedded in visual information are encoded in two processes: representing elapsed time and calculating the probability of an event over time - a computation termed the hazard rate (HR) (Janssen and Shadlen, 2005). If such a computation is fundamental and generic, it should be visible across sensory modalities. Our experimental design is based on the rationale that knowledge of temporal stimulus probability (i.e. HR) enables allocation of sensory resources which modulates reaction time (RT). In a series of psychophysical experiments participants' RTs to auditory and visual stimuli were recorded. The temporal trial structure was the same in auditory and visual blocks and consisted of 'ready', 'set' and 'go' cues. Time between 'set' and 'go' ('go' time) was a random variable drawn from either a uni- or bimodal probability distribution (PD) which was fixed throughout a block. The HRs derived from the two PDs were not correlated with each other and were therefore hypothesized to display individual patterns of RT modulation. We found that irrespective of the presented PD, mean RT was significantly faster in auditory blocks, replicating typical findings in psychophysics (Welford, 1980). In unimodal blocks RT decreased with longer 'go' times (regression analysis). In bimodal blocks RTs were fastest for 'go' times drawn from the second mode. These findings replicate results from a similar visual task in macaque (Janssen et al 2005) and humans (Bueti et al, 2010). To analyse the relationship between HR and RT we fitted a regression model: The HR appropriate for the respective PD modulated RT in both visual and auditory conditions. This indicates that participants learned not only the timespan of possible 'go' times but also the underlying probabilistic structure encoded in the HR. Our findings suggest that the HR may be a basic computation in probability learning in both sensory modalities.

Title: Auditory rhythm entrainment relates to prediction of pitch: the role of beta oscillation

Authors: *L. J. TRAINOR, A. CHANG, K. CLAYWORTH, D. BOSNYAK;
McMaster Univ., Hamilton, ON, Canada

Abstract: Neural activity in auditory cortex predicts upcoming dynamic information prior to an event's occurrence, including predicting when (time) an event will occur and what (e.g., pitch) will occur. These predictions facilitate perceptual processing. Previous studies have shown that the induced power of beta oscillations (15 - 25 Hz) in auditory cortex reflects the characteristic of time prediction. Specifically, beta power fluctuations entrain to the rate of a presented isochronous tone sequence. However, it is unclear whether the beta oscillations only predict the timing of auditory information, or whether they also reflect predictions for the contents of auditory information, such as pitch. Our first study used rhythmic auditory oddball sequences to show that induced beta power entrainment is modulated after the presentation of an unexpected pitch change, even when the change is presented at a predicted time point. This suggests beta oscillatory activity is modulated by the prediction error for pitch in additional to entraining to rhythm. The second study employed rhythmic auditory oddball sequences with predictable versus unpredictable pitch changes (equating change probability) to show that beta oscillation is modulated by the prediction to the deviant pitch prior to its onset: (1) larger beta power entrainment depth prior to deviant pitches was found in the predictable than unpredictable case, (2) predictable deviant pitches evoked smaller P3a amplitude, a late event-related potential reflecting exogenous attentional orienting to deviance, than the unpredictable deviant pitches, and (3) trial-to-trial analyses showed that beta power entrainment depth was negatively correlated with P3a amplitude only in the predictable context. Together, our findings to date suggest that in addition to predicting when an event will occur, beta activities also reflect the prediction of what will occur.

Title: Intentional binding with sustained visual feedback: A paradigm compatible with chronometric TMS

Authors: *A. D. SHAPIRO[1], L. J. VOLZ[2,3,1], T. G. LEE[4], S. T. GRAFTON[1];
[1]Psychological and Brain Sci., [2]SAGE Ctr. for the Study of the Mind, [3]Inst. for Collaborative Biotechnologies, Univ. of California, Santa Barbara, Santa Barbara, CA; [4]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The subjective sense of agency (SoA) we experience over our actions and their consequences may support goal-directed behavior by reinforcing the causal relationship between intentions, actions, and predicted outcomes. One marker of causality is the temporal proximity of two events. On this logic, the intentional binding phenomenon, in which voluntary actions and their intended consequences are perceived as shifted towards each other in time, is thought to be an implicit measure of the SoA. Ongoing debate concerns whether the SoA is primarily a prospective phenomenon driven by predictive motor control processes or a retrospective phenomenon driven by inferences made after the perception of sensory feedback. Relevant work on the functional anatomy supporting these accounts implicates the pre-supplementary motor area (preSMA) and inferior parietal regions including the angular gyrus (AG). Yet this evidence relied on neuroimaging and offline neurostimulation methods that lack sufficient temporal resolution to inspect the interplay between these regions at sub-trial timescales. Chronometric TMS promises the appropriate specificity for such investigations. However, the audible clicks emitted by TMS discharge and targeting sensorimotor regions would confound the brief (100ms) auditory and tactile stimuli traditionally used in intentional binding. Visual stimuli have been sparsely used as sensory feedback in this paradigm and the relative effects of visual feedback, concurrent visual + auditory feedback, and feedback duration had not been explored. In Experiments 1-3 we measured intentional binding of voluntary button presses paired with sustained visual feedback (1.5-2.5s) relative to other feedback stimuli. Intentional binding with sustained visual feedback did not differ significantly from binding with brief auditory feedback (Exp 1, n=21, p=.22) or combined auditory + visual feedback (Exp 3, n=20, p=.62). However, binding was significantly diminished with brief visual feedback relative to sustained visual feedback (Exp 2, n=22, p=.01). This may be due to the flash-lag effect wherein a flashed visual stimulus appears to lag behind a moving stimulus on which it was superimposed, such as the

revolving clock hand used in this study. Taken together, Experiments 1-3 validated that sustained, but not brief, visual feedback evokes intentional binding. Ongoing research investigates the effects of chronometric TMS to preSMA and AG during time windows for predictive processing and retrospective processing during voluntary actions, allowing us to inspect the dynamic contributions of these regions to the SoA in intentional binding.

Title: Eeg and reaction time profiling in novice meditators

Authors: *S. S. JOSHI[1], A. PATEL[1], A. AGARWAL[2], B. F. O'HARA[1];
[1]Biol., Univ. of Kentucky, Lexington, KY; [2]Signal Solutions LLC, Lexington, KY

Abstract: Previous studies on meditation have found EEG spectral properties and other features suggesting that it may be a state that is distinct from sleep and wake. A number of benefits have been claimed by practitioners of meditation which have gained increasing attention over the past several decades, with an increase in the number of scientifically controlled studies in recent years. In a previous study conducted by our group, a short term performance improvement was observed on a psychomotor vigilance task (PVT) in both experienced and novice meditators after completing 40 minutes of meditation. In the PVT, mean reaction time (RT) is typically calculated based on the responses of subjects to a stimulus. In this current study, a similar experiment was conducted on a cohort of 30 subjects wherein the reaction time assessments were done before and after 20 minutes of meditation. Mean RT measurements were done using the standard PVT-192 monitor. While subjects were meditating, EEG recordings were done using Emotiv EPOC wireless EEG systems. All subjects were in the age range of 18-55 years, and were recruited at the University of Kentucky through flyers and word of mouth. In a pairwise t-test, significant improvement was seen in post meditation PVT. Based on the EEG recordings, we intend to prepare models for brain activity in novice meditators during meditation, correlating spectral power, and other EEG features, to performance measures. Data and results from multiple on-going studies will be presented.

Title: Duration adaptation improves time sensitivity

Authors: ***M. J. HAYASHI**[1,2], N. L. HOHERCHAK[1], R. B. IVRY[1];
[1]Psychology, Univ. of California, Berkeley, Berkeley, CA; [2]Grad. Sch. of Frontier Biosci., Osaka Univ., Suita, Japan

Abstract: The ability to precisely estimate time intervals is crucial in many aspects of perception and action. A recent neuroimaging study suggested that time perception may be mediated by a neural population tuned for specific durations: Regions in the right parietal cortex showed duration-specific repetition suppression (Hayashi et al., 2015 *PLoS Biology*). This hypothesis is further supported by psychophysical work showing that adaptation to a specific duration produces a negative aftereffect: Stimulus durations are over-estimated following exposure to a short adaptor and under-estimated following exposure to a long adaptor. Here, we show that adaptation to a specific duration produces, not only systematic biases in perceived durations for longer and shorter durations than the adaptor, but also improvements of sensitivity for the adapted duration. Participants were tested on two perceptual discrimination tasks. On each trial, they were presented with an auditory white noise of 500 ms (standard duration) and asked to judge if a visual stimulus of variable duration (comparison duration, 200 - 800 ms) was shorter or longer than the standard (Experiment 1) or same or different (Experiment 2). In adaptation blocks, the perceptual judgments were preceded by an adaptation period in which a visual stimulus of 500 ms duration was repeatedly presented. In baseline blocks, the adaptation period was absent. We used a cross-modal comparison (auditory standard/visual comparison) so that the effects of adaptation would be limited to the comparison stimulus. In both experiments, there was no change in the point of subjective equality. However, adaptation resulted in a steeper psychophysical function compared to the no-adaptation condition. Moreover, in the same-different judgment task (Experiment 2), adaptation condition showed a higher accuracy in judging the two stimuli as “same” when both stimuli were of 500 ms duration, suggesting that repeated exposure to a specific duration produces higher sensitivity for that duration. The

duration-specific repetition suppression found in the previous neuroimaging study may reflect sharpening tuning curves of duration tuned units rather than neural fatigue/saturation.

Title: A cerebellar role in optimal sub-second trajectory prediction

Authors: ***C. B. OWENS**[1,2], C. DE BOER[1], G. GENNARI[3,1], R. BROERSEN[4], J. PEL[1], J. VAN DER STEEN[1,5], W. CLAPP[5], B. MILLER[5], Y. VAN DER WERF[6], C. DE ZEEUW[1,4]; [1]Neurosci., Erasmus MC, Rotterdam, Netherlands; [2]Agency for Science, Technol. and Res., Singapore, Singapore; [3]Neurosci., Univ. of Padua, Padua, Italy; [4]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [5]Neuroscouting LLC, Cambridge, MA; [6]VU Univ. medical center, Amsterdam, Netherlands

Abstract: Professional athletes like soccer, tennis or baseball players possess superior perceptual, predictive and decision-making skills. However, it is unclear what neural systems play a role and to what extent they utilize both internally (endogenous) and externally (exogenous) generated temporal cues to optimize trajectory prediction of the ball. We subjected expert baseball players and controls to task conditions faced while at bat. While observing a stimulus moving vertically across a touchscreen towards a visible square target, subjects had to predict whether the ball would terminate inside the target prior to the end of its trajectory. Endogenous (fixation time) and exogenous (stimulus movement, speed, and expansion) cues were varied across all trials. Experts were more successful than controls when temporal cue conditions were most challenging. When preparatory time was short, experts allocated attentional resources more quickly, as indicated by faster pupillary responses. When stimulus speed was fast experts exhibited optimal voluntary saccadic eye movements at the early stage of the task. Under both conditions experts exhibited superior performance. Using an fMRI version of the task we found good performance was associated with a brain network consisting of sensorimotor cortex, inferior parietal lobe and cerebellum. These results indicate that 1) experts rely more heavily on endogenous alerting temporal cues than controls, 2) experts utilize externally generated cues more efficiently than controls and 3) the cerebellum is critical to optimal sub-second trajectory prediction.

Title: The effects of age & interaural delay on human cortical processing of changes in interaural correlation

Authors: ***M. WANG**, Y. YANG;
Sch. of Psychology, Beijing Normal Univ., Beijing, China

Abstract: When the listening situation is complex (e.g., when there are many people talking at the same time), older adults often complained that it's difficult to process and comprehend what a target talker is saying, even with the normal hearing. Several studies have indicated the subjective representation of the sounds delivered to the two ears of a human listener is closely associated with the interaural correlation (IAC) and interaural delay of these two-ear sounds. The age-related changes in hearing may make it more difficult for older adults to analysis IAC. This study compares the cortical processing ability of younger and older adults to processing the changes in interaural correlation, by using event-related potential technology. Here we show that participants in older group behaviorally responded slower to a change in IAC than those in younger group only at large interaural delay (6 ms). However, the response speed of older group was the same as those of younger group when the interaural delay is smaller (0 ms, 2 ms and 4 ms). We then recorded the cortical response to the interaural correlation change using event-related potentials. On the contrary, our cortical processing records showed that participates in the older group had longer P2 latency than those in the younger adults group, even with the smaller interaural delay. Accordingly, P2 amplitude of the older group was also smaller than that of the younger group. In addition, participates in the older group had larger N1 amplitude than those in the younger group. The difference between two age groups increased in proportion to the increasing of interaural delay. These results suggest that human's cortical processing of changes in IAC is affected by aging. This age-related deficit appears to be expected as temporal jitter

(loss of neural synchrony in the auditory system) increases with interaural delay. The mismatching between the behavior and cortical results implicated that the perceptual cues could help older adults to overcome this deficit to a certain extent, while the test of cortical processing could reveal the deficit much earlier and clearer.

Title: FAST: a novel, executive function-based approach to cognitive enhancement

Authors: *J. N.-F. ALMQUIST[1], S. MATHAN[1], A.-K. BREM[2], F. PLESSOW[3], J. MCKANNA[4], A. PASCUAL-LEONE[3], R. COHEN KADOSH[2], M. PAVEL[4], D. CORNHILL[1], M. DILLARD[1], D. ERDOGMUS[4], G. KIMBALL[5], K. MANSFIELD[2], E. MYERS[5], U. ORHAN[1], E. SANTARNECCHI[3], T. THOMPSON[3], N. YEUNG[2];
[1]Honeywell Labs, Honeywell Aerospace, Redmond, WA; [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Berenson-Allen Ctr. for Non-Invasive Brain Stimulation & Div. for Cog Neurology, Dept. of Neurol., Beth Israel Deaconess Med. Center, Harvard Med. Sch., Boston, MA; [4]Electrical and Computer Engin. Dept., Northeastern Univ., Boston, MA; [5]SimCoach Games, Pittsburgh, PA

Abstract: The present study introduces a novel cognitive intervention aimed at improving fluid intelligence (G*f*), based on what we call the FAST framework: Flexible, Adaptive, Synergistic Training. FAST leverages a combination of novel executive function-based training and transcranial electrical stimulation, with aims to synergistically activate and strengthen mechanisms of cognitive control critical to G*f*. The question of whether targeted training of cognitive skills can enhance G*f* is a topic of intense debate, and is one of substantial practical and theoretical importance. This study aimed to assess whether the FAST intervention could lead to enhancement of G*f*, relative to both a no-contact and an active control condition. To test our intervention we collected three G*f* measures from 113 participants (BOMAT, Raven's Advanced Progressive Matrices, and matrices similar to those in Raven's, generated by Sandia labs), prior to and following one of three interventions: (1) the FAST intervention, a combination of 30 minutes of daily training with our novel training game, Robot Factory, and 20 minutes of

concurrent transcranial random noise stimulation applied to bilateral dorsolateral prefrontal cortex, (2) an adaptively difficult active control intervention comprised of visuospatial tasks that specifically do not target G*f*, or (3) a no-contact control condition. Logistic regression analyses of performance at posttest, controlling for pretest performance and age, found that the FAST group performed significantly (vs. No-contact) or marginally better (vs. Active Control) in terms of number of items answered correctly across all three G*f* posttests, and significantly better in terms of accuracy (number of correct responses/number of items attempted) against both controls. This enhanced performance was found to be driven by significantly better performance for FAST in the BOMAT (and to a lesser extent Raven's), empirically the most difficult of our tests, indicating performance improvements from potential transfer may be most apparent on more difficult G*f* test items. A final analysis of the FAST group alone found a significant correlation between progress in Robot Factory and posttest performance, implicating the role of FAST training in G*f* enhancement.

Title: Alterations in resting state connectivity within the central executive network in HIV predict neurocognitive impairment

Authors: *R. C. MCINTOSH[1], M. HIDALGO[2], C. SHIKUMA[3], K. KILLIANPUR[4]; [2]Psychology, [1]Univ. of Miami, Coral Gables, FL; [4]Med., [3]John A. Burns Sch. of Med., Honolulu, HI

Abstract: Research suggests that HIV impacts the intrinsic connectivity of functional brain networks at rest. HIV-related deficits have also been identified within a cortico-striatal-thalamo-cortical loop that is recruited during rule-based learning, sequence learning, working memory and planning. This investigation sought to evaluate whether differences in resting-state functional connectivity between 33 HIV-positive (mean age 53.2 years) and 36 HIV-negative

adults (mean age 56.8 years) predicts global neurocognitive function using functional networks derived from independent component analysis (ICA). Resting-state fMRI data was concatenated in time across subjects to create a single 4D dataset and decomposed into 30 ICA maps using Multivariate Exploratory Linear Optimized Decomposition. ICA components were then reconstructed for each subject's 4D data to estimate subject-specific spatial maps using the dual-regression technique. A total of 15 components were identified as noise and removed. The other 15 ICA components were matched with previously established networks. Comparisons between HIV+ and HIV- controls revealed significant contrasts at the 0.01 level. Of the 15 identified components between group differences were observed in the left parietal attention network, left ventral attention network, frontal cortical network, sensory-motor network and central executive network (CEN). To evaluate whether the functional integrity of the CEN relates to global neuropsychological function time courses from seeds within the left and right prefrontal cortex, caudate body, and medial dorsal nucleus of the thalamus (MDT) was correlated with individual subject-level z-scores. Although left and right prefrontal cortex and caudate body did not correlate with global neuropsychological function, connectivity of the right MDT with the CEN was negatively associated with neurocognitive function in HIV+ individuals ($\beta = -0.43$, $p = 0.02$) while the left MDT showed a positive association for the control group ($\beta = 0.363$, $p = 0.04$). After controlling for age, CD4 count and undetectable viral load status right MDT maintained a negative correlation with global neuropsychological function in the HIV+ group ($\beta = -0.60$, $p = 0.001$). This pattern suggests lateralization of MDT recruitment within network designated for cognitive task performance. Furthermore, the absence in left MDT recruitment, as it corresponds to global neuropsychological function, suggests that HIV alters functional connectivity of the CEN. Resting-state connectivity may be a useful biomarker for disorganization of networks that contribute to HIV-associated neurocognitive dysfunction.

Abstract: Emergency medical personnel must act quickly and effectively, both as individuals and as teams. Medical training often includes high-fidelity simulations. However, trainers infer competence by observation alone—a challenging task. We designed and are validating our system to augment training by Monitoring, Extracting, and Decoding Indicators of Cognitive Workload (MEDIC). MEDIC includes: (1) a suite of unobtrusive, field-ready neurophysiological, physiological, and behavioral sensors, including a user interface (UI) for trainers to enter notes during the scenario on team metrics and when important events occur; (2) a Data Processing and Fusion Engine to process and time-align raw data originating from the sensor suite; (3) a Data Interpretation Engine to interpret the best indicators of cognitive workload and team dynamics; and (4) an after-action review UI to display interpreted human states time-aligned with pertinent events that occurred across the scenario. During this validation study, teams of three Arizona State University participants completed an obstacle course of physical and cognitive challenges including (1) memorizing word lists, (2) balancing moving balls on weighted boards, (3) assembling puzzles, (4) passing weighted medicine balls while balancing on Bosu balls, (5) completing logic problems, (6) constructing walls using boxes of different sizes and weights, and (7) jumping rope in sync with other team members. Our data processing and fusion engine de-noises, processes, and time-aligns data from all sensors, then pushes data through our data interpretation engine that uses statistical and probabilistic modeling techniques to output estimates of individual state (e.g., stress and cognitive workload) and team state (e.g., team dynamics). Our next validation is at a simulation center at Vanderbilt Medical School where we will collect data on medical residents during high-fidelity simulations. This work was supported by the U.S. Army Medical Research and Material Command under Contract No. W81XWH-14-C-0018. Title: ERP as a biomarker for tDCS neuromodulation of executive function

Authors: *L. DUBREUIL VALL[1,2,3], P. CHAU[2], G. RUFFINI[1], J. CAMPRODON[2]; [1]Neuroelectrics, Cambridge, MA; [2]Massachusetts Gen. Hosp., Charlestown, MA; [3]Univ. de Barcelona, Barcelona, Spain

Abstract: Background
Executive function is an umbrella term encompassing subdomanins such as attention, working memory and inhibitory control. Recent studies suggest that transcranial direct current stimulation (tDCS) targeting the DLPFC modulates these functions, which are disrupted across the neuropsychiatric spectrum. In the present study, we investigated the role of tDCS in modulating attention and working memory in healthy adults.
Methods
In this crossover study, 20 subjects received 3 different tDCS stimulation conditions over 3 separate visits: Sham, anodal tDCS on the right DLPFC (Anodal Right), and anodal tDCS on the left DLPFC (Anodal Left) using 3cm^2 Ag/AgCl electrodes. The return electrode (cathode) was placed in the contralateral supraorbital region. Participants performed the Flanker and MSIT-IAPS tasks before and after receiving tDCS. In addition to measuring behavioral responses, we recorded EEG and calculated the ERPs over Fz for all tasks.
Results
For the **Flanker task**, we found that Anodal Left stimulation led to a significant increase of P300 amplitudes for incongruent trials versus Sham, which led to significant amplitude decrease. P300 amplitude is associated with attention resource allocation during working memory updating; larger P300 amplitudes indicate greater attention allocation. This is consistent with the behavioral results, which show Anodal Left stimulation led to a significant improvement in reaction time (RT) and a nearly significant improvement in accuracy versus Sham, which led to a smaller increase in RT and a significant decrease in accuracy.
In the **MSIT-IAPS** task**,** the strongest finding is that Anodal Right and Left stimulation significantly increased P600 amplitude versus Sham, which did not have a significant effect. P600 is an index of synchronized operation completion after target detection, having much in common with working memory operation. This is consistent with the behavioral performance, in which Anodal Left stimulation led to a greater improvement in accuracy and RT versus Sham, which led to a smaller improvement.
Conclusions

Our results show that specific working memory and attention-related ERPs are modulated by anodal tDCS applied over DLPFC in healthy adults. This modulation is correlated with an improvement in the behavioral performance, suggesting tDCS as a possible method to improve executive function. Furthermore, the correlation between behavioral performance and ERP modulation presents these ERPs as potential biomarkers and therapeutic targets of executive function modulation.

Title: Selective attention in women victims of domestic violence

Authors: B. BEDOLLA[1], J. NUÑEZ[1], *M. M. LOPEZ-TITLA[2], D. ANGELES[3]; [1]Univ. del Valle de México, MEXICO, Mexico; [2]IMAGENES CEREBRALES, INPRFM, MEXICO, Mexico; [3]Facultad de psicología. UNAM, MEXICO, Mexico

Abstract: Domestic violence has increased in Mexico in the last years. Statistics shows that 47 percent of women (15 years old and older) have experienced some kind of violence by their partner [1]. Previous studies have found that this types of stressful events could cause an alteration in women cognitive process involving executive functions. Muriel Lezak defined these functions as the essential mental abilities to carry out an effective, creative and socially accepted behavior [4,5]. And Mateer suggests that executive functions consist on: direction of attention, pattern recognition priority, formulation of intention, plan achievement or accomplishment and implementing the plan and recognition of achievement [6]. Selective attention and cognitive flexibility are associated with the processing of emotional cues in the ventromedial circuit. The former process guide our decision making towards objectives based on social and ethical judgment[3]. To asses the selective attention performance on women victims of domestic violence we designed two Go/no Go[2] task variants in the software E-prime (version 1.1). Both tasks show several stimulus and the subject must respond to only one kind of stimulus. To discard the size and position stimulus effect, the stimulus in the first task were placed in the center of the screen and all have the same size. In the second task the stimulus changes its position on the screen and its size differs. These tasks were validated by healthy subjects without

psychiatric or psychologic history. The subjects were evaluated with the mini mental test, SCL-90R scale, Rosenberg Self Esteem Scale and the Beck Depression Scale score. The error rate for the first task is 5.10% and for the second task is 8.74% then the error rate for the first task is less than for the second. For that reason we stipulate that the position and the size of the stimulus do matter in the performance of the selective attention of the subjects.

Title: Cognitive control network flexible hub connectivity is altered across distinct mental illnesses

Authors: ***M. SPRONK**[1], A. ANTICEVIC[2], M. W. COLE[1];
[1]Rutgers Univ., Newark, NJ; [2]Yale Univ., New Haven, CT

Abstract: It has recently been suggested that flexible hubs in the human brain's cognitive control networks (CCNs) regulate other brain networks in a goal-directed manner for optimal behavioral outcomes in healthy populations, thereby promoting mental health. In line with this, behavioral and neuroimaging studies have found impaired cognitive control abilities in various mental illnesses, but the underlying neural mechanisms remain unclear. One possibility is that CCN dysfunction is related to altered brain-wide connections of flexible hub regions in CCNs (i.e. in cingulo-opercular, frontoparietal and dorsal attention networks), which could affect CCN capacity in various mental illnesses, eventually leading to impaired regulation of symptoms in clinical compared to healthy individuals. A still outstanding question is whether there are

common alterations in connectivity of CCNs regions across different mental illnesses. In this study, we therefore try to clarify the nature of cognitive control deficits in a range of mental illnesses and across the lifespan. To test the hypothesis that CCN dysfunction may be a common factor in a broad range of mental illnesses and that CCN flexible hubs exhibit comparable altered connections across various clinical populations, we used resting state functional connectivity and graph theoretical measures. More specifically, resting state fMRI data from various publicly available sources including data from subjects with different mental illnesses and age groups (such as ADHD, autism and pre-Alzheimer's disease) were analyzed, and hub-characterizing measures such as global brain connectivity and betweenness centrality were obtained to characterize network architecture of CCN regions. Using these measures we indeed found altered brain-wide connectivity of CCN regions in clinical compared to healthy control groups. Furthermore, we achieved above-chance classification of clinical subjects versus healthy controls based on resting state functional connectivity of the CCNs. These results shed new light on commonalities in the neural mechanisms of cognitive control dysfunction across a broad range of mental illnesses. Finding common factors in control system dysfunction could improve our understanding of the underlying mechanisms of mental illness and have important implications for therapeutic interventions.

Title: Brain network predictors of training-related gains in older adults after exercise intervention

Authors: *P. L. BANIQUED[1], C. L. GALLEN[1], M. W. VOSS[2], C. N. WONG[3], G. E. COOKE[3], A. Z. BURZYNSKA[4], K. DUFFY[3], J. FANNING[3], D. EHLERS[3], E. AWICK[3], E. MCAULEY[3], A. F. KRAMER[3], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA; [2]Univ. of Iowa, Iowa City, IA; [3]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [4]Colorado State Univ., Fort Collins, CO

Abstract: Recent work suggests that the brain can be conceptualized as a network comprised of groups of sub-networks or modules. The extent of modules' segregation can be quantified with a modularity metric, where networks with high modularity have dense connections within modules and sparser connections between modules. Previous work has shown that higher baseline modularity predicts greater improvements after cognitive training in patients with traumatic brain injury, and more recently, in healthy older and young adults. It is not known however, whether modularity can similarly predict cognitive outcomes after a physical exercise intervention. Here, we quantified modularity in a subset of older adults (n=127) who underwent one of the following interventions for 6 months: 1) aerobic exercise (AERO), 2) aerobic exercise plus nutritional supplement (AERO+), 3) stretching, strengthening and stability (SSS), or 4) dance instruction. After the intervention, the AERO, AERO+ and SSS groups showed gains in cardiorespiratory fitness, with larger effects in both aerobic groups compared to the SSS and dance groups. The AERO, AERO+ and SSS groups also improved in cognitive control as measured by reasoning, working memory, and task-switching tests. We derived brain networks using fMRI data from a 6-minute resting state scan collected prior to training, and computed modularity from functional connectivity matrices generated using 264 regions of interest. In the aerobic and SSS subjects that improved in physical fitness and cognitive control, higher baseline modularity was positively related to cognitive control gains, even after controlling for age, years of education, and in-scanner motion. No relationship between modularity and cognitive control gains was observed in the dance group, which did not show training-related gains in cognitive control. Since previous studies have found that the relationship between modularity and training gain is driven by lower performing individuals, we performed a median split in the aerobic and SSS groups based on baseline fluid reasoning ability. The positive relationship between modularity and cognitive control gains was evident only in the groups with lower baseline reasoning ability. These results are in line with previous studies that find that individuals with a more modular brain structure are more responsive to cognitive training. More generally, these findings suggest that the predictive power of modularity may be generalizable across interventions aimed to enhance aspects of cognition and that, especially in low-performing individuals, global network properties can capture individual differences in neuroplasticity.

Title: Binge drinking and neural oscillatory dynamics underlying response inhibition

Authors: *L. A. HOLCOMB[1], S. HUANG[1], S. M. CRUZ[1], L. C. WAGNER[1], A. ANDREWS[1], K. MARINKOVIC[1,2];
[1]Psychology, San Diego State Univ., San Diego, CA; [2]Radiology, UCSD, San Diego, CA

Abstract: Alcohol consumption in young adults is often characterized by heavy episodic, or binge drinking, which is commonly defined as heavy consumption on a single occasion and is associated with a multitude of health risks and social problems. Response inhibition refers to the ability to withhold or suppress prepotent actions and is an important component of executive functions. Previous evidence indicates that response inhibition is affected by acute intoxication as well as by long-term alcohol abuse. Furthermore, it is highly pertinent to binge drinking as impaired response inhibition predicts engaging in binge drinking and is a risk factor for developing alcohol and substance abuse. The current study was designed to investigate the neural dynamics of response inhibition as a function of binge drinking in young adults. Participants were 45 (25 women) healthy, right-handed subjects with a mean age (± st. dev) of 23.64 ± 3.57 years who were prescreened for alcohol use to determine eligibility. Binge and Control participants differed greatly in a number of drinking patterns. Binge subjects reported more binge episodes (defined as consuming 6+ for men or 5+ for women drinks within two hours), blackouts, more drinks consumed per drinking occasion, and drank on more days throughout the week than Controls. Binge subjects also reported higher anxiety, impulsivity, and depression than Control subjects. During a Go/Nogo task, participants were instructed to respond to a prepotent stimulus (80% of the time), and to occasionally withhold response (20% of the time). Scalp EEG was recorded with a 64-channel BrainVision system, and a Morlet wavelet transform for theta (4-7 Hz) frequency was applied. Results suggest that Binge participants responded impulsively to the task, as they committed marginally more premature responses (ones made too early) than Control participants. Indeed, self-reported impulsivity and drinking levels correlated positively with the inability to withhold responses in Binge participants. Theta oscillations peaked at ~350 ms after stimulus onset and were greater to NoGo trials overall. Event-related theta power was marginally reduced in the Binge participants at central and parietal scalp locations from 300-400 ms in NoGo trials. However, no group differences were seen in Go trials.

This suggests that a history of binge drinking is associated with impaired response inhibition as reflected in theta oscillations, which may further contribute to the inability to refrain from harmful levels of drinking. These results are consistent with and extend prior reports of decreased theta in chronic alcoholics and those under acute intoxication.

Title: Neurodynamics of decision making under conditions of high and low response conflict as a function of binge drinking

Authors: *S. CRUZ[1], S. HUANG[1], L. A. HOLCOMB[1], L. E. BEATON[1], N. M. FONG[1], K. MARINKOVIC[1,2];
[1]Psychology, San Diego State Univ., San Diego, CA; [2]Radiology, UCSD, San Diego, CA

Abstract: The ability to override automatic responses with new, adaptive behavior when presented with conflict is an essential function of cognitive control. Previous research has shown that cognitive control is diminished by long-term excessive drinking and during acute alcohol intoxication especially within the prefrontal network. However, despite great prevalence of high risk alcohol consumption in young adults, studies investigating the persistent neurophysiological effects of heavy alcohol consumption are still scarce. The purpose of this study was to investigate brain indices of cognitive control during a modified Stroop naming task in young adults as a function of heavy episodic (binge) drinking pattern. Forty-five (25 women) healthy, right-handed subjects (23.6 ± 3.5 yrs) were screened for their alcohol consumption habits. Twenty-two subjects reported heavy drinking patterns with 11.5 ± 8.4 binge episodes during the last six months, compared to control subjects who had 0.1 ± 0.3 binge episodes. In addition, binge participants reported more blackouts, higher levels of alcohol consumption, higher rates of anxiety, impulsivity and depressive symptoms than control participants. Subjects performed a modified Stroop naming task which elicited high and low levels of response conflict on

congruent and incongruent trials respectively. Continuous EEG signal was recorded with a 64-channel Brain Vision acquisition system and analyzed in both time- and time-frequency domains. The Stroop interference effect was reflected in lower accuracy and slower response times on incongruent trials overall. Binge participants tended to respond more impulsively as shown by higher levels of self-corrected responses. Event-related potentials (ERPs) analysis revealed a smaller N250 deflection in the binge group across all task conditions. The subsequent late positivity tended to be greater in the binge drinkers only on high conflict trials frontocentrally. Event-related theta power (4-7 Hz) was calculated with Morlet wavelets. Incongruent trials evoked the greatest theta power overall confirming that it is a good index of increased demands on cognitive control. Compared to controls, binge drinkers tended to have higher theta power on congruent trials over the frontal sites, possibly suggesting impaired flexibility in cognitive control of resource allocation in situations evoking response conflict. Taken together, these results indicate that binge drinking is associated with impairments of the prefrontal network that subserves decision making under conflict conditions. This impairment could contribute to deficits in self-control and increased drinking.

Title: Cortisol levels and inhibitory control correlated with relapse on a group of addicts in rehab treatment

Authors: ***Y. BENITEZ**[1], Y. RUVALCABA-DELGADILLO[2,3], T. MORALES-SALCEDO[2], A. AGUILAR-DELGADILLO[2], A. LARIOS-RUIZ[2], T. VILLASEÑOR-CABRERA[1], F. JAÚREGUI-HUERTA[2];
[1]Programa de Maestría en Neuropsicología, Univ. De Guadalajara, Guadalajara, Mexico; [2]Dept. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico; [3]Ctr. de Tratamiento Volver a Nacer A.C., Guadalajara, Mexico

Abstract: Addiction is a chronic disease characterized by the compulsive use of drugs. The treatments are not very effective; in fact, 60%-70% of the addicts relapse in the first year of abstinence. Stress and inhibitory control are a risk factor in both consumption and in relapse. In this investigation a group of addicts in rehab were exposed to a model of experimental stress, where the cortisol levels and the inhibitory control ability were assessed in order to correlate them with the incidence of relapse in drug consumption, once rehab treatment was concluded. The Trier Social Stress Test (TSST) was used to produce moderate stress in 60 subjects almost concluding the rehab treatment. Cortisol levels were measured before, during and after TSST, by enzyme immunoassay. In addition, interference control (an ability of the executive function inhibitory control), was evaluated with the Stroop test before and during the TSST. Once the subjects finished the rehab treatment, they were monitored during 1 year in order to register the relapse incidence. 81% of the sample was male and 19% women. The average age for those subjects was 24.6 (SD=5.022) with 11.6 (SD=3.047) years of education. The most used drugs were methamphetamines (51.5%), followed by alcohol (21.2%), cocaine (15.2%), marijuana (9.1%), and inhalants (3%). The mean term of consumption was 4.15 (SD= 3.27). Our preliminary results indicate that in one-year follow-up, incidence of relapse is up to 50%. Evaluated subjects also show differences in interference control before and after the stress stimulus. Changes in cortisol patterns were also observed through time in these subjects. Then, we believe that cortisol fluctuations and interference control may be useful tools trying to predict relapse.

Title: Validity of an online neuropsychological assessment, the NCPT

Authors: *E. CORDELL, N. NG, K. KERLAN, C. SIMONE, G. MORRISON;
Res., Lumos Labs, San Francisco, CA

Abstract: The ability to measure neuropsychological functioning across the lifespan is critical for advancing our understanding of normal, healthy aging and age-related cognitive disorders such as MCI, dementia, and Alzheimer's. The ability to measure an individual's

neuropsychological performance in an actionable and informative way remains an imperative for research studies, clinical diagnoses, and intervention monitoring. However, present day approaches for measuring cognitive performance are lengthy, expensive, and burdensome. The NeuroCognitive Performance Test (NCPT; Lumos Labs, Inc.) is a brief online battery of cognitive assessments used to measure functioning in five cognitive domains. The NCPT is being developed for use in clinical research - as an outcome measure and for screening participants for entry into research trials - and for use in a clinical setting to aid in the diagnosis of cognitive impairment and longitudinal monitoring of cognitive change over time. As with the development of any new assessment or intervention, it is imperative that novel assessments first be validated against conventional present-day evidence-based best-practices. The goal of this study was to evaluate the validity and reliability of the NeuroCognitive Performance Test (NCPT) compared to corresponding conventional pencil-and-paper neuropsychological assessments. This was a multi-site, randomized, counterbalanced study that enrolled 234 healthy adults between the ages of 20-79 (inclusive). The NCPT and conventional neuropsych assessments were conducted at both study visits. In this poster, we will report the NCPT subtests that were used, and their corresponding pencil-paper neuropsychological assessments. Our data analysis will explore the correlations between (1) the NCPT subtests and their pencil-paper correlates and (2) the NCPT total score (known as the Grand Index) and the neuropsych composite scores. Secondly, we will also report test-retest reliability of the NCPT and neuropsych assessments. We anticipate the ability to also report exploratory analyses displaying any significant age, gender, or education-level group differences.

Title: The cortical-subcortical circuit dynamics of OCD and Tourette syndrome as revealed by functional connectivity analysis of simultaneous scalp and depth EEG recordings

Authors: *R. HASHEMIYOON[1], N. PRINS[2], A. COITO[2], M. TOMESCU[2], T. SCHÜLLER[1], T. SCHÜLLER[1], E. SILDATKE[1], J. KUHN[1], V. VISSER-VANDEWALLE[1], C. MICHEL[2]; [1]Univ. Hosp. of Cologne, Cologne, Germany; [2]Univ. of Geneva, Geneva, Switzerland

Abstract: Neuropsychiatric disorders are prevalent in society. Despite the pervasiveness of these illnesses, our understanding of the biological basis of these disorders is severely limited. Two such disorders are Gilles de la Tourette syndrome (GTS) and obsessive compulsive disorder (OCD). Neither of these is well understood in terms of their etiology nor pathomechanisms; however, dysfunction in the circuits of the cortico-basal ganglia-thalamo-cortical network is a suggested source of their respective pathologies. This network regulates motor, emotional, and cognitive function. Perturbations in the balance of its functional connections arguably manifest as the cognitive, motor, and/or limbic deficits seen in GTS and OCD. It is suggested that similar circuit dysfunction underlies these disorders, accounting for their high comorbidity rate; yet, their profiles are asymmetric. In addition to ~ 100% difference in population frequency, GTS occurs with a near 80% comorbidity rate with OCD, while OCD is reported to occur at about 7% comorbidity with GTS. These variances could be pivotal to understanding the foundational mechanisms governing the two disorders. In order to explore the interplay between the subcortical nuclei and the cortex in the large scale network, we recorded from a cohort of male and female OCD and GTS patients (aged 27-55 years old) who had undergone surgery for deep brain stimulation (DBS). Electrophysiological recordings were taken simultaneously from multi-channel scalp EEG combined with externalized DBS electrodes (allowing invasive access to deep structures) bilaterally implanted in the nucleus accumbens or centromedial nucleus of the thalamus, respectively. Effective functional connectivity measures were calculated during the resting state using partial directed coherence based on Granger causality. In all patients, local circumscribed networks surrounding specific subcortical electrodes were identified as major drivers of the large-scale subcortical-cortical networks. They projected to specific electrode sites on the scalp. In turn, some scalp electrodes strongly communicated with the subcortical structures. Interestingly, while the dominant frequency in all electrodes was in the high theta/low alpha range, the subcortical and cortical electrodes had different and preferred frequencies of

communication. Our cortical-subcortical simultaneous recordings provide the platform for a deeper understanding of the temporal dynamics of whole-brain networks in humans, which includes the intimate contribution of deep structures and opens new ways of identifying neurophysiological markers of these psychiatric diseases.

Title: Exercise-induced cognitive fatigue and its brain mechanism in normobaric hypoxia: A neuroimaging study

Authors: ***G. OCHI**[1,2], K. HYODO[1,3], K. SUWABE[1], H. SOYA[1];
[1]Lab. of Exerc Biochem & Neurosci, Univ. of Tsukuba, Tsukuba-Shi, Japan; [2]Res. Fellow of Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Physical Fitness Res. Institute, Meiji Yasuda Life Fndn. of Hlth. and Welfare, Hachioji-City, Japan

Abstract: Exercise-induced fatigue consists of central fatigue, with symptoms such as a reduction of central motor command, and the peripheral fatigue, which occurs in muscles. Exercise-induced central fatigue may also lead to deteriorating cognitive function (cognitive fatigue) mediated by the prefrontal cortex, which carries out executive function, and diminished athletic performance. Although the neural mechanisms behind cognitive fatigue associated with central fatigue are still unclear, cerebral hypoxia is thought to be an important factor. We thus aimed to create an experimental model for exercise-induced cognitive fatigue using hypoxic exercise and to identify the underlying neural mechanisms using multichannel functional near-infrared spectroscopy (fNIRS). Sixteen healthy young adults (mean age 20. 7 ± 1.9 years) participated in this study. They performed a color-word Stroop task (CWST) before and 15 minutes after 10 minutes of moderate exercise (50% VO_2peak; EX) or rest (CON) under moderate hypoxic conditions (13% O_2). Cognitive performance was assessed by reaction time (RT) for the CWST. Difference in RT between incongruent and neutral trials were calculated as $RT_{interference}$ to determine executive function. fNIRS probes were put over the forehead during the

CWST and we monitored brain activity on both sides of the dorsolateral prefrontal cortex (DLPFC), which plays a crucial role in executive function. Task-related oxy-Hb concentration changes were used as indicators of brain activity. Arterial oxygen saturation (SpO_2) was monitored throughout. Results showed that SpO_2 decreased with hypoxia in EX and CON (EX: 87.9±3.3%, CON: 89.9±2.7%, N.S.). In addition, SpO_2 decreased during exercise (81.9±2.1%) and recovered to pre-exercise level after exercise. A two-way ANOVA showed significant interactions between time (pre/post) and condition (EX/CON). Post-hoc analysis revealed that exercise delayed $RT_{interference}$ and decreased task-related oxy-Hb concentration changes in the left DLPFC compared to CON. The Spearman correlation test revealed a negative correlation between $RT_{interference}$ and left DLPFC activity. These results indicate that our moderate exercise under 13% O_2 that elicits apparent hypoxia lowers task-related activities in the DLPFC and deteriorates executive function. We found for the first time that during moderate exercise under 13% O_2, resultant cerebral hypoxia associated reduced neuronal activities of the DLPFC, might be attributed to cognitive fatigue. Thus, moderate exercise under hypoxic conditions could be an experimental model for addressing the neural mechanism underlying exercise-induced central fatigue.

Title: Executive functioning in girls with posttraumatic stress disorder secondary to sexual abuse

Authors: *S. PRECIADO MERCADO, A. SANZ MARTIN;
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: Child sexual abuse is a stressing event which is commonly associated with anatomical and functional changes in prefrontal cortex, impulsive and maladaptive behaviors and psychopathology like Posttraumatic Stress Disorder (PTSD). The aim of this study was to characterize the performance in several task that asses the executive functioning in girls with PTSD secondary to child sexual abuse. Forty 12-15 years old girls were evaluated: 20 with PTSD secondary to sexual abuse (PTSD) and 20 healthy girls without abuse history or psychopathology (CO). The participants were paired according to their socioeconomic status, their IQ and scholarship. To determine the presence and intensity of PTSD, the child PTSD sympton scale (CPSS) was applied. The executive funtioning was evaluated with BANFE battery

(Flores, Ostriosky & Lozano, 2014), which is a set of test that allow to asses cognitive proceses related with anterior, orbital and dorsolateral prefrontal areas. In BANFE, the PTSD group showed compared with CO group, lower scores in all indexes (global, anterior, dorsolateral and orbital). Besides, there were significant negative correlations between the intensity of symptoms of PTSD and the BANFE indexes. These results indicate that girls with PTSD have a generalized prefrontal impariment, wich, probably is related with the history of child abuse. This prefrontal disfunction could predispose them to develop psychopathology and maladaptive behaviors.

Title: Enhancement of multitasking performance by transcranial alternating current stimulation (tACS)

Authors: *W.-Y. HSU, T. ZANTO, A. GAZZALEY;
UCSF, San Francisco, CA

Abstract: Multitasking is associated with the generation of stimulus-locked theta (4-7 Hz) oscillations arising from prefrontal cortex (PFC), and it has further been shown that transcranial direct current stimulation to PFC improves multitasking performance. However, the causal role of PFC theta oscillations in multitasking abilities has not been established. Here, we investigate if oscillatory theta stimulation via transcranial alternating current stimulation (tACS) may be used to enhance endogenous neural oscillations and improve multitasking performance. To address this, eighty healthy young adults received brief sessions of bilateral PFC theta-tACS while they were engaged in a multitasking challenge, along with the collection of electroencephalography (EEG) data. Participants were separated into four subgroups: rapid anti-phase (anti-phase tACS with a 1-min inter-session interval), slow anti-phase (anti-phase tACS with a 5-min inter-session interval), rapid in-phase (in-phase tACS with a 1-min inter-session interval), and sham (those who received sham tACS in all the sessions as control). Anti- and in-phase refers to the tACS current polarity between bilateral PFC. Importantly, the total amount of stimulation (duration and intensity) was equivalent for all of the stimulation groups. Compared to a sham control group, *only the* rapid-rate group showed enhancement of multitasking over time,

coupled with an after-effect modulation of frontal alpha (8-12 Hz) and posterior beta (13-30 Hz) activities. Across participant regression analyses indicated that those participants with the greatest improvement in multitasking performance also exhibited the greatest increases in frontal alpha and posterior beta oscillations. Interestingly, the slow-rate and in-phase groups did not generate noticeable performance improvements compared to the sham control group. These results suggest tACS effects may cumulate when presented in rapid succession with anti-phase stimulation, thus stressing the significance of delivery protocol for generating positive stimulation-effects using tACS. Moreover, these results indicate frontal theta tACS generates benefits on multitasking performance accompanied by widespread neuroplastic changes across multiple oscillatory frequencies.

Abstract: Parkinson's disease (PD) results from the degeneration of the dopaminergic neurons of the sutbstantia nigra pars reticulata. In consequence, the neuronal activity of the basal ganglia circuitry is highly modified with, in particular, an hyperactivity with increased bursts and oscillations in the subthalamic nucleus (STN). The role of these neuronal activity changes of the STN in the occurrence of clinical motor signs is still unknown. Akinesia with slowness and/or reduced amplitude of the movement is one of the cardinal parkinsonian motor signs. Recently, it has been proposed that akinesia may result from an excessive proactive inhibition of the action initiation, a cognitive process known to inhibit undesired or inappropriate prepotent responses to stimuli. Brain networks involve in this mechanism includes, at least, the supplementary motor area, the precuneus and the STN. In this study, we aim to further understand the role of the STN in this proactive inhibitory control. We recorded STN neuronal activity in 17 PD patients during (single unit recordings), and after (local field potentials recordings-LFP) surgery for deep brain stimulation, while subjects performed a cognitive task that involved the proactive inhibitory control. The increased movement initiation latency, induced by the proactive inhibitory control associated with STN neuronal activity changes (30/100 neurons change their activity). The majority of STN neurons recorded intrasurgically exhibited a tonic activity that appeared before the conditioning stimuli and correlated with task performances. STN-LFP recorded post-surgically were modulated in the alpha and beta bands during proactive inhibitory control. Our data suggest that the STN influences the proactive inhibitory control, with PD patients being maintained in an anticipated inhibition, even though the situation did not require action restraint. These data highlight the crucial role of the STN in motor control and shed light on the complex function of this structure in the motor and executive behavior in humans.

Title: A randomized controlled study examining 13 minutes of daily meditation training on attention, mood and the emotional response to acute stress

Authors: *A. C. MCHALE, J. C. BASSO, V. J. ENDE, W. A. SUZUKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Meditation is an ancient practice that stems from Buddhist and Hindu cultures. A major purpose of meditation is to focus the mind, clearing it of the propensity towards wandering or unfocused thought. The scientific literature has examined mainly three types of meditation including focused attention, open monitoring and loving kindness. Recent research assessing the capacity of meditation to change the brain has shown that meditation decreases stress, improves mood, boosts cognitive functioning, increases the brain's functional connectivity, and enhances alpha and theta power—brain states associated with relaxation. Few studies, however, have examined the effects of brief, daily meditation on cognitive functions in a randomized controlled design. To address this hole in the literature, we sought to examine whether only 13 minutes of a daily meditation practice in healthy adults could improve cognitive functioning and mood as well as the emotional response to an acute stressor. In this randomized controlled study, healthy adults (18 to 45 years of age) with little to no experience meditating underwent either 8 weeks of a daily, 13-minute meditation practice (n=16) or listened to a Radiolab podcast (control) (n=15). The meditation practice we utilized involved a simple step-by-step guide in various meditative breathing exercises and a single full-body scan. Before and after the intervention, subjects completed a battery of neuropsychological tasks as well as several self-reported mood questionnaires. At the end of the 8 weeks, subjects also completed the Trier Social Stress Test (TSST), a test combining mental arithmetic with social evaluation that served as an acute stressor. Meditation significantly enhanced attention as assessed by the Stroop Test (Time x Group: $F(1,28)=5.025$, $p=0.033$, partial $\eta 2=0.152$) and decreased anxiety as assessed by the Beck Anxiety Inventory (Time x Group: $F(1,29)=4.758$, $p=0.037$, partial $\eta 2=0.141$). Additionally, compared to controls, meditators showed a significantly diminished emotional response to an acute stressor (Time x Group: $F(3.316,92.843)=2.683$, $p=0.046$, partial $\eta 2=0.087$). These results suggest that even brief, daily meditation training in healthy adults can improve attention and mood as well as decrease emotional activation to an acute stress.

Title: A randomized controlled study examining the effects of enhancing fitness on mood and recognition memory in healthy adults

Authors: ***J. C. BASSO**[1], T. R. LEE[1], C. CROSTA[1], N. PAYNE[1], D. KADAKIA[1], R. TRIVEDI[1], T. WANG[2], W. A. SUZUKI[1];

Abstract: Chronic exercise in rodents causes a variety of plasticity-related changes in the hippocampus, a brain region integral for learning and memory. For example, voluntary wheel running increases levels of neurotrophic factors, neuronal proliferation and survival, long-term potentiation, spinogenesis, angiogenesis and gliogenesis. These changes lead to exercise-induced enhancements in spatial learning, pattern separation, and object recognition memory, as well as improvements in anxiety- and depressive-like behaviors. While many studies have examined the effects of exercise in children and the elderly, surprisingly few studies have examined the effects of chronic exercise on hippocampal-dependent learning and memory in non-aged adults. To address this gap in the literature, we conducted a randomized-controlled study to determine whether engagement in long-term aerobic exercise would result in improvements in hippocampal-dependent behaviors including cognitive functioning and mood. In healthy, previously sedentary and low-fit middle-aged adults (35-59 years of age), recognition memory, pattern separation, episodic memory, spatial navigation ability, and mood as gauged through self-reported questionnaires, were assessed before and after 3 months of indoor cycling involving both high-intensity sprints and endurance training (n=18) or video gaming (control) (n=13). Additionally, changes in cardiopulmonary fitness (VO_2 max) were captured as we hypothesized that those individuals with the greatest changes in fitness would show the largest improvements in cognition and mood. Our results parallel findings in the rodent literature. Both recognition memory as tested with the Mnemonic Similarity Task (Time X Group: $F(1,19)=7.018$, $p=0.016$, partial $\eta 2=0.270$) and general positive affect as measured with the Positive and Negative Affect Scale (Time X Group: $F(1,13)=8.370$, $p=0.013$, partial $\eta 2=0.392$) improved as a result of the exercise intervention. Additionally, those individuals who made the largest gains in cardiopulmonary fitness received the greatest benefits in terms of mood improvement ($R^2=0.686$, $p=0.005$). These results suggest that similar to rodents, chronic exercise produces improvements in both mood and behaviors associated with the hippocampus and associated structures. We hypothesize that a critical factor underlying this outcome was the high-intensity exercise regimen that might have resulted in high levels of neurogenesis in our healthy non-aged adults.

Title: A randomized controlled study comparing the effects of continuous aerobic exercise, high-intensity interval training, and walking on mood and cognition

Authors: *C. CROSTA, J. C. BASSO, M. RASKIN, P. SEHMBEY, W. A. SUZUKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Acute aerobic exercise causes significant improvements in mood and cognitive functioning. High-intensity interval training (HIIT), an exercise regimen comprised of brief bursts of vigorous aerobic exercise interspersed with low intensity recovery periods, has significant physiological advantages over continuous aerobic exercise (CAE). These advantages include significantly higher average heart rates, increased levels of circulating catecholamines, cortisol and growth hormones, increased lactate levels, and enhanced blood glucose utilization. While the enhanced cardiopulmonary benefits of HIIT are well known, it is unknown if HIIT has superior mood and cognitive benefits relative to CAE. As HIIT produces heightened physiological responses over CAE, we hypothesized that an acute bout of HIIT will also produce greater mood and cognitive enhancements over an acute bout of CAE. In this randomized controlled study, we examined whether the enhanced physical benefits of HIIT are accompanied by enhanced cognitive and mood benefits at the behavioral level. Healthy, active adults (ages 18-26) conducted a variety of mood questionnaires and neuropsychological tasks both before and after either a 44-minute session of HIIT (n=13), CAE (n=13) or walking (control) (n=15). All exercise regimens produced significant decreases in total mood disturbance as measured by the Profile of Mood States (Time: $F(1,30)=6.490$, $p=0.016$, partial $\eta2=0.178$), general negative affect as measured by the Positive and Negative Affect Scale (Time: $F(1,30)=18.429$, $p=0.000$, partial $\eta2=0.381$), and anxiety as measured by the Beck Anxiety Inventory (Time: $F(1,30)=5.446$, $p=0.027$, partial $\eta2=0.154$) as well as increases in happiness (Time: $F(1,30)=4.341$, $p=0.046$, partial $\eta2=0.126$) and empathy (Time: $F(1,30)=4.685$, $p=0.039$, partial $\eta2=0.165$) as measured by the fantasy subscale of the interpersonal reactivity index. Additionally, though state-trait anxiety decreased in all groups (Time: $F(1,30)=7.427$, $p=0.011$, partial $\eta2=0.198$), this effect differed between groups (Time X Group: $F(2,30)=4.232$, $p=0.024$, partial $\eta2=0.220$) with the walking intervention showing the strongest effect and the intensity of the workout (based on percentage of VO_2 max) positively correlating with change in state-trait anxiety score ($R^2=0.210$, $p=0.011$). These results suggest that in healthy young adults, low-intensity exercise may

be the best acute workout regimen to enhance mood. We hypothesize that this effect may be due to the fact that compared to the walking group, CAE and HIIT groups found their workout significantly more fatiguing (Subject Exercise Experience Scale; $F(2,40)=4.555$, $p=0.017$).

Title: Binge drinking is associated with reduced EEG-based indices of emotional processing and memory retrieval

Authors: ***S. HUANG**[1], L. A. HOLCOMB[1], S. M. CRUZ[1], K. MARINKOVIC[1,2];
[1]Psychology, San Diego State Univ., San Diego, CA; [2]Radiology, UCSD, San Diego, CA

Abstract: There is a considerable amount of research showing dampening effects of chronic alcohol use on emotional processing but few studies have addressed this topic in individuals with a history of binge drinking. The present study examined the processing of emotional pictures and subsequent memory retrieval as a function of binge drinking. Fifty young, healthy individuals (age = 23.5 ± 3.5 yrs, 22 males) participated in both sessions of the study. Twenty four participants reported drinking heavily with 11.4 ± 7.5 binging episodes and 4.4 ± 3.0 alcohol-induced blackouts in the last 6 months and twenty six participants were light social drinkers. The binge drinking group reported higher depression, anxiety, and impulsivity than the light drinking group. In the first session, participants rated valence of unpleasant, neutral, pleasant, and erotic pictures from the International Affective Picture System. An unexpected recognition task was administered 48 hours later. Scalp EEG was recorded from 64 channels and analyzed in time-domain as event-related potentials (ERPs) and in time-frequency domain with Morlet wavelets. Both groups gave expected ratings of emotional valence. During the rating task, erotic pictures elicited the greatest event-related theta power (4-7Hz) overall. The difference in theta power between all emotional and neutral pictures was apparent in the light drinking group and blunted in binge drinkers. Furthermore, the early differential sensitivity to negative, positive, and neutral

images in 200-300 ms was present only in light drinkers. ERP analysis indicated that erotic pictures elicited the greatest positivity within 400-650ms time window, followed by negative and positive pictures, with the smallest positivity to neutral pictures. During recognition, emotional pictures were remembered better than neutral pictures. Greater theta power was evoked by the remembered pictures as compared to forgotten pictures only for the light drinking group, consistent with theta involvement in memory processes. Similarly, ERP analysis suggested that the remembered pictures elicited higher amplitude of the positive potential in 550-800 ms, which was absent for the binge drinkers. These findings indicate that binge drinking is associated with reduced processing of emotional information and impaired memory retrieval. Even though behavioral measures did not differ between the two groups, theta oscillations were particularly sensitive to these effects in concordance with the theories suggesting that may be an index of affective processing and memory retrieval.

Title: Dynamic quantification of the subjective cost of self-control

Authors: ***C. M. RAIO**[1], P. GLIMCHER[1,2];
[1]New York Univ., New York, NY; [2]Inst. for the Interdisciplinary Study of Decision Making, New York, NY

Abstract: Emerging decision-making research suggests that choosing to forego tempting, but suboptimal, rewards in the service of achieving greater overall outcomes (i.e., exercising self-control) may be intrinsically costly to individuals. These ‘control costs’ are thought to stem from the limited cognitive resources available to support the cognitive demands of exercising self-control. However, an empirical quantification of these costs in humans has not yet been accomplished. We employ a novel decision-making task driven by economic theory to quantify idiosyncratic self-control costs in healthy individuals that are currently on a diet to lose or

maintain weight. Participants first rated a series of food items on level of health, taste and temptation. These subjective ratings allowed us to identify a high and low temptation food for each individual. Participants were asked to remain in the experiment room with the high temptation food for a period of time without eating it in order to acquire a monetary bonus. Critically, before exposure and at regular intervals after exposure, participants reported their willingness to pay (from a $10 endowment) to remove the high tempting good and replace it with the low tempting good, effectively revealing their subjective cost of exercising self-control. Bids were realized using a standard economic auction procedure (Becker-DeGroot-Marschak method) at a fixed low hazard rate. Bidding data revealed that, overall, individuals were willing to pay a monetary cost to eliminate both future and current temptation from their environment. On average, bids to remove the tempting food increased over time, suggesting that the perceived cost of exercising self-control grew the longer participants were exposed to the tempting food. We found that subjective control costs were strongly modulated by how long individuals had successfully maintained their diets. Specifically, a negative correlation emerged between the number of weeks on the diet and average bids across the session. Our results provide novel evidence that self-control costs can be numerically quantified in humans and that these costs increase as exposure to temptation (i.e., self-control duration) increases. These findings may open new avenues of research investigating how manipulating subjective self-control costs can promote more adaptive decision-making in the presence of rewards.

Title: Adaptive task representations in context-based decision making

Authors: *O. LOSITSKY[1], R. C. WILSON[2], M. SHVARTSMAN[1], J. D. COHEN[1];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Contextual information (such as location or current goal) often determines which actions are rewarding at a given moment. For instance, a sudden downpour should trigger opening an umbrella outdoors, but should elicit a different response (such as checking for fire) indoors. How do we develop action priors that are general enough to apply to novel contexts, yet specific enough to maximize reward for a given context?
Here, we investigate how context influences priors for decisions in the simplest task that can be used to study context effects, the AX-continuous performance test (AX-CPT). In this task, a cue (A or B) signals the correct response for a probe (X or Y), which appears two seconds later. An agent seeking to maximize immediate reward rate should use the cue to adapt their starting point for the decision on the probe, whenever the cue provides information about the most likely response. For example, when AX trials (e.g., requiring a left response) are more frequent than AY trials (requiring a right response), participants can respond faster on average if they prepare a left response when the A cue is presented.
To test how the cue affects the prior for the decision on the probe, we built a context-dependent drift diffusion model of behavior in this task, with different starting point and threshold parameters for A and B trials. We then varied the frequency of the probe (X/Y) given the cue (A/B) across participants. Fitting our model to experimental data showed that participants adopted cue-specific priors when the two cues were associated with sufficiently different response probabilities. In contrast, when A and B predicted sufficiently similar responses, participants adopted priors that were indistinguishable for A and B. Furthermore, the difference between the estimated A and B priors was predicted by the improvement in reward rate that could be gained by differentiating contexts.
However, for the case in which the estimated A and B priors were similar, it was not clear whether this reflected the use of a single prior or two distinct priors with similar values. To test this, we changed the frequencies of BX and BY trials mid-way through the experiment. We predicted that, for participants who started out with similar A and B response probabilities, changing the frequencies for B trials would also change their prior on A trials. In contrast, participants who started out with different responses probabilities for the two cues should not show this effect. We report evidence in favor of these predictions.
Our data suggest that humans prefer to adopt simpler, more general priors for decisions, sharing information between contexts, unless the cost in performance becomes too high.

Abstract: Increased brain activity in cognitive control circuits can shift choice behavior away from immediate and risky rewards. Motivated by this evidence, we tested whether training of working memory and executive cognitive function could influence choice behavior and brain responses. In this randomized controlled clinical trial, 128 young adults participated in 10 weeks of training with either a commercial web-based cognitive training program or web-based video games (with no working memory or adaptive training component). Pre- and post-training, participants completed cognitive assessments and functional magnetic resonance imaging (fMRI) during performance of validated decision-making tasks: delay discounting (choices between smaller rewards now vs. larger rewards in the future) and risk sensitivity (choices between larger riskier rewards vs. smaller certain rewards). Contrary to our hypothesis, we found no evidence that commercial cognitive training influences neural activity during decision-making, nor did we find effects of cognitive training on measures of delay discounting or risk sensitivity. Participants in the commercial training condition did improve with experience and practice on the specific tasks they performed during training, but this improvement did not represent growth in cognitive abilities, as participants in both conditions showed similar improvement on standardized cognitive measures over time. Though performance on the specific tasks that comprise commercial cognitive training regimens can improve with practice, commercial adaptive cognitive training in healthy young adults appears to have no generalized effects on neural activity, choice behavior, or cognition.

Title: Using cognitive biomarkers to assist human performance on attention-related tasks

Authors: ***M. D. RIEDY**;
71000 Res. and Applied Sci., SPAWAR Systems Ctr. Atlantic, North Charleston, SC

Abstract: Throughout the Navy and the other armed forces of the United States, human system operators must maintain vigilant attention across a wide variety of system interfaces. They must be constantly prepared to rapidly respond, often with life or death consequences. Importantly, the neurobiological mechanisms that support the ability to maintain focused attention have physical limits. As system operators in demanding environments approach these limits, their task performance will suffer. In order to mitigate the unavoidable negative impact of these limitations on task performance to the greatest extent possible, we must first possess a thorough understanding of the fundamental neural processes, and their related biological indicators, which underlie the maintenance of sustained focused attention. A robust population template of the

biological indicators of focused-attention and performance-related cognitive states in humans has been developed and continues to be refined by the many excellent research teams in this exciting field. This presents an opportunity to leverage this knowledge to supplement the biological limitations of system operators via the integration of computerized attention and decision-making assistance. In order to contribute to the understanding of the basic science of these processes in our own lab, we collect and analyze electroencephalography (EEG) voltage data, heart rate, eye-gaze location and duration, saccade rate, pupillometric dynamics, and other non-invasive biological measurements in the context of visual search and other attentionally-demanding behavioral tasks. Current findings are consistent with the extant literature regarding biological indicators corresponding to the cognitive states of high versus low cognitive load. As we continue to reproduce well-accepted findings in these and other paradigms, we pivot towards the utilization of the most reliable of these measures in the development of an integrated human and computer system, or brain-computer interface, which aims to ameliorate the physical limitations of sustained focused attention, as evidenced in improvements in reaction time and other performance-related parameters.

Title: Electrophysiological dissociation of learning-related uncertainty- and surprise signals

Authors: *R. BRUCKNER[1], M. R. NASSAR[2], H. R. HEEKEREN[1], B. EPPINGER[3]; [1]Biol. Psychology and Cognitive Neurosci., Freie Univ. Berlin, Berlin, Germany; [2]Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI; [3]TU Dresden, Dresden, Germany

Abstract: Adaptive behavior requires the computation of expected future outcomes. Especially in dynamic environments, newly incoming information should be used to adapt beliefs to changing environmental states (e.g., changing stock prices). Previous work suggests that human participants are capable of adjusting their learning rate (i.e., how much to learn from environmental feedback) according to the uncertainty and surprise associated with an outcome

(e.g., Nassar et al. Nat. Commun., in press). Uncertainty reflects the reliability of internal beliefs and is highest immediately after a change in the environment is detected. Surprise reflects the likelihood of a change in outcome contingencies. In this study we were interested in electrophysiological (EEG) correlates of uncertainty- and surprise driven learning. In a predictive inference task younger adults (N=31) had to infer the position of an invisible cannon to catch as many cannonballs as possible. We compared this "learning" condition with two control conditions in which participants did not have to infer the target of the cannon but either followed the visible cannon or "collected" cannonballs by following the outcomes. These control conditions allow a dissociation between learning-related activity and activity that is associated with sensory processing in the task. Behavioral data were analyzed using computational modeling and regression analyses. Consistent with earlier behavioral findings, in the learning condition, we found that participants dynamically adjusted their learning rates in response to uncertainty and surprise. In contrast, in the control conditions, subjects showed constant learning rates that were unaffected by surprise and uncertainty. Preliminary EGG analyses suggest that parietal uncertainty-related learning signals arise before outcomes are presented (~150 ms) whereas surprise is associated with a positive medial prefrontal deflection peaking at 400 ms after the presentation of outcomes. Taken together, our results suggest that electrophysiological correlates of uncertainty- and surprise-related influences on learning are temporally and spatially dissociable.

Title: Examining the role of memory retrieval in value-based decision making

Authors: *A. BAKKOUR[1], Y. H. R. KANG[2], M. N. SHADLEN[2,3,4,5], D. SHOHAMY[1,3,4];

Abstract: The speed and accuracy of many decisions conform to regularities of bounded evidence accumulation. Such models have proven successful for understanding perceptual

decisions made from dynamic sensory input, where integration of independent samples of evidence is normative. However, the same framework applies to value-based decisions that do not implicate integration. Here we test the hypothesis that the sequential character of such tasks involves the retrieval of evidence from memory. In the current study, subjects were scanned with fMRI while performing a value-based decision task, and a perceptual decision task for comparison. The value-based decision task required subjects to make a series of choices between two foods that varied in subjective value ($\Delta V=V_i - V_j$) as assessed prior to scanning. The perceptual task required subjects to discriminate the predominant color in a stochastic random dot display comprised of yellow and blue dots. Difficulty was controlled by the probability that a dot color was yellow or blue and this "color coherence" was chosen randomly on each trial. The ΔV (for value decision task) and color coherence (for the perceptual decision task) were entered as modulated regressors in the imaging analysis and we compared the magnitude of the effects of ΔV and color coherence on BOLD activity. Subjects chose the higher-value food more often and their reaction times decreased as a function of $|\Delta V|$. Similarly, subjects accurately indicated the predominant color in the color dots display more often and their reaction time decreased as a function of the color difficulty. Thus, behavior indicated a good match between the value-based and perceptual decision tasks. FMRI data revealed that the two kinds of decisions, when evaluated separately, were associated with activity in distinct brain regions. Specifically, for value-based decisions, modulation of whole-brain BOLD by $|\Delta V|$ revealed activation in cingulate cortex. By contrast, modulation of whole-brain BOLD by color coherence during perceptual decisions was associated with BOLD activity in lateral parietal cortex. Interestingly, a direct contrast of the two tasks revealed greater BOLD activity in an ROI in the hippocampus, a region known for its role in memory retrieval. This result indicates that the relationship between ΔV and BOLD in the hippocampus during food choice was stronger than the relationship between color coherence and BOLD during perceptual decisions. Value-based decisions were associated with greater hippocampal activity, supporting the hypothesis that memory-related brain regions contribute more to value-based than perceptual decisions.

Title: Caloric primary rewards decrease temporal persistence

Authors: *B. J. FUNG[1], S. BODE[1], C. MURAWSKI[2];
[1]Sch. of Psychological Sci., [2]Dept. of Finance, The Univ. of Melbourne, Melbourne, Australia

Abstract: Intertemporal decisions often involve a tradeoff between delayed rewards and the opportunity costs associated with waiting for those rewards. Thus, optimal intertemporal decision making critically relies on the accurate representation of these temporal opportunity costs. Previous research has suggested that differences in physiological state (e.g. the consumption of caloric rewards) can influence time perception, which may, in turn, alter subjective temporal opportunity costs. Similarly, the energy budget rule in risk-sensitive foraging theory predicts that positive energy balance will result in aversion to uncertain delays. In this study, we investigated whether the consumption of caloric primary rewards could alter subjective temporal opportunity costs and temporal persistence during reward-seeking.

Fifty fasted participants engaged in a temporal persistence task, during which they received either a caloric drink (aspartame and maltodextrin), or water. In this paradigm, participants waited for a large monetary reward (15 cents) delivered at an uncertain time, but at any time could quit waiting in favour of a smaller monetary reward (1 cent). After either reward was received, this process repeated until a 5 minute block elapsed. Thus, this task constituted a reward-maximization problem, akin to foraging. In each block of the task, delivery times of the larger monetary reward were drawn from either a uniform distribution, or a heavy-tailed distribution, which had a higher maximum reward rate. We used survival analysis to estimate participants' probability of quitting conditional on which distribution the delays were drawn from, and conditional on which liquid they consumed.

We found that participants had a higher probability of quitting when rewards were drawn from the distribution with the higher reward rate. This replicates previous findings (McGuire, & Kable, 2012), and suggests that individuals' estimates of opportunity cost are influenced by the reward rate of the environment. Furthermore, we found that participants who consumed the caloric drink had a higher probability of quitting than those who consumed water. This suggests that caloric primary rewards alter perceived temporal opportunity costs and affect temporal persistence, in accordance with the energy budget rule. Our results suggest that both higher monetary reward rates and physiologically relevant rewards can increase impulsive behaviour. This may be especially relevant for disorders such as binge eating disorder, as well as for intertemporal choices in general.

Title: The cost of aggression: predicting behavior using a value-based discounting model

Authors: *H. M. DORFMAN, E. H. PATZELT, M. PRATER-FAHEY, J. BUCKHOLTZ; Harvard Univ., Cambridge, MA

Abstract: Traditional models of aggressive behavior often focus on failures in response inhibition. However, this framework cannot account for instances of instrumental aggression. Inspired by economic models of intertemporal discounting, and previous work in moral decision-making (Shenhav & Greene, 2010; Crockett, et al., 2014), we hypothesized that, given the choice between two rewards, subjects would discount the value of the larger reward choice if it involved an aggressive action, and that individual variability in the willingness to aggress would be driven by differences in how strongly subjects weigh the intrinsic cost of harming another person. We tested this hypothesis in a sample of all-male community volunteers using a noel behavioral paradigm. We found large interindividual variability in the willingness to aggress. Using a formal computational model, we found that individual variability is in fact well-fit by a scaling parameter in a modified hyperbolic discounting model, and that the variance accounted for by the free parameter in the model is significantly correlated with self-report measures of aggression and psychopathy.

Title: Temporal discounting as an individualized computational marker of treatment trajectory for opioid use disorder

Authors: *S. LOPEZ-GUZMAN[1], A. B. KONOVA[1], A. A. URMANCHE[1], J. B. DENNISON[1], S. ROSS[2,3], K. LOUIE[1], J. ROTROSEN[2], P. W. GLIMCHER[1,4];

Abstract: Objective: Temporal discounting (TD), or the tendency to forfeit future larger rewards in favor of sooner smaller ones, is an increasingly widespread proxy measure of impulsivity in studies of substance use disorder. By employing this model-based approach, we derive a parameter - the discount rate (DR) - that encompasses the degree to which a reward loses its value as a function of time for each individual. Previous studies have indicated that patients with opioid use disorder (OUD) exhibit higher DRs compared to controls and that patients' DRs decrease during briefly measured treatment periods. However, this change in TD has not been successfully linked to the main objective of treatment, a reduction in opioid use towards abstinence. The utility of DRs as a predictor of relevant clinical outcomes in OUD thus remains a pressing open question: Does it predict relapse or recovery? We sought to address this by conducting a longitudinal within-subjects study with repeated measures of DRs in a cohort of patients starting treatment for mild to severe OUD when compared to matched community controls.
Methods: Repeated measures of DRs were performed on a cohort of thirty patients with OUD starting treatment consisting of pharmacological maintenance and psychosocial intervention for a period of up to seven months. We also collected repeated DRs in a group of forty matched controls from the same community. In the TD task participants were asked to choose between an immediate monetary reward ($2, $5 or $15) and a larger reward that came with a delay (ranging from $7 to $66 and from 4 to 150 days). At the end of each session, one of the trials was randomly selected for realization. In our OUD cohort, subjects' drug use was assessed on every session by self-report, urine toxicology results, length of abstinence and adherence to their treatment plan.
Results and conclusions: As previously reported, OUD patients have significantly higher DRs compared to community controls. We also found that both groups were steeper discounters than the traditional college student sample. Our results indicate that in OUD patients DRs are a dynamic function of time in treatment. Interestingly, DRs also correlate with relapse events, peaking when these occur. We conclude that TD, when assessed repeatedly over the course of treatment, could be used as a behavioral signature of a patient's treatment success and potentially serve as a useful predictor of prognosis and treatment adherence for OUD. Current and future efforts include increasing our sample size and extending the finding of the correlation between clinical state and TD to the investigation of the neural substrate of change in TD with treatment in OUD.

Title: The effect of acute pain on risky and intertemporal choice

Authors: ***L. KOPPEL**, D. ANDERSSON, I. MORRISON, D. VÄSTFJÄLL, G. TINGHÖG; Linkoping Univ., Linkoeping, Sweden

Abstract: Pain is a highly salient and attention-demanding experience that motivates people to act. We investigated the effect of pain on decision making by delivering acute thermal pain to participants' forearm while they made risky and intertemporal choices involving money. Participants (n = 107) were more risk seeking under pain than in a no-pain control condition when decisions involved monetary gains but not when they involved equivalent monetary losses. Pain also resulted in greater preference for immediate (smaller) over future (larger) monetary rewards. These findings reflect a motivation to offset the aversive, pain-induced state, where monetary rewards become more appealing under pain than under no pain and when delivered sooner rather than later.

Title: Stress exposure decreases cooperative behavior

Authors: ***B. LU**[1], C. M. RAIO[1], M. GRUBB[2], G. S. SHIELDS[3], G. M. SLAVICH[4], P. GLIMCHER[1,5];

Abstract: Although stress exposure is an inevitable part of daily life where decisions that involve risk and uncertainty are often made, reports of stress effects on decisions about uncertainty are equivocal across the literature. Research examining stress effects on these decisions have primarily focused on choices for which outcome probabilities are explicitly known (i.e., risk). However, decisions are often made when the probabilities of different outcomes are unknown (i.e., ambiguity). Here, we used a standard experimental economic paradigm that dissociates attitudes toward risk and ambiguity to assess how both acute and lifetime stress exposure affects economic decisions regarding uncertainty. Thirty-one healthy individuals first completed the decision-making task to characterize attitudes toward risk and ambiguity under non-stressful conditions. Self-reported state anxiety levels were collected using the State Anxiety Inventory before the choice task, and lifetime stress exposure levels was measured using the Stress and Adversity Inventory (STRAIN), a detailed inventory of encountered stressful life events, after the choice task. A week later individuals returned and were randomly assigned to repeat the decision-making task in the presence or absence of acute stress (cold-pressor or matched control task). Saliva was collected throughout each session to assay neuroendocrine markers of stress responses—namely, cortisol and alpha-amylase. Individuals' choice behavior—as measured by the proportion of risky or ambiguous lotteries selected during the choice task—did not change across sessions for either the stress or control condition. Further, choice behavior did not differ between conditions after stress responses were manipulated during session 2, suggesting that exposure to acute stress alone did not influence participants' attitudes toward risk or ambiguity. However, the STRAIN data revealed a negative correlation between two main indices of lifetime stress exposure (i.e., total count and severity of lifetime stressors experienced), and the proportion of ambiguous lotteries selected, indicating

that higher levels of lifetime stress exposure were related to a lower willingness to accept ambiguous lottery offers. A similar association emerged between state anxiety and the proportion of accepted ambiguous lotteries. These effects were selective to decisions about ambiguity, as neither state anxiety nor life adversity was related to risky lottery choices. These findings suggest that higher states of anxiety as well as lifetime stress exposure may confer a lower tolerance for unknown outcomes during economic decision-making.

Title: Emotional and symbolic trust priors differently modulate the reward prediction error signal during trust game.

Authors: ***M. HARUNO**[1], C. FRITH[2];
[1]Natl. Inst. of Information and Communication Technol., Osaka, Japan; [2]Wellcome Trust Ctr. for Neuroimaging, London, United Kingdom

Abstract: Previous human imaging studies demonstrated that reward prediction signal also plays a critical role in establishing human cooperation as in other simpler decision making tasks. However, it remains unexplored how different sources of prior information about partner's trustworthiness affect the reward prediction error signal. Here, to address this issue, we conducted functional magnetic resonance imaging (fMRI) experiments of a trust game (n=28), where in each round, a participant as an investor repeatedly (8 trials) selected to keep or share 20 yen with a trustee (who is a computer agent but instructed as a human) and observed whether the trustee returned the courtesy. The participants were instructed to optimize their behavior by trial and error. Importantly, in each of four sessions, different prior information about trustee's trustworthiness was provided at the beginning: (1) no prior, (2) facial expression prior (Oosterhof and Todorov 2008) (3) symbolic prior representing trustee's social value orientation (Haruno and Frith 2010) and (4) both facial and symbolic priors. In each session, participants played the trust

game against 16 trustees (8: 80% return, 8: 20 % return, and priors were correct for 80% of trustees) and the order of the sessions was counterbalanced across participants. We analyzed behavioral data by a standard reinforcement learning model and used the estimated reward prediction error as a regressor for fMRI analysis (at the timing of feedback, SPM12). We found that activity in the ventral striatum and ventral ACC was correlated with reward prediction error ($p < 0.05$ small volume correction) in the no prior session (i.e., (1)), and no reward prediction error signal when symbolic prior was provided (i.e., ((3) and (4)). However, when only facial expression prior was provided, we found stronger reward prediction error activity ($p < 0.05$ small volume correction) in the ventral striatum and ventral ACC than the no prior case. These results demonstrates that emotional and symbolic trust priors modulate reward prediction error signal in the brain in an opposite way, and may suggest the existence of the hierarchical brain system that determines the reliability on the reward prediction error based on the characteristics of available prior information.

Title: Neural mechanisms and computation that mediates value by others' reward for decision making

Authors: *H. FUKUDA[1], N. MA[1], S. SUZUKI[2], N. HARASAWA[1], K. UENO[1], J. L. GARDNER[3], N. ICHINOHE[4], M. HARUNO[5], K. CHENG[1], H. NAKAHARA[1];

Abstract: Our decisions are often guided by one's own reward, but in social setting, also frequently modified by others' reward. Although well known as behavior, little is known about the underlying neural computations: how others' reward takes part in the process of one's own value-based decision-making and what the neural mechanisms are. For a definite examination of these issues, we devised a novel experimental paradigm that allows us a quantitative assessment under value-based decision-making framework and then combined human fMRI with

computational modeling. Our task was composed of three types of trials (standard, other, and bonus). In standard trials, the subjects performed usual value-based decisions between two options, each of which is associated with probabilistic reward outcome. In other and bonus trials, extra reward to others and the self was attached to either of options so that subjects should consider both standard value and extra value in their decision-making. This setting allowed us to quantify the value of others' reward, in comparison to that of bonus, comparing their relative effect on the choice behavior. Using logistic regression in the behavior, we quantified each value (standard, others', and bonus value) and decision value (final value difference between the options including extra values). We found that others' reward modified the decisions, although the effect is weaker than that by bonus in the same face amount. These quantifications also enabled us to analyze BOLD signal to identify neural correlates for each value and decision value. For the brain signal, we found that both others' and bonus value had significant activations in the dorsolateral prefrontal cortices (dlPFC), whereas only others' value had that in the right temporoparietal junction (rTPJ). Both standard value and decision value had significant activations in the ventromedial prefrontal cortex (vmPFC). Our psychophysical interaction analyses further indicated others' value encoded uniquely in rTPJ is processed in dlPFC and then finally integrated in vmPFC for final decisions. Moreover, we are now investigating the neural correlates that have significant contribution to making decisions in favor of others' reward versus self reward gain in our task, in relation to the individual social value orientation. These together show the neural underpinning for how others' reward take part in the neural processing for self value-based decisions.

Abstract: Humans often make decisions, following reward expectation or value. In social life, however, reward expectation often depends on the behavior of another person. In other words, such social decision-making often involves predicting others' mind and construct the prediction-based value, leading to decisions. However, little is known for neurocomputational mechanisms of combining the prediction of others and making decisions using the prediction-based value. We addressed this question by devising a novel behavioral paradigm and using human fMRI in combination with computational-modeling-based analysis. The basic form of our experiment is to do value-based decision making or choose one of two options for probabilistic reward gain. There are three types of trials, main, self and other. Main trials required the subject to decide based on the prediction of others' decisions, in which the subject chooses for oneself, but each option's value varies upon others behavior (others' decisions in their own choices). Self and other trials examined each component in the main trials; subject performed ordinary, one's own value-based decisions (self trial) or plainly predicted others' decisions (other trial). Using these trial types, we aim to construct the computational model of value-based decision-making with the prediction. In behavior, the subject decisions followed the respective value difference, self-value difference in self trial and predicted-others' value difference in other trial. In main trials, the decisions were captured by three types of value difference: predicted-others' value difference for predicting others and further, based on the prediction, two possible self-value differences, wherein one and the other can be major and minor as accounting the subject's decision and their relative contribution varies dependent on the difficulty of predicting the other in each trial. These results were further confirmed by computational models' fit. We are currently collecting and analyzing human fMRI data. Using model-based analysis, in self and other trials, we got significant activations in valuation and social brain networks, such as vmPFC and right TPJ. In main trials, our preliminary results showed differential neural processing of these key value differences, dependent upon their functions and cognitive demands. For instance, we found that the neural processing of the self-value difference being major and minor is different, depends on how difficult to predict others. These together indicate the hierarchical computational mechanisms from predicting to account for others' mind to making self-decisions.

Title: The social influence on explore-exploit decisions

Authors: *H. SADEGHIYEH[1], S. WANG[2], R. C. WILSON[2];
[2]Psychology, [1]Univ. of Arizona, Tucson, AZ

Abstract: The explore-exploit dilemma is a common behavioral dilemma that arises any time we must choose between exploring unknown options for information and exploiting known options for reward. For example, when ordering dinner at a favorite restaurant, do you explore a new item on the menu, or do you exploit the pizza you usually get? While much work has looked at how humans and animals make explore-exploit decisions in isolation, real world explore-exploit decisions are often made in social situations, and whether other people explore or exploit may influence our own choice. Thus, if a table-mate orders the pizza first, you may be more likely to order something else instead. In this work we investigated the effect of social information on explore-exploit decisions in the lab using a social version of our previously published Horizon Task (Wilson et al. JEP:G 2014). In this task, subjects made a series of decisions between two one-armed bandits that paid out rewards from different Gaussian distributions whose means were initially unknown. To give participants some information about the relative value, at the start of each game, participants saw four examples draws from the bandits (either 2 plays from both, or 3 from one and 1 from the other). We also showed them social information in the form of choices that (we led them to believe) were made by another person faced with the same game. Given this social information there are three ways for subjects to behave: to copy what the other person did (herding), to do the opposite (diversification), or to ignore the other person's response completely. Using a model we quantified the strength of these social effects as the *social bonus*, an extra piece of value given to the other person's choice. By computing the social bonus in a number of different conditions we found it to depend crucially on the interaction of two factors: the number of choices that subjects would make in the future (the horizon) and whether the outcome of the other person's choice would ultimately be revealed. When the other person's outcome would remain hidden, subjects had a higher social bonus in long horizon than short one (more herding) that may reflect the fact that making the right choice is harder in long horizon. When the other person's outcome would be revealed, subjects had a more negative social bonus in long horizon than short one (more diversification) which means that subjects preferred to get more information by choosing the opposite option when there were future opportunities to use them. These findings, suggest that people use social information in nontrivial ways to facilitate explore-exploit decisions.

Title: Event-related potentials associated to differential processing of healthy and unhealthy food in children

Authors: M. DOMÍNGUEZ-MARÍN[1], T. V. ROMÁN-LÓPEZ[2], J. A. FRANCO-RODRÍGUEZ[2], P. I. CLAVEL-PÉREZ[2], M. MÉNDEZ-DÍAZ[1], A. E. RUIZ-CONTRERAS[2], *O. PROSPERO-GARCIA[1];

Abstract: Children aged 11-12 are developing skills in making decisions. One health problem worldwide is that food industry advertising that targets children has been related to the increase of childhood obesity. In this sense, it is important to know if children are able to detect differences between healthy and unhealthy food, and if they are more likely to modify their decision making of buying when a promotion is available. Healthy children between 11 to 12 years-old participated in this study. Participants solved two main tasks. In one task, subjects had to decide if they buy a dish of healthy or of unhealthy food. In 50% of trials, a promotional article was presented above the dish and 50% of trials, a non-promotional stimulus was displayed. In the second task, subjects observed the same stimuli presented in the first task, but only the non-promotional stimulus was shown, and they had to decide if the dish displayed was healthy or unhealthy. Children decided to buy more frequently than not to buy. Also, unhealthy food was more preferred to buy than not to buy. Promotion had an effect in some subjects who augmented their decision making to buy when a promotion stimulus was available, and this increase was larger for unhealthy than for healthy food. For the discrimination task between healthy and unhealthy food, larger reaction times were observed for unhealthy, but no differences were observed in percentage of correct responses. Also, a larger amplitude of N400

at frontal sites was observed for unhealthy than for healthy food. These results suggest that children are able to discriminate the energetic density of food and some of the children are vulnerable to promotion to buy more frequently unhealthy food. This study was conducted with the support of the following grants: DGAPA PAPIIT IN219516, IN218316, IA207416 to AERC, OPG & MMD, respectively.

Title: Information integration in complex decision problems

Authors: ***E. ELDAR**[1,2], G. BAE[1,2], Z. KURTH-NELSON[1,2], P. DAYAN[3], R. J. DOLAN[1,2]; [1]Wellcome Trust Ctr. for Neuroimaging, [2]Max Planck UCL Ctr. for Computat. Psychiatry and Ageing Res., [3]Gatsby Computat. Neurosci. Unit, UCL, London, United Kingdom

Abstract: Making decisions often entails integrating multiple pieces of information. One way to achieve that is to consider each piece of information in turn. However, this strategy will produce poor results when many pieces of information are available and time is limited. In such circumstances, using the potentially faster strategy of processing multiple pieces of information in parallel is likely to be superior. We hypothesized that these two integration strategies would appear as distinct dynamical signatures in the rapid evolution of stimulus representations during deliberation. We recorded magnetoencephalography (MEG) from 38 participants in a novel behavioral task where, on each trial, participants were shown their 'team', comprising four types of 'players' in varying numbers., Participants' task was to predict how many goals this team would score, based on the previously-learned scoring ability of each player type. Across trials, we independently manipulated problem complexity (the number of players and player types in a given team) and time limit (participants had either 1 or 2 seconds to form their prediction). Overall, participants provided more accurate predictions for less complex problems, and when under less time pressure. However, the effect of time on performance was absent in both the simplest and most complex problems. This suggests that for the most complex problems, participants adopted an information integration strategy that was less sensitive to time constraints, for instance, by considering all players simultaneously. In MEG, team compositions

could be decoded during the visual presentation of the team. Decoding was most successful in low complexity problems and primarily reflected the players that were most relevant to forming a decision (i.e., those that score the most goals). Intriguingly, we also found sustained decoding of team composition during the 1-2 s deliberation period when the team was not overtly visible, potentially reflecting a deliberation process. Modeling the relationships between these neural and behavioral data can shed new light on strategies for information integration under time constraints.

Title: Sprint to the finish: how effort and time interact in movement decisions

Authors: *C. M. HEALY, A. A. AHMED;
Univ. of Colorado, Boulder, CO

Abstract: When asked to walk a mile, would you rather walk up a hill at the beginning of the mile, or near the end? Changing the time higher effort is required may determine which route you prefer. Given that all routes have the same metabolic cost and completion time, will the timing of effort change your preference? Here, we sought to clarify the role of time with respect to effort by comparing subjective preferences across equal objective utilities. If effort does interact with time, then an individual would care about when they invested a given amount of effort. Subjects completed 2 sessions (A and B) composed of a *Familiarization Task* and a *Choice Task*. In each session, subjects generated 14 effort profiles by isometrically pushing against a force transducer. Session A included effort profiles with brief periods of high effort ("hills"), while Session B included effort profiles with brief periods of low effort ("valleys"). During the *Familiarization Task*, subjects sat in front of a computer monitor and were asked to trace each profile with a cursor on the screen. The cursor moved horizontally at a fixed rate, while subjects controlled the vertical position with their pushing force. All profiles were 17 seconds in duration and normalized to each subject's maximum force exerted. Subjects then completed a series of two-alternative forced choices, in which they chose between pairs of effort

profiles experienced previously. Each of the combinations were presented 5 times distributed randomly (455 total). Subjects were asked to choose the profile which they felt was least effortful. In 10% of the trials, subjects had to execute the chosen effort profile. Subject choices for both sessions were fit to time-sensitive and time-neutral models, using different effort metrics (force, rate of force, or a combination) by maximizing the log-likelihood of the model representing the data. Initial results (n=12) suggest that subjects have a strong preference for shorter durations of high effort and have a temporal preference for when high force and changes in force occur within a movement. Nine of 12 subjects showed a preference for the time-sensitive model (3 procrastinator, 6 precrastinator) over the time-neutral model. Six of these 9 subjects' data were better represented by a model that included both force and rate of force. These results suggest that the utility of effort is indeed time-sensitive, with subjects exhibiting idiosyncratic temporal preferences. Additionally, a utility function which includes the integral of force and rate of force can better explain subject preference than force alone.

Title: High-resolution imaging of the basal ganglia in rapid choice behavior

Authors: *M. MULDER[1], J. SCHOUTEN[2], M. KEUKEN[1], B. HOMMEL[2], B. U. FORSTMANN[1,2];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Leiden Univ., Leiden, Netherlands

Abstract: In our daily lives we are often confronted with situations in which we have to decide quickly. However, deciding too fast might result in incorrect choices. As such, it is important to find a balance between the speed of our choices and the risk of making an incorrect choice. Typically, the balance between the speed and accuracy of fast (two alternative) choices can be quantified by using accumulation-to-bound models, like the diffusion-decision model (DDM). According to the DDM, the decision process is described as an accumulation of sensory evidence toward a decision threshold. It is assumed that, when speeded choices are required, people select a lower decision threshold that results in faster choices, at the cost of more errors. Imaging studies have shown that nuclei of the basal ganglia (BG) play a role in the selection of the appropriate decision threshold to the demands of the environment (Forstmann et al., 2008). However, in addition to a threshold adaptation, effects of speed-stress on non-decision processes

(e.g., motor preparation) are reported as well (e.g. Rinkenauer et al., 2004). Up until now, this change in the non-decision time has been ignored, since the non-decision time is rather unspecified. Whether nuclei of the BG play a role in changes in non-decision time is unclear.In this study participants (n=20) were asked to perform a perceptual choice paradigm while they underwent high-resolution (7T) functional magnetic resonance imaging (fMRI). During the task, participants were cued to respond either fast or accurate. Modeling the behavioral data with the DDM showed that the best fitting model included changes in both the threshold and non-decision time parameter. To investigate the role of the BG, we selected five regions of interest: striatum, globus pallidus interna/externa, subthalamic nucleus and the substantia nigra.These ROIs were segmented using the individual high-resolution anatomical image. Next, we determined the shape of the hemodynamic response function (HRF) for each participant and ROI separately. These HRFs were used to estimate the BOLD response during task instructions. Additionally, we investigated the relationship between changes in BOLD response and changes in the decision threshold and non-decision time parameters. The results show that activation in different nuclei of the BG seem to drive adaptations of both the decision threshold and non-decision time effects, giving rise to the individual differences in rapid choice behavior. This might indicate that, in addition to a threshold selection, effects of speed instructions on (pre) motor responses can occur even before or after the decision process.

Title: A bias-variance trade-off that governs individual variability in learning and decision-making.

Authors: ***C. M. GLAZE**[1], J. W. KABLE[2], J. I. GOLD[1];
[1]Neurosci., [2]Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Humans often make variable decisions when presented repeatedly with the same stimuli. This trial-to-trial decision noise has typically been considered adaptive only when it promotes exploration of new, potentially useful information sources. Here we propose and

present psychophysical support for the idea that even when no new information can be obtained, decision noise can reflect "mental exploration": adaptive updating of uncertain models of the environment that is promoted by noradrenergic modulation in cortical areas linked with cognitive control. A key prediction is that uncertainty about statistical structure governs a fundamental bias-variance trade-off in decision-making between adaptability (complex models that promote learning but also variable choices) and precision (simpler models that resist change and instead provide reliable choices). We investigate this theory in the context of change detection in volatile environments that challenge subjects to distinguish variability coming from a stable state from volatile changes in the underlying state itself. In several previous experiments, subjects on average could adapt to varying rates of volatile changes, but with an average bias towards immediate sensory information, underweighting the history of task data. However, this degree of adaptability varied considerably across subjects, with those who adapted least doing so by erring more on the side of underweighting data history. We show that a biologically plausible particle-filter algorithm that operates in "hypothesis (model) space" can account for these individual differences. The algorithm fit both choice and reaction time data well for each subject with only 1-2 free parameters governing a prior distribution over this space. The fits captured different dynamics for different subjects, ranging from continuous, adaptive updates to a tendency to treat all conditions in a similar, history-independent manner. The algorithm is normative for learning novel statistical structure given a wide enough prior distribution over hypothesis space, and effectively captures the bias-variance trade-off evident in the behavioral data in terms of the precision of the prior. New experimental work includes change detection experiments paired with pupil diameter measurements recently shown by our group to reliably indicate single-unit activity in the locus coeruleus, the noradrenergic brainstem center. Preliminary data suggest links between pupil diameter and novel latent variables from this particle filter algorithm such as "unexpected certainty" in the decision-making process.

Title: Hebbian mechanisms for task-set learning

Authors: *F. BOUCHACOURT, S. PALMINTERI, E. KOECHLIN, S. OSTOJIC;
Lab. De Neurosciences Cognitives, Ecole Normale Superieure, Paris, France

Abstract: Depending on environmental demands, humans engaged in a given task are capable to adjust and exploit multiple, concurrent strategies. We define the internal representations of such stimuli-response mappings as “task-sets”. Theoretical research on rule-guided behavior and the interdependence between learning and cognitive control mainly focused on abstract computational models at the functional level. Little is known however about the underlying neural implementation and mechanisms.
We examine a candidate neural mechanism for the implementation and learning of task-sets, based on hebbian synaptic plasticity. The model is composed of two interacting neural circuits. A decision module learns one to one associations between visual stimuli and motor responses, but cannot learn more than one stimuli-response mapping. The activity in this module drives synaptic plasticity in a second neural circuit that learns event statistics on a longer timescale. When this second module detects patterns in stimulus-action associations, an inference bias to the decision module influences successive behavior.
We show that simple unsupervised hebbian learning in the second module is sufficient to learn an implementation of task-sets. Their retrieval in the decision module improves behavioral performance. It accounts for fast contextual switching and corrects for environmental noise. The model predicts abrupt changes in behavioral responses depending on the precise statistics of previous responses. We fitted the model to human behavioral data, and produced predictions for learning facilitation or learning reduction based on the inference bias. The predictions of the model were borne out by the data, and enabled to identify from behavior alone subjects who have learned the task structure, confirming a post-test debriefing. Preliminary results of our model-based fMRI analysis show a correlation between the inference signal and BOLD activity in fronto-parietal network. Within this network, a dorsomedial prefrontal node seems to be preferentially recruited when task sets are recurrent, suggesting that activity in this region may provide a bias to decision circuits when a task-set is retrieved.
These results show that simple hebbian mechanisms and temporal contiguity may parsimoniously explain the learning of complex, rule-based behavior.

Title: Brain network connectivity underlying decisions between the "lesser of two evils"

Authors: *C. FINNERTY[1], C. HANSON[2], S. HANSON[2];
[1]Psychiatry, Stanford University/Palo Alto Veterans Administrat, Palo Alto, CA; [2]Rutgers Univ., Newark, NJ

Abstract: While brain response during decisions about appetitive stimuli such as food or money is fairly well characterized, it is less well understood how the brain encodes choices about aversive stimuli. One challenge is that signal related to stimulus salience (e.g. intensity) is often collinear with signal related to valence (e.g. aversiveness). Additionally, if brain areas are valence sensitive, then they should “deactivate” or decrease activation relative to baseline in proportion to how aversive a stimulus is, and increase activation proportional to appetitiveness, whereas areas that respond to salience will increase activation for both appetitive and aversive stimuli. Distinguishing salience from valence specific coding thus requires modeling differences in both increases and decreases in BOLD signal in response to both aversive and appetitive stimuli. Additionally, there is a limited understanding of brain response to stimuli that approximate real-world complexity. Here, we compare two groups of 14 participants who made choices between complex, individualized, hypothetical stimuli during fMRI scanning; one group chose amongst aversive stimuli (e.g. illnesses, car accidents) and one chose between pleasant options (e.g., vacations). We predicted that regions such as the insula, amgydala, and striatum code valence and thus would decrease their activation during aversive, but not appetitive choice. We further characterize this response via graph theoretical connectivity analysis to test whether increased/decreased activation in these regions is also accompanied by increases/decrease in number or strength of connections. This also allows us to compare changes in deactive region connectivity across conditions, which circumvents methodological limits in comparing deactivation using GLM analysis. We found that brain response during hypothetical aversive choices involves activations in areas associated with decision making, including the putamen, insula, and anterior cingulate, as well as deactivations valence sensitive regions, including the amygdala, prefrontal cortex, and hippocampus. In contrast, appetitive choices primarily were related to activations above baseline in these same regions. Further, we find shifts in connectivity between active and deactive brain regions based on task context, with greater connectivity among deactive regions during avoidance choices for aversive stimuli compared to approach choices. This difference in brain network response to decision frame suggests that salience and valence both factor into hypothetical choices to approach or avoid appetitive and aversive stimuli.

Title: Simple economic choice in large choice sets: an investigation of hick's law

Authors: *A. THOMAS[1], I. KRAJBICH[2];
[1]Technische Univ. Berlin, Berlin, Germany; [2]Ohio State Univ., Columbus, OH

Abstract: Objective: We often have to choose from a large number of options (e.g. choosing a yogurt at the supermarket). Hick's Law predicts that the time that we need to make a choice should linearly increase with the logarithm of the number of options. However, this has yet to be tested in economic choice. Moreover, the neural mechanisms underlying this response time phenomenon remain unknown. We explore these questions using an eye-tracking experiment in which hungry subjects choose snack food items from large choice sets of varying size (N: 9-36).
Methods: 51 hungry individuals participated in this experiment, which consisted of choice and rating tasks. During the choice task, subjects faced 200 randomly assembled sets of snack food items (sizes: 9, 16, 25, 36). For each set, subjects were asked to choose the item that they would like to eat most at the end of the experiment. Subjects had as much time as they wanted to make their choice. In the second task, subjects rated each of the 80 food items, which provided independent measures of their values.
Results: We find that subjects' response times do increase as a logarithmic function of choice set size, while their response accuracy remains constant and high, consistent with Hick's Law. In order to shed more light on these findings, we use the choice, response-time, fixation and value data to compare several computational models of the choice process in this class of environments. The results of this comparison show that the attentional drift-diffusion model qualitatively matches subjects' choice and response-time behavior and outperforms the alternative models on several important dimensions.

Title: A model based in brain-computer interface to identify risk situations and support to decision-making

Authors: *R. HÜBNER[1], A. N. S. HÜBNER[2], P. V. O. MIGUEL[4], L. B. R. AYLON[3], G. BARRETO[5];
[1]Computing Dept., Federal Univ. of Technol. - Paraná, Maringá, Brazil; [2]Pharmacol. and Therapeut. Dept., [3]Computer Dept., State Univ. of Maringá, Maringá, Brazil; [4]Tech. High Sch. of Campinas, Campinas, Brazil; [5]State university of Campinas, Campinas, Brazil

Abstract: The purpose of this study is to use a Brain-Computer Interface (BCI) to identify risk situations and assist a person in decision-making. People lives daily with processes like this and such decisions become more critical when involving life-threading. In addition to environmental factors, cognitive process that supports a plan of action and decision-making takes into consideration the ability, the experience and the emotional states of the holder agent. The use of BCI can help identify risk situations through simulations, and propose specific training for the prevention of these cases, however, submitting people to potential damage from these occurrences. These artifacts can still be used for real time monitoring signals related to relaxation ans traditional models of selective attention based on external stimuli such as Steady State Visual Evoked Potential (SSVEP) and P300. Applications in models that use specific stimuli, for example visual or auditory or tactile. The responses of stimulus usually obtained by specif electrodes in BCI, for example, visual stimulus is picked up by electrodes positioned in visual cortex. Four scenarios was created using a computer simulation based on a virtual game “runner” style. A electroencephalography (EEG) equipment non-evasive with 16-channel is used in the experiment and electrodes are spread in regions of the frontal, occipital, parietal and temporal lobe (channels Fp1, Fp2, F7, F3, F4, F8, T7, C3, C4, T8, P7, P3, P4, P8, O1 and O2 of 10-20 location system). The standardization is performed by checking which brain regions of the cortex are active given a particular decision-making in the simulation. Using temporal filters, major artifacts phenomena are excluded from the signal measured, such as eye blink, heartbeat and other that not contribute with the experimentation. Spatial filters are added in the experimentation to determine channels that measure useful data. Each situation class occurred in the simulation has the same time and its events are mapped. The filtered signal are passed by classifiers used to determine which of the four situations are occurring where and each of them has previously correct action response. Thus, given an event occurred in the simulation, the application can aid in the decision to be taken. Related works and preliminary results show that

visual scenarios can be standardized to a BCI application, to classify and use the feedback to decision-making. In this study is being used a more generalized approach through various channels of EEG to identify risk situations. This work if constantly updating and some improvements in the computer simulation, signal filters and classifiers are still necessary.

Title: Making inter-temporal choices in a 3D environment: proximity to rewarding cues weakens self control

Authors: *D. O'CONNOR, R. JANET, J.-C. DREHER;
CNRS, Bron, France

Abstract: Although it has been theorized that physical proximity to reward can lead to more impulsive choices in humans, there has been no systematic study to corroborate this. We developed an immersive inter-temporal choice task, using the Oculus Rift virtual reality headset, to investigate whether mere proximity to immediate appetitive (sweet) rewarding cues increases impulsive choices towards them. We found significant increase in choices for smaller, immediate rewards over larger delayed rewards when they were presented within subjects' grasp (Near; <30cm) compared to when they were presented outside this area (Far; 300cm). Moreover, we observed a correlation between near/far choice ratios and scores on the Barratt Impulsivity Scale (BIS). Specifically, those subjects who reported lower rates of BIS impulsivity were more vulnerable to this proximity choice bias. From an evolutionary perspective, we interpret this tendency for subjects to make more impulsive choices for proximal rewards as an adaptive bias. However, when viewed within the context of a modern consumer society, such a bias could be viewed as potentially detrimental.

Title: Hierarchical environment representations for efficient planning.

Authors: *D. MCNAMEE, D. WOLPERT, M. LENGYEL;
Computat. and Biol. Learning Lab., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The production of rational sequences of decisions in complex environments is a hallmark of adaptive intelligence. However, planning is plagued by the curse of dimensionality. To overcome this, it has long been suggested that the nervous system hierarchically partitions or "chunks" states and actions into distinct "modules" thus enabling more efficient and flexible planning in high-dimensional environments. In such a modular representation, planning can first operate at a global level across modules acquiring a high-level "rough picture" of the trajectory to the goal and, subsequently, locally within each module in order to "fill in the details". However, the neural and computational principles which underpin such representations remain obscure. In order to address this, we developed a normative theory of hierarchical environment decomposition optimized for a given planning algorithm based on optimally trading off the average (information theoretic) description length of path planning at the global and local levels. We used the resulting modular representations to identify behavioral and neural signatures of efficient state-space representation during sequential decision-making.
Our model provides a unifying account for a diverse range of hitherto unrelated phenomena at multiple levels of representation and behaviour across mammalian species. For example, recent neuroimaging work (Javadi et al., BNA, 2014) has identified human hippocampal activity which parametrically covaries with changes in a state's ``degree centrality'' (a topological measure of connectedness) during virtual spatial navigation in London's Soho. We show that this unexplained neural correlation could be due to the initiation of local search processes based on an optimal decomposition of the Soho environment. In (Bonasia et al., Hippocampus, 2016), it was verified that the mental navigation of goal-directed trajectories exhibits the phenomenon of compressed replay. Our model predicts the power-law scaling of such route compression as a function of path length they observed. Furthermore, our model suggests that the emergence of start/stop signals in prefrontal cortex (Fujii & Graybiel, Science, 2003) and striatum (Jin & Costa, Nature, 2010), and "task-bracketing" (Smith & Graybiel, Neuron, 2013) is due to environment representations which are efficiently coded for the production of goal-directed

behavioural sequences and normatively justifies a variety of statistical and representational characteristics experimentally observed in these neural populations.

Title: Computational analyses on the generation process of self-directive responses in neural systems controlled by internal chaotic fluctuations

Authors: ***M. HIRABAYASHI**, H. OHASHI;
Ohashi Toriumi Lab., Dept. of Systems Innovation, Sch. of Engin., The Univ. of Tokyo, Tokyo, Japan

Abstract: Objective
Although recent remarkable advances in brain science, the neural coding mechanisms of higher brain functions, such as perception, memory, learning and thinking, are less understood. Here, focusing on the features of a cell system of a neuron as a component of complex adaptive systems that consist of neural networks, we present computational analyses on the possibilities that a neuron can implement such advanced functions through the process of evolution and development.
Methods
We introduce the action of chaotically behaving neurons to Hodgkin-Huxley model which describes the time evolution of the transmembrane potential in terms of membrane currents. Using a spontaneous-firing neuron, properties of response to input signals are investigated. Previous findings indicate that sensory inputs do not induce an action potential but lock the inner state of a spontaneous-firing system by phase modulation [1-2]. In this case, it can be thought that a cell system of spontaneous-firing neuron is in the critical state from a probabilistic transition state of phase and frequency to a locked state of them. Because this kind of critical states is stable to small perturbation and low noise, spontaneous firing is effective to realize robust information processing.
Results
We observed switching phenomena between excitation and inhibition utilizing resonance caused by chaotic fluctuations. Our results show that there are possibilities that internal states of neurons can be controlled through such fluctuations generated on a cell membrane independently of input

signals. This finding means that systems can generate different outputs from the network without any change of the network structure. For example, by decreasing the sensitivity of cells through the control of chaotic fluctuations, input signals can be cut not to be transmitted downstream. On the other hand, insensible signals can be transmitted by increasing the sensitivity. Because there are several candidates that can regulate such fluctuations by internal signals, these processes may play important roles in the emergence of higher brain functions such as thinking or decision making.
Conclusions
We focused on the aspect of complex adaptive nature of a neuronal cell system as an information processing organization and demonstrated that a neuron has the structure to realize self-directive and flexible responses. By revealing the emerging process of advanced functions step by step, the progressive breakthroughs will be brought in the related fields such as brain science and artificial intelligence.

Title: Distributed representation of task context by fine-scaled subnetworks in prefrontal cortex

Authors: ***M. L. WASKOM**, A. D. WAGNER;
Dept. of Psychology, Stanford Univ., Stanford, CA

Abstract: The cerebral cortex exhibits functional organization at multiple spatial scales. While there is increasing understanding of how the cortex is organized into large-scale networks, which are themselves composed of areas, less is known about the principles that govern finer scales of functional organization. To address this question, we measured task-evoked responses and spontaneous activity from human prefrontal cortex using high-resolution fMRI. Subjects

performed a context-dependent perceptual decision-making task in which they followed a shifting rule to discriminate the features of a bivalent visual stimulus. Multivariate decoding analyses indicated that frontoparietal control network regions in the inferior frontal sulcus (IFS) contained distributed representations of the task context (the rule). We sought to understand the organization of the information underlying these results. Using single-voxel estimates of context preference, we identified populations of voxels with reliable differences in activation for decisions made under the two contexts. These voxels were distributed throughout the IFS, but they also exhibited significant spatial clustering that could not be accounted for by the inherent smoothness of the data. We then tested whether voxels with similar context preferences were organized into subnetworks by analyzing spontaneous correlations in both task residuals and resting-state data. These analyses revealed that spontaneous correlations between voxels with similar context preferences were approximately twice as large as those between voxels with opposing context preferences. Although spatial proximity was a major influence on spontaneous correlation strength, increased correlations between voxels with similar preferences could not be fully accounted for by measures of proximity. These results suggest that distributed representations in human association cortex are supported by fine-scaled subnetworks, which illustrates a novel perspective on the functional organization of higher-order cognitive processes.

Title: Even-related potentials correlated with the evaluation of service-to-service brand extension

Authors: ***T. YANG**, E. SEOMOON, S.-P. KIM;
Dept. of Human Factors Engin., Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: Brand extension refers to the introduction of new service or goods to the market by exploiting an established brand. Brand extension can reduce advertising costs and market entry barrier, whereas it can also jeopardize brand equity by weakening a positive association with the original brand. Therefore, understanding how consumers evaluate brand extension is important to development of brain extension strategy. Many studies have investigated neural mechanisms

underlying consumer's evaluation of brand extension. Yet, the previous studies have focused only on goods-to-goods brand extension to date. Since it is more difficult to categorize services rather than goods, the same neural mechanism may or may not be involved in service-to-service brand extension. In the present study, we investigated whether neural process for evaluating service-to-service is similar to that for goods-to-goods brand extension via an event-related potential (ERP) analysis. We used a prime-probe paradigm in which participants were given a series of stimuli. A popular service brand name in one of the four service categories (e.g., airline, hotel, internet shopping mall service, and bank) was presented as a prime stimulus (S1), followed by one of the seven extension service names (e.g., online travel information service, travel agency service, legal counseling service, etc.) as a probe stimulus (S2). Participants were asked to evaluate the suggested brand extension without explicit response. After the experiment, Participants assessed each S1-S2 combination using the 7-point Likert scale (e.g., similarity between the service of S1 brand and S2 service). Based on the survey result, every S1-S2 combination was divided into three groups: high-, moderate- and low- similarity groups. EEG signals were measured during the experiment. The ERP analysis revealed the modulation of N400 components over the right frontal region with the S1-S2 similarity. The N400 amplitude was significantly increased in the order of moderate, high, and low similarity ($p < 0.05$). However, we did not observe P2 at frontal areas that was shown in the previous studies on goods-to-goods brand extension evaluation. Our results indicate that consumers may use a different cognitive process during evaluating service-to-service brand extension compared to goods-to-goods brand extension. To the best of our knowledge, this is the first study to explore neural activity associated with service-to-service brand extension.

Title: Oxytocinergic modulation of human adaptive communication and broadband neuronal dynamics

Authors: ***A. STOLK**[1], I. KOKAL[2], M. DE BOER[2], R. OOSTENVELD[2], I. TONI[2];
[1]Knight Lab., Helen Wills Neurosci. Institute, UC Berkeley, Berkeley, CA; [2]Donders Inst., Nijmegen, Netherlands

Abstract: Oxytocin is a neuromodulator thought to influence human social and affiliative behavior. Here we explore a neurophysiological mechanism through which oxytocin might influence how we adjust our communication to others. Recent evidence suggests oxytocin might reduce social anxiety and promote sensitivity to social cues. Yet, to date, the neurophysiological mechanism by which oxytocin supports human adaptive social behavior remains largely unknown. This study addresses this issue by exploring the neurocognitive consequences of oxytocin administration during human adaptive communication. Fifty-eight males participated in a randomized, double-blind, placebo-controlled experiment involving the intranasal administration of oxytocin (24 IU). The participants were asked to communicate non-verbally with two addressees, an adult or a child, in an experimentally controlled interactive setting. In reality, a confederate blindly performed the role of both adult and child addressee, such that the two addressees were matched in their level of understanding and differed only in terms of the communicator's prior beliefs. We used magnetoencephalography (MEG) to capture the neuronal dynamics evoked during the live communicative interaction and contrasted neuronal activity evoked after oxytocin administration with that of placebo controls. We focus on broadband changes in neuronal activity, building on recent work showing the importance of those broadband shifts, i.e. changes in mean firing rates of neuronal populations, for integrating driving afferences with contextual information [1]. Oxytocin tonically up-regulated broadband neuronal activity in a right-lateralized fronto-temporal circuit previously found to support human adaptive non-verbal communication in a state-dependent manner. Communicators with stronger broadband fronto-temporal activity adjusted more readily their signals to what the addressees actually understood during the interaction, and were less biased by their prior beliefs about the abilities of those addressees. These findings point to a fundamental neuronal mechanism through which oxytocin influences how we adapt our social behavior, in line with previous work linking tonic up-regulation of broadband activity with on-line communicative alignment between interlocutors [2]. Title: Voxel-wise mapping of the cingulate cortex in impression formation

Authors: *J. AHN[1], Y. NAH[2], S. HAN[1,2];
[1]Dept. of Cognitive Sci., [2]Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of

Abstract: People vary in processing information regarding social others. We conducted an fMRI study to investigate the voxel-wise neural mechanisms on forming impressions while incongruent social information about a person are provided. Participants were shown a male face with four characteristics adjectives consecutively presented beneath. Two of adjectives explained him positively whereas the other two gave negative information. To investigate the order and anchoring effects of incongruent information, two positive adjectives were followed by two negative adjectives in half of the trials and vice versa in the other half. Then participants evaluated impression toward the person on eight-point scale. The bilateral cingulate cortex were selected as a priori regions of interest (ROIs) and were functionally parcellated into anterior (ACC) and posterior cingulate cortex (PCC). Amygdala was also identified as an ROI. Each adjective was considered as single trial and beta estimates of every voxel in ROIs were extracted. We established two ideal models using step functions one of which hypothesized that beta estimates would gradually decrease while four adjectives were presented (model 1) suggesting that impression would be anchored in the initial information. The other model hypothesized the opposite neural activity pattern (model 2) which assumed that neural activities would increase to resolve the conflicts of information and the latter information would alter general impressions toward the person. Parameters that minimized sum of squared deviations between ideal models and signals from each voxel were estimated with GRG nonlinear algorithm of Solver add-in in Microsoft Excel and mapped in the cortex. The results showed that voxels of PCC were mainly fit to model 1 significantly better than model 2 suggesting impression anchoring to initial information. We also found functionally parcellated dorsal ACC from ventral ACC in that voxels in the dorsal ACC followed model 1 while those in the ventral ACC showed similar patterns with model 2. In addition, voxels of the amygdala showed inconsistent patterns of fitting value while generally following model 1 except that small clusters in the left ventral amygdala were fit to model 2. These data-driven findings demonstrate that activity patterns of each brain region during impression formation can be represented in the cingulate cortex via voxel-wise model estimation; the PCC yields anchoring effects of first impression regardless of valence of information and the ACC is involved with resolution of information incongruity.

Title: Neural dynamics surrounding the individual arising of spontaneous thoughts

Authors: ***M. GIRN**[1], M. ELLAMIL[2], L. WARD[1], K. CHRISTOFF[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Max Planck Res. Group Neuroanatomy and Connectivity, Munich, Germany

Abstract: Spontaneous thinking constitutes a ubiquitous aspect of our mental life and has increasingly become a hot topic of research in cognitive neuroscience. To date, functional neuroimaging studies of spontaneous thought have revealed general brain recruitment centered on a combination of default mode network and executive regions. The precise temporal relationship between the regions recruited, however, has yet to be fully elucidated. A previous study by our group employed fMRI to this end (Ellamil et al., Neuroimage, 2016), and characterized regional recruitment in blocks of 2 seconds prior to, during, and after the spontaneous arising of thought. A primary finding was the recruitment of medial temporal lobe (MTL) structures 2 seconds prior to thought onset, suggesting a specific role of the MTL in the inception of spontaneous thoughts. The limited temporal resolution of fMRI, however, strongly constrains the precision of such analyses. The present study seeks to validate and extend our previous findings by employing EEG to perform a more fine-grained analysis of the temporal dynamics of brain activity underlying spontaneously arising thoughts. To do this, we performed independent component analysis (ICA) on high-density EEG recorded using the same paradigm. Pilot data has recovered multiple sources of electrical brain activity in line with those previously identified by our fMRI study. Preliminary results suggest a temporal evolution of recruitment that originates in limbic structures and spreads to cortical heteromodal regions. This temporal evolution of spontaneous thought osberved at the neural level may reflect the cognitive evolution of spontaneous thought as it moves from initial generation, to affective appraisal, to subsequent cognitive elaboration.

Title: The influence of eco-labeling on neural predictors of energy-efficient purchases

Authors: *N. SAWE, A. SAHOO, G. TANG, B. KNUTSON;
Stanford Univ., Stanford, CA

Abstract: Consumers routinely underinvest in energy efficiency by purchasing appliances with high long-term energy costs. The Energy Star labeling program was implemented to highlight energy-efficient products and has been largely successful in increasing investment in energy efficiency, yet consumers still vary widely in their valuations of both the Energy Star label and energy consumption data. In a functional magnetic resonance imaging (fMRI) task involving the incentive-compatible purchase of CFL light bulbs, we aimed to understand neural mechanisms that promote purchases of energy-efficient goods, as well as individual differences in choices. Specifically, we focused on individual differences in temporal discounting, which theorists have posited may contribute to underinvestment in energy efficiency.

During the fMRI task, subjects (n=36) chose in 64 trials whether to buy CFL bulbs which varied with respect to the presence or absence of an Energy Star label, annual energy cost, and price. One trial was randomly chosen at the end of the experiment to count as a binding decision; if purchased, the bulb's cost was deducted from the endowment and provided to the subject. Subjects also completed a questionnaire to ascertain their discount rates.

Logistic regression analyses using volume of interest FMRI activity to predict purchases revealed that choices to purchase CFL light bulbs were positively predicted by activity in the nucleus accumbens ($Z=3.43$, $p<0.001$) and caudate ($Z=3.62$, $p<0.001$) and negatively predicted by activity in the MPFC ($Z=-2.25$, $p=0.025$). Further, the presence of the Energy Star label significantly increased activity in the nucleus accumbens ($T=2.97$, $p=0.003$) and caudate ($T=3.38$, $p<0.001$) during the decision phase.

With respect to individual differences, those with higher discount rates showed more activation in response to the Energy Star label in the anterior insula, caudate, and nucleus accumbens. Logistic regressions revealed that in individuals with high discount rates, purchases were positively predicted by nucleus accumbens activity ($Z=2.95$, $p<0.01$) and negatively predicted by anterior insula activity ($Z=-2.15$, $p<0.05$), but in individuals with low discount rates, purchases were negatively predicted by MPFC activity ($Z=-3.16$, $p<0.01$). These individual differences are

consistent with the notion that people with high discount rates may rely more on affective processes during purchasing, and so may respond more prominently to eco-labeling. These findings may help policy makers to refine eco-labeling to further increase investment in energy efficiency and optimize behavioral interventions across a diverse range of consumers.

Title: Forming a desired belief: a computational account

Authors: ***D. CAHILL**, T. SHAROT;
Psychology, Univ. Col. London, London, United Kingdom

Abstract: How do we form beliefs about hidden states? Past work suggests that such inferences are guided not only by the available evidence but also by the desirability of that evidence. However, the dynamics of this process are largely unknown. Here we use an accumulator model—the drift diffusion model—to describe the formation of such beliefs and the role of valence in this process. In a series of experiments we ask participants to play a slot machine which can either be in a desirable state (more likely to produce gains than losses) or undesirable state (more likely to produce losses than gains), and require them to report which state they believe the machine to be in as they play. Markedly, participants were more likely to report the slot machine as being in a desirable state than an undesirable state than the objective evidence warranted, and were faster to reach desirable conclusions, despite being incentivized for accuracy. Applying a drift diffusion model to this data revealed (1) a larger drift rate towards desirable beliefs than undesirable beliefs and (2) a response bias towards desirable beliefs. This suggests humans both accumulate desirable evidence faster and have a predisposition to hold desirable beliefs. The results offer a computational account of the role of valence in belief formation.

Title: Is there "value" in preference?

Authors: ***D. HANSEL**[1], L. LEBOVICH[2], Y. LAVI[3], R. DARSHAN[2], Y. LOEWENSTEIN[2]; [1]CNRS, Paris, France; [2]The Edmond and Lily Safra Ctr. for Brain Sciences, The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]The Inst. of Life Sciences, The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: It is generally believed that choices between alternative options are based on the subjective value associated with these alternatives. In this framework, choice preference in favor of one alternative over the other reflects a difference in subjective values. Here we challenge this framework and show theoretically and experimentally how preference emerges without value. Theoretically, we studied choice preference in decision-making networks by considering the dynamics of a standard decision-making network model composed of two large populations of spiking neurons that compete via lateral inhibition. We demonstrate using numerical and analytical methods that substantial response bias naturally emerges from the *microscopic* dynamics of the network. This happens even in symmetric settings, in which the two competing populations are statistically identical and receive identical input. We show that the reason for this bias is that the degree of spatial heterogeneities in the network architecture (quenched disorder) and stochasticity of neuronal activity (fast noise) identically scale with the size of the network. As a result, we predict that the *distribution* of response biases would be wide, even in a symmetric decision-making task.Experimentally, we studied choice behavior of human participants in two experiments, in which the "values" associated with the two alternative actions are equal. In the first experiment, we measured the response bias of participants in a symmetrical version of the bisection task and found that the distribution of response biases across the population of participants is substantially and significantly wider than expected by chance, as predicted by our theory. In the second task, participants repeatedly chose the order of two sequentially executed motor plans and we measured their order preference. Again, we found that

despite the task being temporally symmetric, the distribution of order-preference across the population of participants was wide. We conclude that consistent choice preference, even in symmetrical settings, is a natural consequence of the dynamics of competing neural networks and does not require any additional assumptions about a valuation system.

Title: Frontoparietal and salience network activity precedes voluntary decisions in a virtual environment

Authors: *N. RENS[1], H. BURIANOVÁ[2], S. BODE[3], R. CUNNINGTON[1];
[1]Queensland Brain Inst., [2]Ctr. for Advanced Imaging, The Univ. of Queensland, Brisbane, Australia; [3]Melbourne Sch. of Psychological Sci., The Univ. of Melbourne, Melbourne, Australia

Abstract: Studies have demonstrated that freely made decisions are associated with activation of regions of the frontoparietal network (Rowe et al., 2005, Thimm et al., 2012) but it is unclear to which part of the decision-making process this activity relates. We examined whether freely made choices differed from instructed choices in the period of choice selection, prior to both motor preparation and response execution. We further examined to what extent activity at this time would predict the type of decision being made. We created a novel decision-making paradigm in a virtual environment that 22 participants (15 female, mean age 23) performed during fMRI. Participants were required to search for rewards by selecting one of three differently coloured doors at the end of a virtual corridor. The Instructed condition cued participants to choose a specific door colour. The Free condition required participants to choose a colour door of their own volition; however, participants were not permitted to make the same choice as in the previous trial. This rule was implemented to hinder the influence of patterns of choice history on the current decision. The time leading up to the decision point was divided into two epochs, with the doors becoming visible only during the second half. This permitted a time-window of analysis that isolated the process of decision generation, prior to the planning of specific motor responses.

We firstly used multi-voxel pattern analysis (MVPA) with a whole-brain searchlight approach (Kriegeskorte et al., 2006) to investigate where the patterns of neural activity differed between Instructed and Free choice conditions. We found that decision type could be decoded, with a minimum decoding accuracy of 70%, in widespread regions of the brain, predominantly in the frontal and parietal lobes. In order to examine the networks in more detail, we then conducted a mean-centred Partial Least Squares (PLS) analysis (McIntosh et al., 1996). This revealed an increase in activity for Free over Instructed choices that included areas in two key networks: the frontoparietal network and the salience network with bilateral insula. These networks are thought to be involved in attentional processing and the integration of relevant stimuli in order to allow evaluation between options. In conclusion, these findings suggest that activity of the frontoparietal network may be involved in the choice selection process of intentional decision-making and that this occurs at a conceptual level, independent of action preparation.

Title: The temporal parietal junction tracks evidence of guilt in mock criminal scenarios

Authors: R. M. CARTER[1], S. HAKIMI[1], J. M. PARELMAN[1], J. R. LAW[2], N. VIDMAR[2], J. A. G. SKENE[2], D. H. BESKIND[2], J. M. PEARSON[2], *J. SKENE[3];

Abstract: The United States criminal justice system is imperfect, as evidenced by recent high-profile exonerations reminding us that errors in the criminal justice system can and do occur. Reducing the frequency of these errors requires an understanding of the processes by which jurors arrive at a decision of guilt. Of fundamental concern are the juror's goals when making this decision. In addition to the trial evidence, is the process of deciding guilt based on measuring threat, maximizing personal utility, weighing moral culpability, or a combination of each of these? In order to better understand the nature of the neural processes underlying the assessment of guilt, we performed fMRI scanning on 32 jury eligible participants while details of mock criminal cases were revealed to them in a staged fashion. Information provided to the jurors included the type of crime, physical evidence, prior criminal history, and the presence of a

witness. Each of these pieces of evidence contributed to decisions of guilt. With each revealed piece of information, the accumulation of evidence in each scenario was modeled as a sum of the weight of each factor, with model weights determined by previous large-scale behavioral studies. Whole-brain corrected univariate analyses indicated that a single, bilateral region of the brain, the temporal-parietal junction (TPJ) correlates with the linear accumulation of evidence of guilt. Using the perceptual decision making literature as a parallel, evidence accumulation within only the TPJ distinguishes it from decisions about deserved punishment, which have been shown to incorporate assessments of harm or personal utility, associated with activations in the amygdala and striatum. Activation in the TPJ could then imply a dependence on measuring theory of mind which could include moral responsibility, intent, or interpreting another's actions.

Title: Spontaneous blink rate correlates with financial risk taking

Authors: *R. C. WILSON[1], E. SHERMAN[2];
[1]Univ. of Arizona, Tucson, AZ; [2]BASIS Scottsdale, Phoenix, AZ

Abstract: Dopamine has long been thought to play a role in risky decision-making, with higher baseline levels of dopamine thought to drive risk seeking behavior. Despite this progress, the exact nature of the relationship between dopamine and risk taking is incompletely understood. For one thing, dopamine has different effects on different receptors, which are themselves distributed differently in different areas of the brain. Moreover, some studies have found that dopamine genes and drugs have different effects depending on range of other factors including gender, sensation seeking and whether the risks involve gains or losses.
In this work we sought to shed more light on dopamine's role in risk taking by using a remarkable relationship between the rate at which someone blinks and the amount of D2-related dopamine in striatum (Karson, 1983; Elsworth et al., 1991). We therefore hypothesized that if blink rate reflects dopamine and dopamine drives risk taking, then we should see a positive relationship between individual differences in blink rate and risk taking across the population. To investigate the relationship between blink rate and risk seeking, we measured blink rates and

financial risk taking in 45 participants ranging in age from 18 to 59. Blink rates were measured by manually counting blinks in videos of the participants "staring into space". Financial risk taking was measured using a survey in which each question offered participants a choice between a certain outcome (e.g. 100% chance of $240) and a risky outcome (e.g. 25% chance of $1000). The survey consisted of nine questions and included questions with both gain and loss framing of the outcomes.
Consistent with previous work linking dopamine to risky decisions, we found a strong positive correlation between blink rate and the number of risky choices a participant made (Spearman's $\rho(43) = 0.57$, $p = 4.45 \times 10e\text{-}5$). Contrary to prior findings, we found that this correlation was not dependent on age or gender and was identical for both gain and loss framing.
These findings suggests that D2-related dopamine plays a crucial and quite general role in determining financial risk taking across the population. In addition our work demonstrates the potential of spontaneous blink rate as a simple method of probing dopamine for decision-making research.

Title: Metacognition across senses and combination of senses

Authors: *N. FAIVRE[1,2], E. FILEVICH[4], G. SOLOVEY[5], S. KUHN[4], O. BLANKE[3];
[1]CNRS, Paris, France; [2]Lnco, [3]EPFL, Genève, Switzerland; [4]MPI, Berlin, Germany; [5]FCEyN, Buenos Aires, Argentina

Abstract: Humans have the capacity to access and report their own mental states. A widely used method to study these metacognitive capacities is to have observers do a challenging perceptual task followed by a confidence judgment regarding task performance. In this operationalization,

metacognitive accuracy can be quantified as the correspondence between the subjective confidence judgments and objective task performance. While more evidence has been gathered regarding the mechanisms and brain areas involved in metacognitive monitoring, some of the core properties of metacognition remain largely unknown. One of the central questions is whether, and to what extent, metacognitive monitoring should be considered domain-general: is the computation of confidence fully independent of the nature of the task (i.e., domain-generality), or does it also involve task-specific components (i.e., domain-specificity)? Here we sought to further describe the commonalities and specificities of metacognition across vision and audition, and extend it to touch, a sensory modality that has been neglected so far. We first examined correlations between metacognitive accuracy during a visual, auditory, and tactile discrimination task (Experiment 1). Next, extending our paradigm to conditions of audiovisual stimulation, we quantified for the first time the links between unimodal and multimodal metacognition, and assessed through computational modeling how multimodal confidence estimates are built (Experiment 2). Finally, we investigated the neural mechanisms of unimodal and multimodal metacognition by replicating Experiment 2 along with electroencephalographic recordings combined with amplitude and frequency analyses (Experiment 3). Together, these results provide new insights regarding the behavioral, neural, and computational bases of metacognition across different senses, and, crucially, when they are combined. Based on behavioral and neural evidence, we propose that domain-generality during metacognitive judgments are driven by decisional factors during the first-order task which are modality-independent (e.g., reaction times), and thus likely candidates to explain partial domain-generality in metacognition.

Abstract: A coordination with timing and patterns of breathing is thought to be crucial for making an action and succeeding a task performance during sports, such as football (soccer), baseball, tennis, and martial arts. Indeed, autonomic functions including respiration can be controlled by human prefrontal cortex, which is primarily involved in executive functions and cognitive flexibility, such as set shifting and behavioral inhibition. To understand the respiratory patterns regarding cognitive flexibility, we investigated changes in respiration and vagal activity during a complex discrimination task, which demands high cognitive flexibility. We found at least four natural breathing types in 38 healthy subjects during the discrimination task. These breathing types were composed of mainly three elements (periodicity, extension of apnea/expiration, and randomness): 1) periodic type (P, 60.5%, n=23), 2) periodic + apnea/expiration-extending type (PE, 15.8%, n=6), 3) random type, in which the respiration swings quickly between inspiration and expiration or makes two/three peaks during expiration (R, 18.4%, n=7), and 4) apnea/expiration super-extending type (5.3%, n=2). Then, we further analyzed respiration and heart beats during the task in subjects with P, PE, and R respiratory patterns. We showed that the study and test phases in the task had shorter respiratory cycle, smaller respiratory amplitude, and smaller respiratory sinus arrhythmia (RSA) amplitude as compared to those during the pre-task state. Interestingly, the test phase, which demands set shifting, behavioral inhibition, and recognition, had shorter expiratory phase and larger numbers of heart beats in inspiratory phase as compared to those during the pre-task state and study phase. These results suggest that respiratory patterns are well coordinated by cognitive flexibility and/or recognition. More importantly, we found that subjects with R patterns had smaller RSA amplitudes as compared to those with P or PE subjects, suggesting that the sympathetic tone is more likely to be activated in R-type subjects. We will discuss about a further possible correspondence of respiratory types to autonomic patterns regarding a cognitive performance.

Title: Why does the mind move? Explaining the dynamics of mind-wandering through experience-sampling

Authors: *A. HERRERA-BENNETT[1], Q. RAFFAELLI[2], K. CHRISTOFF[2];
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The bulk of the mind-wandering literature has primarily operationalized spontaneous thought as a function of being on- versus off-task, with rates of stimulus-independent or task-unrelated thoughts accounting for 30 -50% of daily life (e.g., Killingsworth & Gilbert, 2010). This task-centric perspective has predominately shaped the way in which researchers have attempted to capture spontaneous mental activity, and has in turn neglected the dynamic property of mind-wandering, namely the tendency of the mind to move in a relatively unconstrained fashion within a broad conceptual scope of ideas from one moment to the next (e.g., Christoff et al., in press). The present study capitalized on experience-sampling methodology to developed novel probe items that aimed at empirically measuring thoughts' dynamic qualities outside of the lab, where thoughts are expected to be subject to a host of potentially concurrent and ongoing tasks and at the mercy of contextual influences. Participants responded to thought probes at randomized times over the course of multiple days, being asked to rate their thoughts on a number of different dimensions (7-point Likert scales), including the apparent randomness and speed in the movement of their current thoughts, their thoughts' relatedness to the current activity (*on- vs. off-task*), as well as the extent to which they felt drawn to think about something (*automatic constraints*). In line with prior research, subjects reported being off-task approximately a third of the time, and experienced similar frequencies of thoughts that were characterized by moderate to high levels of randomness. Our results suggest an overall significantly negative relationship between these two dimensions: The more participants reported being off-task, the more their thoughts moved freely or randomly. This relationship, however, differed considerably among subjects, suggesting that the pervading dynamic quality of mind-wandering is not wholly captured by definitions of mind-wandering exclusively centered around task-focus. This suggests a need to identify what influences the free movement of thought above and beyond those constraints posed by task-focus.

Title: Fast sequences of non-spatial state representations in humans

Authors: *Z. KURTH-NELSON[1], M. ECONOMIDES[2], R. DOLAN[1], P. DAYAN[3];
[1]Max Planck UCL Ctr. for Computat. Psychiatry, [2]Wellcome Trust Ctr. for Neuroimaging, [3]Gatsby Computat. Neurosci. Unit, Univ. Col. London, London, United Kingdom

Abstract: Fast internally generated sequences of neural representations are suggested to support learning and online planning. However, these sequences have only been studied in the context of spatial tasks, and never in humans. Here, we recorded magnetoencephalography (MEG) while human subjects performed a novel non-spatial reasoning task. The task required selecting paths through a set of six visual objects. We trained pattern classifiers on the MEG activity elicited by direct presentation of the visual objects alone, and tested these classifiers on activity recorded during periods when no object was presented. During these object-free periods, the brain spontaneously visited representations of approximately four objects in fast sequences lasting on the order of 120 milliseconds. These sequences followed backward trajectories along the permissible paths in the task. Thus, spontaneous fast sequential representation of states can be measured non-invasively in humans, and these sequences may be a fundamental feature of neural computation across tasks.

Title: P3 like late positivity dissociates young and older adult value-based decision processing

Authors: *P. CHEN[1], H.-Y. HUNG[1,2], J. GOH[1,3,4];
[1]Grad. Inst. of Brain and Mind Sci., Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. of Physics, [3]Dept. of Psychology, [4]Neurobiological and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Value-based decision-making requires the accurate assessment of the likelihoods of outcomes. We previously found that age influences frontostriatal neural activity involved in such valuative processes in older adults. To evaluate temporal counterparts of these age effects on frontostriatal valuative processing, we measured young and older adult event-related potential (ERP) responses towards different likelihoods of reward and cost, 11 young (mean age (SD) = 23 (1.9) yrs; 6/5 males/females) and 11 older (mean age (SD) = 68 (4) yrs; 3/8 males/females) normal participants performed the lottery choice task (LCT) as continuous EEG (32 channels) activities were recorded. In each trial, participants saw reward (or cost) magnitude (high, middle, or low) and probability (high, middle, or low) information, and either accepted or rejected the stakes. Across reward magnitude levels, older adults showed riskier behavior than young adults, having significantly higher acceptance rates (old = 13.3%; young = 4.2%; $p < .05$) for low probability stakes. We also found a general P3-like late positivity response (450-750ms) across the three probability conditions from anterior-to-posterior sites (Fz, Cz, Pz) and focused on this component. Overall, older adults showed an enhanced late positivity amplitude for both high and low probability conditions (mean (SD) amplitude; high, 6.3 uV (1.0); middle, 4.7 uV (1.1), and low, 5.5 uV (1.1)) whereas young adults showed an enhanced amplitude only for the high probability condition (mean (SD) amplitude; high, 6.4 uV (1.0); middle, 5.7 uV (1.0); and low 5.5 uV (1.1)) (F= 2.97, p =.06). Moreover, in middle probability and accepted high probability trials, reward magnitude did not modulate late positivities in young or older adults. In rejected low probability trials, however, lower reward magnitudes significantly decreased the late positivity in old (mean (SD) amplitude; high, 5.1 uV (1.4); middle, 5.7 uV (1.0); and low, 3.2 uV (1.1)) but not young adults (mean (SD) amplitude; high, 3.3 uV (1.4); middle, 2.6 uV (1.0); and low, 3.5 uV (1.1)) (F= 8.03, $p < .05$) . In sum, we identify the P3-like late positivity response as a key ERP indicator of age differences in valuative processing with implications for the temporal dynamic of frontostriatal activity. These results suggest that older adult risk-taking tendency is related to greater salience of low prospects despite costs.

Title: Assessing selectivity in the basal ganglia: the "gearbox" hypothesis.

Authors: *Z. FOUNTAS, M. SHANAHAN;
Imperial Col. London, London, United Kingdom

Abstract: Low-frequency oscillatory activity has been the target of extensive research both in cortical structures and in the basal ganglia (BG), due to numerous reports of associations with brain disorders and the normal functioning of the brain. Additionally, a plethora of evidence and theoretical work indicates that the BG might be the locus where conflicts between prospective actions are being resolved. Whereas a number of computational models of the BG investigate these phenomena, these models tend to focus on intrinsic oscillatory mechanisms, neglecting evidence that points to the cortex as the origin of this oscillatory behaviour. In this study, we employed a new spiking neural model of the BG circuitry to investigate the relationship of wave properties of entrained cortical inputs, dopamine and the transient effectiveness of the BG, when viewed as an action selection device. We found that cortical frequency, phase, dopamine and the examined time scale, all have a very important impact on the ability of our model to select. Our simulations resulted in a canonical profile of selectivity, which we termed selectivity portraits. Taking together, our results suggest that the cortex is the structure that determines whether action selection will be performed and what strategy will be utilized while the role of the BG is to perform this selection. Some frequency ranges promote the exploitation of actions of whom the outcome is known, others promote the exploration of new actions with high uncertainty while the remaining frequencies simply deactivate selection. Based on this behaviour, we propose a metaphor according to which, the basal ganglia can be viewed as the "gearbox" of the cortex. Coalitions of rhythmic cortical areas are able to switch between a repertoire of available BG modes which, in turn, change the course of information flow back to and within the cortex. In the same context, dopamine can be likened to the "control pedals" of action selection that either stop or initiate a decision. Finally, the frequency of active cortical areas that project to the BG acts as a gear lever, that instead of controlling the type and direction of thrust that the throttle provides to an automobile, it dictates the extent to which dopamine can trigger a decision, as well as what type of decision this would be. Finally, we identified a selection cycle with a period of around 200 ms, which was used to assess the biological plausibility of the most popular architectures in cognitive science. Our results agree well with experimental observations, provide new justifications and insights into oscillatory phenomena related to decision making and reaffirm the role of the BG as the selection centre of the brain.

Title: Connnectome analysis of category naming fluency in frontotemporal degeneration

Authors: *M. GROSSMAN[1], P. COOK[2], C. MCMILLAN[3], C. JESTER[4], K. RASCOVSKY[4], A. HALPIN[4], R. LANGEY[4], O. KOFMAN[4], J. GEE[5];

Abstract: A data-driven eigenanatomy approach previously showed that a combination of grey matter (GM) and white matter (WM) was more robust statistically than either of these modalities alone in defining the neuroanatomic basis for the common neuropsychological task - letter-guided category naming fluency (FAS) - in patients with frontotemporal degeneration (FTD) (Cook et al, 2015). Recent advances in imaging analysis have adopted a game theory approach to evaluate the combined role of GM and WM in the identification of the anatomic associations of neurodegenerative syndromes such as Alzheimer's disease and FTD. Here, we used game theory analyses to evaluate the large-scale network subserving FAS performance in non-aphasic patients with behavioral variant FTD (bvFTD). We examined 46 patients meeting research criteria for bvFTD (Rascovsky et al, 2011) and 46 healthy, demographically-matched controls. Patients performed a letter-guided category naming fluency task (FAS). All participants also obtained T1-weighted MRI with 1mm isotropic voxels, and cortical GM was partitioned into 98 regions using the OASIS label set. Diffusion-weighted imaging used a 30-direction protocol. All WM voxels were seeded, and deterministic tractography was used to identify streamlines between 2 different GM regions (nodes). Fractional anisotropy (FA) was averaged across streamlines to weight projections (edges) between nodes. We obtained several measures of network integration and segregation. Our results showed widespread reduction in FA projections between nodes in frontal and left temporal regions. Regression analysis related FAS performance

to these projections ($p<0.05$, Bonferroni-corrected). In addition, we found reduced degree centrality (number of projections between each node and other nodes in the network) and reduced closeness centrality (shortest projections between each node and all other network nodes) in frontal-temporal regions in bvFTD ($p<0.05$, FDR-corrected), and these measures of integration were related to FAS performance in frontal-temporal regions. While there were reduced frontal-temporal hubs (nodes through which shortest-path projections pass, or betweenness centrality) in bvFTD, this was not related to FAS performance. We also found reduced cluster-efficiency (a measure of segregation related to modularity) in frontal-temporal regions of bvFTD, but this was not associated with FAS performance. We conclude that large-scale neural networks are compromised in bvFTD, and that the deficit in these patients is most closely related to a specific disorder of network integration that reflects poorly integrated frontal-temporal nodes.

Title: Neural change-detection without the need to detect changes: leaky integration approaches Bayesian optimality

Authors: C. K. RYALI[1], *A. J. YU[2];
[1]Univ. of California San Diego, La Jolla, CA; [2]Cognitive Sci., Univ. of California San Diego, LA Jolla, CA

Abstract: In recent years, there has been much progress in understanding how humans and animals learn about statistical regularities in the environment to make optimal decisions, as well as how they track changes sudden changes in environmental statistics based on noisy data. Broadly speaking, this problem has been studied using two kinds of data, those that are continuous or ordinal-valued, and those that are binary or categorical. The first kind has often been modeled using variants of the Kalman filter, while the latter kind has been found to be

successfully captured by the Dynamic Belief Model (Yu & Cohen, 2009), or DBM, a variant of a Bayesian hidden Markov model that assumes the observations to be iid distributed from a hidden variable, which itself goes occasional and discrete changes. We previously showed that DBM can explain a variety of behavioral phenomena: sequential adjustment effects in 2AFC discrimination tasks, inhibitory control (e.g. stop-signal) tasks, and explicit prediction tasks, as well as providing a normative explanation for matching-type behavior in a multi-choice visual search task and exploration stochasticity in multi-arm bandit tasks. However, the computational and representational complexity of DBM make it unlikely to be exactly implemented in the brain. Here, we show that DBM can be very well approximated by a simple linear exponential filter, i.e. linearly combining previous observations using weights that decay exponentially into the past. We derive the parametric form of this approximation, showing that the discount factor is a linear function of the assumed hazard rate for change in the corresponding DBM, and that the predictive prior probability of each possible outcome can be computed solely as a function of empirical statistics related to this outcome, with no need to interact with data related to the other alternatives. Interestingly, this approximation is exactly equivalent to the dynamics of an appropriately tuned leaky integrating neuron. Our results also imply that Bayesian learning is achieved to very good approximation by a fixed learning rate in the linear exponential filter, or equivalently a fixed gain in the leaky integrating equation, with no need to explicitly compute the probability of a change having taken place; To conclude, this work makes interesting predictions for how statistical learning and choice behavior depend on experimental variables such as the number of outcome alternatives; it also has direct implications for identifying the neural substrate of statistical learning and change-detection based on noisy categorical data.

Title: Θband occurrence pattern at the onset of a voluntary movement in humans

Authors: *S. KAWASHIMA[1], A. MORI[1], N. MINAKAWA[1], Y. KITA[2];
[1]Grad. Sch. of Literature and Social Sci., Nihon Univ., Tokyo, Japan; [2]Keisen Univ., Faculty of Human and Social Studies, Japan

Abstract: It is known in theta band (3-7 Hz) of electroencephalogram (EEG) studies, theta band in front midline area is associated with focused attention. This band is called frontal midline

theta rhythm (Fmθ), frequency is 6-7 Hz. However, the theta band used in these studies had a wide range (3-7Hz), it is difficult to determine whether Fmθ (6–7Hz) was involved in the results. Therefore, the present study examined to classify theta band into low theta band (3-5Hz; Lθ) or high theta band (6-7Hz; Hθ), and use a 128-channel digital electroencephalograph to compare their appearance patterns in athletes and non-athletes at the onset of voluntary movement.
The subjects were 18 healthy right-handed men, 9 of which were athletes (kendo practitioners; 18-21 years of age (20.6 ± 1.1)) and 9 were non-athletes (18–22 years of age (19.5 ± 2.1 years)). The experimental task consisted of a voluntary movement task, which was pushing a button. The task was performed in sets of 30 and repeated 3 times, for a total of 90 times; a 3-min break time was provided between trials.
The EEGs were recorded on the scalp by 128 channels. The standard electrode during the recording was positioned on the vertex of the head and the grounding electrode was on the Fpz (frontal Midline-Parietal). Recording conditions were defined as follows: 500 Hz as sampling frequency, 0.1 Hz as low frequency filter, 200 Hz as high frequency filter and 100 kΩ or lower as resistance value between the electrode and the scalp.
As a results, the occurrence pattern of the Lθ was especially localized in the prefrontal area from an onset of a voluntary movement. On the other hand, the occurrence pattern of the Hθ was localized in the frontal midline area from 2 seconds before the button press, was localized in the prefrontal area from an onset of a voluntary movement. In addition, there potential powers ware significantly higher in the athletes.
The present result suggested that there is a difference between the occurrence pattern of the Lθ and Hθ at the onset of a voluntary movement. In addition, the potential power of the θband high in athletes, exercise was suggested may enhance the focused attention.

Title: The use of mobile EEG in a pilot study focused on the impact of low current brain stimulation on math understanding and calculations.

Authors: ***R. A. HOUSER**[1], D. FONSECA[2], E. O'CONNOR[3], W. WEBBER[3], I. HEIM[2], A. IRWIN[3];

[1]Educational Studies, The Univ. of Alabama, Tuscaloosa, AL; [2]Engin., [3]Educational Studies, Univ. of Alabama, Tuscaloosa, AL

Abstract: *Introduction*
This project was designed to identify neural correlates of math calculations central to successful functioning in STEM programs of study. The intent was to determine the impact of the low brain current stimulation in effort to enhance performance on math calculations. Outcome data were collected through EEG data collection and performance in math calculations.
Participants
Participants were undergraduates registered for a pre-calculus course at a research university in the southeast. The pilot study included 10 participants, 7 females and 3 males. The age of participants ranged from 19 to 22. Participants were paid $100 for completing six sessions.
Procedures
We initially collected baseline data of brain activity, five minute EEG recording. We used a mobile EEG amplifier so we could move from the laboratory to the natural environment, the classroom. Participants were randomly assigned to either a control (sham) condition or an experimental condition. The sham condition participants received a 1 mA 30 second administration of transcranial direction current stimulation, tDSC. The experimental condition participants received a 2 mA administration for 20 minutes prior to exposure of the instructional video, math calculation performance and classroom experience. Placement for anodal stimulation for both groups was at the P3 electrode based on the 10-20 International System. P3 and the left intraparietal sulcus which has been associated with math calculations. The cathode electrode was place over T4 based on the 10-20 International System and is associated with fine motor and should not impact math performance. Participants were initially shown a video demonstration of pre-calculus problems. Following the video participants completed a calculation based on the video. EEG data were collected while the participants completed the calculations. Participants completed six sessions, a baseline and five sessions involving exposure to math calculations videos and completion of math calculations.
Results
Spectral data were analyzed using ASA Lab software (ANT Neuro). Initially we removed artifacts from raw EEG data. The artifact filter was set at 75 μHz and -75 μHz. Once artifacts were removed data were converted to average spectral outcomes based on four second intervals. Four second intervals were randomly selected from each EEG data collection session. We will discuss preliminary pilot data comparing those receiving tDCS prior to viewing pre-calculus problems and while completing problems.

Title: Negative valence and dysmodulation of orbitofrontal cortical activity in borderline personality disorder: Sensitivity of top-down attention to facial valence

Authors: *R. MANIMALETHU[1], K. RAMASESHAN[2], A. BURGESS[2], P. SOLOFF[3], V. DIWADKAR[2];
[1]Wayne State Univ., Brighton, MI; [2]Wayne State Univ., Detroit, MI; [3]Univ. of Pittsburgh, Pittsburgh, MI

Abstract: Background Attention and stimulus valence independently strongly modulate fMRI-estimated cortico-limbic activity. Generally, fMRI responses represent a combination of top-down (attention & regulatory) and bottom-up (stimulus-driven) processes (Logothetis, 2009), particularly in the context of emotional processing. Inducing congruence between top-down processes ("what is being looked for"?) and bottom-up processes ("does the stimulus conform to what is being looked for"?) may be a way to enhance the sensitivity of the brain's emotion regulatory systems such as the orbitofrontal (OFC) and cingulate cortices (ACC) , and may be particularly valuable in characterizing clinical syndromes characterized by emotional dysregulation. Here we compared effects of positive (+ Context & + Stimuli) and negative (- Context & - Stimuli) congruence in healthy controls (HC) and patients with Borderline Personality Disorder (BPD), an Axis II personality disorder characterized by emotional dysregulation and hyper-lability (Leichsenring et al, 2011). **Methods** fMRI was collected (3T, Siemens Verio) while 42 BPD subjects and 29 healthy controls performed a modified CPT task (Soloff et al, 2015). A block of trials began with instructions specifying the context (+ve or -ve) indicating the affective class of faces on which to enhance vigilance. During the block, participants were shown a series of faces (1 Hz, jittered ISI) with letters ("A" or "X") imposed on the bridge of the nose, where "X" was a target only if facial valence was consistent with the context. Event related analyses (SPM 8) were used to estimate fMRI responses to congruent events in each class (+ve and -ve). Each participant contributed these two contrast maps to a second level using random effects analyses of variance, with Group (HC vs. BPD) modeled as independent factor and valence (-ve vs. +ve) modeled as non-independent factor. The results are specifically focused on Group x Valence interactions ($p<.05$). **Results** In HC, modulation of OFC activity increased from positive to negative congruence, an effect notable given the OFC's cardinal role in emotion regulation under conditions of -ve valence (Underwood et al., 2016). By comparison, in BPD, the modulation of the OFC decreased from positive to negative congruence suggesting reduced modulation under conditions of high emotion regulatory demand.

Conclusions The results imply a "turning off" in BPD of emotion regulatory regions under conditions when negative stimuli are evaluated in negative context. Manipulating top-down and bottom-up mechanisms of evaluating valence may enhance the search for mechanisms of emotional dysregulation in syndromes such as BPD.

Title: Individual differences in frontal alpha asymmetry and achievement goals mastery versus asymmetry

Authors: *M. E. MINEAR, W. SCOTT, 82071, M. COWEN, M. BROWN, T. HOLMES, D. MECHAM, W. MILLER, M. RADICH, A. STILL;
Psychology, Univ. of Wyoming, Laramie, WY

Abstract: Relative differences in left v. right frontal lobe activity at rest as measured by inverse alpha power (8-13Hz) have been shown to correspond to individual differences in approach v. avoidance tendencies as measured by self-report instruments such Carver & White's BIS/BAS Scale with BAS approach motivation associated with greater left resting activity and BIS associated with greater right activity. BAS corresponds to a behavioral tendency to seek out positive and negative reinforcement while BIS reflects sensitivity to punishment & reward and behavioral inhibition. Achievement goals are the reasons why an individual pursues a goal. Two dimensions of achievement goals have been proposed, mastery v. performance and approach v. avoidance motivation.
We hypothesized that frontal asymmetry would correspond to the approach- avoidance dimension such that both mastery and performance avoidance goals would be related to right sided activity while approach goals would correlate with greater left activity.
Methods
23 participants (14 female) completed both the BIS/BAS Personality Survey (Carver & White, 1994) and the Achievement Goal Questionnaire-Revised (AGQ-R; Elliot & Murayama, 2008). To measure frontal asymmetry, we used the resting paradigm reported in many previous studies of temperament and affect. EEG data were collected from the participants while they quietly rested in a darkened room for 8 one minute EEG trials, 4 eyes-open, 4 closed. Data were

collected using a high density 128 channel system (EGI) with a 250Hz sampling rate and a bandpass 0.1 to 100Hz filter. Log transformed power data in the alpha range for channels corresponding to frontal electrodes F3, F5, and F7 on the left and F4, F6 and F8 on the right were computed using EEGLab. Asymmetries scores were computed by averaging the 3 channels on the left and the right and subtracting left activity from right.
Results
BIS scores were negatively correlated with asymmetry scores (r = -.42) i.e. higher BIS scores were associated with greater right frontal activity as has been reported previously. BIS was positively correlated with all four achievement goals. However, only performance goals (both approach and avoidance) showed a relationship with frontal asymmetry scores similar to BIS scores i.e. associated with greater right frontal activity while neither mastery goal was associated with asymmetry.
Our hypothesis was not supported. Instead, these data suggest that performance goals in which a person evaluates her performance against others is related to right hemisphere activity regardless of approach or avoidance motivation.

Title: D-lysergicdiethylamide (LSD) modulates dopaminergic neurons of Ventral Tegmental Area invivo through a pleiotropic mechanism involving D_2 and $TAAR_1$receptors

Authors: D. DE GREGORIO[1], L. POSA[1], R. OCHOA-SANCHEZ[1], R. MCLAUGHLIN[1,2], S. COMAI[1,3], *G. GOBBI[1];
[1]McGill Univ., Montreal, QC, Canada; [2]Washington State Univ., Pullman, WA; [3]Vita-Salute-San Raffaele Univ., Milano, Italy

Abstract: Background: D-lysergic diethylamide (LSD) is a hallucinogenic drug with potent psychotropic effects. LSD may produce psychotic-like symptoms such as visual, tactile, acoustic hallucinations, change in body perception, and synesthesia. Traditionally, the psychotropic properties of LSD have been attributed to its effects at the level of the serotonin (5-HT) system,

but given the role of dopamine (DA) in the pathogenesis of psychosis, an interaction of LSD with the DA system cannot be excluded. Current knowledge regarding a possible *in-vivo* interaction of LSD with mesolimbic dopamine (DA) neurons of the ventral tegmental area (VTA), the main source of DA innervation in the brain, is limited. *In-vitro* studies have demonstrated that LSD has affinity for DA receptors, in particular D2 receptors, and for trace-amine associated receptor 1 ($TAAR_1$), in addition to its affinity for 5-HT_{1A} and 5-HT_{2A} receptors. Thus, we examined the *in-vivo* effects of cumulative doses of LSD on VTA DA neurons, and attempted to identify the underlying neurobiological mechanisms. **Methods**: Using *in-vivo* electrophysiology, we first studied the effects of cumulative doses of LSD (5-120 ug/kg, i.v.) on VTA DA neurons and on 5-HT neurons in Sprague-Dawley male adult rats. Secondly, we tested the contribution of 5-HT_{1A}, D_2, and $TAAR_1$ receptors in the mechanism of action of LSD upon VTA DA neurons by using the D_2 antagonist haloperidol (HALO,50 µg/kg, i.v.), the 5-HT_{1A} antagonist WAY-100,635 (WAY,500 µg/kg, i.v.), or the novel synthesized trace amine-associate receptor 1 ($TAAR_1$) antagonist EPPTB (5 mg/kg, i.v.). **Results**: LSD dose-dependently decreased VTA DA firing activity at doses higher (30-120 µg/kg, i.v.) than those (5-20 µg/kg, i.v.) inhibiting dorsal raphe 5-HT neurons (ED50: 71.8 vs. 13.1 µg/kg; $F(2,7)=39.34$, $P<0.0001$). The inhibitory effects of LSD on VTA DA firing activity were prevented by HALO, WAY and EPPTB, suggesting the involvement of D2, 5-HT1A and $TAAR_1$ receptors in the mechanism of action of LSD. Interestingly, the single i.v. injection of 5 mg/kg EPPTB increased VTA DA firing activity compared to vehicle (2.89±0.60 vs 2.15±0.34 Hz, $P=0.002$). **Discussion**: These results demonstrate that LSD at low doses affects the 5-HT system while at high doses strongly modulates DA mesolimbic neuronal activity with a pleiotropic mechanism of action involving 5-$HT_{1A,}$ D_2 and $TAAR_1$ receptors. Moreover, for the first time, we demonstrated that EPPTB exerts a tonic enhancement of DA firing activity *in vivo*.

Title: The wandering brain: Individual differences in grey and white matter structure predict frequency of goal-related and emotionally positive self-generated thoughts

Authors: *S. SHETH[1], K. C. R. FOX[2], M. S. JARRETT[2], M. GIRN[2], M. DIXON[2], A. RAUSCHER[2], K. CHRISTOFF[2];
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Self-generated thought has been most famously tied to activity in brain regions of the default mode network (DMN), although a number of regions outside the DMN appear to be consistently involved as well (Fox et al., 2015). Little is know, however, about how the brain's anatomical structure might vary in individuals with differing overall patterns of thought. For instance, individuals show marked differences in the frequency with which their thoughts are goal-related (vs. unrelated) and emotionally positive (vs. neutral or negative). Are these individual patterns of thinking related to individual differences in neuroanatomy? We sought to explore the relationships between these individual propensities and both grey matter concentration (using high-resolution T1 anatomical MRI scans) and white matter integrity (using diffusion tensor imaging). Following a morphometric neuroimaging scan, we allowed subjects to rest and think freely, interrupting their thinking at random intervals with occasional thought probes. A total of 120 probes asked subjects (i) whether their thoughts arose spontaneously, or whether they were intentionally directing them; (ii) whether thoughts were related to their current concerns and goals in life, or not; and (iii) whether they were emotionally pleasant, unpleasant or neutral. Overall individual difference scores were calculated for each participant (e.g., proportion of positive thoughts), and correlated with whole-brain grey matter concentration and tract-based white matter integrity. We identified distinctive patterns of both grey and white matter structure that were correlated with individual propensity toward spontaneously arising vs. intentionally directed thoughts; thoughts related vs. unrelated to current concerns and goals; and emotionally pleasant vs. unpleasant thoughts. Moreover, these differences were observed in many regions beyond the DMN. Our results suggest that distinctive individual tendencies in the content and valence of self-generated thinking are linked to correspondingly distinctive neuroanatomy. Our results also show that the brain structure of people who tend to have negative, non-goal-related thoughts is quantitatively distinct from those who tend to spontaneously produce positive, goal-related thinking, suggesting possible implications for understanding clinically relevant alterations of spontaneous thought such as depressive rumination.

Title: Neural abnormalities underlying feedback processing in psychopathy: Processing deficits remain with attention controlled

Authors: *M. S. SHANE[1,2], B. DARLING[1];
[1]Univ. of Ontario Inst. of Technol., Oshawa, ON, Canada; [2]The Mind Res. Network, Albuquerque, NM

Abstract: Real-world and experimental evidence converge in demonstrating that psychopathic individuals exhibit marked deficits learning to adapt maladaptive behaviors. These deficits have been theorized to result from reduced attention to relevant performance feedback, however the precise nature of these attentional abnormalities have yet to be established. The present study utilized functional magnetic resonance imaging (fMRI) to investigate the neural underpinnings of feedback-related learning deficits in psychopathy. 72 antisocial participants recruited through probation parole received a PCL-R interview, and completed a forced-choice learning task while in the scanner. In line with reduced attention to feedback in psychopaths, results indicated that psychopathic individuals (n = 15) showed reduced bilateral caudate response compared to nonpsychopathic individuals (n = 25) following both positive and negative feedback. However, when the duration of attention paid to feedback was controlled by including it as a parametric modulator, neural reductions *extended further,* into left dorsal anterior cingulate cortex (dACC), bilateral insula, left caudate and orbitofrontal cortex (OFC). Thus, even with the duration of attention to feedback controlled, psychopathic individuals showed reduced signaling in response to performance feedback. These results suggest that feedback-related learning deficits in psychopathy may extend beyond current attentional hypotheses, and may include additional underlying disruption in the utilization of attended-to feedback. Further characterization of these processing abnormalities may have important implications for understanding and managing the learning-related abnormalities in psychopathy.

Title: Neural substrate of fatigue in older adults

Authors: ***S. E. BURKE**[1], I. B. H. SAMUEL[1], Q. ZHOU[1], S. N. SIEGEL[1], J. CAGLE[1], B. M. KLUGER[2], M. DING[1];

Abstract: Fatigue is an extremely debilitating condition in older adults. It is associated with increased mortality and decreased quality of life. Despite the significant negative impact of fatigue, we know very little about its actual cause. Currently, there are no objective measures to diagnose the condition, and there is no treatment. Past work has suggested a role of white matter disruption in the pathogenesis of fatigue. To test this hypothesis, we recruited 25 older adults between the ages of 60 to 84 years and assessed their fatigue levels by the fatigue severity scale (FSS). These subjects then underwent diffusion magnetic resonance imaging (MRI). From these diffusion MRI data whole-brain Tract Based Spatial Statistics (TBSS) were obtained and compared between subjects with high levels of fatigue and subjects with low levels of fatigue. Differences between the two groups were detected in the white matter pathways surrounding the substantia nigra and anterior cingulate cortex. To further investigate the mechanism behind these white matter changes, we are analyzing the diffusion MRI data for Free Water, a reliable marker of inflammation that is highly specific to the brain. Through this analysis, we aim to show that neuroinflammation leads to white matter breakdown and that this is a measurable objective marker of fatigue in older adults.

Title: Investigating a novel implicit measurement of self-perception

Authors: *A. TEER, C. V. LEONARD, M. AIREY, N. IRFAN, M. T. TREADWAY; PSYCHOLOGY, EMORY UNIVERSITY, Atlanta, GA

Abstract: Growing evidence suggests that self-perception and self-esteem may be difficult constructs to assess using common self-report measures due to reporter biases. Tasks like the Implicit Association Task (IAT) have helped to address these limitations, but the neural circuitry involved in IAT tasks is unknown. In contrast, the neurobiological mechanisms of fear conditioning and extinction are very well characterized. The current study attempts to take advantage of these well-known circuits to test the feasibility of fear conditioning and extinction to self-related imagery as an objective biomarker of self-esteem.

34 healthy volunteers participated in this study. Participants completed self-report measures including the State Self-Esteem Scale (SSES), and had their photo taken at the beginning of the study. Three photographs served as conditioned stimuli (CS), one of which was the photograph of the participant (CS-Self). The CS-Self and another photograph (CS+) were always paired with the UCS. A third was never paired with the UCS (CS-). The unconditioned stimulus (UCS) was a loud unpleasant noise and pupil dilation served as the unconditioned response (UCR), which is a well-validated metric for autonomic arousal. Following a habituation block, participants completed two blocks of fear acquisition (24 trials each) and then two blocks of extinction. Based on contingency awareness ratings, explicit learning rates were comparable across subjects. All data were analyzed using multi-level mixed-effects GLMs in STATA. As expected, a significant main effect of CS type on pupil area (PA) exists such that CS-Self and CS+ images were associated with larger pupil dilation. Additionally, significant interactions existed between CS-type and the Appearance subscale of the SSES (SSES-A), when predicting PA at a trial-by-trial level. During the first acquisition block, this interaction was significant for CS-Self v. CS+ ($p = .025$). During the first extinction block, this interaction was significant for CS-Self v. CS- ($p= .032$). In both cases, the interaction of CS-type, UCS dislike, and SSES-A was also significant ($p = .037$; $p = .038$).

The aforementioned effects remain significant even when controlling for the ratings of UCS aversiveness. These preliminary findings support the potential for this paradigm to be used as an objective measure of self-esteem.

Title: Altered prefrontal cortical gray matter volume is associated with the relationship between depression and Internet gaming

Authors: ***J. CHOI**[1], J.-W. CHUN[2], H. CHO[2], J.-Y. KIM[2], K. AHN[3], D. KIM[2];
[2]Dept. of Psychiatry, [3]Dept. of Radiology, [1]Seoul St. Mary's Hosp., Seoul, Korea, Republic of

Abstract: Playing Internet games has become one of the most popular leisure activities for adolescents and young adults. Adaptive use of Internet games is associated with entertainment and improved spatial cognition, whereas previous studies have been frequently reported depression is prevalent in Internet gaming disorder (IGD). However, the neural mechanism underlying the association between depression and Internet gaming remains unclear. The aim of the current study is to investigate the structural brain alterations related to IGD and examine whether the alteration is associated with the relationship between depression and Internet gaming. Twenty-four controls (CON), who were not played Internet games, 25 subjects with Internet gaming control (IGC), and 22 subjects with IGD underwent structural magnetic resonance imaging. All subjects were males in their 2-30s without psychiatric disorder such as major depressive disorder. Using a voxel-based morphometric (VBM) approach, a voxel-wise whole brain analysis identified gray matter difference in the left dorsolateral prefrontal cortex (DLPFC) among three groups. Post-hoc analysis revealed the IGD group exhibited the lowest GMV in this region compared with the CON and IGC groups. Gray matter volume in the left DLPFC was negatively correlated with the amount of lifetime gaming and level of depression in the Internet gaming users (IGC+IGD groups). Furthermore, a mediation analysis revealed that the lifetime usage had indirect influence on the level of depression through the structural alteration in the DLPFC. The VBM results implicate that the brain structural alteration is involved in IGD. Additionally, the result of the current study may provide an intervention strategy for patients with IGD coexisting depression, one of the most common comorbid psychiatric symptoms of IGD.

Title: Behavioral phenotyping of impulsivity with a dynamic decision-making task

Authors: ***M. CARLAND**[1], G. DEROSIERE[3], D. THURA[2], P. CISEK[2];
[1]Physiologie, [2]Neurosci., Univ. De Montréal, Montreal, QC, Canada; [3]Inst. of Neurosci., Catholic Univ. of Louvain, Brussels, Belgium

Abstract: *Impulsivity* is a multidimensional construct that represents a well-known vulnerability factor for a variety of clinical disorders including addiction, problem gambling, and other forms of compulsive behavior. In the laboratory, impulsivity is typically measured with a variety of behavioral tasks including *go/no-go* paradigms and the Iowa Gambling Task, whereas researchers and practitioners in the clinical domain often rely primarily on self-reported psychometric batteries. One example is the widely-used *UPPS Impulsivity Scale* (Whiteside & Lynam, 2001, *Pers. & Indiv. Diff.*), which partitions impulsivity into five sub-factors including *Positive-* and *Negative Urgency*, *(Lack of) Premeditation, (Lack of) Perseverance*, and *Sensation-Seeking*.
However, recent meta-analyses have revealed that behavioral- and self-report measures of impulsivity account for separate sources of individual variance in impulsivity-related traits, suggesting that these assessment measures are tapping into distinct and non-overlapping dimensions within a broader underlying construct (Cyders & Coskunpinar, 2012, *J. Res. Personality*). This lack of agreement between measurement approaches thus represents an outstanding challenge to the utility of impulsivity as an explanatory construct in conceptual and clinical domains alike.
Here we present a novel dynamic decision-making task that yields a variety of discrete behavioral measures related to individual differences in risk- and reward sensitivity, response

inhibition, and speed-accuracy preferences. We also report initial findings regarding the relationship of these performance measures to various sub-factors of the UPPS impulsivity scale, thereby bridging the gap between behavioral and self-report measures of impulsivity. We conclude that this task offers the possibility to develop more precise cognitive-behavioral phenotypes of impulsivity, as well as to clarify the potential contributions of these phenotypes to a variety of clinical disorders.

Title: Altered orbitofrontal reactivity during reward processing among pathological gamblers and problematic pornography users

Authors: ***M. K. GOLA**[1], M. WORDECHA[2], G. SESCOUSSE[3], M. LEW-STAROWICZ[4], M. WYPYCH[5], B. KOSSOWSKI[5], S. MAKEIG[1], A. MARCHEWKA[5], M. POTENZA[6];
[1]UC San Diego, INC, SCCN, San Diego, CA; [2]Inst. of Psychology, Polish Acad. of Sci., Warsaw, Poland; [3]Radboud University, Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands; [4]III Dept. of Psychiatry, Inst. of Psychiatry and Neurol., Warsaw, Poland; [5]Lab. of Brain Imaging, Neurobio. Center, Nencki Inst. of Exptl. Biol. of Polish Acad. of Sci., Warsaw, Poland; [6]Departments of Psychiatry and Neurobiology, Child Study Ctr. and CASAColumbia, Yale Sch. of Med., New Haven, CT

Abstract: Pornography consumption has become highly prevalent in part given Internet availability. Approximately 70% of males and 20% of females aged 18-30 years use pornography weekly. For most people, pornography viewing is a form of entertainment, but for some individuals problematic pornography use (PPU) accompanied by excessive masturbation is a reason for treatment seeking (Gola et al., 2016). Such observations raise a number of societally, scientifically and clinically important questions: Can pornography consumption be addictive? What are the neural mechanisms underlying PPU? How might one best conceptualize PPU and intervene most effectively?
Recently using fMRI methodology we examined brain reactivity towards erotic and monetary stimuli, disentangling cue-related ‘wanting’ from reward-related ‘liking’ among 28 heterosexual

males seeking treatment for PPU and 24 matched controls (Gola et al., in press). Compared with control subjects, PPU subjects showed increased activation of brain reward circuits (ventral striatum) specifically for cues predicting erotic pictures but not for cues predicting monetary gains, which exactly mimics results of previous study with the same method on individuals with gambling disorder (Sescousse, et al., 2013)
Here we focused on other brain region involved in reward processing - orbitofrontal cortex (OFC). As it had been shown, evolutionally older posterior OFC in healthy subjects is involved in processing of primary rewards (food and sex), while anterior OFC process secondary rewards (such as money or social reinforces). According to this state of art aOFC is in our study it was the only ROI expressing higher activations for monetary gains than erotic rewards in control subjects. But interestingly, for PPU subjects the aOFC was more active for erotic pictures than monetary rewards, while pOFC remained unchanged. The amount of this shift in aOFC was related to PPU severity measures. Among subjects witch pathological gambling opposite pattern of changes was observed: pOFC was activated more for monetary rewards, while aOFC activations remained unchanged when compared to controls.
Our results suggests that PPU subjects may experience difficulties in differentiating between value of erotic and non-erotic rewards similarly to pathological gamblers in case of monetary and non-monetary rewards. Our results show also that PPU resembles neural and behavioral patterns well-described in gambling disorder. The findings suggest that for some people pornography may be addictive and that behavioral treatments for addictions, warrant investigation in PPU.

Title: A metacognitive model of personality.

Authors: *K. MOGI;
Sony Comp Sci. Lab., Shinagawa-Ku, Japan

Abstract: In personality research, the big five model (openness, conscientiousness, extraversion, agreeableness, and neuroticism) is considered to provide a standard description of people's traits (Digman 1990, Shrout and Fiske 1995). The variability in personality has been linked to

academic performance (Poropat 2009), work success (Mount and Barrick 1998), and the tendency to innovate (Fairweather 2012).
Although the big five model is based on a large body of research and is statistically robust, one of the drawbacks is the descriptive nature of its methodology. In order to quantitatively characterize personality traits, we need to have a dynamic and quantitatively structured model of personality, which, in turn, might be compared and linked to the traditional personality model. Uncertainty is one of the most important environmental and interaction elements in the makeup of personality. People have different attitudes toward the handling of uncertainty, and risk taking and/or aversion. The human brain's reward systems (e.g. dopamine pathways) are known to modulate their activities based on the (perceived) nature of uncertainties involved (Schultz 1998). In development, secure base (Bowlby 1990) provides the basis for people's exploration of uncertain rewards. From the theoretical perspective, the balance between exploitation and exploration has been shown to be important in reinforcement learning (Sutton and Barto 1998) Here I present a generic model of personality based on a subject's dynamic reaction pattern to actual and perceived uncertainties in the interaction with the environment. The subject's perceived level of secure base, as well as the metacognition of the contexts involved (Redford 2010), are integrated to give a generic agent model compatible with the available data. Elements of emotion connected to this model is described, with other elements of emotion accounted for as secondary traits arising from the processing of information related to the interaction with the environment in the presence of uncertainty.

Title: Age-related differences in the organization of large-scale functional brain networks during successful memory formation

Authors: *G. S. WIG[1,2], F. ALHAZMI[1], M. Y. CHAN[1], N. K. SAVALIA[1];
[1]Ctr. for Vital Longevity, Univ. of Texas at Dallas Ctr. for Vital Longevity, Dallas, TX; [2]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: We recently reported age-related differences in the organization of resting-state brain networks (Chan et al., 2014). Increasing age was associated with decreasing segregation of functional sub-networks (systems); lesser segregation was also associated with poorer memory

ability, independent of age. While these results highlight the potential age-related differences in ‘intrinsic’ network organization, they don’t reveal how task-oriented information processing may modify brain network organization, and whether this may differ with age.
Here we examined large-scale network patterns defined by both resting-state functional connectivity (RSFC) and task-evoked functional connectivity in a large group of participants sampled from a wide range of the healthy adult lifespan (The Dallas Lifespan Brain Study; N=208; 20 to 89 yrs). Task-based connectivity was characterized by analyzing participants' blood-oxygen-level dependent (BOLD) activity from an event-related visual discrimination fMRI task; this scanned task was followed by a surprise memory test which allowed us to examine differences in brain connectivity associated with subsequently remembered versus forgotten items. Brain networks were constructed using a pre-defined set of nodes (volumetric regions of interest). Task network edges were calculated between all node pairs using a psychophysiological interaction analysis (PPI). RSFC network edges were calculated between all node pairs using a Fisher-z-transformed Pearson's correlation of their resting-state time-course. Independent of age, system segregation decreased during task performance compared to rest. Further, while younger adults exhibited greater network segregation during encoding of items that were subsequently remembered versus those that were subsequently forgotten, older participants did not exhibit these trial-type segregation differences. Importantly, we also found age-related differences in patterns of task-based connectivity associated with successful memory formation. Younger adults exhibited greater successful encoding-related connectivity between nodes associated with control and default operations (association systems), while older adults exhibited greater successful encoding-related connectivity between nodes of sensory-motor systems and between nodes of association to sensory-motor systems. These results suggest that aging is associated with differences in the organization of large-scale networks both at rest and in the context of goal-directed tasks. They also suggest that patterns of large-scale network connectivity associated with successful encoding differ with age.

Title: Long-term vegetable, fruit, fruit juice intake and subjective cognitive decline in men

Authors: *C. YUAN[1], E. FONDELL[1], A. BHUSHAN[2], A. ASCHERIO[1], F. GRODSTEIN[3], W. WILLETT[1];
[1]Nutr., Harvard T.H. Chan Sch. of Publ. Hlth., Boston, MA; [3]Channing Div. of Network Med., [2]Harvard Med. Sch., Boston, MA

Abstract: Background: Inconsistent findings have been reported on the cognitive effects of fruit, vegetable, and juice consumption, and previous studies have had relatively small sample size and limited period of follow up. This study aimed to investigate the long-term associations of vegetable, fruit, and juice intakes across adulthood with later-life subjective cognitive decline (SCD).
Methods: We conducted a prospective evaluation of vegetable, fruit, juice intakes and SCD among participants from the Health Professionals Follow-up Study. The final study included 26,808 men with a mean age of 51 years at enrollment in 1986, and self-reported SCD in 2008-2012. Cumulative average intakes of vegetable, fruit, and fruit juice were calculated from five repeated food frequency questionnaires collected every four years to 2002. SCD was assessed by a 6-item self-reported questionnaire and the average of the two SCD scores was used to classify participants' cognitive function as "good" (54.4%), "moderate" (38.2%) or "poor" (7.4%).
Results: Intakes of total vegetables, fruits, and fruit juice were significantly inversely associated with the odds of moderate or poor cognitive function after controlling for age, smoking, physical activity, BMI, multivitamin use, disease history of diabetes, high blood pressure, elevated high cholesterol level, cardiovascular disease and depression, alcohol intake and total energy intake. The association became null for fruit intake after further adjusting for intakes of total vegetable, fruit juice, coffee, potatoes, legumes, refined grains, fish and processed red meat. In this model the multivariate odds ratios (95% confidence intervals) for vegetable intake (top vs. bottom quintile) was 0.85 (0.77, 0.95), p-trend=0.003 for moderate SCD and 0.69 (0.57, 0.85), p-trend=0.01 for poor SCD. Similar inverse associations were found for green leafy, and carotenoid-rich vegetables. We also observed inverse associations of non-citrus fruit and berry subgroups with poor SCD. For fruit juice intake, the odd ratios were 0.75 (0.68, 0.82), p-trend<0.001 for moderate SCD and 0.64 (0.54, 0.76), p-trend<0.001 for poor SCD.
Conclusions: Our findings support a potential beneficial role of vegetable and fruit juice consumption to reduce cognitive decline in U.S. men.

Abstract: Research using non-invasive methods to parcellate functional brain areas has largely focused on parcellating healthy young adult brains by identifying variations in patterns of evoked-activity, connectivity, or anatomy. However, individuals advanced in age exhibit substantial structural and functional differences relative to younger adults. It is unclear whether a parcellation map derived from young adult brains is entirely suitable for understanding the organization and function of older adults' brains.

A number of recent studies have leveraged patterns of resting-state functional correlations (RSFC) to conduct rapid parcellation of the cerebral cortex and subcortical structures. For example, identifying transitions in patterns of RSFC across the cortical surface has revealed locations of putative areal borders (Cohen et al., 2008). Importantly, RSFC parcellation has been shown to correspond well to parcellation information from other modalities such as task-activity and distinctions in architectonics (Wig et al., 2014). In addition to validating the approach, these observations also suggest that RSFC-based parcellation could be used for characterizing and understanding age-related differences in functional parcellation.

We analyzed data from a large sample of healthy adult participants collected under the Dallas Lifespan Brain Study (DLBS; N=238; 20-89 yrs) for whom RSFC and anatomical information was acquired. Participants were separated into 4 age groups to create age group-specific RSFC-defined parcellation maps across the cortical surface, using modifications of previously published procedures for generating group-based parcellations (Wig et al., 2014; Gordon et al., 2015). The current work focused on describing the age-related variations in parcellation by characterizing differences in parcel position/size and functional connectivity in various locations throughout the cerebral cortex.

Parcellation features were qualitatively similar across age groups: the general topographical organization of parcellated areas did not differ vastly from younger to older age. In addition, seed-based RSFC maps generated from a collection of overlapping parcels across groups exhibited largely similar connectivity patterns. Interestingly, the homogeneity of parcels did exhibit age-related differences, with the most prominent differences occurring between the younger (20-34 yrs) and older adult (65+ yrs) parcellations. Together these results suggest that aging may be accompanied by subtle differences in the parcellation of functional areas, possibly brought on by morphometric changes in anatomy that accompany healthy aging.

Title: A cognitive stressor for event-related potential studies: the portland arithmetic stress task

Authors: *R. M. ATCHLEY[1], R. ELLINGSON[2], D. KLEE[2], T. MEMMOTT[2], B. OKEN[2]; [1]Neurol., Oregon Hlth. and Sci. Univ. Dept. of Neurol., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Background: There is a need for tasks that better define resilience to stress either as the amplitude or duration of stress-related changes. To this end, we developed a cognitive stressor that can be readily adapted for event-related potential studies. We named the task the Portland Arithmetic Stress Task (PAST) and modeled it on the well-validated Montreal Imaging Stress Task (MIST). The goal of this experiment was to evaluate changes in autonomic stress reactivity of biomarkers elicited by the PAST before incorporating event-related measures. Methods: Sixteen older adults (aged 50-80 years, *M* = 59) with Perceived Stress Scores ≥9 were recruited as part of a randomized clinical trial of mindfulness meditation. Participants first completed a set of standard self-assessment scales of stress, depression and neuroticism. Prior to randomization in the meditation study, the PAST was administered during an in-lab baseline assessment visit. The PAST, as a cognitive stressor, is composed of computerized mental arithmetic problems with an adaptive failure algorithm. It attempts to maintain an error rate of approximately 40% for the duration of the test and includes a social-evaluative threat component and auditory feedback components. The titrated difficulty of the arithmetic problems is performed using five levels based on number of numerals (2-4), number of digits in the numbers (1 or 2), types of operators (+, -, x, and /), presence or absence of fractions, and time window length allowed for responses. The task is approximately 10 minutes long and was repeated twice. To control for normal levels of autonomic arousal during cognitive tasks, participants completed a tones task in which they were instructed to press a button in response to the infrequent (occurrence: 15%), higher pitched tone. Several measures of stress were evaluated: blood pressure (BP), heart rate (HR), heart rate variability (HRV), and respiration rate. BP and HR were taken at time points before, during, and after administration of the PAST. Results: BP increased significantly immediately after the task compared to just prior to the task, with systolic increasing from *M*=131 to 137, p=0.035; and diastolic increasing from *M*=79 to 88, p=.026. HR and HRV were unchanged. Respiration rate increased significantly from 14.5 breaths per minute to 16.3 per minute, p=0.017. The relationships of changes in autonomic measures with self-rated

measures will be discussed.Conclusion: The PAST successfully produced deviations in autonomic nervous system markers consistent with stress-induced changes. Further research is needed to determine any cognitive or other changes occurred as a result of this stress task.

Title: Smoking effects on attentional control: More than just withdrawal?

Authors: ***J. NICOSIA**, C. LUSTIG;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Addiction is often linked to poor attentional control, especially strong involuntary attention to and distraction from drug-related cues. On the other hand, it has also been hypothesized that individuals and groups (e.g., patients with schizophrenia or attention deficit disorder) with attentional vulnerabilities use psychoactive drugs, especially nicotine, in attempts at self-medication. We tested smokers and non-smokers in the Continuous Temporal Expectancy Task (CTET; O'Connell et al., 2009) with a video distractor (Berry et al., 2014b). The video CTET allows for simultaneous independent assessment of initial focus/level of performance, the ability to maintain performance over time, and the ability to resist distraction. Using genetic and patient groups, we have previously shown that performance, especially the ability to resist the distractor, is related to cholinergic capacity (Berry et al., 2014a; Kim et al., 2015). Contrary to our initial hypothesis, smokers were not differentially vulnerable to distractor videos with smoking-related content. Instead, smokers had generally higher performance overall. Numerical trends also suggested that smokers had less memory for the distracting video content. Preliminary analyses suggest that those who had smoked recently (within the last 60 minutes) out performed non-recent smokers. Non-recent smokers also reported more subjective distraction from the videos, and had increased memory specifically for those distractor videos with smoking-related content. These results are generally consistent with the idea that cholinergic function supports attentional control, in particular the ability to resist external distraction.

Further, they suggest that nicotine may have pro-cognitive effects on attention that go beyond the amelioration of withdrawal-related deficits.

Title: Resting fMRI signal predicts evoked connectivity with TMS-fMRI

Authors: *D. OATHES[1], M. GOODKIND[2], G. FONZO[3], G. GLOVER[4], B. PATENAUDE[3], A. ETKIN[3];
[1]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA; [2]New Mexico VA Hlth. Care Syst., Albuquerque, NM; [3]Psychiatry, [4]Radiology, Stanford Univ., Palo Alto, CA

Abstract: Resting fMRI is a widely used method for assessing 'intrinsic' brain processes and connectivity. However, maps of these signals are often distributed and little causal information can be gained by examining correlations in time course or amplitude across the resting brain. In this investigation, we sought to determine a possible correspondence between signal amplitudes in the low frequency band typically measured with resting fMRI and brain responses to TMS recorded with fMRI. We therefore regressed site of stimulation signal amplitudes from a previously acquired resting scan onto TMS evoked connectivity (psychophysiological interaction) seeding the site of stimulation to both the central executive (dorsolateral prefrontal cortex) and the salience network (anterior middle frontal gyrus) and found robust evidence for a positive relationship between resting signal amplitudes and TMS evoked connectivity within each targeted network (cluster FWE corrected). Our results suggest that resting fMRI signal predicts causal information flow to distributed networks from prefrontal cortex.

Title: Self-estimates of cognitive abilities predict performance on the NeuroCognitive Performance Test

Authors: *K. D. BIDDLE[1,2], N. F. NG[2], C. SIMONE[2], G. MORRISON[2];
[1]Dartmouth Col., Hanover, NH; [2]Lumos Labs, Inc., San Francisco, CA

Abstract: To determine if perception of cognitive abilities is a good predictor of NeuroCognitive Performance Test (NCPT) score. To investigate how self-estimates (subjective) and NCPT scores (objective), as well as the subjective-objective relationship, are influenced by individual differences.
An email invitation was sent to Lumosity users (~177k) who were asked to complete a questionnaire via www.surveygizmo.com, followed by the NCPT. The questionnaire collected demographics, self-estimate of cognitive abilities relative to same-aged peers, happiness score (Subjective Happiness Scale), optimism score, and depression severity (Beck Depression Inventory (BDI)). The NCPT is a brief, repeatable, online battery of cognitive assessments that measures cognitive performance in multiple domains. Statistical analysis, including calculation of the correlation (Pearson's r) between self-estimates and NCPT scores and cross-demographic differences, was performed using R.
686 total subjects were analyzed. A correlation of $r=0.37$ ($p<0.001$) between self-estimates and NCPT was observed. 69% reported cognitive abilities as "better than peers," while only 55% scored above average on the age-matched NCPT. The 35-45 year-old group showed the strongest relationship between self-estimates and NCPT ($r=0.46$, $p<0.001$). Education positively correlated with self-estimates and NCPT (education-self-estimate: $r=0.2$, $p<0.001$; education-NCPT: $r=0.1$, $p=0.01$), but there was no significant correlation between education and subjective-objective correlation. There was a positive correlation between both happiness and optimism and self-estimates, but not between these covariates and NCPT (happiness-self-estimate: $r=0.17$, $p<0.001$, optimism-self-estimate: $r=0.18$, $p<0.001$). There was a significant, negative correlation between severity of depression and both self-estimates and NCPT score (BDI-self-estimate: $r=-0.22$, $p<0.001$; BDI-NCPT: $r=-0.1$, $p=0.01$). In a linear model of the effect of self-estimate, happiness, optimism, depression, and education, self-estimate showed the only significant effect on the NCPT (adjusted $R^2=0.14$, $p<0.001$).
Self-estimates are reasonably predictive of normalized NCPT scores, though differences exist across gender, age, and country. There is a stronger relationship between self-estimates and NCPT than education and NCPT. People who score higher on happiness/optimism scales rate

cognitive abilities as better, but do not necessarily perform better/worse on the NCPT. The opposite is true for people who score higher on depression scales, who rate themselves less favorably and perform slightly worse on the NCPT.

Title: Monomeric far-red and near-infrared fluorescent proteins for neuroimaging

Authors: *K. D. PIATKEVICH[1], E. JUNG[1], C. LINGHU[1], H.-J. SUK[1], D. PARK[1], B. SZABO[2], M. DROBIZHEV[3], F. CHEN[1], O. SHAMESH[1], E. S. BOYDEN[1];

Abstract: Currently, most genetically encoded molecular tools used to study the brain are adopted from nature. However, the majority of naturally occurring proteins must to be optimized or reengineered before they can be adopted by researchers. We developed a simple approach that enables rapid directed molecular evolution of fluorescent proteins in mammalian cells to select for variants with several simultaneously optimized characteristics such as brightness, photostability, and cytotoxicity, in a single round of evolution, using a hierarchical screening strategy.
Using this method, we developed a pair of monomeric fluorescent proteins with far-red and near-infrared fluorescence spectra, named mfRFP and miRFP respectively, which are characterized by superior brightness, photostability and lower cytotoxicity in comparison to spectrally similar fluorescent proteins. Both mfRFP with excitation/emission maxima at 611/658 nm and miRFP with excitation/emission maxima at 674/703 nm correctly label fusion proteins in live cells and demonstrate excellent performance in neurons in culture and *in vivo*.
In contrast to earlier monomeric phytochrome-derived fluorescent probes, miRFP does not require co-expression of heme oxygenase 1 to enable its bright fluorescence in neurons in culture and *in vivo*. Furthermore, substantial overlap between the two-photon excitation spectra of

miRFP and blue-green fluorophores enables multicolor imaging using a single wavelength of excitation from a standard Ti-Sapphire laser. In addition, mfRFP expands the palette of fluorescent proteins compatible with our recently developed super-resolution imaging technique, protein retention expansion microscopy (proExM). We believe that mfRFP and miRFP will find broad applications as protein and cellular labels for *in vivo* imaging. Furthermore, directed evolution in mammalian cells may enable more rapid generation of synthetic biology tools for neuroscience than screens in bacteria.

Title: Stability of lentivirus over hours at room temperature facilitates convection-enhanced delivery of DREADD expressing vectors into Rhesus monkey amygdala

Authors: *W. LERCHNER, M. A. G. ELDRIDGE, D. DEBORAH ROSE, V. DER MINASSIAN, V. COSTA, B. AVERBECK, B. J. RICHMOND;
LN/NIMH, NIH, Bethesda, MD

Abstract: To study the connection between behavior and its neural substrates we are using chemogenetic tools, such as DREADDs, in Rhesus monkeys to modulate neuronal activity. To carry out these experiments we would like to modulate the activity in volumes of tissue on the order of 10s of mm^3. Here we show results from slow infusions of lentivirus into the amygdala of rhesus monkeys using convection-enhanced delivery (CED). *Lentivirus stability.* We investigated the stability of lentivirus at room temperature (RT) with *in vitro* assays. Lentivirus expressing the hM_4Di-CFP DREADD under the control of the human synapsin promoter (Lenti-syn::hM4Di-CFP) was loaded into a syringe and expelled at six time-points between zero and six hours. Transduced T293 cells were harvested after 48 hours and used to determine viral titers. We also transduced T293 cells at the same time points with virus kept on ice. For the virus at RT the titer fell slightly between 0 and 30 minutes from 1.4x10E9 particles/ml to approximately 10E9 particles/ml but remained stable at from 30 minutes to 6 hours. The experiment was

repeated three times with consistent results. *DREADD expression in amygdala.* In a rhesus monkey, we made a single injection of 80 ul lenti-syn::hM4Di-CFP vector into the right amygdala at 1 ul/minute. In the same monkey we made four 20 ul injections into the left amygdala on a 2 x 2 mm grid, again at 1 ul/minute. For the injections into each amygdala a Hamilton syringe was filled with 90 ul of lentivirus before starting injections. Including loading, handling of the syringe and 10 minute wait times before removing the syringe after injections, the 80 ul injection into the right amygdala took approximately 100 minutes, and the four 20 ul injections into the left amygdala took a total of 140 min. Areas on histological sections where at least 50% of the neurons showed expression after post-mortem staining (penetrance) were outlined. Reconstruction showed that the single 80 ul injection filled a volume of ~45 mm^3 and the combined four 20 ul injections filled ~53 mm^3 with an average penetrance of >80%. Peak penetrance was close to 100% in approximately 30% of the tissue volume showing expression. The volume filled by the single injection was relatively uniform in distribution, whereas the four smaller injections covered a larger total volume of the amygdala, as there were some gaps with no cellular expression between injections**.** There was no decrease in coverage across the four individual injections on the left side, leading us to conclude that there is no degradation of virus transduction across the 4 injections (13, 12, 16, 12 mm^3). The beginnings of the first and last injections were separated by more than 100 min.

Title: A Novel cell based assay for screening Muscarinic M1 allosteric modulators

Authors: R. SUBRAMANIAN[1], S. EDULA[1], S. PETLU[1], M. NISSANKARARAO[1], M. SRIRANGAVARAM[1], V. MEKALA[1], *K. MUDIGONDA[2], R. NIROGI[1];
[1]Suven Life Sci. Ltd, Hyderabad, India; [2]Suven Life Sci., Hyderabad, India

Abstract: Alzheimer's disease (AD) is a debilitating neurodegenerative disorder afflicting millions of people. Cholinergic neurons degeneration and hypofunction are pathologies associated with Alzheimer's disease (AD). Earlier clinical studies has shown involvement of muscarinic acetylcholine subtype 1 (M_1) receptor in cognitive improvement and their clinical utility was limited by in-sufficient selectivity leading to cholinergic side effects. Muscarinic

acetylcholine receptors (mAChRs) mediate acetylcholine-induced neurotransmission and five mAChR subtypes (M1-M5) have been identified. Among them, M1 mAChR is widely expressed in the central nervous system and has been implicated in many physiological and pathological brain functions. In addition, M1 mAChR is postulated to be an important therapeutic target for AD and several other neurodegenerative diseases. Cholinergic side effects are due to conserved nature of the orthosteric site as a result it is difficult to identify selective M_1 receptor agonists. Allosteric modulation offer greater selectivity, physiological control retention and reduced over dose risk in comparison to traditional orthosteric compounds. Currently Calcium mobilization assay using Fluorescence Imaging Plate Reader (FLIPR); a kinetic assay which measures difference in Ca2+ levels in real time being widely used for Positive allosteric modulators of M1 receptor. Muscarinic receptors have biased signaling mechanism they primarily signal via Gαq and also couples to Gαs secondarily. Hence, we have developed cell based luciferase assay for screening the compounds which might mitigate the disadvantages of the existing method

Title: An experimental and bioinformatics pipeline for determining the contribution of alternative splicing to cell surface receptor diversity

Authors: *T. RAY[1], K. J. COCHRAN[2], O. FEDRIGO[3], M.-M. WANG[4], M.-X. HE[4], E. PARK[4], J. N. KAY[5];
[2]Computer Sci., [3]Duke Ctr. for Genomic and Computat. Biol., [1]Duke Univ., Durham, NC;
[4]Advanced Cell Diagnostics, Inc, Newark, CA; [5]Neurobio., Du, Durham, NC

Abstract: During development, neurons express an array of cell surface proteins that are instrumental to selective circuit wiring. These highly specific neural connections support cognitive abilities and perception. It has long been hypothesized that the number of cell surface proteins required for selective circuit wiring exceeds the number of protein coding genes in the genome. What mechanisms generate the required protein diversity? One possibility is alternative splicing of gene transcripts, which can greatly expand the functional coding capacity of the genome by generating multiple proteins from the same gene that differ in their receptor/ligand specificity. A few examples of this phenomenon are known (notably insect *Dscam*) but the extent to which alternative splicing diversifies neuronal receptor-ligand repertoires is unclear. A major obstacle to investigating this question is the lack of reliable methods to catalog and quantify the full-length transcripts generated by individual genes. We also lack methods to discern cell type-specific isoform expression patterns, limiting our ability to study protein isoform function in the context of neural circuit wiring. To overcome these obstacles, we developed a pipeline for identifying alternative splicing events relevant to forming the neural circuitry of mouse retina. First, we used traditional short read RNAseq datasets from retina to identify genes with significant alternative splicing within protein-coding regions. We identified 30 highly-expressed members of the epidermal growth factor and immunoglobulin superfamilies as candidate spliced cell-surface molecules. We developed a full-length cDNA-capture approach to sequence our 30 candidates at high depth on the PacBio RSII platform. This analysis was performed at various developmental time points. Custom bioinformatics algorithms were developed to identify and quantify known and novel isoforms. In this way we identified thousands of new splice isoforms of these 30 cell surface molecules, many of which are likely to change functional properties of the encoded proteins. We further identified novel genomic features including alternative promoter sites and alternative 5' and 3' UTRs, which might influence expression levels or subcellular localization of mRNA/protein. Finally, we used novel next generation *in situ* hybridization probes and assay technology to determine isoform specific spatial and temporal expression across retinal cell types. Our data reveal that isoform diversity for many cell surface receptors is greatly unresolved. How this diversity influences wiring of the nervous system is currently under investigation.

Title: Phagocyte recruitment signals in apoptotic vesicles present in exosomal preparations

Authors: *V. V. DIDENKO;
Neurosurg., Baylor Col. of Med., Houston, TX

Abstract: Apoptotic bodies are the characteristic membrane blebs released by cells undergoing apoptosis. They carry “find-me” and “eat-me” signals which ensure migration of phagocytic cells to apoptotic sites and effective clearance of apoptotic debris. We developed a novel labeling approach for the detection and analysis of apoptotic bodies based on the composition of their cargo. Using this technique, we detected and investigated a population of small apoptotic bodies present in exosomal preparations isolated from various biological fluids by standard exosome purification methods. These apoptotic vesicles carry phagocyte recruitment signals and molecular markers identifying apoptotic mechanisms.
The new approach and the results of its application can be useful in studies of cell signaling in apoptosis and phagocytosis.

Title: Doxycycline (DOX)-controlled gating of gene expression in Rhesus monkey brain

Authors: *H. LAM, W. LERCHNER, M. A. G. ELDRIDGE, V. DER MINASSIAN, B. J. RICHMOND;
LN/NIMH, NIH, Bethesda, MD

Abstract: We are manipulating neural tissue using genetic techniques to probe the connection between neuronal function and behavior. To do this, we express proteins such as DREADDs that can affect the activity of neurons. By adding a means to gate gene expression, i.e. an 'on/off switch', it becomes possible to regulate expression of a gene of interest during desired intervals e.g. an shRNA to knock down a receptor or the overexpression of a protein affecting neural activity. In rodents, this has been done using DOX systems.
Here we test 4 different potentially useful DOX-inducible systems using lentivirus in cell culture and in the monkey brain:
1) A two-vector DOX-ON system using neuron specific rtTA expression (DOX^{ON}-2),
2) A two-vector DOX-OFF system using neuron specific tTA expression (DOX^{OFF}-2),
3) A one-vector DOX-ON system using neuron specific rtTA expression (DOX^{ON}-1),
4) A one-vector DOX-ON system with auto-regulatory loop using neuron specific tTS^{kid} expression (DOX^{AUTO}-1).
All systems were initially tested with the mCherry-2A-dsGFP reporter gene to visualize short-term expression via destabilized GFP (2 hours half-life) and long-term expression including axonal terminals via mCherry. *In vitro* studies (fluorescent protein imaging in cell culture and Western Blots) revealed that all systems produced on/off switching and strong induction with the exception of *DOX^{AUTO}-1* for which only weak expression was detected after prolonged treatment with DOX. Replacing mCherry-2AdsGFP with the hM4Di-CFP DREADD yielded similar results.
We then tested the constructs in monkeys under the following conditions:
Monkey A: No DOX for 4 weeks.
Monkey B: No DOX for 4 weeks, then 10mg/kg DOX daily for 4 days.
Monkey C: 10mg/kg DOX daily for 4 weeks, then no DOX for 2 days.
DOX^{AUTO}-1 performed as expected with no detectable expression in the absence of DOX and strong expression in the presence of DOX; after 2 days of DOX removal following prolonged treatment, only mCherry persisted in some cells and projections. *DOX^{OFF}-2* performed more or less as expected with strong expression both in the absence of DOX and after 2 days of DOX removal following prolonged treatment; however, in the prolonged presence of DOX, we did observe some weak expression of mCherry. Results from the other systems remain inconclusive at this time and are being tested further. Our findings demonstrate that DOX-inducible systems (single and dual vector) are capable of regulating gene expression in the monkey brain.

Title: Autoradiography as a universal tool to measure quantitative receptor density and G protein-coupled receptor activation

Authors: J. RYTKÖNEN, T. PARKKARI, J. PUOLIVÄLI, S. ALASTALO, *O. M. KONTKANEN, P. J. SWEENEY, A. NURMI, T. HUHTALA;
Charles River Discovery, Kuopio, Finland

Abstract: Autoradiography is a powerful technique that can be applied to study receptor density and activation of G protein-coupled receptors (GPCRs) by novel pharmacological compounds in the brain. These methodologies are easily applicable to various disease models, and combining them with behavioral readouts allows a versatile evaluation of pathophysiology of the CNS disorders and mechanisms of action of novel therapies. GPCRs are involved in a wide variety of physiological processes, including regulation of behavior and mood. They activate intercellular signal transduction pathways and cellular responses. Cannabinoid, serotonin, dopamine, GABAB, and metabotropic glutamate receptors are among neurologically interesting GPCR targets. Ligand binding to GPCRs induces an interaction of the receptor with G protein that stimulates the release of GDP simultaneously with the exchange of GTP. ^{35}S-GTPγS autoradiography has been applied to study receptor activation after ligand binding to GPCRs of Gi and Gs types. In this study, we analyzed changes in the receptor density in chronic social defeat (CSD) model that has robust depression-like behavioral endpoints. To assess receptor density alterations, tritiated ligands to dopamine receptors 1 and 2, serotonin transporters and cannabinoid receptor 1 (CB1) were used and Bmax values of corresponding ligands were determined in relevant brain regions. Changes in Bmax values correlate with alterations in the number of available receptors sites and which may correlate with the phase or severity of the disease. We also determined the dose-response relationship of GPCR activation by the CB1 agonist HU-210 by detecting consumption of GTPγ^{35}S in the somatomotor cortex, cingulate cortex, striatum, globus pallidus and substantia nigra in mice. The potency (half maximal effective concentration, EC50) as well as efficacy (Emax) of interaction of HU-210 with CB1 was calculated from the obtained dose-response curves. The current examples demonstrate how a combination of assays can be utilized to advance our understanding of the disease state and measure effects of pharmacological treatments. Also, applied digital scintillation autoradiography enables quantitative and real-time imaging of tritiated samples within hours, compared to minimum of several weeks of exposure time required to phosphoscreens or films. This accelerates method development and analysis substantially. As a summary, the combination

of receptor and functional autoradiography offers a powerful tool to comprehensively measure changes in disease models or responses to novel molecules.

Title: Fret for measuring distances of connexin containing gap junctions

Authors: ***H. DECKER**[1,2,3], N. MARTINEZ-RIVERA[2], S. LIN[4], M. BROWNE[5], E. ROSA-MOLINAR[1,2,3];
[1]Microscopy and Analytical Imaging Lab., [2]Biol. Imaging Group, [3]Neurosci. Grad. Program, Univ. of Kansas, Lawrence, KS; [4]Andor Technology, Inc., Belfast, United Kingdom; [5]Andor Technologies, Belfast, United Kingdom

Abstract: In this study, we characterized a developmental 2D model approach using Förster Resonance Energy Transfer (FRET) to determine the spatial distance of connexin-containing gap-junctions within a stimulated synapse. FRET has long been used as a method to increase fluorescence resolution, the transfer of energy from a donor to an acceptor which generally occurs between 10-100Å, allowing one to determine the relative distance between the donor molecular and the acceptor molecule. In this study, we focused on a specific method to determine FRET, acceptor photo-bleaching. This method occurs when the acceptor fluorophore is completely photo-bleached or destroyed. If the FRET pair is close enough, there will be an increase in donor fluorescence. In order to establish that FRET is possible on a structure as small as a connexin-containing-gap junction, we immuno-labeled GFP-tagged Connexin 35 expressing cells with anti-connexin 35 and photobleached the connexin. This strategy a) allowed us to characterize the methodology necessary to determine FRET of the connexin, b) assisted in the

development of a 2D model that allows the precise testing of multiple parameters, and c) increased throughput. Once this model was established, cells were labeled with the fixable plasma membrane dye, mCling647N, and a connexin 35 antibody for FRET analysis. The FRET efficiency for each Connexin containing gap junction was calculated using the acceptor photo-bleaching method established by Kenworthy and Edidin (1997; J Cell Biol, 142:69-84). Future work will include the use of different sizes of fluoronanogold conjugated antibodies for correlative microscopy in order to determine accurate distance between connexins.

Title: Using the halotag technology to investigate the turnover of psd-95 at single synapses.

Authors: *M. KRATSCHKE[1], D. FRICKER[1], N. H. KOMIYAMA[2], S. G. N. GRANT[2];
[2]Ctr. for Clin. Brain Sci., [1]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Existing methods for analysing synaptic protein turnover are unable to provide adequate information about synthesis and degradation, particularly at single synapses. PSD95 is an abundant scaffolding protein found in the postsynaptic densities of excitatory synapses throughout the mammalian brain, and plays a critical role in innate and learned behaviours. PSD95 assembles with many other proteins into postsynaptic supercomplexes (Frank et al, 2016) that are then organised into nanoclusters that comprise the postsynaptic density of excitatory synapses (Broadhead et al, 2016).
The HaloTag consists of a modified bacterial haloalkane dehalogenase protein domain that covalently binds synthetic chloroalkane ligands that can be labelled with fluorescent and affinity moieties. Hence, cells expressing proteins fused to the HaloTag can be used to study protein levels, complexes and turnover using the different ligands.
We have adapted this method to study synaptic proteins by fusing the HaloTag to endogenous

PSD95 using gene targeting in the mouse. Using primary cultured neurons from PSD95-HaloTag mice we have shown that the HaloTag does not alter the expression level of PSD95, nor its normal assembly into 1.5 MDa supercomplexes. Next we show that ligands coupled to fluorophores label virtually 100% of PSD95 and individual postsynaptic puncta can be visualised with confocal microscopy. Using a pulse-chase paradigm, where one ligand (R110) is used to label all existing PSD95 first, we can then label any newly synthesised PSD95 using a second ligand (TMR). We can thus identify and characterise subpopulations of PSD95 and thereby analyse its synthesis and degradation. We find that PSD95 has a half-life of 33.2 hours ±2.5 (SEM) at single synapses, consistent with previous literature (El-Husseini et al, 2002). Furthermore, we have observed marked synaptic heterogeneity in PSD95 turnover, suggesting some synapses have more stable PSD95 complexes.
We also applied drugs known to modulate protein turnover and neuronal activity and analysed their effect on PSD95 turnover. We found that the proteasome inhibitor Lactacystin (1μM) not only significantly reduces PSD95 degradation, but concomitantly inhibits PSD95 synthesis over a 24-hour time period. This method offers a unique way of investigating the turnover of a specific, tagged protein. The effects of various modulatory drugs on PSD95 turnover are currently being investigated.

Title: Analysis of mitochondrial transport dynamics in axons

Authors: *K.-T. MIN;
UNIST, Ulsan, Korea, Republic of

Abstract: The polarized structure and extremely long neurites pose a unique challenge for neurons to distribute mitochondria to the appropriate locations. Hence, proper transport of

mitochondria to the appropriate locations is especially important for neuronal functions. Consequently, defective mitochondrial transport can have deleterious effects on neuronal functions and survival. It is widely accepted that mitochondria move from the cell body to axon terminals and vice versa. Although mitochondria are known to move bi-directionally from the cell body to axon terminals and vice versa, the dynamic pattern of mitochondrial transport in the entire length of axons for an extended period of time have not been thoroughly examined. Using the photo-switchable fluorescent protein dendra-2 targeted to mitochondria, we tracked individual mitochondria in the whole axon. Surprisingly, we find mitochondria that originated from the axon terminals traveling in the retrograde direction never reach at the cell body. Retrogradely moving mitochondria failed to enter the cell body due to fusion to existing mitochondria or pausing in the middle of axons, while anterogradely moving mitochondria reach the axon terminals with less interruption. In addition, the speed of mitochondrial transport varies along regions with different densities of stationary mitochondria. Stationary mitochondria were present at higher density in axon proximal to the cell body, although inter-mitochondrial spacing is random following Gumble-like distribution. Furthermore, we derived a mathematical model using the Fokker- Planck equation to characterize the features of mitochondria movement, which was successfully adopted to determine altered mitochondrial transport in axons overexpressing parkin. Our analysis and model provide new insights into the dynamics of mitochondria transport in axons of normal or unhealthy neurons.

Title: Immunolocalization of melatonin and its analogue M3C in testis of rat

Authors: *E. N. RODRIGUEZ;
Univ. Nacional Autónoma De México, Mexico City, Mexico

Abstract: Melatonin (MT) (N-Acetyl5-metoxytryptamine) is a lipophilic hormone produced by the pineal gland during the scotophase. The MT has activities in regulating biological rhythms

neuroimmunologic, antioxidant, gastroprotective, antiinflammatory, anxiolytic-antidepressant-like, antiproliferative and reproduction. In humans, (>60 years old) the concentration of MT and decreases less than that at puberty 80%. Currently, there is a therapeutic use exogenous MT without known toxicity and side effects. Debeliuk et al. (1969) showed that 300 µg of MT for 30 days, reduces the weight of the testes and affects the production of testosterone in rats. Redins et al., (2002) administered, 100 µg of MT (22 days), show a level ultrastructure damage in mouse Leydig cells. In 2011, Tuncer et al., reported a tubular degeneration, edema and obstruction of seminiferous tubules, with 3 mg/kg of MT (30 days) in rats. On this basis, we made studies with MT and it´s analogue 1-N-substituted (M3C) and to know if the testicular seminiferous tubule cell structure (ST) have any changes in rat by chronic administration for both substances, and demonstrate the immunolocalization of TM in this structure in male rats. Independent treatment with 300 µg of two substances (30 days) was applied. Post-treatment, the animals were perfused with buffered formaldehyde with saline solution and the testes for histopathological study (hematoxylin-eosin staining) and immunolocalization of MT with specific antibody anti-melatonin. The MT and M3C were located in ERA. Supported by UNAM-PAPIIT-DGAPA Key: IT201112 PAL Program UNAM-Facultad de Química. Key: 3000/3070

Title: Deciphering the cellular and physiological actions of cell-penetrating pepducins affecting NTS1 signaling

Authors: *R. L. BROUILLETTE, C. MONA, É. BESSERER-OFFROY, S. LAVENUS, J. CÔTÉ, M. SOUSBIE, J.-M. LONGPRÉ, R. LEDUC, M. GRANDBOIS, É. MARSAULT, P. SARRET;
Pharmacologie-Physiologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: G protein-coupled receptors (GPCRs) have proven to be effective targets in drug discovery. However, many believe that the therapeutic potential of this protein class remains

largely untapped. In recent years, new strategies have been developed to more fully exploit this potential, including cell-penetrating peptides known as pepducins. These lipidated peptides are able to translocate across the cell membrane and target the intracellular loop of a GPCR of interest, interacting at the receptor-effector interface. There, pepducins have been shown to act as allosteric agonists as well as positive or negative allosteric modulators of their cognate receptor. In the present study, we generated a series of pepducins targeting the first intracellular loop of the human neurotensin receptor 1 (hNTS1), a class A GPCR shown to mediate many of the physiological effects of the neurotensin (NT) tridecapeptide including analgesia, hypotension, and hypothermia. In CHO-K1 cells stably expressing hNTS1, we investigated the pepducins' effect on the orthosteric binding of ^{125}I-labeled NT. We also used BRET-based biosensors to verify the pepducins' ability to engage the Gαq, Gαi1, GαoA, and Gα13 pathways, as well as to recruit β-arrestins 1 and 2. Furthermore, we monitored pepducin-induced changes in whole-cell integrated response by surface plasmon resonance (SPR) in the same cell-type. Finally, in *in vivo* and *ex vivo* experiments, respectively, we evaluated the pepducins' ability to trigger blood pressure changes in carotid artery-cannulated rats and to induce smooth muscle relaxation of pre-contracted rat ileum tissue in isolated organ baths. Our *in vitro* results showed a partial decrease in [^{125}I]-NT binding and only minimal G protein-dependent and G protein-independent signaling pathway activation in agonist mode at concentrations of 10^{-5} M. Intriguingly, the noninvasive label-free whole-cell sensing assays revealed the existence of distinct and dissimilar SPR profiles following incubation with our pepducin series. Moreover, when systemically injected in rats, NTS1-selective pepducins were shown to exert more potent hypotensive effects at 55 nmol/kg than NT(8-13) at the same dose, and to induce a sustained mean drop in blood pressure of 30 mm Hg. We also observed ileum relaxation at high pepducin concentrations of 10^{-5} M. In summary, our results show that our set of pepducins participates in cellular and physiological effects linked to NTS1 activation, and may thus constitute a promising avenue of research into other properties of the neurotensinergic system, such as NT-induced analgesia.

Title: Light-inducible cre recombinase: using LOV domains to create a single-molecule light activated DNA recombinase enzyme

Authors: *D. M. OPLAND[1], D. S. ABRAMOV[2], C. W. BOND[2], E. P. FOSCUE[2], R. J. DILEONE[2];
[1]Mol. Psychiatry, [2]Yale Univ., New Haven, CT

Abstract: As a primary tool for controlled gene expression, DNA recombination is widely used throughout neuroscience. Gated control of recombinase activity has several current applications ranging from specific developmental studies as well as in defining the time window for tagging active neural ensembles. Current inducible gene expression systems rely on pharmacological ligands to gate DNA recombinase activity. The two most ubiquitous systems use either the antibiotic tetracycline or the estrogen receptor antagonist tamoxifen for control of recombinase activity. With both systems, the innate pharmacokinetics of the effector ligand defines the time-window of enzyme action, typically lasting hours to days. While this level of temporal specificity is sufficient for some implementations, improved temporal dynamics will broaden the use and impact of these approaches in neuroscience. We are developing and testing an alternative inducible recombinase system in which light controls the temporal dynamics of enzyme activity to increase the precision of controlled gene expression. This system is reliant on fusion proteins of Cre recombinase and the light-responsive subunit of the phototropin 1 gene (the LOV domain). In the absence of light, the LOV domain remains in a tightly bound formation preventing Cre recombination. However, when illuminated with blue (488 nm) light, the LOV domain unfurls and permits recombinase activity. Initial LOV-Cre fusion variants were created by varying the length of the amino acid tether connecting the protein domains and show moderate dark-state inhibition of Cre activity. Light stimulation of LOV-Cre (30 - 180 minutes) in an in vitro model system show a small increase in recombinase activity demonstrating proof of principle that this strategy can be leveraged to create a functional light-inducible DNA recombinase enzyme. Current work is focused on increasing the dynamic range of the early LOV-Cre fusion proteins via rational amino acid substitutions [Strickland D et al (2008) PNAS Aug 5; 105(31):10709-14] and to extending testing to in vivo models of recombinase mediated gene expression.

Title: Using CLIP to measure alternative polyadenylation in specific neurons

Authors: *S. JEREB, H.-W. HWANG, R. B. DARNELL;
The Rockefeller Univ., New York, NY

Abstract: Alternative polyadenylation is a process where different ends to an mRNA transcript are selected. These alternative ends contain regulatory 3′ untranslated regions (3'UTRs) and/or coding sequences. Recent evidence has shown that mammalian and fly brains express particularly long 3'UTR isoforms compared to other tissues. Alternative polyadenylation has been implicated in the regulation of subcellular protein and mRNA localization, translational regulation and mRNA stability. However, little is known about the *in vivo* functional roles of alternative polyadenylation in neurons. To form a more comprehensive view of alternative polyadenylation in the brain, we set out to determine the 3'UTR isoform diversity in two types of functionally and morphologically distinct neurons in the mouse cerebellum: excitatory granule neurons and inhibitory Purkinje neurons. By expressing GFP-tagged poly(A) binding protein cytoplasmic 1 (Pabpc1) in each cell type separately, we were able to sequence 3' mRNA ends using anti-GFP crosslinking immunoprecipitation (CLIP). Annotation of 3' ends revealed extensive isoform diversity between Purkinje and granule neurons with 1041 genes displaying differential 3'UTR isoform usage. Notably, Purkinje neurons tended to express fewer long 3'UTR isoforms compared to granule neurons. Moreover, it has been reported that alternative polyadenylation changes during embryonic development of an organism. To explore the role of alternative polyadenylation during neuronal development in more detail we focused on the development of cerebellar granule neurons. We annotated 3' ends in proliferating precursors of granule neurons and in mature granule neurons. 852 genes displayed differential 3'UTR isoform usage between the two developmental time points, most of the genes expressed a longer isoform in mature granule neurons. Interestingly, genes involved in ubiquitination were enriched both among genes that change 3'UTR isoform expression during development as well as those that differ in 3'UTR isoform expression between Purkinje and granule neurons. We are currently exploring the functional roles of the mRNAs that show 3'UTR isoform shift during granule neuron development.

Title: Probing synaptic plasticity: a single cell RNA sequencing approach

Authors: *H. J. MCQUILLAN[1], P. J. GUILFORD[1], R. C. DAY[1], B. J. SNOW[2], J. N. J. REYNOLDS[1];
[1]Univ. of Otago, Dunedin, New Zealand; [2]Auckland District Hlth. Board, Auckland, New Zealand

Abstract: Much of our current knowledge about synaptic plasticity has stemmed from electrophysiological recordings from single cells. However, such an approach, particularly *in vivo*, is inherently low yield and time consuming. Single-cell RNA sequencing represents an alternative approach with great potential, largely due to the recent development of several new RNA sequencing methodologies.
Single cell resolution lends itself well to studies of complex heterogeneous areas of the brain such as the striatum. In order to accurately identify single neurons not readily distinguishable by conventional microscopy, we first established a rapid (10 minute) labeling method by immunofluorescence on fresh frozen 12 μm sections. Antigens specific to the direct spiny neurons (substance P), indirect spiny neurons (enkephalin) and the cholinergic interneurons (choline acetyltransferase) of the striatum were able to be detected, while maintaining RNA integrity. Laser capture microdissection was then used to isolate neurons as either single cells or pools of single cell types. The Smart-seq 2 methodology for transcriptomic analysis was used due to the high level of cDNA yield, sensitivity, accuracy and full length coverage afforded by this approach.
We present an evaluation of the quality of the transcriptomic data obtained from the striatum by combining immunohistochemical labelling and laser capture isolation with the Smart-seq2 RNA sequencing approach. We explore the application of the approach across different paradigms of synaptic plasticity and the potential application of this approach to the investigation of neurological disorders.

Title: Novel approaches to visualise the expression, localization, and signaling of TLR4

Authors: *J. THOMAS[1,3], S. MUSTAFA[1,3], C. ASHWOOD[2,4], L. M. PARKER[2,4], N. H. PACKER[2,4], M. R. HUTCHINSON[1,3];
[1]Ctr. For Nanoscale Biophotonics, Adelaide, Australia; [2]Ctr. For Nanoscale Biophotonics, Sydney, Australia; [3]Univ. of Adelaide, Adelaide, Australia; [4]Macquarie Univ., Sydney, Australia

Abstract: Toll-Like receptors (TLR) are classically viewed as a type of pattern recognition receptor involved in peripheral innate immune responses, leading to the upregulation, synthesis and secretion of pro-inflammatory mediators. However, it is now becoming apparent that TLR4 is involved in more than just innate immunity, with major links to the etiology of opioid tolerance, chronic pain, addiction, itch, and depression. Current techniques that are used to study the localization and signaling of TLR4 have been optimized for the study of classical peripheral immunity. In the pursuit of a more comprehensive understanding of the involvement of TLR4 in these pathologies, it has become apparent there are limitations to applying the current techniques for studying TLR4 in CNS tissue. Here we aim to develop new methods for identifying TLR4 protein and mRNA localization, and TLR4 signaling cascades, with an influence on optimising for CNS tissues. A transdisciplinary approach has been applied to identify the problems and source the experimental solutions to this TLR4 measurement and visualisation challenge. A novel in situ hybridization approach was developed using the application of photostable nanoparticles to visualize the localization and expression of TLR4 mRNA. This technique demonstrates significant TLR4 specificity in both cells and tissue samples with exceptional photostability compared with traditional fluorescent methods. The challenges with imaging and quantifying TLR4 protein have also been explored, with the non-specificity of commercially available antibodies highlighted. Additionally, development of a novel workflow for targeted mass spectrometric quantification of TLR4 has demonstrated surprising challenges associated with the detection and measurement of TLR4. Finally, the creation of novel fluorescent constructs of TLR4 has allowed visualization of cellular localization of TLR4 and the potential use in bioluminescent resonance energy transfer assays for real time quantification of TLR4 activation. The collective use of these tools will be presented in the context of chronic pain and opioid exposure.

Title: Novel therapeutic strategies in nbia: a gene therapy approach for pla2g6-associated neurodegeneration

Authors: *S. CUKA[1], J. NG[2], K. SEINO[5], M. HUGHES[3], S. WADDINGTON[2], M. KURIAN[4], A. RAHIM[3];
[1]UCL Sch. of Pharm., UCL, Kent, United Kingdom; [2]Inst. for Women's Hlth., [3]Sch. of Pharm., [4]Inst. of Child Hlth., Univ. Col. London, London, United Kingdom; [5]Inst. of Med. Sci., St Marianna Univ. Sch. of Med., Kanagawa, Japan

Abstract: Infantile neuroaxonal dystrophy (INAD) is a debilitating, intractable and ultimately lethal neurodegenerative disorder. It is caused by mutations in the PLA2G6 gene that encodes for phospholipase A. Patients present neurodegeneration-associated symptoms between six months and three years of age. Severe spasticity, progressive cognitive decline, and visual impairment typically result in death during the first decade. There is no disease-modifying treatment available and palliative care focuses on quality of life. There is an overwhelming need to develop novel therapies to treat INAD patients.
We aim to conduct a preclinical AAV-mediated gene therapy study to prevent neurodegeneration and rescue a mouse model of INAD from premature death. We will use recombinant adeno-associated virus serotype 9 vector (AAV9) to deliver therapeutic human PLA2G6 gene to the neonatal INAD mouse CNS via either intracranial or intravenous administration. The human PLA2G6 and control GFP gene were cloned into an AAV9 backbone plasmid, driven by the synapsin-I promoter and used to produce high titre viral preparations. Furthermore, the INAD mouse model recapitulates many features of the human phenotype. Investigating indices of neuropathology will not only provide us with readouts against which to gauge therapeutic efficacy but also increase our understanding of the underlying disease mechanisms.

Title: Non-biased miRNA purification from clinical samples stored in TRIzol.

Authors: S. FORMAN, D. CABAYA, *J. A. VALADEZ, X. JIA;
Zymo Res. Corp, Irvine, CA

Abstract: Organic extraction, with TRIzol, TRI Reagent or similar, is often a method of choice for pathogen inactivation and sample stabilization and thus plays a significant role in clinical sample processing prior to nucleic acid analysis. However, the organic extraction methods were shown to introduce significant bias, specifically into the small RNA (miRNA) recovery. We have developed a non-biased method that allows for binding nucleic acids, including miRNAs, directly, i.e., without phase separation or precipitation, following the organic extraction step. We have compared the miRNA profiles obtained through next generation sequencing as well as a hybridization approach with an existing non-biased "double extraction" protocol (Ambion) and confirmed the non-biased purification results.This novel "direct nucleic acid binding" approach is fully automatable and allows the use of organic extraction in high-throughput applications.

Title: miR-126 mediates Tβ4-induced neurovascular remodeling in diabetic peripheral neuropathy

Authors: *X. LU;
Henry Ford Hosp., Detroit, MI

Abstract: Background: MicroRNAs (miRs) play pivotal roles in regulating post transcriptional gene translation and mediating biological function. We previously demonstrated that treatment of diabetic mice with thymosin-β4 (Tβ4) significantly ameliorated neurological dysfunction caused by diabetic peripheral neuropathy, which associated with Angiopoietin1 (Ang1) promotes neurovascular function. In this study, we investigated whether miR-126 is involved in the effect of Tβ4 on Ang1 expression and neurovascular remodeling.
Methods and Results: Male BKS.Cg-m+/+Leprdb/J (db/db) mice (n=10) were treated with Tβ4 (30 mg/kg, i.p. daily) for 8 consecutive weeks, and db/db mice (n=10) were used as a control group. Compared with non-diabetic mice (dm), diabetic mice (db/db) exhibited significant reduction of miR-126 expression in peripheral serum samples (0.4±0. 2 vs.1.0±0.1, $p<0.05$) and sciatic nerve tissue (0.3±0.07 vs.1.0±0.07, $p<0.05$). Treatment of db/db mice with Tβ4 significantly upregulated miR-126 expression in serum samples (1.2±0.1 vs. 0.4±0.2 in saline, $p<0.05$) and sciatic nerve tissue (0.8±0.02 vs.0.3±0.07 in saline, $p<0.05$), measured by quantitative RT- PCR. Western blot analysis revealed that diabetes decreased levels of Ang1 (0.4±0.07 vs.1.0±0.1, in dm mice, $p<0.05$) and AKT activity (pAKT, 0.3±0.03 vs.1.0±0.04 in dm mice, $p<0.05$) in sciatic nerve tissue compared to dm mice. However, Tβ4 treatment overcame the effect of diabetes on these proteins (Ang1, 0.9±0.06 vs. 0.4±0.07 in saline, pAKT 0.7±0.05 vs.0.3±0.03 in saline, $p<0.05$). In vitro, treatment of mouse dermal endothelial cells (MDE) and DRG neurons with Tβ4 significantly increased capillary-like tube formation (1.1±0.06 vs. 0.6±0.06 in control, $p<0.05$) and axonal outgrowth (1,231±75.1*u*m vs.1,008±77.2*u*m in control, $p<0.05$), respectively, under hyperglycemia conditions, whereas attenuation of endogenous miR-126 by siRNA against miR-126 abolished the effect of Tβ4 on endothelial cell capillary tube formation (0.7±0.07 vs.1.0±0.08 in scramble control, $p<0.05$) and DRG neuron axonal outgrowth (1,079±42.5*u*m vs.1,235±48.6*u*m in scramble control, $p<0.05$). Quantitative RT-PCR analysis showed that Tβ4 increased Ang1 expression in MDE (2.35±0.1 vs.1.06±0.2 in control, $p<0.05$) under hyperglycemia and that blockage of miR-126 suppressed Tβ4-increased Ang1 expression (0.49±0.2 vs. 1.47±0.1 in scramble control, $p<0.05$).
Conclusion: These data suggest that Ang/Tie2 and PI3K/Akt signaling pathways mediate the therapeutic effect of Tβ4 on vascular remodeling and axonal outgrowth. miR-126 regulates Ang1 expression under diabetic conditions with and without treatment of Tβ4.

Title: Second-generation brainbow adeno-associated virus with improved labeling brightness, color diversity and neuronal subtype identity

Authors: F. LU, A. STOLZ, *D. CAI, J. S. STECHER, D. ROOSSIEN, Z. HALL;
Cell and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Creating random colors in individual cells, the Brainbow technology allows labeling and distinguishing intermingled neighboring neurons in the same brain. The introduction of Brainbow labeling by adeno-associated virus (AAV), a safe and chronic gene delivery vector broadly used in neuroscience, expanded the application potentials of Brainbow. The first generation of Brainbow AAV system delivers 4 spectrally distinguishable fluorescent proteins (FP) by mixing two viral species, each of which packaged two FPs and upon Cre recombination, a non-fluorescent or either FP (total of 3) outcome will be generated. Therefore, a 1:1 mix of these AAVs allows up to (3x3-1) eight possible color combinations. The first generation of Brainbow AAV also targets FPs to the cytoplasmic membrane to homogenously label even the finest axonal and dendritic processes. However, immunofluorescence amplification is often required to increase the labeling brightness, which costs additional experimental procedures and time. We created the second generation of Brainbow AAV to overcome the labeling brightness limitation and brought additional improvements including increased labeling color diversity and neuronal subtype identity. We further reduced the AAV packaging content to one FP species per virus, which allowed us introducing FPs in tandem copies to increase native fluorescent intensity. We also redesigned the recombination scheme that either an ON or an OFF outcome will be created after Cre recombination. Therefore, mixing equal amount of 4 spectrally distinguishable FPs will generate (2^4-1) fifteen possible color combinations. Finally, a new set of Brainbow AAVs are created to allow labeling of two neuronal subtypes in the same animal, in which Cre and Flp recombinases are expressed in two distinct population of neurons.

Title: Novel sample preservation for non-biased recovery and detection of miRNA markers in clinical samples.

Authors: S. FORMAN, L. BASILIO, *A. D. CLAUSEN, X. JIA;
Zymo Res. Corp., Irvine, CA

Abstract: Sample collection and preservation is crucial for accurate and non-biased nucleic acid analysis. We have identified major biases in detection of miRNA species implicated in neurodegenerative disease. We tested and compared collection devices, reagents and purification workflows in their ability to preserve and allow for efficient recovery of nucleic acids, specifically miRNAs from whole blood. To evaluate the miRNA expression in clinical samples we used the next generation sequencing (Illumina) and hybridization-based analysis (Nanostring). The expression profile comparison shows high correlation between the two detection methods. However, our study identifies workflows and reagents that result in absence or underrepresentation of miRNA species, including those implicated in neurodegenerative disease (e.g., miR-126; Parkinson's disease).

Title: Novel method to ascertain chromatin accessibility at specific genomic loci from frozen brain homogenates and laser capture microdissected defined cells

Authors: E. DELVAUX[1], D. MASTROENI[1,2], J. NOLZ[1], *P. D. COLEMAN[1,2];

Abstract: Numerous epigenetic mechanisms converge to modulate chromatin structure and many methods exist to delineate this structure. DNase I digestion is a conventional method used. However, a major limitation of DNase I based methods is the susceptibility of DNase I to inhibition by actin, a component of many cells and tissues. Recently, a protocol was developed for determining chromatin accessibility in frozen tissue homogenates using Benzonase, a robust nuclease whose efficacy is not affected by the presence of actin (Grøntved et. al, 2012). Here we describe a protocol to assess chromatin structure at specific loci using Benzonase digestion and qPCR of DNA extracted from frozen tissue homogenates and laser capture microdissected (LCM) defined cells. This protocol is relatively quick, inexpensive and achievable in any research laboratory outfitted with standard real time PCR equipment. This novel method will allow a more focused examination of chromatin structure, its influence on gene expression and the impact it may have on gene expression in normal and diseased brain as well as other tissues.

Title: Translation Dysregulation in ALS

Authors: *S. YAO[1], A. COYNE[2], D. ZARNESCU[2];
[1]Mol. and Cell. Biol., [2]Univ. of Arizona, Tucson, AZ

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease that affects the lives of at least 30,000 people in the United States, annually. It is often categorized by the progressive neurodegeneration of motor neurons. TAR DNA Binding Protein (TDP-43) is normally found within the nucleus having known roles in RNA splicing as well as DNA-binding. Mislocalization of TDP-43 to the cytoplasm, either due to mutations or to environmental stressors leads to accumulation of TDP-43 in cytoplasmic inclusions. Notably, in the cytoplasm, TDP-43 associates with RNA stress granules and also affects mRNA translation, both of which are thought to contribute to disease pathology. In order to study the effects that cytoplasmic TDP-43 mutations have on translation, a technique called polysome fractionation is utilized. This technique uses sucrose gradients to effectively separate different ribosomal populations. The mRNAs that are bound to multiple ribosomes, or polysomes, are separated from the mRNAs bound to single ribosomes. This allows the pinpointing of specific defects in protein production as well as potential explanations to how it may affect cellular metabolism. Furthermore, this technique is able to provide information about the halting of protein production in response to stress which is a potential factor that contributes to ALS. Western blotting and quantitative PCR (qPCR) allow us to observe the protein and transcript distribution within the polyribosome fractions, respectively. Using these approaches we found that TDP-43 associates with both translating polyribosomes as well and untranslated fractions (RNP and the ribosomal subunits). qPCR of *futsch*, an mRNA target of TDP-43 showed a shift in transcript levels from actively translated to untranslated fractions in the context of TDP-43, indicating that *futsch* mRNA is being repressed by TDP-43 in motor neurons. Taken together, these findings indicate that TDP-43 regulates the translation of specific mRNAs and defects in translation may contribute to ALS. Experiments will focus on additional candidate mRNA targets that will be tested for their distribution within polysome fractionations to determine their translational status in disease. Candidate mRNAs that are identified by Translating Ribosome Affinity Purification (TRAP) that also associate with TDP-43 in complex will be tested. Specifically, qPCR will used to distinguish shifts in translational targets in polysomes. Targets that are downtranslated should exhibit a shift into the RNP fractions while uptranslated targets will exhibit a shift into the polysomes.

Title: Validation of the use of voltage-sensitive fluorescent proteins in *C. elegans*

Authors: *K. M. WEBSTER[1], M. CHATZIGEORGIOU[2], W. R. SCHAFER[1];
[1]MRC Lab. of Mol. Biol., Cambridge, United Kingdom; [2]Sars Intl. Ctr. for Marine Mol. Biol., Bergen, Norway

Abstract: *C. elegans* is an ideal model organism to use for studies involving optical imaging of neuronal activity. Its genetic tractability means that it is feasible to express genetically encoded proteins in specific neuronal populations, or even individual pairs of neurons. Many labs have successfully used genetically encoded calcium indicators (GECIs), such as Cameleon or GCaMPs, to monitor fluctuations in neuronal calcium levels in responses to a variety of stimuli. However, GECIs are regarded as a proxy for neuronal activity. It is technically challenging to record neuronal activity in *C. elegans* for several reasons, the foremost of which is that their pressurized cuticle makes accessing the neurons difficult. However, genetically encoded voltage-sensitive fluorescent proteins (VSFPs) offer an alternative to optically measure neuronal activity. The VSFP Butterfly 1.2 protein has been optimized to detect sub-threshold fluctuations in neural activity in mammalian cells. We have been able to visualize and record activity from a codon optimized version of VSFP Butterfly 1.2 in *C. elegans* neurons. This construct successfully traffics to the plasma membrane and is functional in multiple types of neurons. We have expressed this protein under a variety of promoters and have used it to record neuronal responses to mechanical and other stimuli, including nose press. It is also possible to record spontaneous activity from motor neurons in young, freely moving worms. The combination of the stereotyped development of the *C. elegans* nervous system with the known physical connectome and well characterized functional circuits presents the opportunity to use this tool to simultaneously record the activity of an entire circuit. Further, we are able to correlate the changes in fluorescence intensity in the two different components of the FRET pair with specific voltage changes across the membrane in a whole cell patch-clamp electrophysiology configuration in dissociated *C. elegans* neurons. The data we present validate the usefulness of VSFP Butterfly 1.2 as a method to optically measure neuronal activity in *C. elegans* and demonstrate the range of experimental uses to which it can be applied.

Title: Enrichment of unamplified DNA and long-read smrt sequencing to unlock repeat expansion disorders

Authors: *J. EKHOLM[1], Y.-C. TSAI[2], T. A. CLARK[2];
[1]Marketing, Pacific Biosci. Inc, Menlo Park, CA; [2]Pacific Biosci., Menlo Park, CA

Abstract: Many neurological and neuromuscular disorders are caused by repeat expansions that span large genomic regions. Despite the fact that the causative disease genes have been uncovered, the underlying biological disease mechanisms are still largely unknown. This is mainly due to technological limitations that do not allow for the needed base-pair resolution of the repetitive DNA. Research has shown that in addition to accurately accessing the repetitive elements, the interruption sequences found in the midst of these repetitive regions have an impact on DNA stability, disease anticipation and disease severity. Other aspects that seem to be key in further understanding the disease etiology of repeat expansion disorders are base modifications and the transcriptional activity of the mutated genes.
We have developed a novel, amplification-free enrichment technique that uses the CRISPR/Cas9 system to target large repeat expansions. This method, in conjunction with PacBio's long reads and uniform coverage, enables sequencing of these complex genomic regions. By using a PCR-free amplification method, we are able to access not only the repetitive elements and interruption sequences accurately, but also the epigenetic information. In addition, we also avoid any biases that would be introduced by PCR. This method has successfully been used in sequencing the causative repeat expansions for Huntington's Disease (HTT; CAG repeat), Fragile X (FMR1; CGG repeat), ALS (C9orf72; GGGGCC repeat), and Spinocerebellar ataxia type 10 (SCA10; variable ATTCT repeat). With this data, we demonstrate the ability to isolate hundreds of individual on-target molecules and accurately sequence through long repeat stretches, regardless of the extreme GC-content. We also demonstrate the ability to directly detect and characterize epigenetic signatures. Lastly, we have also built the first comprehensive isoform map for the FMR1 gene and identified transcripts that seem to have functional relevance in the pathology of FMR1-associated disorders such as fragile X-associated tremor/ataxia syndrome.

Title: Two-color bioluminescence for sensitive and quantitative discrimination of cell grafts in the mouse brain

Authors: *M. ASWENDT[1], S. VOGEL[1], C. SCHÄFER[1], A. JATHOUL[2], M. HOEHN[1,3]; [1]Max Planck Inst. For Metabolism Res., Koeln, Germany; [2]Sch. of Biosci., Cardiff Univ., Cardiff, United Kingdom; [3]Radiology, Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Objectives
Bioluminescence imaging (BLI) holds great potential for sensitive and quantitative in vivo monitoring of mouse brain cells. We have validated and optimized BLI for tracking viability and fate of transplanted stem cells longitudinally. Here, we present a novel multicolor luciferase approach, in which spectral unmixing is applied to calculate individual cell numbers in vivo.
Methods
We used firefly luciferases x5g and x5r, which are codon-optimized for high expression in mammalian cells and mutated for green (Em=540 nm) and red (Em=614 nm) photon emission. Luciferases were cloned into lentiviral plasmids and used to transfect HEK-293T cells. BLI and spectral unmixing was performed using the IVIS Spectrum CT system (18 emission filter, 500-840 nm). A cell dilution series with variable ratio of x5g/r cells was used *in vitro* (1 mM D-Luciferin, 1 min acquisition). Discrimination and quantification by imaging cell grafts containing different mixtures of x5r and x5g cells (50,000-150,000 cells) in the cortex or striatum of nude (Nu/Nu) mice (n=40) *in vivo* (300 mg/kg D-Luciferin i.p. pre-Isoflurane anaesthesia).
Results

The spectral unmixing algorithm was found to predict the ratio of x5g/r cells in the micture accurately because of the strictly linear relation between photon flux and x5g/r cell numbers (Fig. 1A, B). The in vivo spectra of x5g/r were shifted towards higher wavelengths and much broader, however, still distinct enough to be identified as two emission peaks by the spectral unmixing algorithm (Fig. 1 C). The in vivo data on cortical and striatal cell grafts revealed efficient spectral unmixing of red and green signals in correct quantity (e.g. 71% x5g calculated by the algorithm and 75% x5g actually transplanted) (Fig. 1 D).

Conclusions

We have demonstrated efficient unmixing of novel red and green firefly luciferases *in vitro* and *in vivo*. For the first time, this two-color BLI promotes sensitive and quantitative tracking of distinct cell populations. We are currently translating this approach to the spectral unmixing of neurons and astrocytes in vivo.

Title: Analysis on neurotoxicity of gold nanoparticles on neurons and glia

Authors: *S. KIM[1], S. HWANG[1], S. JUN[1,2];
[1]Electronics Engin., [2]Dept. of Brain and Cognitive Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Among various types of nanoparticles, gold nanoparticles in particular are stealing the spotlight for its stability and suitability for bio-related studies. Recently, for various purposes such as bioimaging, drug delivery, and neuromodulation, researches utilizing nanoparticles are being conducted. Whereas gold nanoparticles are known to be biocompatible, the particle itself is, after all, a foreign substance both *in vivo* and *in vitro*. To date, there have been prior investigations to assess the toxicity of nanoparticles upon non-neuronal cells. In this study, we attempt to assess neurotoxicity of gold nanoparticles by observing cultured hippocampal neurons and glial cells. They were separately cultured and grown for 14 days, seeded with gold nanorods, and then observed for seven consecutive days. The particles used were 59 nm and 146 nm in length, and the concentration rate varies from $8.5x10^{10}$ nps/mL to $3.4x10^{11}$ nps/mL. The effects are different depending on the size and the concentration of the particles. We focus especially on the aspect of cell death linked with neurotoxicity, mainly utilizing live dead cell assays. In addition, correlation between glial death and the survival of neurons under nanoparticle-seeded environment are interpreted. In general, severe toxicity was observed with the larger size and heavier concentration rates. This study is expected to serve as a foundation experiment for further research on the cytotoxicity of gold nanoparticles. Furthermore, *in vivo* experiments by injecting gold nanoparticles in Sprague-Dawley rats are to follow.

Title: Low access resistance subcortical whole cell recordings *In vivo*

Authors: *W. STOY[1], Y. J. LIEW[1], B. YANG[2], C. J. WHITMIRE[1], A. PALA[1], C. CAPOCASALE[2], T. LEE[2], A. ORTIZ[1], P. Y. BORDEN[1], G. B. STANLEY[1], C. R. FOREST[2,1]; [1]Wallace H. Coulter Dept. of Biomed. Engin., [2]George W. Woodruff Sch. of Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Patch clamp recordings deep in the intact living brain (e.g. >1 mm) have long suffered from low yield and high access resistance, primarily due to pipette electrode contamination during descent to subcortical nuclei. In the mouse, for example, pipettes are significantly less likely to be inserted cleanly to the thalamus, located at a depth of 3 mm in C57BL/6 mice as compared to, the cortex, located at a depth of approximately 0.5 mm. This degradation limits the utility of patch clamping, the gold-standard method of cellular electrophysiology, where it could be extremely useful for studying cellular function and synaptic connectivity below superficial layers. In addition, this limitation renders patch clamping virtually prohibitive for large brain models such as Rhesus macaque.

After systematically measuring the effect of depth on pipette cleanliness, we developed an algorithm and best practices for reducing pipette tip contamination and improving access resistance when targeting deep, subcortical neurons in mice. Our results show that decent to depth of 0.5 mm increases electrode resistance by more than 300 kOhm in 32% of trials, while descents to 3.0 mm increase electrode resistance above this threshold in 88% of trials.

Our algorithm and methods improve these results substantially. By utilizing robotically controlled pipette motion and continuous electrical resistance feedback, we are able to "dodge" obstructions such as neurons and blood vessels during descent. Using this new algorithm, pipette resistance is measured at 128 Hz during descent for a high spatial resolution. If an obstruction is encountered prior to the region of interest (as indicated by an increase in resistance >1 MOhm threshold), the pipette is stopped, retracted, and moved laterally in 20 um steps. Lateral steps are repeated until resistance decreases below threshold, indicating that the obstruction has been circumvented and descent is resumed until the region of interest is reached.

Pipettes inserted using this method arrived at the region of interest without a significant change in resistance (<300 kOhms at 3 mm) 69% of the time (n=46), while pipettes inserted using traditional blind, linear methods were inserted successfully 32% of the time (n=31); Whole cell recordings following successful descent resulted in lower access resistance than those inserted with the traditional algorithm. This pipette localization method therefore greatly improves the quality and accessibility of subcortical tissues in the intact brain.

Title: Rapid cortical barrel mapping using automated multi-whisker stimulation and intrinsic optical signal imaging

Authors: *T. LEE[1], C. M. CAPOCASALE[1], P. Y. BORDEN[2], W. STOY[2], C. J. WHITMIRE[2], Y. LIEW[2], A. PALA[2], A. D. ORTIZ[2], B. YANG[1], G. B. STANLEY[2], C. R. FOREST[1];
[1]George W. Woodruff Sch. of Mechanical Engin., [2]Wallace H. Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: The study of single-unit, whisker-evoked activity in the mouse somatosensory cortex through targeted electrophysiology requires multi-whisker stimulation and knowledge of the corresponding barrel location. Tools for addressing multiple whiskers are slow and manual (e.g. galvanometer) or inordinately expensive and complex (e.g. piezoelectric array). Imaging tools for barrel mapping have been well studied but require users to manually relate manipulator coordinates to anatomical coordinates. To address these limitations, we describe two tools for rapid, automated cortical barrel mapping: (1) a low cost, compact device for multi-whisker probing and (2) an automated system for Intrinsic Optical Signal Imaging (IOSI) barrel localization and precision electrode placement. (1) To provide independent actuation of vibrissa, whiskers are manually threaded into a comb-like, linear array. Individual whiskers are constrained in the dorsal-ventral direction but free to move in the rostral-caudal direction. Whiskers are actuated within the slot of the comb-like array in the rostral-caudal direction using directed puffs of air; we can deliver a maximum angular velocity of 250 degrees per second and a maximum absolute deflection of 5 degrees at the whisker pad (stimulator located 10 mm from the facial skin) at up to 10 Hz. To functionally validate the stimulator, we used voltage sensitive fluorescent protein imaging of barrel activation in response to whisker movement from our stimulator and from a galvanometer. We find no difference in the cortical barrel centroid location and the spatial spread of barrel activation between the two stimulating paradigms. (2) In conjunction with the whisker stimulator, we have developed a system for automated, IOSI-guided, electrode placement in the barrel cortex. Prior to cortical optical imaging, the electrode tip is imaged and located in the imaging volume. Cortical barrel centroids are found immediately using IOSI followed by automated image processing for rapid functional mapping. We report accurate and repeatable IOSI-guided, automated barrel localization when compared against post-mortem histological stains. With machine vision, we transform electrode coordinates into

manipulator coordinates for precision electrode placement. We have demonstrated the ability to automatically place an electrode at desired positions within the system's imaging volume to within 40.3 μm, 95% of the time. Integrating these tools enables rapid, automated barrel mapping and targeted electrode placement.

Title: Experimental and analytical approaches for multi-site electrophysiology in the topographically aligned thalamocortical circuit

Authors: ***Y. LIEW**[1], C. J. WHITMIRE[1], W. A. STOY[1], A. PALA[1], A. SEDERBERG[1], A. D. ORTIZ[1], P. Y. BORDEN[1], B. YANG[2], C. M. CAPOCASALE[2], T. LEE[2], C. R. FOREST[2], G. B. STANLEY[1];
[1]Wallace H Coulter Dept. of Biomed. Engin., [2]George W Woodruff Sch. of Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Dynamic interaction between neurons determines the nature and efficiency of information transmission across neural networks. To quantify sensory encoding at each stage of neural processing, simultaneous recording along a feedforward pathway is critical yet challenging. Previous work has demonstrated that targeting topographically aligned regions in vivo is experimentally tractable and could reveal synaptically coupled neurons in the intact circuit. However, a well-documented systematic approach is lacking. In this work, we optimize the experimental approach to reliably record from neuronal pairs in the thalamocortical (TC) circuit of the vibrissa pathway in the anesthetized rodent and assess the conventional spike cross-correlation methods typically used to infer monosynaptic connectivity from simultaneously recorded neurons. Taking advantage of the well-known anatomical and functional organization of the rodent's whisker pathway, we first perform functional mapping of primary somatosensory cortex (S1). We assess the single unit layer 4 response to deflections of different individual whiskers, and create a stereotypical functional map to align with a template anatomical map

using stereotaxic coordinates. After identifying a barreloid in the ventroposteromedial thalamus (Vpm) responding to one primary whisker, we then utilize the map to target the corresponding cortical barrel. To verify the accuracy of the thalamic and cortical recording locations, we quantify response latencies and adapting properties of the neuronal pair in response to whisker deflection. Drawing inference of monosynaptic connection relies on spike count of coordinated firing between thalamic and cortical neurons, which is challenging given the typically low spontaneous TC activity. To probe the TC synaptic connectivity, we deliver a low velocity sinusoidal whisker stimulus to evoke decorrelated thalamic spikes while performing simultaneous recordings in topographically aligned TC regions. Using cross-correlation analysis of the spiking activity, we examine the functional relationship between identified neuronal pairs and classify monosynaptic connectivity. Systematic evaluation of the effects of parameters such as length of acquired data and the absolute firing rate of the recorded neurons suggests a set of guidelines for assessing monosynaptic connectivity through this method. Taken together, we have developed a step-by-step experimental and analytical approach for obtaining paired neural data, laying the foundation for multi-site, multi-electrode and even intracellular recording across different connected brain structures.

Title: Cleaning patch-clamp pipettes enables their re-use

Authors: ***I. KOLB**[1], W. A. STOY[1], E. ROUSSEAU[2], O. A. MOODY[3], A. JENKINS[4], C. R. FOREST[1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]SUNY Polytechnic Inst., Albany, NY; [3]Emory Univ., Atlanta, GA; [4]Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Patch-clamp recording is a gold-standard technique for the accurate measurement of membrane voltage and current fluctuations in electrically active cells. From the advent of the technique in the late 1970s, it has been widely accepted that using a fresh pipette to patch every cell is critical to form a high-quality gigaohm-seal with the cell and yield a successful recording. On the other hand, the ability to reuse pipettes would greatly facilitate patch-clamp experiments, particularly those involving specially-treated pipette tips or multiple simultaneous recordings. We demonstrate for the first time that a simple cleaning procedure can enable pipettes to be reused. This fast (60 s) fully-automated cleaning procedure consists of dipping used pipettes into a commercially available detergent, pneumatically forcing the detergent into the tip, and finally rinsing the tip in a non-cytotoxic solution.

With pipette cleaning, 8 pipettes were used to whole-cell patch 84 Human Embryonic Kidney (HEK293) cells out of 88 attempts (95% success rate), demonstrating that pipettes can be reused 10 times. To confirm, we patched and reused pipettes on neurons in culture, acute brain slice, and in-vivo (Fig. 1). The pharmacological safety of pipette cleaning was demonstrated by patching HEK293 cells transfected with a γ-Aminobutyric acid receptor type A ($GABA_AR$). No difference was seen in the dose response of cells patched with fresh and cleaned pipettes in response to GABA (peak current: fresh: 3.1 ± 1.54 nA, n=13, after 4^{th} clean: 2.8 ± 1.13 nA, n=8). Finally, we integrated the pipette cleaning algorithm into our previously-developed automated patch-clamp robot, the Autopatcher. This enabled the Autopatcher to patch multiple HEK293 cells serially, without human intervention, at a maximal rate of approximately 1 cell per 5 min. These results demonstrate for the first time that pipettes can be reused multiple times with a simple automated cleaning procedure, yielding a widely applicable tool for a variety of patch-clamp preparations, especially those requiring high throughput and automation.

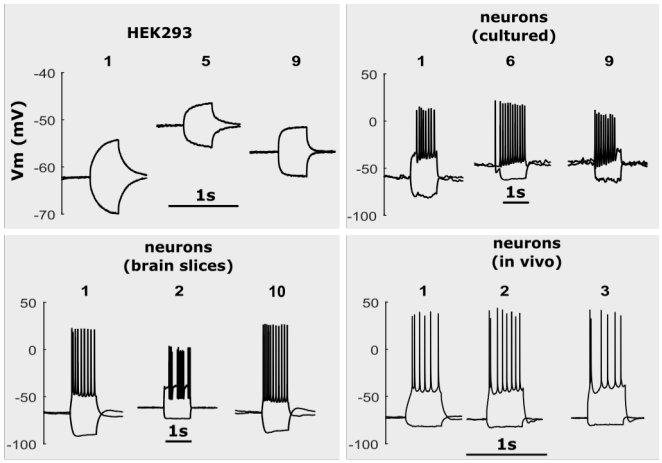

Figure 1: A single pipette can be used to patch-clamp multiple cells in different experimental preparations. Number above recording indicates number of times pipette was used.

Title: Scaled electrophysiological, morphological, and transcriptomic characterization of mouse cortical neurons using an *In vitro* slice electrophysiology platform.

Authors: K. HADLEY, B. LEE, T. KIM, D. HILL, T. JARSKY, L. KIM, R. MANN, A. OLDRE, S. SORENSEN, K. SMITH, *J. BERG, B. TASIC, G. MURPHY, H. ZENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The Allen Institute has undertaken a comprehensive, multi-year endeavor to understand the diversity and hierarchical organization of neuronal cell types. As part of this effort, the Institute has published electrophysiological, morphological, and transcriptomic data from hundreds of individual neurons of the mouse brain in the Allen Cell Types Database. The existing program utilizes parallel pathways for transcriptomic and electrophysiological/morphologic profiling, both of which take advantage of Cre lines that target subpopulations of neurons and allow for the comparison of the same types of cells across many animals: an *in vitro* slice electrophysiology platform allows for concurrent cell recording and filling with biocytin, followed by histological processing, imaging, and morphological reconstruction, while RNA-Seq is performed on dissociated single cells isolated by fluorescence activated cell sorting (FACS). In order to combine these two approaches and collect data from all three modalities for each individual cell, we have developed an approach to obtain RNA sequence data from recorded cells while maintaining intact morphologies from a substantial fraction of neurons. To scale this technique to reliably obtain high quality transcriptome and morphology data across multiple electrophysiology rigs and operators, we have standardized specific aspects of the protocol. Patch pipette characteristics, contents of the internal solution, and pressures required for cytoplasmic extraction, among other features, have been optimized to maximize the amount of electrophysiology data generated, while increasing the quality of transcriptomic data, as well as the morphological integrity. The ability to collect and analyze all three types of data from a single neuron will further our ongoing efforts to identify distinct cell classes and expand our understanding of the genetic mechanisms underlying neuronal diversity in the cortex.

Title: *In vitro* electrophysiological recordings of multiple brain regions from aged pig tailed Macaques

Authors: A. D. WHYMENT[1,2], F. ZHAO[1,2], M. VAN DEN TOP[1,2], J. PRYOR[1,3], *D. SPANSWICK[1,3,2];

Abstract: The relatively long lifespan, extended infancy and social cognition of non-human primates (NHPs) parallels many aspects of human development and the physiological, behavioural, and neuroanatomical similarities to humans can facilitate translation of therapeutic strategies to a range of human conditions. To date, the vast majority of electrophysiological recordings performed in NHPs have been achieved in juvenile animals with little if any work performed in aged animals. Here, data was obtained from two aged (20 years) female pig-tailed macaques (Macaque nemestrina). Both animals were scheduled for euthanasia due to significant health issues. On the day of experiments, animals were maintained under deep anaesthesia and a craniotomy performed to expose the brain. Animals were perfused with ice-cold, oxygenated artificial cerebrospinal fluid (aCSF, in mM: NaCl 124, KCl 5, KH_2PO_4 3, $MgCl_2$ 2, $CaCl_2$ 2, $NaHCO_3$ 23 and glucose 10) to displace blood and to rapidly reduce the temperature of the brain. The brain was removed within a few minutes of death and specific regions were immediately dissected for subsequent slice preparation and *in vitro* electrophysiological recording. The post-mortem interval between death and tissue acquisition was measured in minutes as compared to the often hours to days that can elapse in other studies. Brain slices of 400 μm thickness were cut in chilled (<4°C) aCSF using multiple Leica VT1000s microtomes. Whole-cell patch-clamp recordings were successfully performed from multiple brain regions from a single animal with recordings performed from neurones within slices prepared from cortical, hippocampal, striatal, hypothalamic and cerebellar tissue. Simultaneously, extracellular recordings were performed in hippocampal slice tissue and long-term potentiation (LTP) of field excitatory postsynaptic potentials (fEPSPs) induced in the CA1 region following brief high-frequency electrical stimulation of the Schafer-collateral pathway. This approach enabled *in vitro* brain slice preparations to be maintained viable for at least 36 hours with the intrinsic, electrophysiological, synaptic and pharmacological properties of neurones characterised over this period. Our data show the viability of recording *in vitro* in aged NHP and highlights the potential of such studies

for future translational studies, maximising the opportunity for NHP tissue use whilst minimising animal suffering.

Title: Flexible microelectrode arrays for high-density subsecond dopamine recording

Authors: ***H. N. SCHWERDT**[1,2], M. KIM[2], D. HOMMA[2], S. AMEMORI[2], T. YOSHIDA[2], H. SHIMAZU[2], R. S. LANGER[1], A. M. GRAYBIEL[2], M. J. CIMA[1];

Abstract: Multichannel electrochemical recording techniques are needed to reliably monitor the spatiotemporal activity of dopamine (DA) and other electroactive neurotransmitters, which collectively influence brain function. Fast-scan cyclic voltammetry (FSCV) is a well-established technique for monitoring changes in DA concentration and other electroactive substances with *millisecond* temporal resolution. Experiments using FSCV have shown that the spatiotemporal dynamics of DA release are heterogeneous within the striatum, a region that receives robust DA innervation. Traditional carbon fiber (CF) microelectrodes used in FSCV are, however, usually encased in glass or fused silica shafts with nominal diameters of ~100 μm that may compromise the intrinsic functionality and vasculature of the brain sites into which they are introduced. Persisting inflammatory responses to these implants may further alter intrinsic DA signaling processes as well as those recorded by such sensors. We have developed flexible CF microelectrode arrays (MEAs) in order to enhance electrochemical recording functionality and to ameliorate chronic inflammatory processes. Microfabrication processes are used to construct 8-channel CF MEAs having individual electrode lengths of 5-6 mm with a pitch of 250 μm. CF

electrodes are insulated with ~700 nm thick parylene-C for overall diameters of ~8.4 μm. Active recording sites are formed by exposing a ~150 μm length from the CF tips. DA recording capacity was assessed *in vitro* and *in vivo* in anesthetized rats. DA concentration was recorded concurrently from 4 recording sites of the CF MEA across the mediolateral axis of the dorsal striatum as evoked by medial forebrain bundle (MFB) stimulation. Controlled current stimulation was delivered at bipolar platinum-iridium electrodes with a train of 48 biphasic pulses (2 ms pulse-width, 60 Hz, 200 μA). DA selectivity was conferred by demonstration of redox potentials at ~−0.25 and 0.6 V and by principle component analysis. The concentration of DA induced across the 4 sites was heterogeneous and dependent on location of MFB electrodes, with evoked DA oxidation current amplitudes ranging from −5 to 40 nA. Our results demonstrate the potential of microfabricated CF MEAs in elaborating the spatiotemporal dynamics of DA and other neurotransmitters in the brain.

Title: Nano-electrode arrays for simultaneous optical and electrical interrogation of *C. elegans* and Hydra

Authors: *K. N. BADHIWALA[1], D. L. GONZALES[2,3], D. G. VERCOSA[2,3], C. DUPRE[4], R. YUSTE[4], J. T. ROBINSON[1,2,3,5];

Abstract: Advances in technologies for electrophysiology combined with optical and genetic manipulations have greatly improved our understanding of the brain. Yet, the complexity of the human brain makes it difficult to develop a complete understanding of how sensory information

is processed and transformed into behavior, and how this information processing changes with time. To better understand the dynamics of an entire nervous system, it is useful to work with model organisms with fewer neurons. Small transparent organisms like the roundworm *C. elegans* and freshwater jellyfish *Hydra vulgaris* provide us with nervous systems that can be imaged in their entirety at cellular resolution using a variety of optical microscopy techniques. While these optical methods provide excellent spatial resolution, they typically lack the millisecond temporal resolution possible with electrophysiology. Thus electrophysiology is an important complement to optical techniques that would provide precise timing of individual action potentials. However, electrophysiology remains a difficult and invasive process in these small organisms. Here we present a platform technology that can perform simultaneous high-resolution optical imaging and electrophysiology in small model organisms. This device is based on our recently developed nanoscale suspended electrode arrays (nano-SPEARS) combined with inverted confocal microscopy allowing us to image neuronal calcium activity while simultaneously measuring electrical activity associated with rhythmic potentials in *Hydra* or neuromuscular junction activity in worms. Taking advantage of the microfluidic environment, we can also measure the response of organisms to specific stimuli such as chemical or thermal cues. As a result, we can improve the understanding of neural information processing by probing whole-brain neural dynamics with high-temporal, and high-spatial resolution in small model organisms as they interact with their environment.

Title: Nano electrode array for electrical impedance tomography of neural network activity.

Authors: *H. YOON, M. H. KIM;
Norfolk State Univ., Yorktown, VA

Abstract: Real time imaging of fast electrical activity in the nervous system is a major current goal in neuroscience. Electrical Impedance Tomography (EIT) enables tomographic imaging of impedance changes related to fast neuronal activity. For neural activity imaging, EIT has been

implemented with surface electrodes placed on the skull or directly on the surface of the cerebral cortex in recent researches. The aim of this research is to perform EIT in the deep brain using depth electrode arrays. As part of an effort to develop deep electrode array, we applied nanotechnology on electrodes to enhance electrochemical impedance characteristics. In this research, various designs of depth probes were investigated to minimize damage to the brain tissue and overcome size constraints in the brain. For nano-electrode fabrication, we applied electrodeposited iridium oxide film neural probes. Iridium oxide showed high charge density and high charge injection rate which are ideal for EIT application. To enhance mechanical adhesion of the nanostructure film, we developed a new fabrication process that amplifies the nucleation of iridium oxide at the initial stage of deposition process. Measured results were analyzed using electrical impedance spectroscopy and compared with theoretical models. Measured electrochemical impedance values demonstrated significant reduction of electrochemical impedance. Applying measured impedance values and the size of electrodes, a spatial resolution of EIT imaging is expected to be less than 200 μm. Future work is required to apply nano-depth probes for in-vitro and in-vivo studies and characterize their functionality in the rat brain model.

Title: MIES: a electrophysiology experiment automation software.

Authors: *T. JARSKY[1], L. CAMPAGNOLA[1], D. REID[1], J. BERG[1], T. BRAUN[2];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]() byte physics, Berlin, Germany

Abstract: Multi-channel Igor Electrophysiology Software (MIES) is a major component of the software tools the Allen Institute for Brain Science is using to fully automate electrophysiology recordings. A key feature of MIES, not commonly found in other electrophysiology data acquisition software, is the ability to acquire data on more than four channels at the same time. To counteract the complexity that arises from recordings from multiple cells simultaneously, MIES provides an integrated user interface that simplifies hardware control and data visualization. Another mechanism by which MIES facilitates data acquisition on multiple channels is by automation of experiment documentation. Finally, MIES automates pressure regulation, with the use of only two commercial off-the-shelf components, to relieve the user of this manually intensive task. MIES is built with the widely used, affordable, well supported, and

professionally documented scientific and engineering software package Igor Pro (Wavemetrics), however, MIES data is accessible outside of Igor because data is stored the standardized data format Neurodata Without Borders (NWB). MIES is designed to integrate with other software packages for imaging or micromanipulator automation. MIES has been comprehensively tested, in part, because of its primary role in data acquisition for the Allen Cell Types Database. In short, MIES is scalable, comprehensive, and customizable and is intended for acquisition, visualization, and analysis of electrophysiology data on multiple channels simultaneously.

Abstract: The development of implantable devices to record and stimulate neural circuits has led to breakthrough discoveries on the connectivity and functionality of the brain in healthy and diseased states. Despite tremendous advances, technologies for high-resolution electrical recording and modulation of neural activity at the cellular level still rely on rigid metals or silicon components, which poorly match soft brain tissue and cause extensive acute and chronic injury.[1,2]
Flexible electrodes and ultra-small microwires approximating cellular scale have been shown to significantly reduce neural damage during chronic implantation and increase the quality and longevity of neural recordings.[3] However, flexible electrodes require stiffening agents (i.e., polymeric coatings or rigid needles) to overcome the buckling force upon implantation. These stiffening agents increase device footprint and potentially cause additional neuronal death or damage to the blood brain barrier during implantation.[3]
To overcome this challenge we have developed a novel technology to precisely actuate, control and implant high-performance, soft carbon nanotube fiber (CNTf) microelectrodes without using

a stiffening agent or shuttle. Instead, our technology uses fluid flow within a microfluidic device to drive electrodes into tissue. The hydraulic design of the microfluidic device and the on-chip valves enable precise bidirectional control of the fiber motion, velocity and position, by simply tuning the flow parameters. *In vitro* experiments in agar phantoms mimicking the mechanical properties of the brain, show that microfluidic actuated CNTf can be implanted at 1.5 mm depth with 30 μm precision, while keeping the total volume of fluid injected below 0.1 μL.
To demonstrate the feasibility of this novel technology as a tool for inserting flexible CNTf electrodes and probing neural activity *in vivo,* we utilized the small cnidarian *Hydra vulgaris* as model organism. CNTfs were implanted in *Hydra* and used to interrogate neural circuits over a period of several hours and isolate the specific activity of the neural networks located in different regions of the *Hydra* body.

Title: Fully automated closed-loop two-photon guided patch-clamp electrophysiology *In vivo*

Authors: ***H.-J. SUK**[1], I. VAN WELIE[2], S. B. KODANDARAMAIAH[6,3,4], B. D. ALLEN[3], C. R. FOREST[7], E. S. BOYDEN[3,5,4];
[1]Hlth. Sci. and Technol., [3]Media Lab., [4]McGovern Inst. for Brain Research, Dept. of Brain and Cognitive Sci., [5]Biol. Engin., [2]MIT, Cambridge, MA; [6]Dept. of Mechanical Engin., Univ. of

Minnesota, Twin Cities, Minneapolis, MN; [7]Bioengineering, Georgia Inst. of Technol., Atlanta, GA

Abstract: Two-photon guided patch-clamp is a technique that combines two-photon laser scanning microscopy with whole cell patch-clamp recording. By enabling specific identification of cells and analysis of their subthreshold and synaptic neural activity *in vivo*, it has become a powerful tool for studying the electrophysiological properties of individual neurons in the intact brain. However, performing this technique in a high-throughput fashion is a major challenge, because it involves complicated and laborious procedures that require much skill and experience. We have now, building from our prior development of an automated blind patch system (Nature Protocols 11:634-654, Nature Methods 9:585-587), developed a robotic system that automatically completes the tasks involved in two-photon guided patch-clamp recordings, reducing the need for human expertise and labor.
For automated imaging and identification of fluorescently labeled cells and fluorescent dye-filled pipettes during the patch-clamp process, we have created a Matlab-based module that runs in parallel with ScanImage, an open-source software package commonly used for image-guided patch-clamp recordings *in vivo*. Our system fully automates pipette movement onto the target cell, gigaseal formation, and break-in, by dynamically controlling an automated pressure box and a micromanipulator. Importantly, the pipette movement occurs in a fully closed-loop fashion, adjusting the pipette trajectory according to the target cell movements that are automatically captured by the two-photon microscope images. We tested our automated patch-clamp strategy on fluorescently labeled parvalbumin-positive interneurons in the mouse cortex, and we were able to achieve the whole-cell configuration that enabled recordings of the spiking and subthreshold electrical activity of these cells. Our system has the potential to become a useful tool for skilled electrophysiologists as well as for those new to the field, as it eliminates several laborious manual procedures involved with the two-photon guided patch-clamp process. Furthermore, our system may be scalable to the recording of many cells, if the code and algorithms for all of the automated procedures are extended to multi-cell patch-clamp recordings.

Title: Reconstruction of optogenetically induced oscillations using magnetoencephalography

Authors: *G. ALBERTO[1,2], D. KLORIG[2], J. STAPLETON-KOTLOSKI[3], G. POPLI[3], C. CONSTANTINIDIS[2], J. DAUNAIS[4], D. GODWIN[2];

Abstract: Oscillatory activity has been observed across nearly every system in the mammalian brain at a wide range of spatial and temporal scales. Oscillations are suspected to have a functional role in the organization, transmission, and processing of information. However, measuring oscillations often requires a tradeoff between spatial and temporal resolution. The temporal resolution afforded with electrophysiological recordings is offset by its restricted anatomical coverage; whereas the whole brain coverage granted with functional MRI does not provide sufficient temporal resolution to capture the transient and high-frequency nature of most oscillations. Magnetoencephalography (MEG) is a whole brain neurophysiological recording technique that allows for both high temporal and spatial resolution when appropriate analytics are applied. We have developed a method that allows for optically generating oscillatory activity in a non-human primate while recording MEG data. We demonstrate that we can localize the site of evoked signals and reconstruct accurately and precisely spectral features of the recorded neural activity with the beamformer SAM, which allows time series-based analysis of oscillations at discrete anatomical sites across the whole brain. CA3 of hippocampus and prefrontal area 8 of vervet monkeys were transfected with AAV10-CaMKIIα-ChR2-eYFP and an optrode was implanted at the transfection site, allowing for simultaneous optical stimulation and electrophysiological recordings. Animals were optically stimulated with 3 seconds of theta (8Hz) or gamma (40Hz) frequency modulated light source. This stimulation pattern elicited a neural response at the frequency of stimulation (8 and 40 Hz) as recorded by the implanted electrode. The same stimulation pattern was then applied during MEG recording. MEG data were analyzed using the beamformer Synthetic Aperture Magnetometry (SAM) from MISL. First, the beamformer was used to identify coordinates of peak activity concordant with the known site of activation. After identifying peak generators a weight matrix was calculated for that location with the same temporal resolution as the MEG recording. This weight matrix was used to calculate an estimated source series, or virtual electrode. Comparison of the directly recorded

electrode data with the source series showed that the source series accurately estimates optically evoked oscillatory behavior. The ability to generate and reconstruct neural oscillations across the whole brain at temporal scales relevant to neural function will allow for testing hypotheses related to the role of native oscillations.

Title: Functional network parcellation of human cortex using ECoG

Authors: Y. YAN[1], T. QIAN[1,2], W. ZHOU[3], Z. LING[4], H. LIU[2], *B. HONG[1];
[1]Tsinghua Univ., Beijing City, China; [2]Dept. of Radiology, Harvard Med. Sch., Charlestown, MA; [3]Dept. of Neurosurg., Yuquan Hospital, Tsinghua Univ., Beijing, China; [4]Dept. of Neurosurgery,, PLA Gen. Hosp., Beijing, China

Abstract: Large-scale cortical networking patterns have been established based on the correlation of slow fluctuations of resting BOLD signals. However, its electrophysiological basis remained to be elucidated. For the slow nature of hemodynamic signals, the evolution of these networks during rest and tasks is hard to be captured. Here, we developed a novel approach for functional networks parcellation on the basis of the probability of spontaneous co-activation among ECoG electrodes. The accuracy of this parcellation approach was verified by electrical cortical stimulation (ECS) and somatosensory evoked potentials. A further analysis revealed that the brain-wide connectivity is likely built on the ECoG synchrony of power envelop at a common carrier frequency ranging from alpha to low-beta (8-22.5Hz) with slight individual difference. And the synchronization frequency approximated the slow fluctuation (<0.1 Hz) of resting BOLD signals. The high similarity between the above functional network parcellation and the fMRI resting network atlas in individuals also suggested the power-envelope synchrony of neural oscillations as the electrophysiological basis of spontaneous BOLD signals. Furthermore, the slow carrier frequency (8-22.5Hz) based functional network parcellation atlas was found to be consistent across various tasks, and to resemble the resting networks. However, the networking patterns in tasks could be easily distinguished from each other using the carrier

frequency of high gamma band (60-140Hz) instead. This may suggest a common networking mechanism of task and resting brain, with only difference in carrier frequency.

Title: High information content on-chip read-outs based on large-scale monitoring of neural network activity in healthy and diseased conditions

Authors: ***H. AMIN**, F. MARINARO, T. NIEUS, A. MACCIONE, D. DE PIETRI TONELLI, L. BERDONDINI;
Fondazione Inst. Italiano Di Tecnologia (IIT), Genova, Italy

Abstract: Over the past decades, notwithstanding remarkable advances in biotechnology and neurotechnologies, progress in elucidating brain disorders and in the development of novel therapeutic strategies has stalled. Among the different research directions that need to be progressed in parallel to face this challenge, a valuable approach consists in the development of efficient predictive *in vitro* methodologies that exploit emerging neurotechnologies to support elucidating the functional responses of neural circuits involved in different pathophysiological processes. Specifically, we target cell-based assays enabling to better understand the neurophysiology of networks and to pinpoint neurodevelopment and neurodegenerative disease mechanisms, as needed to establish simple, yet well-controlled, disease models for cell therapies and functional drug screening.
In this respect, the confluence of new emerging technological approach realized with low-power CMOS active circuits has been recently introduced. This enables recordings of spiking activity simultaneously from several thousands of densely integrated electrodes (i.e. 4096 electrodes). The result is a unique sensing capability that provides access to extracellular signals at multiple scales in large-scale neuronal networks cultured on-chip.
As it will be presented here, CMOS-MEAs can be applied for studying neuronal ensembles

(murine or human-derived) and their response (with single-neuron detail) to chemicals and drugs as well as for assessing developmental impairments of neuronal spiking activity in genetic models of diseases. On the other hand, high-content imaging (HCI) is combined with these electrical measures to provide multiple cellular measurements from each single experiment. These multimodal read-outs will be demonstrated: i) to assess the use of neural stem cells and of potential biochemical therapies to rescue the early activity-dependent degeneration induced by the toxicity of Aβ oligomers on primary rat hippocampal neurons; ii) to characterize neurodevelopmental alterations of the *in vitro* development of hippocampal neuronal networks from a disease mouse model, in particular, focusing on homeostatic plasticity properties, and iii) to study the development of electrical activity and evoked responses of human-derived neuronal networks over several months.

Title: Modular and patterned 3D cortical networks on microelectrode arrays as a brain on a chip model

Authors: *R. HABIBEY, A. BLAU;
Italian Inst. of Technol. (IIT), Genova, Italy

Abstract: The brain is composed of modular sub-networks with defined connectivity patterns, a key feature to let higher cognitive capacities emerge. Substrate patterning and physical confinement allow for structuring of neural networks *in vitro* to mimic a brain-like modularity. To this end, we paired a polydimethylsiloxane (PDMS) multi-well microchannel device with microelectrode arrays (MEAs) to connect 64 3D cortical network nodes through four microchannels each (Fig. 1C). Thin (100 μm) PDMS devices were fabricated by soft lithography (1). Each device included 8x8 microwells (h=100 μm, r=80-120 μm) and interconnecting microchannels (h=5 μm, w=20 μm or 30 μm, l=80-120 μm). Microwell were paired with recording electrode (Fig. 1 A and B). Rat cortical neurons were seeded at different densities (~ 10, 50 and 100 cells/well). 3D structures did not develop in low-density modules. However, in dense cultures 3D neural structures appeared in each module residing on a glial carpets at their bottom (Fig. 1G and H). Extracellular signals in patterned cultures appeared around 8 DIV, first

as single spikes, which then turned into burst activity around 14 DIV. The signal amplitudes in patterned cultures were significantly higher than in random cultures (Fig. 1I). The connectivity density between modules varied with the microchannel width and the overall cell density. The transparent microchannel devices on MEAs not only gave clear optical access to the 3D sub-populations, but created a stable cellular microenvironment for long-term recording and microscopy. Simplifying the 2D neural networks by decreasing the total number of cells by a factor of 10 and by compartmentalizing them into 3D modules coupled to electrodes allowed us to model some aspects of the brain's modularity on a chip and also increased the spatial accuracy of the recorded data. The system can be easily adapted to different experimental paradigms that may include pharmacological and molecular studies on separate modules without affecting other compartments. 1. Title: Objective detection criteria and analyses of theta (θ) and gamma (γ) oscillations and their phase-amplitude coupling (PAC) during long-term continuous intrahippocampal LFP recordings in mice

Authors: L. MOLNAR[1], J. DOMOKOS[1], I. FERANDO[2], *I. MODY[2];
[1]Electrical Engin., Sapientia Univ., Targu-Mures, Romania; [2]Dept Neurol., UCLA Sch. Med., Los Angeles, CA

Abstract: In rodents θ oscillations (5-10 Hz) provide a framework for spatial navigation and memory-related tasks, and in single neurons ensure somatic synchronization of dendritic events. During memory tasks the phase (P) of the θ oscillations is coupled to the amplitude (A) of γ oscillations (30-120 Hz), termed PAC. The θ oscillations can be readily detected in local field potential (LFP) recordings, but there is no universal consensus about an objective threshold for their detection. We bilaterally recorded CA1 or dentate gyrus θ and γ oscillations (2048 Hz sampling) in adult mice freely moving in their home cages. Mice with *ad libitum* access to water and food, were kept on a 12:12 hours dark(D):light(L) cycle. Each 24 hrs, recordings were down-sampled (DS) 32× and 8× for detection of θ and γ oscillations, respectively. Using Igor Pro, the DS traces were band-pass filtered with an FIR filter between 5-12 Hz for θ, and 30-120 Hz for γ oscillations. The RMS values of 8 s epochs (0.5 s overlaps) were obtained from the filtered recordings and all-point histograms of θRMS and γRMS values were plotted for 24 hr periods (separately for 12 hr L and 12 hr D). For both θ and γ, the histograms showed a bimodal distribution well fitted by two Gaussians. After testing various thresholds, the point of intersection between the two distributions proved to be most reliable for separating the RMS values belonging to the two Gaussians. Thus, θ and γ oscillatory epochs were identified when RMS values in the epochs were larger than this objective threshold. The presence or absence of θ or γ oscillations were registered in a binary file with "0" for no oscillations and "1" when oscillations were present. Thus, the recordings separately categorized during D and L periods into 4 different types: θ/γ, θ/Nγ, Nθ/γ, and Nθ/Nγ ("N" means "no"). We analyzed the FFT spectra of the 4 types of θ/γ combinations in 8 s epochs of the original recordings sampled at

2048 Hz. Interestingly, peaks on FFTs in the γ range were found in both θ/γ and Nθ/γ types, but not in Nγ. In contrast, peaks in the θ range were only found in recordings where γ was present (θ/γ, and Nθ/γ). When a large θ power was not well delineated from power in neighboring frequencies (δ, and α/β) there was little γ activity. Therefore, a θ oscillation frequency that is clean from contaminations by neighboring frequencies, rather than its absolute amplitude, determines whether simultaneous γ oscillations will be present. Data will be presented on the PAC of P(θ):A(γ) for various θ/γ conditions during L and D cycles as well as the time-dependent alterations and duration of θ/γ epochs over days and weeks.

Title: Automatic, reliable and practical approach to extracellular neural action potential sorting using model-based clustering, discriminant model selection, and component agglomeration

Authors: *W. MA, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: Automatic spike clustering without human intervention is critically needed as single unit high channel count extracellular recording becomes increasingly available. To effectively process an overwhelming amount of data, a successful automatic spike sorting algorithm is expected to be 1) accurate in inferring spike-neuron lineage; 2) robust to data condition changes; 3) computationally affordable; and 4) objective in outcomes. We propose a novel spike clustering method which aims at meeting the above expectations. The minimum message length (MML) is known to capture costs of fully-specified models in terms of model complexity and goodness of fit. It is therefore theoretically and practically considered to provide statistically consistent results and stably support models of different complexity. These properties are realized in our method according to the following principles: 1) an unnecessary cluster is unlabeled if it leads to minor change in total message length; and 2) the quality of fit term results in a sudden increase in total message length if a true cluster is unlabeled. Initialized to a greater-than-the-true-number of clusters, our algorithm drives the model complexity through an agglomerative process. It infers the optimal number of clusters based on the first derivative of the

total message length over cluster numbers. Parameter estimation is performed by a modified expectation-maximization (EM) algorithm based on MML for multivariate t-mixtures. Performance evaluation of the algorithm was conducted using simulated data from a known t-distribution. Our method was 1) insensitive to inherent free parameters over a wide range of values; 2) able to infer the correct number of clusters despite data condition changes and model uncertainties. We also compared our algorithm with other popular automatic sorting methods: the t-distribution EM in Plexon's Offline sorter, the Superparamagnetic Clustering in Wave Clus (Quiroga et al., 2004) and the robust variational Bayes (Takashi et al., 2012). Our method was performed truly automatic without human intervention while others were fine tuned for improved performance. Comparisons were made using artificial dataset from Wave Clus package, labeled real dataset from Buzsaki lab and our lab. Our algorithm outperformed all other methods because of the highest classification accuracy and lowest variances over 20 runs, even when subject to worsened SNR and increased similarity among clusters. For unlabeled real dataset from our lab, we evaluated sorting quality by spike statistics such as shape, firing rate and inter-spike-interval. Our algorithm was comparable to or more reasonable than other methods.

Title: Automatic procedures for segmenting and tracking hundreds to thousands of individual neurons recorded by wide-field calcium imaging

Authors: S. SHEN[1], R. WU[1], H.-A. TSENG[2], X. HAN[2], *J. SI[1];
[1]Sch. of Electrical, Computer and Energy Engin., Arizona State Univ., Tempe, AZ; [2]Dept. of Biomed. Engin., Boston Univ., Boston, MA

Abstract: Our recent results demonstrated that using wide-field imaging, we were able to capture the concurrent dynamic activity from hundreds to thousands of neurons over millimeters of brain tissue in behaving mice for an extended period of time. Our data showed that a large fraction of anatomically distinct hippocampal neurons responded to discrete environmental stimuli associated with classical conditioning, and that the observed temporal dynamics of transient calcium signals are sufficient for exploring certain spatiotemporal features of large

neural networks. This advance in neurotechnology has provided new capabilities to the investigation of neural circuit function in systems neuroscience. Along with implementing this imaging technique is the problem associated with processing multi gigabytes of data after each recording session. Analyzing such expansive data sets that contain dynamic information of hundreds to thousands of neurons is an overwhelming task, which is nearly impossible by manual operation.
We therefore developed a new, automatic procedure to segment and track single neurons for their dynamic behavior through each experimental session. First, a template image was formulated by filling up each pixel of the template with the maximum intensity value of that pixel throughout the whole session. Based on the distribution of pixel intensities in the template image, the initial threshold value was chosen within the long-tailed region of the resulting histogram. Next, this threshold value is refined in a feedback loop. The threshold value is applied to the template frame, and all resulting regions of interest are collected and collated. Based on the number of regions of interest that meet the predetermined cell area criteria, the threshold value is adjusted to maximize the cell count: a high threshold value will produce fewer segmented cells while a low threshold value will produce segmented cells that include parts of the background and whose cell areas are too large. We tested our automatic single neuron identification and tracking procedures on multiple datasets, and further validated by manual inspection with a subset of data sets. For the dataset that we validated using manual inspection, the algorithm produced no false positives, and the false negative results were due to either purposely removed overlapping cells or the lack of activity during the time window analyzed.

Title: Hippocampal EEG state-dependent cortical calcium dynamics

Authors: *Y. SHINOHARA, H. HIRASE;
RIKEN, Wako, Japan

Abstract: Phase-locked synchronization between the hippocampus and cerebral cortex has been reported during working memory task and spatial navigation. However, the spatio-temporal dynamics of the hippocampus and wide cortical areas is largely unknown. Functional imaging methods such as PET and fMRI lack the temporal resolution to analyze synchronized neural activities between the hippocampus and various cortical areas. Owing to the large volume conductance, surface EEG recording cannot precisely identify the location of activity source. Our transgenic mouse line (G7NG817), which expresses the calcium indicator G-CaMP7 in astrocytes and the majority of excitatory neurons in the cortex, enables us to observe the temporal dynamics of cortical calcium in 30Hz-100Hz transcranially. Utilizing this mouse line as an experimental tool, we performed simultaneous recording of hippocampal EEGs and imaging of cortical calcium activities under urethane anesthesia. We found that the cortical calcium dynamics was closely correlated to hippocampal EEG status. Calcium activities observed during theta and non-theta states showed distinct spatial and temporal patterns. Cortical calcium level was higher in wide areas of the cortex during the theta state, and the temporal calcium fluctuation was relatively mild. During non-theta states, basal calcium level was lower, but larger cortical calcium elevations that spread over cortical areas co-occurred with hippocampal ripple oscillations. These cortical calcium transients were observed in various cortical areas such as visual, auditory and somatosensory cortex, and showed a distinct spreading pattern at each ripple event. This observation indicates a rapid and dynamical switching of synchronized activities between the cortex and hippocampus during non-theta states.

Title: Investigation of inter-areal communication through targeted electrophysiological recordings

Authors: *P. JENDRITZA, C. M. LEWIS, P. FRIES;
Ernst Struengmann Inst. (ESI) For Neurosci., Frankfurt, Germany

Abstract: In order to understand neural communication between brain areas it is necessary to record activity from functionally connected populations. Here, we demonstrate how large-scale electrocorticographic (ECoG) recordings can be used to map functional properties of visual cortical areas and to target subsequent intracortical recordings. Local field potentials (LFPs) as well as multiunit activity (MUA) can be recorded from the surface of the cortex, enabling the functional characterization of underlying areas, e.g. the estimation of the local retinotopic map. This map can be used to guide the positioning of electrodes and optic fibers for targeted recordings and optogenetic stimulation, respectively. The application of multiple ECoG arrays to characterize distinct areas in a sensory hierarchy, enables targeted recording from functionally related populations. We show that our approach is applicable at different spatial scales and discuss how it could be extended to target injections of drugs or viral vectors and closed-loop feedback experiments in multiple species, including non-human primates.

Title: Magnetic resonance as wireless power supply for EEG systems

Authors: *J. BERGELER[1], N. V. DE CAMP[2];
[1]Physiol., Universitätsmedizin Mainz, Mainz, Germany; [2]Physiol., Med. Univ. Mainz, Mainz, Germany

Abstract: Wireless EEG systems are of interest for medical applications as well as scientific research, especially in the field of behavioral physiology. One major challenge for the long-term operation of telemetric EEG systems is the power supply, since battery and accumulator technology are not following Moore's law to date. In order to achieve miniaturized, energy autarkic EEG systems, we developed a wireless power supply with resonant coils. In contrast to inductive coupling, which is restricted to very short distances as well as precise alignment of the coils, resonant inductive coupling (also known as magnetic resonance) is useful as mid field power supply, bridging a space in the range of meters depending on the wavelength. Furthermore, resonant inductive coupling does only power coils which are resonant (defined by

the oscillating circuit consisting of a coil and a capacitor). In contrast to inductive coupling without resonance, the power harvesting efficiency of small receiver coils is superior in the case of magnetic resonance. Therefore, our development is extremely useful for future energy autarkic neural implants with the need of strong miniaturization. Our receiver coil has a dimension of 8x15x1mm. The transmitter board has a dimension of 50x50 cm with one power coil and four resonant coils in which the power coil is supplied with up to 10 Watt. Alternating current sine wave frequency is 13,56 MHz (International Industrial, Scientific and Medical Band). It is possible to support several systems in parallel.

Title: Open-source software development kit for adaptive optics and optogenetics with a spatial light modulator

Authors: *R. LIU[1], J. BROCKILL[2], P. LEDOCHOWITSCH[2], P. SAGGAU[2];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Liquid crystal spatial light modulators (SLM) have become essential components in wavefront shaping for optical imaging and manipulation of the nervous system. For example, SLM-utilizing techniques such as adaptive optics have been successfully applied to achieve deep imaging of brain tissue with synaptic resolution, and holographic optical stimulation has been employed to perturb neuronal activities.
However, in the setting of a typical neuroscience lab, technical hurdles to develop those tools remain daunting. We will present results from recent efforts to develop a LabVIEW-based open-source software development kit (SDK) for adaptive optics and optogenetics, with the aim to promote the proliferation of new neurotechniques through the open science activities at Allen Institute for Brain Science. The SDK is fully compatible with both the Meadowlark Optics SLMs and the National Instruments hardware bundles for ScanImage 2015. The SDK will incorporate the SLM calibration routines, arbitrary beam steering and refocusing using SLM, hologram generation, and a method to measure wavefronts based on a multi-dither coherent optical adaptive technique.

Different from other open-source software, we intended to provide functional units for each application suited for adaptation and further expansion by the users rather than a comprehensive solution for a particular application.

Title: Online analysis and perturbation of brain-wide activity in zebrafish

Authors: N. VLADIMIROV, C. WANG, S. NARAYAN, J. FREEMAN, P. J. KELLER, *M. B. AHRENS;
Janelia Res. Campus / HHMI, Ashburn, VA

Abstract: Understanding how sensory signals drive behavior requires a combination of tools for interrogating brain function, including large-scale neuronal recordings, neural perturbations, and large-scale data analysis. Here we combine whole-brain imaging with online perturbation techniques to a) map the tuning of most neurons in the brain of larval zebrafish to behavioral and sensory variables, and b) perform targeted circuit perturbations to test functional roles of the identified populations.
As a model of sensorimotor transformation, we use the optomotor response (OMR), in which larval zebrafish orient and swim along the direction of visual motion. Using regression analysis, we identify, on a brain-wide scale, populations of neurons whose activity correlates with swimming, visual input, or both. With online analysis during data collection, the whole-brain maps are then used as a guide for targeted cell ablations. Several motor-correlated bilateral groups of neurons in the hindbrain, when perturbed, showed strong and reproducible effects on the behavior. Ablating these cells caused a severe reduction in the dynamic range of swim power and swim duration during the OMR. Our method can also be applied with two-photon optogenetic stimulation instead of ablation.
These methods, combined, establish a technique for perturbing brain activity based on whole-brain functional mapping and large-scale online analysis.

Title: Simultaneous calcium imaging and optogenetic manipulation in freely behaving mice

Authors: *A. M. STAMATAKIS, S. GULATI, M. TRULSON, S. L. OTTE;
Inscopix, Palo Alto, CA

Abstract: Optogenetics has revolutionized systems neuroscience by providing a tool to causally link distinct neurocircuit activity to behavior. In addition, advances in calcium indicators and imaging techniques have led to important discoveries on how various internal and external stimuli drive the activity of distinct neuronal populations. Here, we introduce a miniaturized lightweight microscope that allows for simultaneous cellular-resolution imaging and optical manipulation within the same field of view in freely behaving mice. This microscope contains a 455 nm LED (EX-LED) for excitation of GCaMP and a 590 nm LED (OG-LED) for selective activation of red-shifted opsins. Both LEDs are housed within the microscope and are emitted through the imaging objective. Paired with an implanted GRIN lens, this microscope allows for long-term, cortical and subcortical simultaneous brain imaging and optogenetic manipulation in freely-behaving mice. We found that the red-shifted inhibitory opsins halorhodopsin (NpHR3.0) and Jaws, are minimally activated by the EX-LED in brain slices. In addition, although we observed significant depolarization of somas expressing the red-shifted excitatory opsin ChrimsonR with the EX-LED in brain slices, we observed minimal postsynaptic currents when stimulating terminals expressing ChrimsonR. Thus, we have demonstrated that it is feasible to pair imaging with somatic and terminal inhibition using NpHR3.0 and Jaws. Furthermore, we have demonstrated that it is feasible to pair imaging with terminal stimulation using ChrimsonR. We also found that GCaMP does not significantly respond to OG-LED stimulation in vivo. Finally, we demonstrate the feasibility of simultaneous optogenetic manipulation and calcium imaging in freely behaving mice.

Title: Linear two-color uncaging with zero optical crosstalk

Authors: *S. PASSLICK, M. T. RICHERS, G. C. R. ELLIS-DAVIES;
Dept. of Neurosci., Mount Sinai Sch. of Med., New York, NY

Abstract: Multichromatic uncaging of intra- or extracellular signaling molecules is a powerful means to study neuronal physiology. The greatest challenge of multicolor actuation is to minimize excitation crosstalk, allowing activation of a short wavelength absorbing chromophore without activation of its long wavelength counterpart and vice versa.
The majority of caging chromophores show maximum absorbance at short wavelengths (in the UV range), while exhibiting no to very low absorbance at longer wavelengths. In contrast, designing suitable partner chromophores that absorb at longer wavelengths with minimal absorbance in the short wavelength range has proven to be much more challenging.
The aim of our current work was to develop a pair of caging chromophores suitable for dual-color one photon (1P) uncaging with minimal optical crosstalk. Our lab recently synthesized the caging chromophore “DEAC450” which shows maximum absorbance at 450 nm. By modifying its structure, we were able to significantly reduce its UV light absorbance making it a promising candidate for dual-color 1P uncaging.
We attached this new caging chromophore to the neurotransmitter GABA and co-applied it with the short wavelength caged compound dcPNPP-glutamate to CA1 pyramidal neurons of acute

brain slices. Brief full-field illumination with UV light (375 nm, LED) elicited single or multiple action potentials. If this stimulus was preceded by illumination with longer wavelength light (470 nm), the action potentials were reversibly blocked. Detailed analysis irradiating both compounds with varying power and duration at both wavelengths, demonstrated that the power window for crosstalk is virtually infinite at powers used to evoke physiological signals. As a result of the high uncaging efficiency of these molecules, we were able to apply them at very low concentrations, significantly reducing the antagonism of both compounds against $GABA_A$ receptors. Another advantage of the high uncaging efficiency and the LED full-field illumination used was that UV-uncaging showed little to no cytotoxicity even after many (>100) uncaging pulses.
In summary, we were able to develop a long wavelength caging chromophore that shows so little absorption of short wavelength light that 1P/1P uncaging is possible with zero optical crosstalk.

Title: ProjectorScope 2: an updated optical system for patterned optogenetic stimulation and intrinsic signal imaging

Authors: ***S. WANG**, J. J. OSIK, S. D. VAN HOOSER;
Biol. Dept., Brandeis Univ., Waltham, MA

Abstract: Understanding the operating principles of the cortex is critical to understand the mechanisms by which neural circuits enable perception and behavior, and to understand how these mechanisms go awry in diseases of the nervous system, such as in epilepsy and autism. Optogenetic tools have progressed to enable neuroscientists to directly manipulate neuronal networks with high temporal resolution, opening a new avenue by which to unravel the underlying mechanisms of neural systems by stimulating neurons with light.
My colleagues and I previously developed an optical projection system, called “ProjectorScope 1”, which can play “movies” to the brain surface in intact animals to optogenetically activate

different cortical areas in space and time in order to dissect the role of individual circuit components in neural computation. Recently, we have made several improvements to the optical system and updated a new version, “ProjectorScope 2”, which will further let us perform brain surface imaging to identify functional brain areas, e.g. orientation columns of ferret visual cortex, and subsequently activate these local areas with spatiotemporal control in intact animals that express optogenetic channels.
The new optical system includes a commercial projector that functions as an image generator, and a custom made single-reflex lens connector that replaces the native projection lens and so receives light directly from the projector’s inside prism. This helps to eliminate the misalignment between the projector and the external lenses and thus greatly reduce the optical aberrations. Two juxtaposed achromatic lenses of 30 mm focal length are in place to further minify the image so that the size of the projection area, approximately 4 mm by 4mm, matches the size of the brain surface imaging area. Four identical single-reflex lenses are used in the system to achieve parfocality between the imaging camera and the projector. These adjustments grant ProjectorScope 2 the capabilities of simultaneous projection and imaging. The system can provide 8-11 mW/mm^2 power on the brain surface from a single blue channel that will be sufficient to activate channelrhodopsin-2 channels.
Preliminary results have shown that this system is able to perform brain surface imaging to identify orientation columns of ferret visual cortex and project image masks to subsequently target any patterns of columns. We will use ProjectorScope 2 to assay cortical circuit mechanisms to understand how multiple cortical inputs influence receptive field properties by directly activating local functional areas of the cortex *in vivo*.

Title: Multimodal nonlinear and thermal imaging platform for assessing infrared neural stimulation

Authors: ***W. R. ADAMS**[1], A. MAHADEVAN-JANSEN[2,3];
[1]Biomed. Engin., [2]Dept. of Biomed. Engin., Vanderbilt Univ., Nashville, TN; [3]Dept. of Neurosurg., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: In recent years, the application of light to modulate neural activity has revolutionized the progression of modern neuroscience research. Infrared neural stimulation (INS), which uses low-energy pulsed infrared light to evoke biochemical and electrical neural responses, is gaining traction as a spatially-selective, artifact-free method of exciting neural activity without genetic modification or introduction of exogenous substances. Current research into the fundamental mechanisms of INS points to a variety of physical and chemical changes that result from a transient local temperature change in irradiated tissue. Despite investigation, the underlying biophysical principles for infrared excitability have yet to be fully elucidated. In efforts to probe these mechanisms, our group has developed a novel microscope that is capable of obtaining label-free, chemically-selective images coregistered with thermal profiles in real time. The microscope combines nonlinear imaging capabilities- including Coherent Anti-Stokes Raman Scattering (CARS), Stimulated Raman Scattering (SRS), Two-Photon Fluorescence (2P), Second Harmonic Generation (SHG)- with real-time temperature distributions through thermal microscopy. CARS and SRS provide a means of real-time, label-free contrast by means of intrinsic, Raman-active vibrational modes present in a particular sample. Two-Photon and SHG imaging allow for label-free probing of cytoarchitecture and metabolic activity alongside standard labelling of physiological dynamics. Coregistration of thermal images with nonlinear imaging provides a unique, real-time perspective of the complex molecular processes during INS. Here we demonstrate the ability of our multimodal microscope to image neural tissue and elucidate molecular changes at the cellular level to provide further insight towards the biophysical mechanisms of INS. Comparison of stimulation paradigms are compared to electrical stimulation. More broadly, we demonstrate the power of applying multimodal, nonlinear, label-free imaging techniques towards neuroscience research to provide unique insight into cellular details and to visualize the dynamics of physiological processes in real time.

Title: Light gated neurons: The co-varying roles of laser wavelength, power level, and voltage-gated conductances in infrared neural stimulation

Authors: *B. S. COVENTRY[1,2,3], J. T. SICK[4], A. L. SOMMER[2,3], C. A. HADDIX[2], T. M. TALAVAGE[2,5,3], K. M. STANTZ[4,7], E. L. BARTLETT[2,6,3];

Abstract: Electrical stimulation of the nervous system is an invaluable tool for studies in basic science and as an effective therapeutic in cochlear implant and deep brain stimulators. However, use of electrical stimulation is hindered by its propensity for non-specific activation and adverse electro-chemical reactions in neural tissue. Infrared Neural Stimulation (INS) is a relatively new stimulation paradigm which utilizes infrared irradiation in the near infrared range (700-2000nm typically) to evoke excitatory responses in neurons and nerves with higher spatial specificity than electrical stimulation (Izzo et al, 2007) and mitigation of adverse electro-chemical reactions. INS has been applied to diverse areas of the nervous system including sciatic (Wells et al, 2005), auditory nerves (Izzo et al, 2006), and thalamocortical circuits (Cayce et al, 2010) in the central nervous system. Despite these studies, the mechanisms of INS are still not well understood. Furthermore, previous studies were limited in that only single wavelengths at fixed lasing power levels were utilized. In this study, we explore the role of wavelength and power levels in infrared excitation of the rat sciatic nerve and compare these responses to those elicited by electrical stimulation. We found that INS stimulation in the 700-900 nm range, especially at 800 nm, consistently evoked short-latency compound nerve action potentials (CNAP) using very low powers (~10 mW). Additionally, CNAP amplitudes were dependent on laser wavelength and power level, but not energy alone. CNAP amplitude and width were increased by application of the voltage-dependent potassium channel blocker 4-AP and further tests will outline the cellular requirements to evoke the INS-induced CAPs. Concurrently, we explore the ionic basis of INS by selectively blocking sodium, potassium, or TRPV4 channels. Given that INS is wavelength and power level dependent while remaining artifact free, INS laser stimulation parameters can be fine-tuned for a wide variety of basic science and therapeutic applications.

Title: Spatially and temporally controlled photomanipulation of neurons

Authors: ***S. JUNEK**[1], J. AULBACH[1], M. FICHTE[2], A. HECKEL[2], A. WINGERT[1], O. WENDT[3];
[1]Max Planck Inst. For Brain Res., Frankfurt Am Main, Germany; [2]Univ. of Frankfurt, Frankfurt am Main, Germany; [3]Rapp OptoElectronic GmbH, Hamburg, Germany

Abstract: Manipulation of cells with light has become a powerful and widely used tool in neuroscience. For this approach to reach its full potential, two conditions need to be met: the precise spatial and temporal control of light delivery inside the sample, and the availability of light-controllable molecules that can modify crucial cellular and neuronal functions.
We present a novel holographic illumination system that can be coupled to existing microscopes (e.g. two-photon microscopes) which provides high resolution control for photomanipulation experiments. The system is optimized for two-photon excitation to improve axial confinement of the excitation patterns as well as tissue penetration. 4d light patterns (x,y,z,t) can be defined by the user based on fluorescence images of the sample.
In addition to a technical characterization of the system we present biological applications of the illumination module using various types of light-sensitive molecules, including caged compounds, photo-switchable ligands of neuronal receptors and optogenetics molecules.

Abstract: Genetically encoded calcium indicators and optogenetic actuators are powerful tools to explore the functional organization of neural circuits. To fully exploit these tools we need a technology that allows fast optical readout of neuronal signals and simultaneous manipulation of network function. However, combing high-speed imaging and optogenetic perturbation simultaneously has been difficult to establish in the mammalian brain because of the poor signal-to-noise ratio that characterizes fast functional imaging and because of potential cross-talk between the different wavelengths that are used for imaging and for optogenetic stimulation. Here, we developed a technique based on patterned two-photon illumination that allows fast (up to 1 kHz) imaging of GCaMP6 signals *in vivo* while manipulating circuit activity with single-photon optogenetic inhibition of Archaerhodopsin (Arch). By combining imaging and electrophysiological recordings *in vivo*, we found that in the scanless configuration single and short trains of action potentials in layer II/III pyramidal neurons could be detected with millisecond precision and improved signal-to-noise ratio compared to the raster scanning approach. Moreover, the artifacts in the fluorescence detection due to single-photon optogenetic illumination were removed in the scanless configuration. As proof of concept, we applied our technique to study the role of parvalbumin-positive (PV) interneurons in the control of spontaneous cortical dynamics. By allowing the readout of the effect of the optogenetic manipulation on neuronal network with unprecedented spatial and temporal resolution *in vivo*, simultaneous high-speed imaging and optogenetics can strongly advance our knowledge of the functional organization of mammalian neural circuits.

Title: Tracking compound action potential features to identify areas of inhibition

Authors: *J. FORD[1], M. W. JENKINS[3], H. J. CHIEL[4], E. D. JANSEN[2];
[2]Biomed. Engin., [1]Vanderbilt Univ., Nashville, TN; [3]Pediatrics, [4]Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Classical analysis of peripheral nerve activity focuses on changes in the compound action potential (CAP). Most studies use the CAP to study motor signals. Some nerves, such as the vagus, contain both motor and sensory axons. We have recently focused on the use of infrared (IR) laser light to block activity in peripheral neuron sub-populations (Jenkins *et al*. at this meeting). It is imperative to analyze CAPs with a method that can quantify changes, including shifts, in the signal's sub-components. Common analysis techniques filter the signal, remove stimulation artifacts, and quantify changes in amplitude, rectified area under the curve, or frequency spectrum. These methods are insensitive to changes in individual CAP features, which are a result of activity changes in axons with differing conduction velocities (indicative of different diameters). In addition, with repeated stimulation, it is often observed that components of the CAP may shift relative to one another. To the best of our knowledge, current tools do not identify CAP features, track those changing features, and identify feature inhibition. Here we present a novel algorithm, implemented in MATLAB, with these capabilities. To test our code, suction electrode recordings from pleural-abdominal nerve in *Aplysia californica* were acquired. CAPs were induced electrically for 37.5 seconds at 4 Hz (150 traces per recording), and features within each CAP were inhibited using a pulsed IR laser (1875nm, 400µm diameter optical fiber, 200Hz pulse frequency, 200µs pulse width, 15 sec duration). Radiant exposures at the fiber output ranged from 123 to 286 mJ/cm^2/pulse to achieve varying degrees of inhibition. First, features (peaks and troughs) were identified in a baseline trace. Features are extracted using the following steps: 1) the signal was smoothed to reduce noise; 2) derivative values were calculated from the slope of a linear fit to a sliding window, reducing the susceptibility to high frequency noise; 3) derivative values were analyzed for sign to identify peaks and troughs; 4) points were only kept if the differences between both neighboring features was above threshold. Extracted features were then tracked through all subsequent traces in the recording using MATLAB's template matching algorithm (Computer Vision System toolbox) to identify features common to all traces. This algorithm is designed to quantify both feature shift and inhibition, comparing baseline and treatment traces to identify inhibited features. Understanding which features are inhibited will help users identify affected populations of neurons and help further guide the application of targeted inhibition.

Title: A depolarization-activated increase in voltage-dependent potassium currents in response to elevated temperature may account for action potential block in models of the squid giant axon.

Authors: *M. GANGULY[1], M. W. JENKINS[2], H. J. CHIEL[3], E. JANSEN[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Pediatrics, [3]Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Elevated temperatures are known to inhibit generation and propagation of nerve action potentials in myelinated and unmyelinated nerves. For example, it has been shown that infrared lasers (1.87 μm) that heat the tissue due to water absorption can be used to block action potential propagation in *Aplysia* and in the rat sciatic nerve. A comprehensive computational model will be helpful in deciphering the biophysical mechanisms responsible for infrared block and optimizing parameter space to deliver more efficient/safe block for a variety of different tissues and geometries. We present a computational model that predicts the behavior of an unmyelinated nerve axon, the squid giant axon, that is subjected to elevated temperatures. The computational model was created in NEURON and can be combined with a time-dependent temperature distribution from any heat source. The elevated temperatures used are in the form of spatial and temporal distributions such as those produced during infrared laser heating. Model validation was performed by comparing the effects of change in temperature predicted by the computational model with the published experimental observations in squid giant axon. In response to stimulating currents, regions of elevated temperatures in the squid giant axon show an increase in potassium current that lead to a hyperpolarization of the axon. This depolarization-induced hyperpolarization of the axon may be a significant mechanism for blocking of action potentials at elevated temperatures. Since the standard Hodgkin-Huxley model does not take into account the effects of peri-axonal potassium accumulation or the Na-K pump, we are also exploring their effects on the phenomenon of infrared laser induced thermal inhibition. This model provides us a platform for the preliminary design of a neural interface for selective nerve inhibition that may be used in higher animals, and eventually in humans for chronic pain management.

Title: Safety and selectivity of infrared block for small diameter axons.

Authors: ***E. LOTHET**[1], H. LU[1], S. LEWIS[2], M. JENKINS[3], H. CHIEL[4];
[1]Biol., [2]Pediatrics and Pharmacol., [3]Pediatrics and Biomed. Engin., [4]Biology, Biomed. Engin. and Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Controlling subpopulations of unmyelinated axons within peripheral nerves would make it possible to treat a very wide variety of clinical syndromes. Within the last few years, implanted neural devices have been developed to control peripheral nerve activity. Infrared (IR) light has recently been described as a promising modality for control of neural activity. Previous studies have shown that brief pulses of IR can induce excitation of neurons. Recent studies have shown that IR can inhibit neurons with high spatial specificity. We found that IR light can block nerves with axonal subpopulation selectivity, where smaller diameter axons with slower conduction velocities are more sensitive to the effect of the IR light and are therefore more readily blocked by light than larger diameter axons with faster conduction velocities.
To evaluate infrared settings that can effectively block compound action potentials in an unmyelinated nerve, we used *Aplysia* pleural-abdominal connectives to establish reliability and repeatability of block. We hypothesized that the block will progress through the following events: selective block of smaller-diameter axons, complete block of both small and large-diameter axons with immediate reversibility, and complete block exhibiting irreversibility.
We found that we could rapidly, repeatedly and reversibly inhibit action potential propagation in the slower conducting smaller axons before inhibiting the faster conducting larger axons. At the highest radiant exposure used in these experiments, the shortest delay between the onset of

infrared and partial block of the smaller axons was within 1 second. This delay became longer as we decreased the laser radiant exposure. We also found that it was possible to reversibly block either selectively (only small-diameter, slow-conducting axons) or completely (both slow-conducting and fast-conducting axons) for a prolonged period of time, up to 5 hours.
These results suggest that IR light might be a clinically relevant technique to block unmyelinated C fibers selectively, reversibly and for an extended period of time. In future studies, it may be possible to establish whether this could serve as a novel treatment for significant clinical challenges such as chronic pain.

Engin., Vanderbilt Univ., Nashville, TN; [6]Med: Div. of Gastroent, Hepatology, and Nutrition; Anesthesiology; Biobeharvioral Oncology Prog, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Modulation of peripheral sensory nerve signaling is being investigated as a novel treatment for a variety of diseases (e.g., rheumatoid arthritis, pain, obesity, hypertension). Electrical excitation or inhibition of nerve activity is the established approach, but there is a substantial interest in developing techniques to produce greater selectivity in modulating nerve function by targeting specific subpopulations of nerve fibers. Recently, our group demonstrated

that pulsed infrared (IR) light (1860 nm, 200 Hz pulse frequency, 200 μs pulse width) can inhibit peripheral nerve activity with high spatial and temporal specificity. Here, we provide evidence that IR can selectively and reversibly inhibit small-diameter axons at lower radiant exposures than large-diameter axons. We present a mathematical analysis of the cable equation that reveals that modulation techniques primarily affecting the axon surface would preferentially control small-diameter fibers. To validate our mathematical theory, we experimentally demonstrated the effect of infrared light applied to identified neurons of the marine mollusk *Aplysia californica* and in axons within the vagus nerve of the musk shrew. The *Aplysia* model allowed us to directly compare the axonal responses to IR light of two identified neurons (B3 and B43), which have a large and small diameter axon, respectively. IR light consistently blocked B43 at lower radiant exposures (0.0967 J/cm^2 versus 0.131 J/cm^2) than B3 (N=5). We utilized an *in vitro* and *in vivo* Suncus murinus (musk shrew) model to demonstrate selective block in whole vertebrate nerves and small fiber bundles. Again, IR light consistently blocked slow-conducting compound action potentials (CAPs), which correspond to the small-diameter fibers, before blocking faster CAPs (N=3 *in vitro* prep, N=3 *in vivo* prep). Radiant exposures as low as 0.038 J/cm^2/pulse blocked small-diameter fibers. The ability of IR laser to selectively, rapidly, and reversibly control the signaling of small-diameter axons has a large number of applications, including its use as a research tool to investigate the mechanisms of neural circuits and for the treatment of disease.

Abstract: In vivo brain imaging in rodent models using multiphoton microscopy (MPM) has greatly enhanced our understanding of the brain. Yet, MPM has depth limitations that generally restricts imaging to a few hundred microns below the pial surface. Implantation of gradient index lenses, or GRIN lenses, has greatly extended the imaging depth to lower cortical layers and even subcortical regions of the mouse brain. Using GRIN lenses, researchers can now visualize dynamic activities, such as Ca2+ signaling, with fine spatiotemporal resolution. Moreover, they can conduct repeated imaging over weeks and months. This presents an opportunity to conduct behavioral tests to correlate performance with changes in network dynamics and cellular structure. Thus, it is critical to know if and how an implanted GRIN lens might affect behavioral test performance. Additionally, it is important to know if the glial scar, which forms around all neural implants, would appear in the tissue being imaged.
To determine the effects of implantation on behavior and imaging, a GRIN lens was implanted in the prefrontal cortex (PFC) of experimental mice, using a minimally invasive surgical technique, and behavioral tests were performed over a seven-week period (three presurgical and five postsurgical sets). Behavioral tests included foot fault, rotarod, and Morris water maze tests. No significant differences were detected between the performance of experimental mice and mice that had either a craniectomy with a cranial window or a sham surgery. Additionally, the 46-micron mean thickness of the glial scar at the bottom of the lens was much thinner than the 125-micron working distance of the lens, which means that scar tissue did not appear in the imaging region. Thus, GRIN lenses can be used for longitudinal imaging in the PFC, and possibly other brain regions, with concurrent behavioral tests in mice as long as the working distance of the GRIN lens exceeds the thickness of the scar and a minimally invasive surgical technique is used.

Title: Efficacy profiling of T-817MA, anti-Alzheimer drug candidate, and sigma-1 receptor agonists

Authors: T. YANO, H. TANABE, A. NABETANI, T. OKUDA, *M. NAKAGAWA, T. NAKAMURA;
Toyama Chem. Co Ltd, Toyama 930-8508, Japan

Abstract: T-817MA is an orally available agent, which is in the phase 2 clinical trial for Alzheimer's disease (AD) in the US and Japan. We previously reported that T-817MA recovered cognitive impairment in an AD animal model (Kimura et al., SfN 2006). T-817MA demonstrated a neuroprotective activity against the toxicity induced by amyloid β or oxidative stress such as sodium nitroprusside (SNP). T-817MA promoted neurite outgrowth in reaggregation culture of rat cortical neurons. T-817MA bound to Sigma-1 (σ1) receptor (Ki = 16 nM), which is reportedly involved in oxidative stress resistance and neuritogenesis. σ1 antagonists abrogated efficacy of T-817MA. We hypothesize that T-817MA may exert its pharmacological activity as a σ1 agonist. To compare pharmacological profiles of T-817MA and known σ1 agonists, (+)-pentazocine (Ki = 4.59 nM (Skuza et al., 2003)) and donepezil (Ki = 14.6 nM (Kato et.al., 1999)), neuroprotection assay was undertaken using cultured cortical neurons of rat embryos. T-817MA and (+)-pentazocine showed neuroprotection against SNP-induced cell death (EC_{50} of 5 nM and 500 nM in this study, respectively). Donepezil had no neuroprotection against SNP-induced cell death. In conclusion, T-817MA has potent neuroprotective activity, while other σ1 receptor agonists tested have weak or no activity.

Title: Mechanism of PAMAM dendrimers internalization in hippocampal neurons

Authors: *F. VIDAL[1], P. VÁSQUEZ[1], C. DÍAZ[2], D. NOVA[1], J. ALDERETE[2], L. GUZMÁN[1]; [1]Dept. of Physiol., [2]Dept. of Organic Chem., Univ. of Concepcion, Concepcion, Chile

Abstract: PAMAM dendrimers are hyperbranched macromolecules which have been described as one of the most promising drug nanocarrier systems. A key process to understand is their cellular internalization mechanism because of its direct influence on their intracellular distribution, association to organelles, entry kinetics, and cargo release. Despite that these mechanisms have been studied in different cell types, in the case of neurons they are not completely described. Considering the relevance of central nervous system (CNS) diseases and neuropharmacology, the aim of this report is to describe the molecular internalization mechanism of different PAMAM dendrimers-based nanocarrier systems in hippocampal neurons. Four dendrimers with different surface properties were studied: G4 with a positive charged surface, PP50 with polyethyleneglycol neutral groups, PAc with acrylate anionic groups and PFO with folic acid molecules. Confocal images show that both G4 and PFO are able to enter the neurons, but not PP50 and PAc. Colocalization study with specific endocytosis markers and specific endocytosis inhibitors assay demonstrate that clathrin-mediated endocytosis would be the main internalization mechanism for G4, whereas clathrin and caveolae-mediated endocytosis would be implicated in PFO internalization. These results show the existence of different internalization mechanisms for PAMAM dendrimers in hippocampal neurons, which opens the possibility to specifically direct them to particular applications and intracellular targets.

Title: P-glycoprotein (Abcb1a/Mdr1a) limits brain exposure to anti-cancer drug candidate R-roscovitine/seliciclib

Authors: *F. ERDO[1], I. NAGY[2], M. SIKE[3], P. KRAJCSI[2];
[1]Fac. of Information Technol. and Bionics, Pázmány Péter Catholic Univ., Budapest, Hungary; [2]Solvo Biotech., Budaörs, Hungary; [3]CEVA-Phylaxia, Budapest, Hungary

Abstract: Background: Seliciclib (R-Roscovitine) a cyclin -dependent kinase inhibitor, is a promising drug candidate to treat a variety of cancer. R-roscovitine has displayed activity against non-small cell lung-, colon-, breast- and prostate cancer in cell lines. Recently revealed its high activity in patients with chronic lymphatic leukemia or nasopharyngeal carcinoma. Pharmacokinetic studies have shown its high oral bioavailability but limited brain exposure. Rajnai and coworkers reported that seliciclib is a high affinity, selective P-gp substrate *in vitro* in ATPase assay, vesicular transport assay, Hoechst assay, calcein assay and MDCKII-MDR1 monolayer. This interaction is likely to affect its disposition. **Objective**: The aim of our study was to confirm the *in vitro* findings *in vivo* by the investigation of the effect of a specific P-gp inhibitor (PSC-833) on the brain distribution of R-roscovitine in anesthetized and freely moving mice. For making *in vivo-in vitro* (IVIV) correlation a mouse Mdr1a expressing LLC-PK1 monolayer cell line was also applied. **Methods**: To investigate the brain exposure of R-roscovitine dual-probe microdialysis technique was applied in anesthetized and singe-probe microdialysis in freely moving mice. R-roscovitine was administered in a dose of 50 mg/kg i.p. and either vehicle (control group) or PSC-833 (10 mg/kg i.p.) was applied as a pretreatment. Concentration-time profiles were determined in the blood and in the brain and AUC_{brain}/AUC_{blood} was calculated. For IVIV correlation seliciblib alone or LY335979 +seliciclib in combination were tested in LLC-PK1-mock and LLC-PK1-mMdr1a monolayers. **Results:** The brain concentrations of seliciclib increased in a statistically significant manner after co-administration with the P-gp inhibitor in anesthetized mice. The AUC_{brain} values changed from 131 to 327 pmol/mL h ($p<0.05$ by Student t-test compared to the control). In awake animals the AUC value changed from 136 to 242 pmol/mL h in the presence of PSC-833. In the mMdr1a transfected LLC-PK1 monolayer the efflux ratio of seliciclib transport changed from 6 to 1 after incubation with the specific inhibitor LY335979. **Conclusion**: Our results indicate that brain penetration of seliciclib is regulated by the efflux transporter P-gp *in vivo* in accordance with the previous *in*

vitro observations and our IVIV correlation study. The coadministration of seliciclib with a transporter inhibitor may offer a new opportunity for the drug delivery through the blood-brain barrier in case of the treatment of cerebral malignancies.

Title: Nose-to-brain transport of oxytocin following intranasal delivery with Precision Olfactory Delivery (POD) technology.

Authors: *A. E. BUSTION;
Impel Neuropharma, Seattle, WA

Abstract: Oxytocin (OXT) is a nine amino acid neuromodulatory peptide hormone synthesized in the CNS and in the periphery. Endogenous OXT plays a major role in relationship formation and social function of animals and humans. Hence, exogenous OXT holds potential therapeutic use for disorders that negatively affect social interaction, such as anxiety and schizophrenia. The possible benefits are complicated, however, by OXT's short half-life, metabolic instability, and poor transport across the blood-brain-barrier (BBB). Intranasal (IN) delivery of OXT as a means of bypassing the BBB has been explored both clinically and preclinically, but this is the first time, to our knowledge, that the ability to deliver exogenous IN OXT to different brain regions has been quantified. In the first portion of this study, wildtype C57BL/6 adult mice were dosed with 10 µL (1.2 µg/µL) of radiolabeled OXT (^{125}I-OXT, 2200 Ci/mmol) via the mouse precision olfactory delivery (mPOD) device (Impel NeuroPharma). The pharmacokinetics (PK) and biodistribution of exogenous OXT were assessed at 15, 30, 45, 60 and 90 minutes. In this study, the olfactory bulb exhibited significantly higher concentrations of ^{125}I-OXT compared to other brain regions, indicative of direct nose-to-brain transport along olfactory nerve pathways. Also, the brainstem presented higher peak concentrations than any non-olfactory brain region, suggestive of transport to the CNS along trigeminal nerve pathways. At the cortex and diencephalon T_{max} (30 min), a low pH (pH 4.65) OXT formulation and varying dose levels (0.1 µg/µL, 0.5 µg/µL, and 2.4 µg/µL) were studied to determine the pH sensitivity, linearity, and saturation of absorption of IN OXT. The results showed that OXT absorbs well across the nasal epithelium with no signs of pH sensitivity or saturation of absorption. The dose ranging experiment showed that lower doses result in lower brain levels of OXT, but at a slightly lower

concentration than would be expected if tissue uptake was linearly correlated to the amount of dose administered. This may be due to non-specific binding in the nasal cavity, or to metabolism reducing the rate of uptake at decreased concentrations. In all, this study shows that IN delivered OXT results in nose-to-brain transport and that saturation of uptake is not observed at the dose levels examined.

Title: Zirconium phosphate nanoparticle studies on sleep behavior and mortality in *Drosophila melanogaster*

Authors: ***J. J. GORBEA-COLON**[1], N. RODRÍGUEZ[3], B. CASAÑAS[4], J. L. COLÓN[4], J. L. AGOSTO, 00912[2];
[1]Dept. of Biol., Univ. of Puerto Rico - Río Piedras, Guaynabo, PR; [2]Dept. of Biol., Univ. of Puerto Rico - Río Piedras, San Juan, PR; [3]Biol., [4]Chem., Univ. of Puerto Rico Río Piedras, San Juan, PR

Abstract: Drug delivery systems aim to circumvent the difficult process of novel drug discovery by modifying the in vivo activity of known compounds. Zirconium phosphate (ZrP) nanoparticles have shown to be a viable non-cytotoxic platform for the delivery of several drugs including carbamazepine (CBZ). Given the potential medicinal use of ZrP, we test the effects of peroral ZrP administration on Drosophila melanogaster (D. mel) sleep behavior, establish a lethal dose for future experimentation using this combination, and address whether these behavioral effects can be reversed and mortality reduced by discontinuing regimens. We also present studies administering CBZ, a drug known to deprive sleep in D. mel, and CBZ delivered via the ZrP system. To achieve this, ZrP nanoparticles were synthesized from zirconium (IV) chloride and phosphoric acid and assayed using powder X-ray diffraction. For the intercalation of CBZ in the ZrP nanoparticles, stoichiometric amounts of CBZ were added and monitored intercalation by UV-Vis spectroscopy, monitoring total loading efficiency by thermogravimetric methods. ZrP nanoparticles were then suspended in fly food in concentrations of 0.00 mg/mL, 0.25 mg/mL, 2.50 mg/mL and 25.00 mg/mL, while the CBZ-ZrP was loaded at 1mg/mL and CBZ alone was

administered at 1mg/mL as well. The sleep patterns of wild type Oregon R (OreR) flies were assayed under standard Light/Dark (LD) cycles. Assayed flies had continuous access to food stocks for 1 week before exchanging stocks with new ones containing either the same ZrP concentrations or switching their stocks to new food without ZrP, except for CBZ-ZrP and CBZ treatments. After acquiring two weeks' worth of sleep behavior data, analyses were run using MatLab, Prism, and JMP computer software. From these studies, we report that concentrations of up to 2.50 mg/mL were safe in terms of mortality rate. However, in terms of sleep behavior, we observed alterations suggesting that sleep is a more sensitive measure of toxicity. Non-continuous treatment reversed sleep behavior phenotypes in some cases and reduced mortality for some groups. Even though CBZ administration followed previously reported patterns, CBZ-ZrP revealed inconsistent behavior needing further investigation. In conclusion, further studies are needed; however lower ZrP concentrations seem to be a promising alternative for the development of new drug delivery strategies, although biodistribution studies are of utmost importance before moving to next steps.

Title: T-817MA ameliorates cognitive impairment in the Tg2576 transgenic mouse

Authors: *T. OKUDA, T. MIYASHITA, H. SUZUKI, H. KOBAYASHI, T. YANO, A. NAKAMURA, M. NAKAGAWA, T. NAKAMURA;
Toyama Chem. Co., Ltd., Toyama-Shi, Japan

Abstract: T-817MA (1-{3-[2-(1-benzothiophen-5-yl)ethoxy]propyl}azetidin-3-ol maleate), was discovered by Toyama Chemical Co., Ltd. and has been developed as a therapeutic agent for Alzheimer's disease in Phase II clinical study. We previously demonstrated that T-817MA exerted neuroprotective effects against neurotoxicity induced by amyloid β (Aβ) and H_2O_2, and promoted neurite outgrowth in the primary culture of rat neurons (Yamaguchi et al., SfN 2003). Oral T-817MA ameliorated cognitive dysfunctions in the rat intracerebroventricularly infused with Aβ peptide (Kimura et al., SfN 2006). In the present study, we investigated the effect of T-817MA on cognitive dysfunction in the Tg2576 mouse. Tg2576 mice showed progressively impaired cognition in Y-maze test at 14 months of ages, while normal cognition at 5 months. T-

817MA was administered in drinking water at 0.21 and 0.7 mg/mL, corresponding to clinical doses of 112 mg and 224 mg respectively, from 4 to 14 months for the prophylactic treatment. T-817MA in drinking water at 0.7 mg/mL (corresponding to 224 mg) was dosed from 15 to 18 months of ages for therapeutic treatment. In both prophylactic and therapeutic treatments, T-817MA significantly improved memory and cognitive deficits in Y-maze and novel object recognition tests. T-817MA did not change Tris-soluble and insoluble Aβ levels in the brain in all T-817MA dose groups. These results suggest that T-817MA exerts improving effects on cognitive performance without modulating Aβ contents in the Tg2576 mouse.

Title: Validation of 6-[^{18}F]fluorodopa PET measures

Authors: ***L. TIAN**[1], S. K. LOFTIN[2], S. A. NORRIS[2], H. P. FLORES[2], J. S. PERLMUTTER[2]; [1]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Objective: 6-[^{18}F]fluorodopa (FD), an analog of L-DOPA (L-dihydroxyphenylalanine), is a positron emission tomography (PET) tracer used to evaluate

striatal presynaptic dopaminergic function in neurodegenerative diseases, e.g. Parkinson disease (PD). Specific regional brain uptake radioactivity reflects conversion of FD by L-aromatic amino acid decarboxylase (AADC) into ^{18}F-dopamine and retention of this and further metabolites. However, direct comparison of PET-measured *in vivo* regional uptake with local *in vitro* AADC activity has not been done. The purpose of this study is to attempt such validation. **Methods:** Fourteen macaques had baseline MRI and PET using FD, [^{11}C]dihydrotetrabenazine (DTBZ), and 2beta-[^{11}C]carbomethoxy-3beta-(4-fluorophenyl)tropane (CFT), then received unilateral intracarotid MPTP. After several weeks, PETs were repeated. The animals were euthanized at different time points for measurements of striatal AADC enzymatic activities, dopamine concentration. The influx constant (K_{occ}) for FD and non-displaceable binding potential (BP_{ND}) for CFT and DTBZ were calculated for caudate and putamen using an occipital reference region. The AADC enzymatic activity was measured using an enzymatic assay with L-DOPA as substrate using HPLC. **Results:** For all 14 monkeys, the FD K_{occ} strongly correlates with the AADC enzymatic activity in the left caudate (Spearman's correlation $r_s = 0.80$, $p = 0.001$, $n = 14$), ratio of right to left caudate ($r_s = 0.75$, $p = 0.002$, $n = 14$), and ratio of right to left putamen ($r_s = 0.66$, $p = 0.01$, $n = 14$). FD K_{occ} correlates with CFT BP_{ND} in the left caudate ($r_s = 0.59$, $p = 0.06$, $n = 11$), right putamen ($r_s = 0.67$, $p = 0.03$, $n = 10$), ratio of right to left putamen ($r_s = 0.70$, $p = 0.01$, $n = 13$). AADC enzymatic activity correlates with CFT BP_{ND} in left caudate ($r_s = 0.65$, $p = 0.02$, $n = 12$), ratio of right to left caudate ($r_s = 0.73$, $p = 0.005$, $n = 13$), right putamen ($r_s = 0.67$, $p = 0.03$, $n = 10$), ratio of right to left putamen ($r_s = 0.83$, $p = 0.00$, $n = 12$). FD K_{occ} correlates with DTBZ BP_{ND} in the ratio of right to left caudate ($r_s = 0.82$, $p = 0.0001$, $n = 10$), ratio of right to left putamen ($r_s = 0.79$, $p = 0.0002$, $n = 13$). AADC enzymatic activity correlates with DTBZ BP_{ND} in the ratio of right to left caudate ($r_s = 0.69$, $p = 0.01$, $n = 13$), ratio of right to left putamen ($r_s = 0.76$, $p = 0.0001$, $n = 12$). **Conclusions:** Taken together these results show that *in vivo* measured striatal FD K_{occ} reflects in vitro measured striatal AADC activity. Since striatal uptake of CFT and DTBZ correlate with striatal FD uptake, all of these PET measures reflect *in vitro* AADC activity. These findings play a critical role in interpretation of clinical studies using FD PET.

Title: A new method for detection of region- and enzyme-specific bioconversion of neuropeptides by combining *In situ* histochemistry and MALDI imaging mass spectrometry.

Authors: R. STRÖMVALL, E. BIVEHED, G. TOMASDOTTIR, *M. E. ANDERSSON; Neurotoxicology, Drug Safety and Tox., Dept. Pharm. Biosci, Uppsala Univ., Uppsala, Sweden

Abstract: Region-specific expression of proteolytic enzymes controls the biological activity of endogenous neuropeptides and has recently been targeted for the development of novel drugs, for example in neuropathic pain, depression, and for L-DOPA-induced dyskinesia in Parkinson's disease. Rapid and sensitive analytical methods to profile modulators of enzymatic activity are important for finding effective inhibitors with high therapeutic value.
Here we combined *in situ* histochemistry with MALDI imaging mass spectrometry and demonstrate that this is a highly sensitive method for analysis of brain-area specific neuropeptide conversion of synthetic neuropeptides, and for selection of peptidase inhibitors that differentially target conversion enzymes at specific anatomical sites.
Dynorphin B (DynB) was used as model neuropeptide and effects of peptidase inhibitors applied to brain tissue sections were analyzed. Synthetic DynB (2pmol) was found to be converted to both N-terminal and C-terminal fragments. Several specific and non-specific inhibitors were tested, some of which completely blocked conversion of fragments at 20 attomols on target. We also show dose-dependent inhibition of bioconversion and strain-specific differences in the bioconversion of DynB.
Bioconversion of synthetic DynB was region-specific, producing DynB(1-7) in the cortex and DynB(2-13) in the striatum. Both phosphoramidon (inhibitor of neprilysin) and opiorphin (inhibitor of neprilysin and aminopeptidase N) blocked cortical bioconversion to DynB(1-7), whereas only opiorphin blocked striatal bioconversion to DynB(2-13).
This new unbiased method ISH-MALDI imaging MS will be a very effective tool in the development of novel pharmaceuticals targeting enzyme activity, as it requires no labeling and detects both substrates and metabolites in one single experiment. It can reveal multiple cleavage sites and indicate if several enzymes are involved in bioconversion. Used in profiling mode it is very fast for screening purposes and can also detect the region-specific effects of enzymatic activity.

Title: Putamen and lateral ventricle adminstration in the cynomolgus monkey

Authors: ***J. DOUVILLE**, G. IACONO, F. EMOND, C. FOUCAULT, J.-F. LAFOND, R. ST-JACQUES, C. COPEMAN;
Charles River Labs. Montreal, Senneville, QC, Canada

Abstract: The putamen along with the caudate nucleus forms the dorsal striatum of the brain. It plays a key role in movement coordination, and in various types of learning. It is involved in many degenerative neurological disorders, like Parkinsons's and Huntington's diseases. Novel therapies, such as large molecules, have low penetration potential due to the blood-brain barrier or due to a short half-life. Therefore, delivery of drugs directly into the target brain compartments may be indicated. In large animals, accurate delivery into a specific brain structure represents a greater challenge. In monkeys, because of marked variability in the size and shape of the head, documented coordinates are considered approximations. To support the development of drugs intended for intracerebral administration, feasibility, reproducibility and tolerability of targeted putamen and lateral ventricle injections were evaluated in 8 terminal and 4 recovery animals. Once the surgical approach was established, a range of volumes were injected bilaterally at different rates to evaluate diffusion and reflux using ink. Following recovery from surgery, the animals were kept for an observation period of 14 days. Clinical signs, body weights, food intake, neurological evaluations, and clinical pathology parameters were monitored to ensure tolerability and evaluate any procedure-related effects. The animals were then euthanized, sequential sectioning of the brain was performed and tissues were embedded in paraffin and stained with H&E for histopathological evaluation. The actual localization of the injection sites, through ink diffusion and needle tracts, was then confirmed by detailed histopathology of the targeted structures. The animals showed no clinical signs related to the injections. There was no effect on body weight or food intake. A standard panel of hematology, coagulation and biochemistry parameters was evaluated and all results were within normal biological ranges. Neurological evaluations showed normal behavior, gait, postural reactions, cranial and spinal nerve functions. The histopathology evaluation demonstrated that the targeted brain structures were reached with minimal background changes. Overall, the putamen and lateral ventricle administration was successfully established.

Abstract: Lipid nanoparticles (LNPs) are used to deliver nucleic acids in vitro and in vivo. Here, we describe the robust manufacture and use of clinical-grade lipid-based nanoparticles for nucleic acids delivery at scales suitable for both in vitro screening and in vivo applications. We have conducted studies to evaluate the merits of the technology and further provide insights for delivering short interfering RNA (siRNA) and mRNA. RNA-LNPs were formulated to encapsulate a potent siRNA directed against PTEN. Exceptional cellular uptake (>98%) with minimal toxicity was observed in both primary rat hippocampal and mixed cortical cell cultures. High transfection efficency (>95%) of the encapsulated material resulted in high-level (>85%) PTEN knockdown within the first 4 hours of a low dose (100 ng/ml) treatment; knockdown was sustained for 21 days. Additionally, more than 80% knock-down of a housekeeping gene was observed in primary rat cortical astrocytes, neurons and human iPS-derived neurons using this technology. Similarly, RNA-LNPs encapsulating mRNA were also found to mediate early (< 4 hours) and sustained gene expression (>75% for 7 days) following a single (500 ng/ml) treatment in primary rat mixed cortical cultures. Strategies for locally administering RNA-LNPs into the brain and spinal cord of adult Sprague Dawley rats were also investigated. Localized injections of PTEN-encaspulated siRNA into the motorcortex resulted in significant and sustained (7 days) knockdown. Similarly, local administration at the site of a cervical spinal cord injury significantly reduced target PTEN expression, 10 days later. Collectively, these studies reflect the simplicity and efficacy of this technology in validating new targeted nucleic acid therapies.

Title: Neuronal autophagy stimulation by nanostructured oxygen solutions.

Authors: *M. V. IVANNIKOV, M. SUGIMORI, R. R. LLINAS;
Neurosci. and Physiol., NYUSOM, New York, NY

Abstract: Neurons rely on basal macroautophagy for protein quality control. Reduction in cellular ATP levels in cells, such as during starvation, potently activates macroautophagy to produce substrates to fuel their mitochondria. Decreased ATP levels in neurons are also a feature of many neurodegenerative conditions, which is mostly the result of mitochondrial inhibition by protein aggregates. Severe declines in neuronal ATP are disruptive to energy-dependent autophagy steps, promoting further protein aggregation and loss of mitochondrial function. Thus, stimulation of mitochondrial or glycolytic ATP output is necessary to boost autophagy to break the cycle and alleviate neuronal protein-aggregate load. In this study, we explore the effects of mitochondrial stimulation by hyperoxic and oxygen nanobubble containing solutions on autophagy in PC-12 cells.
PC-12Adh cells grown in DMEM with 1% horse serum and differentiated with 100 ng/ml nerve growth factor were transfected with pSELECT-GFP-mLC3B construct. Autophagy rate was quantified by monitoring changes in the number of GFP-LC3II puncta using time-lapse microscopy in cells perfused with core HEPES based Tyrode's solution (total observation time ~ 2 h). Perfusion with either hyperoxic Tyrode's solution(HO-T) or Tyrode's solution enriched with oxygen nanobubbles (ON-T) and similar oxygen concentration, ~ 1250 μM, (based on RNS60,

Revalesio, WA) had no effects on autophagy. Mitochondrial oxidative phosphorylation uncouplers 10 μM FCCP or 500 μM MPP^+ with or without ON-T produced no immediate effects on autophagy. Inhibition of mitochondrial respiration with 500 nM antimycin A (AtA), which also increases mitochondrial generation of radicals, also had no immediate effects on the number of autophagosomes (puncta number/cell: control, 36±4; AtA, 37±4; n=10 cells, each). However, perfusion of AtA exposed cells with ON-T but not HO-T led to a dramatic increase in autophagosomes (puncta number/cell: ON-T, 67±13, n=10 cells; HO-T, 31±8, n=8 cells, p=0.021). This together with our previous findings showing mitochondrial ATP synthesis stimulation by oxygen nanobubbles suggests that ON-T upregulates autophagosome formation only during mitochondrial/protein damage. To further confirm that oxygen nanobubbles increase overall autophagic flux, we will image autolysosome formation and acidification by using RFP-GFP-LC3B chimera.

Title: Discovery of a prototype furoxan as a novel attenuated nitric oxide mimetic for the treatment of neurodegenerative disorders: proof-of-concept studies

Authors: ***I. T. SCHIEFER**, K. NASH, A. KOSTREVSKI, A. NOVAK, A. RAGHAVAN, J. TULSULKAR, Q. ALHADIDI, S. BHATTI, N. WAMER, E. TISHENKEL, B. LANGENDERFER, K. HAGOOD, A. HORTON, E. N. O. TACKIE-YARBOI, Z. SHAH; Medicinal and Biol. Chem., Univ. of Toledo, Toledo, OH

Abstract: Nitric oxide (NO) mimetics capable of enhancing cGMP/CREB signaling have demonstrated efficacy as potential novel therapies for neurodegeneration. Development of NO mimetic chemical classes, often termed "NO donors" or "NO mimetics", has faced challenges centralized around poor pharmacokinetic (PK) profiles which result in risk of adverse effects related to transient spikes in NO signaling, such as acute hypotension. We are developing an NO mimetic class known as furoxans as slow-onset NO mimetics. Furoxans are unique because they exhibit 'tunable' NO mimetic effects. Rate of furoxan NO mimetic effects can be significantly attenuated to produce molecules with superior metabolic stability compared to other NO mimetic chemical classes. We have reported furoxan efficacy in multiple *in vitro* and *ex vivo* systems, including reversal of $A\beta_{42}$ induced synaptic dysfunction in LTP and protection against oxygen glucose deprivation (OGD), a cellular model of ischemia. The present study represents the proof-of-concept examination of furoxans to demonstrate *in vivo* neuromodulatory activity and potential as a novel therapeutic class for the CNS. Our drug development efforts have resulted in the discovery of a prototype attenuated furoxan, designated **IS-1-41**. *In vitro* neuroprotection against OGD and cGMP/CREB target pathway engagement endorsed the advancement of **IS-1-41** to *in vivo* studies. A focused PK study confirmed brain bioavailability and a favorable duration of CNS exposure. In a model of memory, **IS-1-41** provided dose-dependent improvement of scopolamine induced hippocampal-dependent memory deficits in step-through passive avoidance (STPA). In a model of stroke, **IS-1-41** improved motor function and reduced infarct volume when administered following middle carotid artery occlusion (MCAO). Cumulatively, our data supports our hypothesis that an attenuated furoxan can possess the beneficial neuromodulatory effects seen previously for other NO mimetics whilst possessing superior metabolic stability.

Title: No association between levels of uric acid and the rs1014290 polymorphism in Mexican subjects with Parkinson's Disease

Authors: *E. ROMERO GUTIERREZ[1], G. HARO HERRERA[2], E. HERNANDEZ-MENDEZ[2], J. SALAS-PACHECO[2], O. ARIAS-CARRION[3];
[1]Inst. De Fisiología Celular, Univ. Nacional Autónoma De México, Ciudad DE Mexico, Mexico; [2]Univ. Juarez del Estado de Durango, Mexico, Durango, Mexico; [3]Univ. Nacional Autónoma de Mexico, Inst. de Fisiología Celular / Hosp. Gen. Dr. Manuel Gea González, Ciudad de Mexico, Mexico

Abstract: Mexico is dramatically facing the problem of population aging, which has led to an increase in epidemiology of Parkinson's disease (PD). PD is characterized by changes in motor functions due to the death of dopaminergic neurons in the substantia nigra pars compacta. The etiology and pathophysiology of this disease suggest that oxidative stress plays an important role. In this context, antioxidants such as uric acid (UA) could have neuroprotective properties. Low UA levels have been proposed as a risk factor for PD and its progression. In light of these findings, the rs1014290 single nucleotide polymorphism (SNP) in the gene SLC2A9 has been linked to the reduction of UA.
The aim of this study is to determine the association between UA levels and the rs1014290 SNP in a case-control study. The case group included 59 PD patients, while the control group included 169 non-PD subjects matched by gender and age. The clinical diagnosis of PD was according to the criteria established by The Parkinson's UK Brain Bank. Whole blood samples were taken to determine the serum UA levels and to extract genomic DNA. The rs1014290 SNP was genotyped by qPCR.
Our results show that UA serum levels are not significantly different (4.7 ± 1.13 vs 4.8 ± 1.39, $p = 0.652$) in case group vs control group. In the analysis stratified by sex, we did not find significant differences in the levels of UA compared with controls, neither for women nor men

with PD (4.3 ± 1.25 vs 1.15 ± 4.5, p = 0.449 in women and 5.15 ± 1.27 vs 5.21 ± 1.56, p = 0.87 in men). The allele frequency of the mutated variant was increased in patients with PD, but no significant difference was observed vs controls (33.3 vs 29.16 %, p = 0.476). Regarding the genotype frequencies for the mutated homozygous and heterozygous alleles, there was also an elevation in the case group relative to the control group, however the difference was not significant (9 vs 11% and 40 vs 49 %, p = 0.88).
This is the first study exploring the association between levels of UA and the rs1014290 SNP of the SLC2A9 gene in Mexican subjects with PD. Our findings indicate that levels of UA and the rs1014290 polymorphism might not be associated in PD. Nevertheless, the number of patients needs to be increased in order to draw stronger conclusions.

Title: Rapid phenotypic and functional maturation of iPSC-derived human neurons for drug discovery

Authors: *Z.-W. DU[1,2], M. HENDRICKSON[1], B. DUNGAR[1], S.-C. ZHANG[2];
[1]BrainXell Inc., Madison, WI; [2]Waisman Ctr., Univ. of Wisconsin, Madison, WI

Abstract: Neurons derived from human induced pluripotent stem cells (iPSCs) represent a tremendous opportunity to create platforms for drug discovery with a high relevance to human psychiatric and neurological diseases. iPSCs can be generated from both healthy individuals and from patients with a diagnosed CNS disorder. Indeed, for patients harboring a known genetic mutation, isogenic control iPSCs can also be created using gene-editing technologies such as CRISPR. A range of neuronal subtypes can then be generated from these iPSC lines. However, implementation of this approach has been slowed due to long maturation times for cultured human neurons. Here, we demonstrate the rapid maturation of four subtypes of neurons derived from human iPSCs: (1) spinal motor neurons, (2) midbrain dopaminergic neurons, (3) cortical glutamatergic neurons, and (4) cortical GABAergic neurons. These neurons mature within 7-14 days after plating as evidenced by diverse measures. They display a complex morphology,

including extensive neurite branching. The neurons express classical subtype-specific markers as well as pre- and post-synaptic proteins. Finally, they show functional activity as demonstrated by robust spiking in multi-electrode array (MEA) studies and calcium imaging. As a proof-of-concept for high throughput screening, we knocked a nanoluciferase reporter into the survival motor neuron gene in iPSCs derived from spinal muscular atrophy patients. Motor neurons from the reporter SMA iPSCs respond to positive compounds in a dose-dependent manner in a 384-well format. Given that these neurons can be produced in high purity (>70-90%) and mature in approximately one week, they provide a powerful system for CNS drug discovery and development.

Title: Mems based gene and drug delivery system: voltage controlled accumulation and release of molecules

Authors: S. SAMPATH KUMAR, A. MOORE, A. SRIDHARAN, *J. MUTHUSWAMY; Dept Bioengineering, Arizona State Univ., Tempe, AZ

Abstract: Delivering genes to targeted neurons in the brain is critical for the success of gene therapy and basic neurophysiology studies focused on understanding the functional role of specific brain circuits. However, current non-viral gene delivery technologies are inefficient and imprecise in spatial localization. We report a novel MEMS based system for targeted delivery, which can also facilitate automation of the process. Polycrystalline silicon nanoelectrodes were milled using focused ion beam (FIB) to enable delivery of payloads into single neurons. A voltage controlled method was optimized that allows for immobilization of a payload to the tip of the electrode in a way that a) prevents any loss of payload until the electrode penetrates the neuron; and b) allows for controlled injection and release of the payload inside the neuronal cell

body. Payloads of two different sizes were tested - scrambled siRNA conjugated with Alexa Fluor and fluorescein dye conjugated with dextran. First, glass micropipettes were used to determine the parameters required for reproducible charge-mediated accumulation and release of payloads. Next, the parameters to achieve efficient voltage controlled accumulation of payloads onto the polysilicon nanoelectrodes and their release were optimized. Finally, ability of these electrodes to achieve controlled delivery into targeted neurons of abdominal ganglion of Aplysia was tested. Fluorescence imaging confirmed successful delivery of both types of payloads in n = 15 neurons. Propidium iodide staining of the cells confirmed that they were viable after injections with the nanoelectrode. Although preliminary, these results suggest that this technique offers a promising method of single cell gene and drug delivery.

Title: 2-photon evaluation in-vivo of acute microglial response to induced tissue damage in vicinity of implanted neural probe embedded in gelatin loaded with minocycline

Authors: *J. AGORELIUS[1,2], A. D. HOLMKVIST[2], M. FORNI[2], C. E. LINSMEIER[2], J. SCHOUENBORG[2];

Abstract: A major issue in the field of neural interface is the foreign body response and the subsequent glial scaring around implanted probes which is believed to lead to electrical insulation and subsequent failure of the implant.
One of the first cells to react to a foreign body is the Microglia, which quickly (within minutes) after tissue damage prolongs its motile processes to the site of damage. One strategy beyond controlling the flexibility and integration of neural probes into the tissue could be controlling the local milieu in the near vicinity of the electrode with local delivery of drugs around the implant. For example minocycline has been shown to inhibit the microglial activity.
In this study, gelatin embedded neural probes was implanted into the cortex of transgenic mice (CX3CR1-GFP knock-in mice) with has fluorescently labeled microglial cells, and a cranial window was created for in-vivo imaging. A controlled and very local tissue damage was induced in the tissue at a fixed distance from the implanted probe, by continuously scanning with high

intensity laser from the 2-photon microscope. And the subsequent acute tissue response was monitored with 2-photon microscopy by collecting z-stack time series to monitor the dynamics of the microglial cells in vicinity of the damage. Quantification of the microglial response was made by comparing the normalized intensity of the region closest to the damage with a region outside as well as by analyzing conformational changes of the individual cells. Probes embedded with pure gelatin was compared to probes with gelatin loaded with minocycline in order to evaluate the minocycline's effect on the acute microglia response to the damage around the implant.

Title: Wireless control for simultaneous drug administration in micropump-implanted mice in an array of vivarium cages

Authors: ***T. Q. HOANG**[1,2], M. VAISHYA[1], C. JONES[1], S. STRONKS[1], L. RODRIGUEZ[1], M. MAHDI[3], G. SHACKLEFORD[3], R. CASTRO[1], C. GUTIERREZ[1], J. FIELD[1], A. EPSTEIN[3], R. MOATS[3], E. F. MENG[2,1];

Abstract: For new drug development, advanced biologics and neurologic research, rodent studies requiring chronic drug administration can be very labor intensive and result in dramatic increases in exposure and handling of the animals. To improve both animal care and researchers working conditions, an automated wireless-operated microinfusion system has been developed for the vivarium environment. The system consists of a miniaturized drug pump that is implanted

subcutaneously in each rodent, an external wirelessly inductive controller, and a programmable dosing software. Advantages include minimal handling, fewer interventions, and tether-free dosing for more normal, stress-free behavior. We demonstrated simultaneous microinfusion pumping in mice using an array of external controllers that instrument a standard vivarium cage rack system. A micropump was implanted subcutaneously in the back of transgenic mice expressing the luciferase gene. Each animal was housed in a single vivarium cage and array of six instrumented cages were configured in a vivarium cage rack system. The dosing regimen, bolus dose of ~30 microliter of luciferin solution, was programmed into the dosing software installed on a laptop. Upon command by the software, all micropumps in the mice were activated as indicated by visual observation of the red light shining through the skin from the activated LED (light-Emitting Diode) in each micropump. 90 minutes after the bolus injection, all animals were imaged using a Xenogen bioluminescence imager. Two animals showed comparable bioluminescence intensity levels to those from control animals manually injected with a syringe with similar bolus dose. Electromagnetic interference was identified as major concern for array configuration in the cage rack. Specific strategies to minimize this interference were investigated including synchronized activation, optimal spacing and signal dither. Benchtop evaluation was done by simulating a cage matrix and running up to 6 pairings of pump-controller simultaneously in different configurations, and the delivered fluid was measured using micro-pipettes. Our research confirmed the scalability of our array for simultaneous wireless control of multiple pumps to enable a very efficient microinfusion system with high throughput, automated dosing.

Title: Investigations into whether dose volume and exogenous mechanical force can enhance antisense oligonucleotide distribution in the central nervous system following lumbar intrathecal administration in cynomolgus monkeys

Authors: *C. MAZUR[1], D. WOLF[2], B. POWERS[1], J. SULLIVAN[3], J. HOPPIN[3], E. SWAYZE[1], A. VERMA[2];
[1]Neurosci. Drug Discovery, Ionis Pharmaceuticals, Inc., Carlsbad, CA; [2]Biogen, Inc., Cambridge,, MA; [3]inviCRO, LLC, Boston, MA

Abstract: The intrathecal (IT) dosing route has been used to bypass the blood-brain barrier and deliver drugs directly to the central nervous system (CNS). Difficulties with delivering drugs to the brain by intrathecal dosing have been noted due to large caudal to rostral drug concentration gradients. The distribution of drugs administered directly to the cerebral spinal fluid (CSF) has been shown to be affected by CSF pressure differences due to respiration and heart rate. We attempted to model the caudal to rostral drug concentration gradients in monkeys by intrathecal administration of an antisense oligonucleotide (ASO). We tested the effects of different volumes of injection and the application of exogenous mechanical forces, to mimic enhanced respiration effects, on the caudal to rostral distribution of the ASO.
Cynomolgus monkeys (4 groups of N=5) received a lumbar puncture injection of a pharmacological dose of an ASO targeted to the ubiquitously expressed long non-coding RNA MALAT1 in either a low (0.8 mL) or high (2.4 mL) volume of injection, and either with or without immediate application of high frequency chest wall oscillation. A dose of ^{99m}Tc-DTPA was spiked into the formulation and the quality of each lumbar injection was monitored by SPECT/CT. Animals were euthanized 7 days after drug administration and CNS tissues were collected for measurement of tissue ASO concentration and MALAT1 RNA expression by qRT-PCR. CNS tissues were also collected and fixed for immunohistochemistry with an anti-ASO antibody and for in situ hybridization with MALAT1 probes.
The high volume bolus resulted in broader distribution, higher ASO concentrations and decreased MALAT1 RNA expression in the structures of the rostral CNS than did the low

volume bolus. The high volume bolus also decreased local drug concentration in the lumbar spinal cord near the injection site and yielded lower inter-patient variability compared to the low volume dose. The broad distribution resulting from the high dose volume of the ASO was demonstrated by immunohistochemical staining. The MALAT1 expression reduction coincided with these areas of ASO distribution as evidenced by the in situ hybridization. Treatment with exogenous mechanical forces slightly improved distribution in the low volume dose groups in this study.
These results will be used in the future to guide the practices used in the clinic for the IT administration of ASOs directed towards targets involved in CNS diseases.

Title: Identification of ER-000444793, a Cyclophilin D-independent inhibitor of mitochondrial permeability transition using a high-throughput screen in cryopreserved mitochondria

Authors: *T. BRISTON[1], S. LEWIS[1], M. KOGLIN[1], K. MISTRY[1], Y. SHEN[2], N. HARTOPP[1], H. FUKUMOTO[3], M. R. DUCHEN[4], G. SZABADKAI[4], J. STADDON[1], M. ROBERTS[1], B. POWNEY[1];
[1]Eisai Ltd., Hatfield, United Kingdom; [2]Eisai Inc., Andover, MA; [3]Eisai Co. Ltd., Tsukuba, Japan; [4]UCL, London, United Kingdom

Abstract: Growing evidence suggests that persistent mitochondrial permeability transition pore (mPTP) opening is a key pathophysiological event in cell death underlying multiple neurodegenerative disease states. Current agents targeting the mPTP are limited by off-target effects and low therapeutic efficacy, therefore identification and development of novel inhibitors is necessary. A method was developed to cryopreserve large batches of functionally active mitochondria from cells and tissue. Assessment of cryopreserved mitochondria revealed preserved respiratory coupling and ATP synthesis, Ca^{2+} uptake and maintenance of transmembrane potential.
A high-throughput screen (HTS), using an assay of Ca^{2+}-induced mitochondrial swelling using cryopreserved mitochondria identified ER-000444793 as a potent inhibitor of mPTP opening. ER-000444793 was further evaluated using assays of Ca^{2+}-induced membrane depolarisation and Ca^{2+} retention capacity. ER-000444793 failed to affect cyclophilin D (CypD) enzymatic activity, nor did it displace CsA from CypD protein, suggesting a mechanism independent of CypD inhibition.
The ability to maintain mitochondrial function after freeze-thaw provides a platform to perform rapid, large scale compound screens. Here, we identified a novel and CypD-independent inhibitor of mitochondrial permeability transition. The screening flow and compound described will be useful for advancing the search for novel agents targeting mitochondrial permeability transition and understanding the molecular nature of the pore.

Title: Neuron-specific intracellular delivery of therapeutic cargo with atoxic derivatives of botulinum neurotoxins.

Authors: *P. H. BESKE[1], E. J. CINTRON-VAZQUEZ[2], M. R. EISEN[1], C. ANGELES[3], P. A. BAND[2], P. M. MCNUTT[1], K. ICHTCHENKO[3];
[1]US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD; [2]CytoDel LLC, New York, NY; [3]New York Univ. Sch. of Med., New York, NY

Abstract: Inefficient cytosolic delivery limits the therapeutic utility of many biologic drugs for treating neurotoxic and neurodegenerative disease states. Although recent advances in biologic formulation have achieved some success, more robust strategies are needed for effective transport of biologics to the neuronal cytosol. In this study, we explore the modular protein nanomachine - botulinum neurotoxin (BoNT) - as a prototype neuron-specific vehicle for intracellular delivery of biologic cargo. BoNT contains a 100 kDa heavy chain (HC) and a 50 kDa light chain (LC) that remain associated through a disulfide bond. The C-terminal of the HC mediates highly selective and efficient binding to receptors on the presynaptic membrane of neurons. Following synaptic endocytosis, the N-terminal domain of the HC forms a pore that facilitates translocation of the catalytically active LC through the endosomal membrane to the presynaptic cytosol. The combination of efficient neuronal targeting and potent presynaptic activity renders BoNTs the most poisonous substances known. However, recent studies have shown that point mutations to the active site of the LC can dramatically decrease toxicity while maintaining specific neuronal targeting. The Ichtchenko lab has systematically designed and expressed a library of atoxic BoNT derivatives as prototype vehicles to deliver therapeutic cargo to the neuronal cytoplasm. Here, we provide a functional characterization of the localization and activity of select atoxic BoNT derivatives and their cargo *in vitro* and *in vivo*. In synaptically active cultures of neurons, molecular and electrophysiological readouts of host:toxin activity demonstrated that atoxic BoNT derivatives can successfully deliver diverse biologic cargo to the neuronal cytoplasm. In murine models of botulism, atoxic BoNT-mediated intracellular delivery of single chain antibodies against wild type BoNT/A provided protection from lethality. Protection was provided at post-intoxication treatment times beyond the effective window for cell impermeant antitoxin treatment, thus demonstrating an intracellular mode of action. These studies serve as an important proof-of-concept for future development of atoxic BoNTs as

vehicles for neuron-specific delivery of therapeutic cargo. *Disclaimer: The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of the Army, Department of Defense, or the U.S. Government.*

Abstract: Introduction: For the treatment of neurodegenerative disorders and neuro-oncological disorders, various drug and chemotherapy agents have been developed and tried in clinical field. However, these drugs or chemotherapeutic agents showed limited efficacy because of blocking by the blood brain barrier (BBB). Recently, a local and selective drug delivery method using focused ultrasound (FUS), which was traditionally used for tissue destruction, was introduced for localized and transient opening of BBB. In this study, we tried to evaluate various parameter factors for optimized BBB opening condition in small animals. **Materials and Methods:** We have observed changes in BBB permeability of SD-rat during transcranial sonication with microbubble (MB) using low-intensity focused ultrasound. Moreover, to find the optimal sonication parameters for BBB-disruption, we examined various sonication factors: MB

injection type, MB type, pulse frequency, acoustic pressure, pulse repeated frequency and duty cycle. The animals were sacrificed and perfused 4h after FUS sonication. Brain tissues were obtained, sectioned and stained with hematoxylin and eosin (H&E) for histological examination **Results:** BBB opening at the sonication region was visualized using Evans blue (EB), which has a very large molecular weight of about 900Da and normally does not pass through the BBB. When BBB was disrupted, however, EB diffused through the barrier. Moreover, we were able to detect various amounts and forms of EB extravasation depending on the various sonication factors. Based on these results, we also demonstrated the optimal BBB-opening condition of the ultra-sonication for drug delivery. **Conclusion:** In this pre-clinical study, we demonstrated that FUS can facilitate optimized opening of BBB at the focal area. It is expected that this technique can be applied to targeted drug delivery into a localized brain area. However, further investigation regarding the limitation of molecular weight for transposition across the BBB, controlling of focus size and location, and optimal parameters for drug delivery according to the molecular weight is necessary before application to the clinical field.**Acknowledgement:** This study was supported by the grant from the Yonsei University Future-leading Research Initiative (Yonsei Challenge) of 2015 (2015-22-0137) and Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and Future Planning (2015R1C1A1A02036851).

Title: Behavioral comparison of two methods of drug administration in the earthworm

Authors: B. A. JOHNSON, E. K. SEARS, *W. J. WILSON;
Psychological Sci., Albion Col., Albion, MI

Abstract: Earthworms are capable of Pavlovian and instrumental learning, offering an inexpensive and readily available alternative to mammalian or more exotic invertebrate species used in studies of memory. Drug studies in these soft-bodied organisms are made difficult by some uncertainty about methods of administration. Injection is possible; e.g., Watanabe et al. (2005) anesthetized worms for 10 min in 10% ethanol in order to inject protein synthesis inhibitors. A simpler approach that avoids anesthesia exists: worms can absorb drugs through their skin. We immersed worms in drug solutions, comparing time of immersion and concentration of solution as ways to manipulate dosage.Movement of *Lumbricus terrestris* was monitored in a running wheel in the dark before and after exposure to an aversive light. Worms received doses of caffeine by immersion in three different concentrations (9.15mM, 22.46mM, or 82.38mM) for an equivalent time (1 min), or in one concentration (9.15mM) for three different times (1, 3, or 9 min). The concentration-dependent doses caused different effects on the worms, with the low dose decreasing locomotion compared to either a high dose or water. The caffeine also decreased locomotion generally in the time-based doses, but there was no significant difference in locomotion between the doses. With both methods of administration, caffeine at lower doses decreased movement in response to the aversive light. We conclude that immersion in differing concentrations is a more reliable way to effect differing drug exposures than varying time of exposure. Analysis of drug within the worm after these manipulations is an obvious next step.

Title: A correlation of serotonin 2A receptor occupancy and free fraction in rats.

Authors: J. THENTU, *G. BHYRAPUNENI, V. PALACHARLA, R. NIROGI;
Suven Life Sci., Hyderabad, India

Abstract: Second generation antipsychotics (atypical) affinity towards 5-HT_{2A} receptors could be the reason for reduced side effects. Aiming this receptor type has been the predominant target in drug discovery next to major D_2 receptor in schizophrenia treatment. Further, 5-HT_{2A} receptor antagonists have antidepressant and anti-anxiety properties and agonists have hallucinogenic effect. It is necessary to introduce a better parameter to predict the amount of 5-HT_{2A} receptors being interacted (occupied) with selective ligand concentration that shows desired

pharmacological actions. Supporting studies towards free drug hypothesis at different targets can be applied to bring a correlation between in-vivo 5-HT_{2A} receptor occupancy and in-vitro drug parameters (free fractions) at target site. Five standard compounds (quetiapine, eplivanserin, ketanserin, clozapine and olanzapine) were selected for in-vivo 5-HT_{2A} receptor occupancy assay using non-radiolabelled tracer (MDL 100907) in rats. Brain regional tracer concentration, drug exposures in brain and plasma from treated rats were analyzed by LC/MS-MS. Unbound fractions of compound in brain and plasma was estimated by HT-dialysis. Free forms of compound in plasma or brain are calculated from the product of in-vivo total plasma or brain drug concentrations and in-vitro free fractional value. Brain or plasma concentrations were normalized with their Ki before bringing a comparison. An association was inspected among in-vitro affinity constant (Ki); in-vitro free fractions of drug in plasma or brain; dose producing 50% occupancy at 5-HT_{2A} receptors (ED_{50}). The dose dependent % $5HT_{2A}$ receptor occupancy was found for all tested compounds which are consistent with in-vitro affinity profile (Ki, nM). Significant improvement in correlation was seen between free brain or plasma EC_{50} vs in-vitro Ki than with total compound concentration. Comparison between total brain and free brain concentration revealed the impact of permeability and efflux pumps on compound concentrations. Linear relation (R^2) between occupancy and free brain concentrations favors exact prediction of receptor occupancy.

Title: A small molecule therapy for MS patients appears to override inhibitors of oligodendrogenesis to induce remyelination

Authors: ***S. H. NYE**, J. G. YARGER;
Discovery, ENDECE, LLC, Mequon, WI

Abstract: There is an unmet need for remyelinating therapies to treat multiple sclerosis (MS) patients. NDC-1308 is an analog of estradiol (E2) that harnesses the body's natural remyelinating system to drive oligodendrogenesis, a process resulting in mature, myelinating oligodendrocytes (OLs) that can repair damaged myelin sheaths. NDC-1308 was previously shown in oligodendrocyte progenitor cell (OPC) cultures to induce a 3-fold increase in OLs compared to vehicle. Structurally related estrogens, E2 and estriol, do not possess this activity. Side-by-side comparison of NDC-1308 and E2 activity, following chronic treatment in the cuprizone mouse model of demyelination, showed only NDC-1308 could significantly repair the myelin sheath (a 44% increase in hippocampus). NDC-1308 can apparently accomplish this by overriding inhibitors of oligodendrogenesis, such as Lingo-1. Here, we investigated how NDC-1308 has gained the biological activity to repair demyelinated axons, but lost the deleterious side-effects commonly associated with estrogens. While NDC-1308 and E2 are both ER agonists, we found the remyelinating activity of NDC-1308 can be traced back to its unique ability to significantly up-regulate key genes (OLIG2, DNER, MOG and MBP) for oligodendrogenesis. Real-time qPCR analysis showed these same genes are up-regulated 2-3 fold in human PBMCs treated for 12 hours with NDC-1308, suggesting they could serve as potential therapeutic biomarkers. Potential safety concerns for NDC-1308 were addressed. Estrogenicity was directly measured in a mouse uterotrophic assay since E2 treatment is known to cause a rapid and dramatic increase in uterine weight in this assay. Unlike E2, NDC-1308 was not found to be estrogenic. Further testing revealed that NDC-1308 is not mutagenic (Ames assay) and not genotoxic (micronucleus assay). The OPC pool remained intact after six weeks of chronic NDC-1308 treatment, demonstrating that it can serve as a renewable source for sustaining oligodendrogenesis. In conclusion, NDC-1308 is a potential first-in-class remyelinating therapy that possesses many key qualities needed to effectively treat secondary progress (SPMS) and relapsing-remitting (RRMS) MS patients.

Title: RNA-based agonists and antagonists (aptamers) for FGFR3 to modulate activation of astrocytes in a glial scar model

Authors: *N. KAMATKAR[1], M. LEVY[2], J. HÉBERT[3];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Biochem., [3]Neuroscience, Genet., Albert Einstein Col. of Med., Bronx, New York City, NY

Abstract: Astrogliosis is the process by which astrocytes become activated after brain injury. Astrocyte activation takes place after virtually any insult to the central nervous system including trauma, infection, and cell death. It is a complex and graded process that relies on multiple cellular signals for not only astrocyte activation but also to inactivate astrocytes. In severe instances, astrocyte activation can result in the formation of a glial scar that can be both beneficial in terms of restricting inflammation and detrimental since it inhibits axon regeneration. Recently, my lab has discovered that the fibroblast growth factor (FGF) signaling pathway plays a critical role in the inhibition of astrocyte activation in the normal and injured brain. Moreover, we have also demonstrated that both gain-of-function and loss-of-function studies of FGF signaling result in a decrease in glial scar size. The FGFs are a family of secreted proteins used for angiogenesis, wound healing, and multiple other roles in the developing organism and also play an important role in numerous pathological processes. To date, there are limited options for people who suffer from FGF signaling related diseases since there are no specific agonists or antagonists for the receptors of FGF signaling. Here, I plan to develop novel molecular tools specific for all three fibroblast growth factor receptors (FGFRs) expressed in the brain (FGFR1,2,3) and test them as therapeutics in glial scar formation. To achieve this goal, I will develop aptamers, nucleic acid ligands that have the potential to be specific antagonists and agonists to modulate signaling through the FGFRs. Importantly, I have already identified a number of nuclease stabilized ligands to FGFR3. One aptamer specifically, NK01, demonstrates high affinity for FGFR3 and inhibits FGF2 from binding FGFR3. Perhaps more interestingly, another aptamer, C20, stimulates signaling from FGFR3 when presented to the cells as a multimer. Ultimately, I will develop a suite of novel tools to interrogate FGF signaling at the level of the receptor that can be used as possible therapeutics, particularly in glial scar formation.

Title: Does cognitive fatigue correlate with brain iron deposition in basal ganglia in Multiple Sclerosis?

Authors: S. WOOD[1], E. DOBRYAKOVA[2], Z. JIANG[3], E. HAVRILLA[4], *B. YAO[1,5]; [1]Neuroimaging Ctr., [2]Traumatic Brain Injury Lab., [3]Human Performance Engin. Lab., Kessler Fndn., West Orange, NJ; [4]Montclair State Univ., Montclair, NJ; [5]Dept. of Physical Med. & Rehabil., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: BACKGROUND: Fatigue, defined as an overwhelming feeling of lack of both mental and physical energy, has been reported in over 90% of individuals with multiple sclerosis (MS). Studies have shown basal ganglia structures play a central role in fatigue. Meanwhile, abnormal iron deposition has been observed in the deep gray matter structures including basal ganglia in MS. In this study, we aimed to examine the correlation between brain iron concentration indicated by susceptibility contrast imaging and the severity of fatigue in MS. **METHODS:** Six clinically definite MS patients participated in this study. *MRI:* A 3D multi-echo gradient-echo acquisition was performed on a 3T scanner. Quantitative R_2^* maps were derived from exponential fitting over five echo data. The susceptibility maps (QSM) were calculated using the LSQR algorithm based on the unwrapped phase maps. Six regions of interest (ROIs) including substantia nigra (SN), red nucleus (RN), globus pallidus (GP), putamen (PU), caudate nucleus (CN), and thalamus (TH) were manually drawn on the magnitude images. R_2^*, and Frequency, and QSM values were averaged in each ROI, respectively, and then averaged across all the subjects in the group. *Fatigue measures:* Each individual were administrated a Fatigue Severity Scale (FSS) test and a Modified Fatigue Impact Scale (MFIS) test to measure their fatigue levels. The FSS scores and total MFIS scores with its subcategories (Physical, Cognitive, Psychosocial) subscales from each individual were correlated with R_2^*, Frequency shift and QSM values in all ROIs. **RESULTS:** Significant positive correlations ($p < 0.05$) between Frequency and FSS Total ($r = 0.79$), MFIS Total ($r = 0.97$), MFIS Physical subscale ($r = 0.94$) and MFIS Psychosocial subscale ($r = 0.86$) are found in CN. QSM also correlates with MFIS Total ($r = 0.76$) and MFIS Physical subscales ($r = 0.82$) significantly. No significant consistent positive correlations in the other ROIs are found. No significant correlations between R_2^* and all fatigue measures are observed. **DISCUSSION:** Basal ganglia is of particular interest as its damage is often associated with clinical disorders including MS. Our results show a promising correlation between iron-related MRI indices with fatigue scores, indicating the severity of fatigue may correspond to iron accumulation in CN. This result is consistent with our previous findings that iron deposition is found to be higher in basal ganglia in MS patients comparing to healthy control individuals. These findings are of particular interesting to understanding the fatigue mechanisms, which may lead to an effective treatment on reducing clinical symptoms in MS patients.

Title: Minocycline-loaded nanoparticles for reducing tissue reactions after neural electrode implantation

Authors: *A. D. HOLMKVIST[1,2], J. AGORELIUS[1], M. FORNI[1], C. ERIKSSON LINSMEIER[1], U. J. NILSSON[2], J. SCHOUENBORG[1];
[1]Neuronano Res. Ctr., Lund, Sweden; [2]Dept. of Chem., Ctr. for Analysis and Synthesis, Lund, Sweden

Abstract: Implantable neural interfaces are important tools for the investigation of neurophysiological systems and have several clinical applications. However, the biocompatibility and chronic functional stability of these implanted interfaces are far from optimized. It is well known that the implant subsequently elicits both acute and chronic reactions in the surrounding tissue, which leads to the formation of an insulating glial scar and electrode failure.The objective of this work is to investigate the use of biodegradable nanoparticles for sustained delivery of minocycline, a neuro-protective and anti-inflammatory drug, locally in the brain after electrode implantation. Minocycline-loaded PLGA nanoparticles were prepared by a single oil-in-water based preparation technique and characterized for size (~220 nm), drug content (1.1%) and drug release. The *in vitro* release profile showed drug release over 30 days, which provides a good match to the normal time course of brain tissue responses associated with electrode implantations.Stainless steel needles were embedded with gelatin containing the minocycline-loaded nanoparticles and implanted into cortex of CX3CR1-GFP knock-in mice with fluorescently labeled microglial cells. The tissue response after implantation was studied. The results presented here show the importance of controlling the local milieu in the near vicinity of the electrode for mastering tissue reactions and provides an additional step in designing fully biocompatible neural interfaces.

Title: A novel approach to ischemic stroke biomarker discovery

Authors: *A. A. DAUBENSPECK[1], D. R. COOL[2], B. R. LUDWIG[3], J. E. OLSON[1]; [1]Emergency Med., Wright State Univ., Kettering, OH; [2]Pharmacol. and Toxicology, Wright State Univ., Dayton, OH; [3]Neurol., Premier Hlth. Clin. Neurosci. Institute, Wright State Univ. Boonshoft Sch. of Med., Dayton, OH

Abstract: Ischemic stroke (IS), a leading cause of death and disability worldwide, requires rapid and accurate diagnosis. However, IS diagnosis in the emergency setting is currently limited to clinical examination of symptoms and low-sensitivity CT imaging. No direct, objective, point of care test is currently available that can diagnose IS in the time frame needed to institute appropriate therapy. This need could be met by measuring levels of protein biomarkers in circulating blood. Several proteins have shown promise in pre-clinical trials; however, because of the heterogeneity of the disease, these singular biomarker candidates have shown inadequate sensitivity and specificity in clinical studies. Therefore, a combination of protein biomarkers associated with brain ischemia is thought to be necessary for emergency IS diagnosis.
We take a novel approach to ischemic stroke biomarker discovery. Combining an endovascular procedure with proteomic analysis we quantitatively catalogue changes in the abundance of all serum proteins present in blood from the penumbra of stroke patients. Patients diagnosed with ischemic stroke who undergo mechanical thrombectomy are included in this IRB-approved study. During the thrombectomy procedure a micro-catheter is used to withdraw arterial blood samples from the general circulation (peripheral) and from the region of ischemic brain area (penumbral) prior to clot removal. For each blood sample, the serum is depleted of albumin, salts, lipids, and nucleic acids. Then an aliquot of each blood sample containing 25 μg protein is labeled with a different fluorescent dye. Samples are combined and then separated by 2-dimensional gel electrophoresis (2D-DIGE) first by isoelectric focusing (pH=3 to pH=10), then by SDS-PAGE. The resulting gel images are analyzed using Image J software for changes in relative protein abundance as determined by their respective fluorescence intensities.
Gels from 4 initial patients showed over 50 individual protein spots. Twenty-five of these spots were chosen for analysis in this preliminary study. The ratio of fluorescence intensities between peripheral and penumbral samples was used for univariate analysis and pair-wise statistics. Of the 25 protein spots analyzed, 5 proteins show a significant change of 20% or more and thus may constitute an initial test panel of protein stroke biomarkers. Proteins with differential expression in the penumbral blood are likely to originate from ischemic brain tissue and could be considered

biomarker candidates. Furthermore, the changes in multiple protein abundances found in penumbral blood support our approach to novel biomarker discovery.

Title: Evaluation of brain pharmacokinetic properties in awake animals: from rodents to non-human primates

Authors: ***M. VAN GAALEN**[1], G. FLIK[2], J. H. A. FOLGERING[2], A. RASSOULPOUR[3], M. CHOI[4], R. STRATFORD[4], T. I. F. H. CREMERS[5];
[1]Encepharm, Goettingen, Germany; [2]Brains On-Line, Groningen, Netherlands; [3]Brains On-Line, San Francisco, CA; [4]Duquesne Univ., Pittsburgh, KS; [5]Dept. of Pharmaceut. Analysis, Univ. of Groningen, Groningen, Netherlands

Abstract: Of the clinical candidates that enter phase 1, approximately one out of ten is approved by FDA. This low success rate is very concerning for drug developers, regulators and patients. Unacceptable pharmacokinetic properties is in part the reason for discontinuation of clinical development. An additional hurdle comes in play for neurological and psychiatric indications: the blood brain barrier. Clinical candidates need to be selected on the property to reach the target, and therefore, adequate free brain concentrations need to be reached that can induce the desired pharmacodynamic effects. This can be directly measured in awake animals by using Metaquant microdialysis in various species. In the present study, we compared the absolute brain concentrations as well as CSF concentrations of dextroamphetamine and its pharmacodynamics effect in rats and non-humans primates (NHPs). Wistar rats and cynomolgus monkeys received dextroamphetamine. The concentration of dextroamphetamine was measured bilaterally in the prefrontal cortex (PFC) and striatum (Str) up to 6 hours post dosing. A separate group of animals receiving the same dose had an indwelling catheter surgically placed into the cisterna magna to support cerebrospinal fluid (CSF) sampling for up to 4 hours post-dosing. Compound concentrations in plasma were measured via venous sampling. In monkeys, ECF and CSF dextroamphetamine concentrations were similar to each other and to unbound plasma drug concentrations across the time course and brain regions, supporting rapid equilibration of compound throughout the monkey CNS. In rats, ECF and CSF concentrations were similar, but

appeared to be 1.5 to 2 times greater than plasma unbound concentrations over the sample time course. Equilibration was also achieved by the first sample time point (30 minutes). These results suggest facile movement of dextroamphetamine across the blood-brain barrier of both species, possibly also the choroid plexus, and rapid equilibration within the CNS. Observation of a net uptake of dextroamphetamine into rat CNS, but not monkeys, may indicate an important species difference in the absorption of this drug into the brain. This study confirms that pharmacokinetic and pharmacodynamics properties may differ between species. Furthermore, it indicates that cross species evaluation is valuable to select clinical candidates and their predictive efficacy dose.

Title: Ultrasound-mediated delivery across the blood brain barrier.

Authors: *E. G. FERNANDEZ[1], M. VALDEZ[2], M. ROMANOWSKI[2], T. MATSUNAGA[3], R. WITTE[3], T. P. TROUARD[2];
[1]Neurosci. and Cognitive Sci., [2]Biomed. Engin., [3]Med. Imaging, The Univ. of Arizona, Tucson, AZ

Abstract: Treatment of neurological disorders is often hampered by the inability of therapeutics to cross the blood-brain barrier (BBB). Over the last several years, novel techniques have been developed that use focused ultrasound (FUS) in combination with microbubble (μB) contrast agents to temporarily open up the BBB and allow therapeutics into the brain. Foundational studies have shown BBB-opening is clearly visible via contrast-enhanced MRI. In this work, MRI and fluorescence microscopy were used to analyze the distribution of different sized molecules following BBB-opening in mice. BBB-opening was carried out in anesthetized mice using a custom-made cradle and FUS system. Following a 0.2 μL/g IV injection of μBs and an IP injection of Gd-DTPA, FUS was applied for 2 min (10 ms pulse at 1 Hz). Mice were then given another IV injection of 3, 70, and 500 kD dextran (1 mg each) with a different fluorescent labels. Mice were imaged using T1-weighted MRI on a 7T Bruker BioSpec MRI system and then

perfused with PBS and paraformaldehyde. Brains were cryosectioned and imaged with an Olympus MVX10 fluorescence microscope. Fluorescent signal was quantified by determining the volume of brain exhibiting fluorescent signal greater than the background autofluorescence. Safety of the procedure was evaluated by opening the BBB using different levels of FUS pressures (72, 120 and 214 kPa peak negative pressures). These brains were H&E-stained and imaged to quantify microbleeds and neuronal damage. MRI and fluorescence microscopy images following BBB-opening showed a strong co-localization of MRI signal enhancement with the fluorescent dextrans. The volume of brain with Gd-enhancement and dye increased with pressure and decreased with dextran size. The smaller molecules showed a diffuse pattern of enhancement while the larger molecules appeared in punctate patterns. Significant opening of the BBB with no visible damage was observed at120 kPa. Higher pressures showed damage, and lower pressures showed little to no BBB-opening. These results demonstrate FUS can safely open the BBB and allow molecules of various sizes to enter the brain with differential distribution. While the BBB-opening technique is intended to increase drug delivery to the brain for neurological disorders (e.g. Alzheimer's and Parkinson's), these imaging experiments could also be utilized to evaluate the loss of BBB integrity caused by other pathologies such as brain tumors, TBI, and viral infections.

Abstract: Originally developed as an adjunctive neuroprotective and anti-inflammatory agent for HIV-1 associated neurocognitive disorders (HAND), URMC-099, a mixed lineage kinase-3

inhibitor also modulates long-acting nanoformulated antiretroviral therapy (nanoART) biodistribution, pharmacokinetic and pharmacodynamics (PD) responses by sequestering ART particles in early, late and recycling endosomes. However, obstacles in the bench to bedside translation of nanoART remain including optimization of drug retention, ease of administration and toxicity for the nervous and reticuloendothelial systems. We demonstrated that decreased phosphorylation of JNK and changes in the trafficking of nanoART lead to reduced viral loads and increased CD4+ T lymphocyte in HIV-1 infected humanized mice. Since, JNK regulates mTORC1 and mTORC1 controls vesicular trafficking through Transcription Factor EB (TFEB), we hypothesized that URMC-099 can affect vesicular trafficking through TFEB. To test this notion we used human monocyte-derived macrophages (MDM) pretreated with nanoformulated atazanavir (nanoATV) and infected the cells with the HIV-1 Ada viral strain with or without URMC-099. Increased nuclear translocation of TFEB was observed by inhibition mTORC1 following URMC-099 treatments. As TFEB regulates autophagy, we now show that increases in LC3B, BECN1 and decreased P62 by Western blot and qRT-PCR assays. Increased numbers of autophagosomes were seen following URMC-099 treatment that were decreased by inhibition of autophagy. Increased mitochondrial activity also followed URMC-099 treatment. NanoATV was increased in URMC-099 treated MDM and found specifically localized in LC3B autophagosomes. As autophagosomes are involved in HIV-1 assembly and maturation, increase in autophagy with retention of nanoATV in autophagosomes by URMC-099 facilitated viral clearance in MDM exposed to virus. Together, URMC-099 improves cell health, retains nanoART and facilitates HIV-1 clearance through induction of autophagy. As URMC-099 is a brain penetrant and have shown neuro protective activity, this finding opens up novel therapeutic strategies for URMC-099 for neuroAIDS.

Title: Bioinspired Neuroprosthetic Design Environment (BNDE): A platform for creating hybrid biological/in silico neural networks for motor neuroprosthetic control

Authors: *M. KOCATURK[1], S. TOPKARAOGLU[2], K. N. ISIK[2], S. KOCATURK[1], F. Y. YAMANER[2], T. BAYKAS[2], A. GUVENIS[3], H. O. GULCUR[3], R. CANBEYLI[4];

Abstract: Motor neuroprostheses aim to restore functions lost to disease or injury by directly communicating with the brain tissue. In the design of neuroprosthetic controllers, an input-output mathematical model, generally based on a filter (e.g. Kalman filter) is used conventionally to convert firing rates of recorded neurons into control commands for prosthetic actuators. Based on an input-output model or transform, information processing principles of these systems are fundamentally different from those of natural neural circuits. In this work, we present the Bioinspired Neuroprosthetic Design Environment (BNDE) which enables the development of neuroprosthetic controllers from a novel, more biologically plausible design perspective. The BNDE has been implemented to create neuroprosthetic controllers which are based on spiking neural networks (SNNs). The SNN-based controller in the present architecture receives simulated synaptic inputs from extracellularly recorded neurons and forms a hybrid biological/in silico neural network with the neuronal circuits of the user's brain.
We developed a new, adaptive neuroprosthetic controller using real-time closed-loop simulations to test the BNDE prior to its use in in vivo experiments. The controller consists of two model (in silico) medium spiny neurons, each of which receives simulated synaptic inputs from recorded motor cortical neurons. In the closed-loop simulations, the recordings from the cortical neurons were imitated using an external, hardware-based neural signal synthesizer. By implementing a dopamine-dependent spike timing-dependent plasticity (STDP) rule, the controller achieves perfect target reach accuracy for a two-target reaching task in one-dimensional space.
The BNDE, developed around a PC equipped with an Intel Core i7-4790K CPU and RTAI 5.0 (Real-time Application Interface for Linux), is capable of real-time simulation of 180 Izhikevich neurons receiving virtual synaptic inputs from external spike data resources through 32 data acquisition channels.
In the BNDE, the spike events recorded from real neurons are directly forwarded to the SNN-based neuroprosthetic controller. Since there is no spike binning process in the present system in contrast to the conventional neuroprosthetic systems, the information encoded by the timing of the spikes are also used by the controller. As spike timing plays a critical role in neuroplasticity and neuroprosthetic learning, the SNN-based neuroprosthetic controllers updating their parameters by simulating mechanisms of STDP may have superior adaptation performance than existing firing rate-based neuroprosthetic systems.

Title: Application of the k-nearest neighbor algorithm and multiple look integration to fuse information for intelligent decision making processes

Authors: *H. C. YUAN[1], M. V. CHAO[2];
[1]Independent Lab., San Marino, CA; [2]Independent Lab., Palos Verdes, CA

Abstract: The k-Nearest Neighbor (kNN)algorithm has been used for a wide spectrum of classification problems as predicting heart attack based on patient diet and clinical measurements, bank customer profiling based credit ratings and income, and text classification based on training documents of known categories. Features used for these classification applications are rather static or do not change rapidly with time. The timeframes could be in weeks for patient diet measurements, in months for credit card usage information, or in hours for text classification training documents. In contrast, intelligent decision making processes may require rapid information updates over multiple looks as fast as 1 update per second, or faster. An extension of multiple look in machine learning to how the brain might integrate and fuse dynamic information could be posed to answer the question: “Is it a bird or a plane?” Multiple look could be a natural process in the brain. This leads to consideration of the multiple look processes to handle noisy, scintillating data, or imperfect data, then using a simple instance-based classifer as kNN to process a classifer result. In aerospace applications, radar kinematic data as distance, altitude, velocity, and acceleration can be used to classify different types of airborne vehicles as: helicopters, commercial passenger jets, crop dusters, or fighter jets. Prototype vectors of typical, measured, or theoretical kinematic data of these different types of airborne vehicles could be stored in a computer database. A radar sensor collecting and measuring kinematic information would form a kinematic data vector and the k-nearest neighboring known prototype vectors would be polled for a majority and the resulting airborne vehicle classified according to the majority of k-nearest prototype vectors. The update rate for radar kinematic being rapid could provide options to integrate multiple looks of input kinematic data vectors over a very short period of time to overcome system noise, scintillation, errors in the radar sensor, or errors in the kinematic measurement. In similar contrast, high range resolution feature data vectors of aircraft were combined in a multiple look integration [Kahler and Blasch, 2008] to distinguish between multiple moving targets in clutter. Similarly, the brain could be rapidly integrating multiple looks of data or sensor inputs in order to make timely, intelligent decisions. This poster examines the use of multiple look integration with the k-Nearest-Neighbor

algorithm as a computational model for intelligent decision making in machine learning processes and artificial intelligence.

Abstract: To help keep pace with the publication rate in the biomedical literature, there is a need for machine-driven approaches to automated and semi-automated knowledgebase curation. Such techniques have been shown to be particularly useful for the identification of publications containing information of interest for neuroinformaticians who are curating knowledge bases for informing multi-level models of brain function. Although using such systems to classify and prioritize documents for curation workflows is not a new idea, there continues to be developments in scalable text analytic and graphical machine learning methodology that uncover the possibilities of new approaches to this problem. Here, we describe the implementation of a scalable cloud-based document classification pipeline for identifying publications in the neurosciences that contain novel information for a neuron morphophysiology knowledgebase. Our series of experiments describe the textual and graph-derived feature selection and machine learning algorithm optimization experiments that led to the best-performing system. Further, we describe the open source cloud architecture used to deploy this machine learning solution, and how it can be incorporated into a neuroscience research workflow.

Abstract: *Objective.* We elaborate on the algorithmic aspects of a closed-loop subthalamic nucleus (STN) *deep brain stimulation* (DBS) system for advanced Parkinson's disease (PD) and treatment-refractory obsessive-compulsive disorder (OCD), ensuring optimal performance in terms of both efficiency and selectivity of stimulation, as well as in terms of computational speed. *Methods.* Relying upon a series of methods robust to the presence of measurement noise, we first assess the presence of significant nonlinear coupling between beta and high-frequency subthalamic neuronal activity, as a biomarker for feedback control in the proposed closed-loop neuromodulation scheme. We then present a *model-based* strategy through which optimal and individually tailored parameters of stimulation for desynchronizing *control* of neuronal activity are being identified. Simulations are being performed utilizing microelectrode recordings (MERs) acquired during STN-DBS surgical interventions for PD and OCD. *Results.* Cross-frequency coupling proves to be a potentially appropriate biomarker for feedback control in case of PD, but may display subject-specific applicability in case of OCD. We demonstrate the ability of the presented modeling approach to identify, at a relatively low computational cost, personalized stimulation settings potentially associated with a significantly higher efficiency and selectivity compared with stimulation settings determined during post-operative clinical management of patients with PD and treatment-refractory OCD. *Conclusion.* Together, our data provide strong evidence for the applicability of computational neurostimulation to the

development of personalized stimulation protocols for the treatment of movement and neuropsychiatric disorders.

Title: Modeling the impact of time-delay effects on the memory capacity, cognition capability and energy efficiency of neuronal structures

Authors: *Y. G. TIRAT-GEFEN;
Castel Res. Inc., Fairfax, VA

Abstract: This study discusses a mathematical model incorporating time delay effects in large biological neuronal nets. We use mathematical techniques, such as perturbation theory and linearization by parts, to handle the highly nonlinear equations describing biological neural nets in the presence of large propagation delays. We consider the possibility that these delays can be modulated, instead of assuming time invariant delays. We consider time-delay effects due to other effects such as gene expression, which may be relevant on how stimulus can be stored as a long term memory. We investigate the impact of signal propagation delays on increasing the cognitive capacity of biological neuronal nets and their complexity. Our model considers the interplay between energy efficiency, partitioning of cognitive and sensory functions in large neuronal structures, and time delays. We found that the presence of time-delays in neuronal nets actually increases the number of available states to represent knowledge and improve the cognitive capability of neuronal structures. Another interesting effect if the apparent impossibility to determine both the neuronal state values and their derivatives in time with precision simultaneously. This implies a trade-off between increased cognition capability when time delays are present, and decreased state observability. We conclude with an analysis on how the emergence of large time delays and their impact on energy consumption in animals may have influenced the evolution of the human brain.

Title: Measuring direction of synaptic transmission via cross frequency coupling

Authors: *B. NANDI[1], B. KOCSIS[2], M. DING[3];
[1]Biomed. Engin., Univ. of Florida, Gainesville, Gainesville, FL; [2]Harvard Med. Sch., Boston, MA; [3]Univ. of Florida, Gainesville, FL

Abstract: Cross Frequency Coupling (CFC) assesses the relationship between oscillatory activities in different frequency bands. The frequently applied phase-amplitude CFC estimates the statistical dependence between the phase of a low frequency oscillation and the amplitude of a high frequency oscillation and provides an index of effective integration of neural activities across different spatial and temporal scales. To date, CFC analysis has been mainly applied in a univariate fashion, namely, the high frequency amplitude and the low frequency phase are obtained from the same signal. In this work we considered phase-amplitude CFC between two different signals representing two different brain areas or neuronal ensembles. Assuming that the high frequency oscillatory amplitude reflects population spiking, therefore the output activity of a neuronal ensemble, and that the lower frequency oscillation reflects dendritic processing, therefore the input activity of a neuronal ensemble, we hypothesized that cross-area phase-amplitude CFC may be used to infer the direction and strength of synaptic transmission. We tested our hypothesis by analyzing laminar recordings from the hippocampus of anesthetized rats during theta rhythm elicited by brainstem stimulation. The 16-channel multi-electrode (100um separation between contacts) spanned CA1, dentate gyrus (DG), and hilar regions. The layers were identified by perforant path evoked potentials. We found that (1) the amplitude of gamma oscillations in DG was significantly coupled to the phase of theta oscillations in CA1 and (2) the amplitude of gamma oscillations in CA1 was not significantly coupled to the phase of theta oscillations in DG. These results, suggesting a unidirectional synaptic transmission from DG to CA1, are consistent with the prediction of the trisynaptic pathway linking DG to CA1 (DG to CA3 to CA1) as well as Granger causality analysis of the same data.

Title: Performance driven neural network model representation: a relational approach

Authors: *S. L. GRATIY, A. ARKHIPOV, D. FENG, N. GOUWENS, N. CAIN, R. IYER, M. BUICE, S. MIHALAS, C. ANASTASSIOU;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The development of large-scale network simulations of brain circuits strongly benefits from having a standardized data schema for representing the parameters of a network and of individual neurons. A standardized data schema creates a common interface between modeling tools and allows for the splitting of the network modeling workflow into separate consecutive steps: building, simulation, and analysis/visualization. Furthermore, standardization is crucial for model sharing and reuse, as well as collaboration between scientists using a diverse set of computational tools.
Based on the needs of our research in the directions of biophysically detailed, point-neuron, and population-based network modeling, we have identified a number of essential requirements for network model representation. These are computational efficiency, scalability to large model size, simplicity (minimal need for external software tools), generality (allow for different levels of model detail), modularity (altering model components without affecting other aspects), human readability, and minimization of redundancy. Here we present progress in developing a network representation reflecting these principles.
We utilized the relational (i.e., table-based) approach for representing parameters of network entities that are linked by keys. We have identified several network entities each of which are represented within individual tables, e.g. cells, cell models, connection types, connections, cell morphology and cell intrinsic electrophysiology properties. The rows in tables contain the instances of each entity and the columns contain their attributes. Most attributes in tables may be viewed as optional allowing for greater flexibility of the data schema. Similarly, the number of entities described by individual tables is flexible and accommodates a specific network's level of detail. The data is stored on disk using either CSV or hdf5 file formats and is loaded into the memory as pandas data frames and numpy arrays, respectively. Concomitantly, we are working with the Blue Brain Project to arrive at an overall standardized network representation, which would meet joint modeling needs.

Title: Link between the infrared light power emitted by an implantable medical device and thermal elevation induced locally

Authors: *C. MORO[1], J. MOLET[1], V. AUBOIROUX[1], F. REINHART[1], S. RENAULT[1], C. CHABROL[1], N. TORRES-MARTINEZ[1], J. MITROFANIS[2], A.-L. BENABID[1];
[1]Cea-Grenoble, Leti-Clinatec, Grenoble, France; [2]Anat. department, Univ. of Sydney, Sydney, Australia

Abstract: Rationale: Several studies have highlighted the therapeutic potential of low-intensity light (near infrared) on various pathologies and neurodegenerative diseases such as Parkinson's disease. This new therapy has led to the development of novel implanted optical fiber devices. These devices may generate heat, that would lead to an increase tissue temperature and subsequent damage. In this study, we present a high spatial resolution, high precision characterization of the thermal effects of active, implanted optical fiber devices in order to assess their safety. We used high resolution MR-thermometry that allows quantification of thermal variations in the animal brain, without any bias such as induced by a thermocouple. **Methods:** We tested a device specifically designed for low-light intra-cerebral laser therapy at 670 nm, with optical fibers designed for the delivery of light in deep regions of the rat and monkey brain. We measured temperature at several light powers at the fiber tip. Total amount of light, instantaneous power emission, illumination length and schedule and wavelength were varied. Using proton resonance frequency shift (PRFS)-based MR-thermometry (resonance frequency dependence to biological tissue temperature), high resolution (0.3 x 0.3 x 0.1 mm^3) thermal maps were acquired during in vivo illumination in rat and monkey. Multi-slice MR acquisitions were performed using a 4.7 T Bruker imager. **Results:** We evaluated the temperature increase induced by varying optical powers applied at the end of the fiber. The objective was to determine optical powers that do not lead to a temperature increase above 2 °C. Preliminary data in rats showed that a 15 mW optical power did not cause a temperature increase above 2°C and mid-height energy was observed at a radius of about 1 mm, depending on the implanted anatomical structure **Conclusions:** MR-thermometry is an adequate method to precisely measuring in vivo deep brain thermal variations and allows thermal characterization of chronic implantable medical devices. The heat increase pattern was correlated to the light power delivered.

Title: Application of spatiotemporal variations of correlation dimension & nonlinear interdependence of scalp EEG for seizure prediction in pediatric myoclonic epilepsy

Authors: M. SHARIFI KOLARIJANI[1], S. AMIRSALARI[2], *M. RAZA[3];
[1]New Hearing Technologies Res. Ctr., [2]Dept. of Paediatrics, Fac. of Med., [3]Baqiyatallah Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: During the last two decades, several studies have shown that the information extracted from EEG recordings of epileptic patients can improve understanding of spatiotemporal dynamics of seizures. These studies have specifically investigated the possibility of seizure prediction using nonlinear time series analysis of EEG with evidence for the existence of a pre-

seizure state. In this study, we evaluated the predictive ability of two nonlinear measures of correlation dimension (CD) and nonlinear interdependence (NI) for seizures in pediatric myoclonic epilepsy patients using scalp EEG recordings. The sample contained EEG recordings of 11 patients (4 females with the average age of 10.3±4.6 yrs) using the 10-20 scheme or its extended version. The data was collected at Shifa Neuroscience Research Center, Khatam ul Anbia Hospital, Iran, during the period of 2010 to 2015. For each subject, one myoclonic seizure is analyzed. The exact onset of seizures was determined by a neurologist. The time profile of CD & NI were derived for each channel (pair) using a windowing technique for a 65 min EEG data (60 min before and 5 min after seizure onset) - for two patients, a portion of total 65 min data was available. For NI, only local combinations of channel pairs were included. Also, for each channel pair, the average of two NIs calculated for that pair was used as a symmetrized measure of NI. Finally, in a 60 min time interval before seizure onset, the amplitude distribution of CD and NI in inter-ictal period was compared to that of pre-ictal period using Receiver Operating Curve (ROC) analysis, for five different pre-ictal periods of 5, 10, 15, 20 and 25 min. The same analysis was performed comparing 2 & 5 min periods after seizures with 60 min period before seizure. The analyses were performed for two different schemes of all channels & individual channels. Furthermore, the spatiotemporal patterns of nonlinear measures in clinically relevant areas of the brain were compared with other areas for each patient. The results showed that these measures can differentiate the pre-ictal phase from the corresponding inter-ictal phase. However, there was no specific general behavior in either the timing or the direction (increase / decrease) of the pre-ictal change amongst patients, except for the observed increase in clinically relevant areas for NI in 70% of the cases. This observations indicate the importance of patient-wise tuning of any automated system for seizure prediction as well as suggest further studies for better evaluation of NI using scalp EEG in pediatric myoclonic epilepsy patients.

Title: Lyapunov Exponent as a tool to evaluate the degree of neuronal insult in rat model of ischemic stroke

Authors: *S. PAUL[1], T. K. SINHA[1], R. PATNAIK[2];
[1]North-Eastern Hill Univ. (NEHU), Shillong, India; [2]Indian Inst. of Technol. (BHU), Varanasi, India

Abstract: Ischemic stroke is one of the enigmatic neurological disorders with least understood injuries. Electroencephalography (EEG) has been traditionally used to detect residual neural dysfunctions after cerebral ischemia but have several shortcomings yielding controversial and inconsistent results. This study involves lyapunov exponent analysis of electroencephalographic signals that can provide clear information regarding the long lasting neural impairment in the subjects suffered from ischemic injury. We have collected the EEG time series data of the fronto-parietal, occipital and temporal regions of three rat groups i.e. control, induced stroke and drug treated the rat brain. Lyapunov exponent is used to quantify the nonlinear chaotic dynamics of the signal. Furthermore, the distinct states of brain activity had different chaotic dynamics quantified by nonlinear invariant measures. It is generally estimated from the observed EEG time series data and that are used to confirm the chaotic nature of the EEG signals. The Lyapunov exponents are quantitative measure for distinguishing among the various types of orbits based upon their sensitive dependence on the initial conditions, and are used to determine the stability of any steady-state behavior, including chaotic solutions. Percentage recovery of signals from fronto parietal, occipital and temporal regions (all frequency bands) is analyzed. The lyapunov exponent was executed in Matlab platform. Our results clearly prove that Piroxicam is effective in reviving neuronal firing. This is the first ever finding which advocates the role of Piroxicam in neuronal firing apart from its other neuroprotective roles. Thus, the possibility of modulation of neuronal firing can act as a therapeutic strategy to prevent neuronal dysfunctions in cerebral ischemia.

Title: Model definition and benchmarks for the Myriad parallel simulator

Authors: *P. RITTNER[1], T. A. CLELAND[2];
[1]Psychology, Cornell Univ. Dept. of Psychology, Ithaca, NY; [2]Psychology, Cornell Univ., Ithaca, NY

Abstract: Myriad is a compartmental biophysical simulator designed to parallelize even "densely integrated" neuronal and network simulations (in which many compartments affect one another at every time step) for high-performance execution on multicore CPUs or on nVIDIA GPUs under CUDA. Hence, large models can be designed with dense analogue interactions (e.g., graded synapses, gap junctions, mass diffusion) rather than being constrained to event-based coupling because of hardware limitations. This is accomplished via code generation techniques transparent to end users, who do not need to facilitate parallelization in their model descriptions. Specifically, models are dynamically translated into a custom-designed minimal object framework for C99 that runs natively on nVIDIA GPUs as well as on CPUs. Consequently, the same model can be executed on CPU or GPU via a compiler option, and models are fully thread-scalable to any number of available threads without user optimization. Dynamic parallelism on CPUs now is also supported via OpenMP, and asynchronous I/O support has been added to enable the concurrent streaming of data to storage, enabling simulations of indefinite duration. The C99 backend also has been refactored for greater efficiency. While the implementation layer is in C99 (with a custom-designed minimal object framework), users can design their Myriad models in any Python environment. Interface and display functions can use any Python-compatible frameworks and tools, whereas model design *per se* utilizes a subset of Python established as Myriad's domain-specific model description language (DSL). Within these DSL constraints, arbitrary user-defined functions and equations can be implemented. (Standard libraries will be provided for the established features of neural systems). The framework for high-level object construction in Python has been substantially expanded, and benchmarks for CPU and GPU simulations have been generated that demonstrate the efficiency of Myriad's architecture. We also discuss the potential for the Myriad backend to support other simulation frameworks.

Title: Recent advances in ModelDB

Authors: *T. M. MORSE[1], R. A. MCDOUGAL[1], N. T. CARNEVALE[1], L. MARENCO[1,4,2], R. WANG[2,3], M. MIGLIORE[1,5], P. L. MILLER[4,2,3], G. M. SHEPHERD[1], M. L. HINES[1]; [1]Neurosci., [2]Ctr. for Med. Informatics, [3]Anesthesiol., Yale Univ. Sch. Med., New Haven, CT; [4]VA Connecticut Healthcare Syst., West Haven, CT; [5]Inst. of Biophysics, Natl. Res. Council, Palermo, CT

Abstract: Experiment-based models of neurons and neuronal circuits have grown increasingly complex since the early computational neuroscience work of Hodgkin and Huxley and Rall. Complexity potentially improves realism, but at the cost of reproducibility. ModelDB, founded in 1996, addresses this difficulty and enhances the scientific utility of computational neuroscience models by providing a convenient venue to share and discover model computer code associated with peer-reviewed publications. ModelDB now contains approximately 1100 published models covering more than 130 research topics built using a wide variety of simulation software. It is actively curated and developed to help users locate and understand models of interest. For example, every model entry is tagged with searchable metadata about the biological system and phenomena that it addresses. ModelDB also provides mechanisms to assist running models both locally and remotely, and has a graphical tool that enables users to explore the anatomical and biophysical properties that are represented in hundreds of the model entries. Each of its capabilities, from the model entry submitting and editing forms that the modeling community uses, to the search engines used to find models, the metadata itself such as the curated list of neuron and cell names, as well as the topic keywords used to further describe the models, is undergoing continued refinement and improvement.

Large research groups (Allen Brain Institute, Human Brain Project, etc.) are emerging that collect data across multiple scales and integrate that data into complex and numerous models. To support this new modeling paradigm, we have developed scripts to facilitate importing a large number of models. In the case of the Allen Institute models, our scripts produced a pure-NEURON version that is shared in addition to the original version which uses the Allen Institute's Software Development Kit. By using a semi-automated import process, not only are we able to reduce curation time, but we improve consistency and quality: the quality improves because advanced features like interactive results graphs for the readme can be developed once and used for all, making a low per-model investment in feature support. We are developing strategies to ensure that models from these large groups are individually discoverable while simultaneously ensuring that they do not impair the discovery of the contributions of other researchers.

Title: Automated metadata identification for better model discovery

Authors: *G. M. SHEPHERD, T. M. MORSE, R. A. MCDOUGAL;
Dept. Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Computational methods are now firmly embedded in neuroscience as techniques for extending experimental observations into predictive models. The ModelDB repository, home to over 1000 published neuroscience models, is a resource for sharing code, reducing the work and risk for creating new models. With the growth of ModelDB, it has become increasingly important that researchers can submit and locate models as efficiently as possible. To aid model discovery, submitters are asked to provide categorized metadata (cell type, brain region, ion channels, etc) describing their model. Unfortunately, this approach imposes a time burden on the submitter, and it risks an incomplete set of metadata due to misunderstandings or insufficient time. The ModelDB curator can also provide this metadata, but that shifts rather than eliminates the difficulty. To reduce the metadata entry time and to increase metadata completeness in both new and existing models, we have developed a tool that automatically makes suggestions for ModelDB metadata based on the abstract of a model's accompanying paper. Of the ModelDB abstracts we have tested as of our survey date, there were 1353 two-word phrases, 203 three-word phrases, 17 four word phrases, and 1 five word phrase appearing in the abstracts for at least five model papers. Repeated phrases like these often matched to neuroscience concepts. For example, the most common four word phrases were "spike timing dependent plasticity", "long term potentiation ltp", "timing dependent plasticity stdp", "cell patch clamp recording", and "deep brain stimulation dbs". We augmented this list of phrases with phrases identified as statistically correlated with given database metadata concepts and those identified by manual review of abstracts. Our suggestion tool uses generalized regular expression rules developed from this list of phrases, where the rules map generalized regular expressions to ModelDB metadata terms. Using this tool we were able to improve the completion of the existing ModelDB metadata fields, which will enable support for an increased number of searchable identifiers. This tool may have general applicability to enhancing searches for relevant metadata in neuroscience publications.

Title: Computer-aided skeleton analysis of microglia de-ramification after experimental diffuse brain injury.

Authors: H. MORRISON[1], K. YOUNG[1], M. QURESHI[2], *J. LIFSHITZ[3];
[1]Univ. of Arizona, Tucson, AZ; [2]Barrow Neurolog. Inst., Phoenix Children's Hosp., Pheonix, AZ; [3]Barrow Neurolog. Inst., Phoenix Children's Hosp., Phoenix, AZ

Abstract: Traumatic brain injury (TBI) impacts the lives of over 2.2 million children and adults each year. Of additional concern are those that suffer more mild TBI, often not seeking medical attention, and minimizing the epidemiology of TBI. After the mechanical forces injure the brain, cellular processes include hemorrhage, edema, and inflammation that go on to exacerbate cellular damage. Microglia, brain immune cells, are constitutively active and finely attuned to change in the microenvironment surrounding neurons and glia. A hyper-ramified morphology represents microglial surveillance transitioning in response to first signs of pathophysiology and injury. Severe focal TBI results in rapid microglia de-ramification and amoeboid morphologies proximal to the lesion. However, following experimental diffuse brain injury, a model of mild TBI, amoeboid microglia are rarely observed and instead microglial hyper-ramification, activation, and rod morphology are observed across cortical regions by day 7 post-injury. Our purpose here was to map the spatiotemporal changes in microglial ramification after diffuse brain injury using a computer-automated, quantitative skeleton analysis. Rats were subjected to midline fluid percussion injury and tissue was harvested at 1, 2, 7 or 28 days post-injury (DPI; n = 3 per time point). Microglia were visualized by Iba-1 immunohistochemistry and captured on 40x digital photomicrographs. Images were processed using ImageJ protocols to visualize all microglia soma and process as binary and then skeletonized representations prior to Analyze Skeleton plugin and morphology data collection (number of microglia process endpoints/cell and process length/cell). The number of microglia endpoints/cell were decreased by ~30% (p<0.05, vs sham) in the injury site and beneath the temporal ridge at 1, 2, 7, and 28 DPI; microglia endpoints/cell were decreased in remote cortex only at 28 DPI (p=0.03). Also, summed microglia process length/cell was decreased at 7 and 28 DPI in the injury site and beneath the temporal ridge (p <0.05). Summarizing all data, we reveal spatiotemporal change in microglia process

length/cell (2-way ANOVA region: $F_{(2, 24)} = 28.8$, $p < 0.0001$; time $F_{(3, 24)} = 4.9$, $p=0.008$, no interaction) and a regional change in the number of endpoints/cell (region $F_{(2, 24)} = 14.6$ $p < 0.0001$; time $F_{(3, 24)} = 2.4$ $p = 0.09$; no interaction). By applying a skeleton analysis method to quantify microglia ramification, we reveal that microglia de-ramification occurs 1 day post-injury and progresses to remote areas over a 28 day time course. Skeleton analysis provides a quantitative approach to evaluate anti-inflammatory therapeutic efficacy.

Title: Brain-wide and fast reconstruction of sparsely distributed neuronal trees

Authors: ***H. ZHOU**, S. LI, T. QUAN, J. LI, A. LI, Y. LI, H. GONG, S. ZENG;
Wuhan Natl. Lab. for Optoelectronics, Huazhong Univ. of Sci. & Technol., Hubei, China

Abstract: Digital reconstructed neural circuit helps us acquire the structural information of brain, and have a better understanding of how brain works. Reconstruction of single neural tree is one of the most important steps to reconstruct digital neural circuit. With the progress of sparse labeling and imaging technology, we obtain whole mouse imaging datasets with sparsely distributed neurons at micron spatial resolution. These neuron imaging datasets show us the fine structure of single neuron eliminating the adjacent signals interference, which makes it possible to fast reconstruct single neuron at brain-wide scale. Considering the size of the original datasets is more than 10 TB, manual reconstruction of a single neuron is labor intensive and time-consuming. Here we report a novel method of single completed neuron reconstruction introducing machine learning and big data technology. Assisted by only a few human interventions, our method can reconstruct the sparsely distributed neuronal trees at brain-wide scale within several hours 10 times faster than manual reconstruction.

Title: Leaders and followers: Quantifying consistency of synfire chain patterns in neuronal spike trains

Authors: *T. KREUZ[1], M. POFAHL[2], E. RÄISÄNEN[1], M. MULANSKY[1];
[1]Inst. For Complex Systems, Sesto Fiorentino, Italy; [2]Dept. of Epileptology, University of Bonn, Germany

Abstract: In spiking neuronal networks perfectly consistent repetitions of the same global propagation pattern are called a synfire chain. For any set of spike trains the questions arise how closely it resembles such a synfire chain and which are the spike trains that lead/follow. Here we address these questions and introduce an algorithm based on two new indicators (termed SPIKE-Order and Spike Train Order) that allows to sort multiple spike trains from leader to follower and to quantify the consistency of the leader-follower relationships for both the original and the optimized sorting.
We illustrate our new method using spike train recordings from a neuronal network exhibiting Giant Depolarized Potentials. In the first analysis step we apply the adaptive coincidence detection originally proposed for the bivariate measure event synchronization [1] to act as match maker and to pair spikes such that each spike is matched with at most one spike in each of the other spike trains. We assign two bivariate order indicators to each spike. The SPIKE-Order distinguishes leading and following spikes, whereas the Spike Train Order evaluates the order of spike trains and allows to sort spike trains from leaders to followers. From these indicators we can define the Synfire Indicator which quantifies to what degree the unsorted spike trains resemble a perfect synfire chain. Since this Synfire Indicator is dependent on the order of spike trains we can search the permutation space of all spike trains to search for the order which results in the highest Synfire Indicator for the sorted spike trains. In a final step we evaluate the statistical significance of the results using a set of carefully constructed spike train surrogates. The algorithm is distinguished by conceptual simplicity, flexibility, low computational cost, and universality (parameter-free and time-scale adaptive). While here we present an application to neuronal spike trains, the algorithm is very generic and applicable to any kind of discrete data. Together with previous measures ISI-distance, SPIKE- distance and SPIKE Synchronization [2,3], SPIKE-Order is implemented in both the Matlab-based graphical user interface SPIKY and

the Python library PySpike [4].

Title: Combined electrophysiological and morphological classification of neuronal cell types

Authors: *E. COTTERILL, S. J. EGLEN;
DAMTP, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Comprehensive classification of the numerous categories of neuronal cell types is an essential step in understanding the composition and functional properties of neuronal networks, as well as allowing for the precise manipulation of cellular activity using optogenetic techniques. Recently, several studies have examined the efficacy of using a combined data set consisting of both the morphological and electrophysiological properties of neurons to perform computational classification of cell types, and have come to conflicting conclusions about the value of utilizing both feature types for classification.
In the present study, we use data from the Allen Brain Atlas cell types database, which provides both electrophysiological recordings and reconstructions of a large number of cells in the mouse visual cortex, and morphological features calculated using the L-Measure software. We examined the impact of using this combined morphological and electrophysiological data set to classify neuronal cell types, and the level of class refinement that can be achieved by employing this combined feature set compared to a single feature type.

Results so far suggest that both the morphological and electrophysiological features provide important structure in this data set. These features do not produce a clear separation of cells by cortical layer, however, using Ward's hierarchical clustering method on the combined feature set, we can reliably differentiate between excitatory and inhibitory cells in the mouse primary visual cortex with over 90% accuracy (n=140 cells). Our analyses also show that strong correlations exist between certain morphological and electrophysiological features, and we explore which electrophysiological features are most tightly constrained by the underlying anatomical properties of a neuron.

Title: Neural network hidden layer units may model cortical neuron responses

Authors: *D. GARDNER[1], E. P. GARDNER[2];
[1]Physiol. & Biophysics, Weill Cornell Med. Col., New York, NY; [2]Neurosci. and Physiol., NYU Sch. of Med., New York, NY

Abstract: Connectionist or 'deep learning' neural networks, substrates for classifiers in both neural and artificial systems (Gardner, D. 1993, *The Neurobiology of Neural Networks*, MIT Press), are characterized by hidden layers. These leverage all-to-all or random connectivity and synaptic learning rules to instantiate intermediary representations of stimuli, serving as essential links between primary sensory information and object- or place-based or salient recognition and perception.
Both cortical and subcortical processing of sensory information may include distributed processing similar to that performed by hidden layers and units of such artificial neural networks. In 1989, neural network models were invoked to represent both transformation (Bankman,

Johnson and Hsiao) and plasticity (Grajski and Merzenech) in somatosensory systems. Subsequently, the neural network paradigm has been applied to sensorimotor behavior (Fetz 1993), magnetic fields evoked by somatosensory stimulation (Mauguiere et al 1997), the gate control theory (Melzack 1999), stationary vs. moving stimuli (Roy and Alloway 1999), and somatosensory working memory (Miller, Brody, Romo and Wang 2003).
Application of the neural network model may thus aid analysis of sensory representations. A parallel sensory system in *Drosophila* confirms the cross-phyla and cross-modality relevance of neuronal hidden layers. Here, Kenyon cells (KC) form a large hidden layer between input olfactory receptors and mushroom body output neurons (MBON). Caron, Ruta, Abbott and Axel (2013) reported that KCs receive random inputs from olfactory and odor-coded sensory glomeruli; they note this scheme is well suited for imposing learned valence on odors that lack innate hard-wired behavioral responses. Aso et al (2014) explicitly described a 'multi-layer feedforward readout network' of MBONs, extended by Hige et al (2015a,b).
Informing mammalian vision, Yamins and DiCarlo (2016) reviewed evidence that hierarchical convolutional networks, trained for visual object categorization, evolve firing patterns like cortical V4 and IT neurons.
Supporting tests of the relevance of this hidden-layer model for sensory processing, we offer STAToolkit, a set of information-theoretic tools (Goldberg, D.H. et al 2009, *Neuroinformatics* 7: 165 - 178). STAToolkit analyses of spike trains can reveal if these are consistent with a view of cortical neurons as hidden distributed-processing units that also incorporate biological variability.

Title: Measures of spike train synchrony: Defining a minimum time scale for the ISI- and the SPIKE-distance

Authors: *E. A. RÄISÄNEN[1,2], M. MULANSKY[2], T. KREUZ[2];
[1]Univ. of Florence, Sesto Fiorentino, Italy; [2]Inst. for complex systems, CNR, Sesto Fiorentino, Italy

Abstract: Over the years many different methods have been developed in order to quantify similarity of spike trains. For example, the Victor-Purpura [1] and van Rossum [2] metrics describe spike train (dis)similarity based on user-given time scales. The main drawback of these measures is the fixed time scale, since it sets a boundary between rate and time coding for the whole recording. This means that the result depends on the user input and the measures do not perform well if the spike trains contain more than one time scale.
These drawbacks have been eliminated in the time scale independent ISI-distance [3] and SPIKE-distance [4] by Kreuz et al., since these methods adapt to the local firing rate. However, while they identify correctly the relative firing rate differences, they have no concept of actual time scales. Especially in the presence of bursts this may lead to situations, where the time scale independence identifies small deviations from perfect synchrony as highly dissimilar.
Here we propose an extension to the existing ISI-distance and SPIKE-distance that is based on using a minimum relevant time scale (MRTS). This extension starts to gradually ignore differences in ISI that are smaller than the MRTS. The MRTS can be a parameter, but we also introduce a method for estimating it directly from the data. We perform a pairwise analysis on a library of stereotypical spike trains to show that the correction addresses the shortcomings of the original measures without introducing any side effects.
In summary, our new extension allows for a more accurate estimation of similarity with certain types of neuronal data. Especially in the presence of bursts the new version has the advantage of being able to disregard the differences that are too small for the time scales of the underlying system. Together with another new measure SPIKE Synchronization [5,6], all measures are implemented in both the Matlab-based graphical user interface SPIKY [7] and the Python library PySpike [8].

Title: Constraints and spandrels of inter-areal connectomes

Authors: *M. RUBINOV[1,2];
[1]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [2]Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Understanding the principles of connectome organization is a grand challenge in systems neuroscience. Recently, module hierarchies and rich clubs have been described as two such organizational principles. Module hierarchies are nestings of smaller modules within larger modules, and are thought to enable complex brain dynamics by facilitating diverse functional states. Rich clubs are densely intra-connected groups of hub areas, and are thought to provide a backbone of functional integration. The prevailing paradigm underlying these discoveries, the cost-efficiency paradigm, postulates that hierarchies and rich clubs arise from competing pressures for wiring cost and information processing efficiency, in contrast to connectome modules, which arise primarily from wiring-cost pressures. Here we describe constraint network modeling, a distinct approach to the study of connectome organization. Our approach is based on constraining empirically observed - and therefore *a priori* biologically valid - connectome features, and on the study of the effect of these constraints on connectome organization. The presence of higher-order, not explicitly constrained, features in constraint network models, implies that such higher-order features are structural by-products, also known as spandrels, of the *a priori* specified constraints. Our results challenge the cost-efficiency paradigm of connectome organization in current gold-standard mouse and Drosophila inter-areal connectome reconstructions. Firstly, the results refute the determinacy of wiring-cost constraints on module organization, and show that hierarchies and rich clubs are structural by-products or spandrels of basic connectome organizational features. Secondly, the results imply that the currently standard literature reports of simultaneously present connectome modules, hubs, hierarchies and rich clubs are based on circular analyses. Finally, the generality and biological validity of constraint network models allows the future study of connectome organization in a more direct and principled way.

Title: Building an active digital atlas for the mouse brainstem

Authors: ***Y. CHEN**[1], A. TOLPYGO[3], D. FERRANTE[3], P. MITRA[3], M. GOULDING[4], H. KARTEN[2], D. KLEINFELD[2], Y. FREUND[1];
[1]Dept. of Computer Sci., [2]Dept. of Physics, UCSD, San Diego, CA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, CA; [4]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Anatomical maps play an essential role in the deconstruction of neuronal circuits. We aim at creating a digital atlas, with near-term focus on the mouse brainstem. The digital atlas allows us to form the mean position of brainstem nuclei, defining the notion of an average brain and the variations about it. This is essential as a framework to compile anatomical and functional measurements across experiments and experimental groups, including tracing studies of neuronal connections, electrophysiological recording studies of the action of neurons in different areas, and anatomical studies of different cell types. Further, the digital atlas is a guide to stereotaxic surgery and the placement of brain activity probes. Our atlas is an active atlas. Unlike a traditional graphic atlas, an active atlas is a software system that automatically maps image series of a brain to a standard coordinate system. It provides an anatomical reference model with position statistics of major structures computed from many subjects. It also contains texture detectors for salient regions like nuclei and tracts, which are used as landmarks for registration. Most importantly, it is updatable from new data to improve the estimate of position statistics; by mapping with the reference model, structure annotations are automatically transferred to new images, augmenting training examples for landmark detectors. Our data-driven approach (figure) builds an active atlas starting with images of 11 Nissl-stained Cryo-Jane sectioned brains. The reference model is bootstrapped by three annotated brains. For a new brain, the images are rigidly aligned, detectors are then applied to the images to generate a set of score volumes for different structures, and these are used to compute a global alignment that maps the reference model to the subject volume. Each structure in the model is then separately adjusted to better fit the subject, resulting in automatic annotations. Data from animals with labeled cells and/or cell types are then mapped back to the atlas coordinate system, allowing the position statistics to be computed.

Title: Spatio-temporal classification of neural activity patterns in dynamic brain imaging data

Authors: ***M. SONG**[1,2], M. KANG1[1], H. LEE[1], H. LEE[1], Y. JEONG[1,2], S.-B. PAIK[1,2]; [1]Dept. of Bio and Brain Engin, [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Neural activity patterns observed in dynamic brain imaging data hold the clue to the mechanism of information processing in the brain. However, quantitative analysis or classification of these patterns has been considered as a challenging task, due to the nonlinearity

and complexity of neural activity patterns. Here we suggest a novel method of pattern classification that can represent both geometric structure and dynamic propagation of neural activity. We show that our method can successfully classify activity patterns in various types of imaging data, such as voltage-sensitive dye imaging (VSDI) and intrinsic optical signals imaging (IOSI) data.
To describe respectively the geometric structure and the propagation dynamics of activity patterns, we defined the geometric and dynamic profiles of spatio-temporal activity pattern. The geometric profile represents the information of size, amplitude and contour shape of activity, while the dynamic profile provides the information about propagation trajectory and degree of dispersion of activity.
We hypothesized the geometric and dynamic profiles can successfully classify different aspects of activity patterns in experimental imaging data. To test this, we tried to categorize VSDI and IOSI data of whole brain activity from Alzheimer (AD) and normal mouse groups. Using our geometric and dynamic profile analysis, we could hierarchically cluster the activity patterns from the paired correlation between the profiles of single pattern. As a result, the activity patterns of AD and normal mouse group appeared significantly separated clusters. This result suggests that our classification method can readily distinguish different dynamics of complicated activity patterns.
Our method provides an intuitive description of complex activity patterns and enables us to classify dynamics of various brain states effectively, which is generally applicable to various types of brain imaging data.

Title: Estimating dynamic functional networks of larger neural populations

Authors: *C. DONNER[1,2], H. SHIMAZAKI[3];
[1]BCCN Berlin, Berlin, Germany; [2]Tech. Univ. Berlin, Berlin, Germany; [3]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: Information in the brain is encoded in spiking activity of neural populations. However the number of activity patterns that a population can generate increases exponentially with the

number of neurons. The maximum entropy method provides a principled way to describe the population activity using a tractable amount of parameters. This method successfully explained stationary spiking activity of neural populations by using less features, such as spike-rates of individual neurons and interactions among pairs of neurons, than the number of possible activity patterns. Modeling activity of cortical circuitries in vivo, however, has been challenging because both, the spike-rates and interactions, can change according to sensory stimulation, behavior, or an internal state of the brain. To capture the non-stationary functional network activity, a state-space framework was suggested to model dynamics of the neural interactions (Shimazaki et al. PLOS Comp Biol, 2012). However, based on exact analysis, the method suffers from computational cost; therefore its application was limited to only ~15 neurons. Here we introduce multiple analytic approximation methods to the state-space model, and make it possible to estimate dynamic pairwise interactions of up to 30 neurons. More specifically, we applied the pseudolikelihood approximation to the neural interaction model, and combined it with the TAP mean-field or Bethe approximation methods to carry out sequential Bayesian estimation of the model parameters. We found that belief propagation algorithm finds the solution of the Bethe approximation fast, and the provided solution is more precise than the TAP method. However, the belief propagation method sometimes fails to converge to a unique solution. Here we propose a hybrid method in which we use an alternative approach, the concave convex procedure (CCCP) that guarantees convergence, when a solution was not found by belief propagation. We compare the performance of these methods using simulated data, and demonstrate applicability of the method to experimental data recorded from awake animals. In addition to the time-varying interactions, the method allows us to investigate dynamics of global properties of recorded networks, such as entropy or sparsity of the population activity.

Title: Changes in spatiotemporal network dynamics during learning

Authors: ***Q. SKILLING**[1], N. OGJANOVSKI[2], S. ATON[2], M. ZOCHOWSKI[3];
[1]Program in Biophysics, [2]Dept. of Molecular, Cellular, and Developmental Biol., [3]Dept. of Physics and Program in Biophysics, Univ. of Michigan, Ann Arbor, MI

Abstract: In order to function properly, the brain must operate in a dynamical regime which facilitates appropriate behavioral response to incoming stimuli. Such spatiotemporal dynamics of the brain are often quantified as functional connections between neurons using various statistical metrics on the available neural activity. Additionally, many studies have shown that neural networks of the brain exhibit phase transitions in activity; at a critical point along this transition, neural activity arranges as neuronal avalanches, where the probability of observing large events of consecutive activity follows a power law relationship with specific slope. In this study, we investigate the correlation between functional connectivity motifs, network proximity to a critical point, and their collective relationship to learning behavior. Using a simulated attractor neural network based on the Hopfield formalism, we change the system proximity to a critical point by varying a control parameter and show that training the network to store a new memory causes specific changes in functional connectivity only when the system resides near a phase transition in activity. Further, we analyze the spatiotemporal dynamics of hippocampal CA1 activity in mice undergoing contextual fear conditioning (CFC). Mice experiencing CFC show an increase in contextual freezing behavior after a single training trial. We examine the functional connectivity of these biological neural systems using the average minimum distance (AMD) metric of detecting statistically relevant coincident spiking between neurons, then, using cosine similarity between these AMD functional connections, we measure stability of these functional representations. We also measure the changes in the avalanche statistics. We show that learning novel information on one hand stabilizes functional representations in the hippocampus while on the other hand increases the spread of spiking avalanches in the network. Taken together, these results indicate that contextual learning imposes specific changes on the spatiotemporal network dynamics, affecting the functional connectivity of hippocampal nodes as well as neural population avalanche distributions, both of which may be used as reliable indicators of expected biological function.

Title: Structural and functional connectivity relationships in the brain: How do they vary between large-scale networks and across individuals?

Authors: *K. G. SOLAR[1], J. KORNELSEN[2], S. M. COURTNEY[3], C. R. FIGLEY[2];
[1]Physiol. and Pathophysiology, [2]Radiology, Univ. of Manitoba, Winnipeg, MB, Canada;
[3]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Structural connectivity (SC) between two locations in the brain indicates that these locations have physical white matter tracts connecting them, as visualized using structural MRI. Functional connectivity (FC) between two locations in the brain indicates that these locations have temporally correlated neural activity, as visualized by fMRI. Brain regions with FC are organized into large-scale networks that are involved in daily tasks. Data-driven examinations of SC-FC relationships in the brain have revealed that direct SC is generally predictive of FC, but that FC is not necessarily predictive of direct SC. These results suggest that SC-FC relationships are not one-to-one but highly complex. In order to elucidate the SC-FC relationships within brain networks, we conducted novel tests of these relationships using a hypothesis-driven, region-of-interest (ROI) approach. To do so, we employed the recently reported UManitoba-JHU Functionally-Defined Human White Matter Atlas, which provides group probability maps of white matter regions underlying six resting state networks, including the dorsal and ventral default mode, left and right executive control, and anterior and posterior salience networks. The current study utilized 3T MRI data (diffusion tensor imaging [DTI]; Myelin Water Imaging [MWI]; and resting-state fMRI) from 32 neurologically-healthy adults. For SC, subject mean diffusivity (MD) and fractional anisotropy (FA) maps were calculated from the DTI data, and myelin water fraction (MWF) maps were calculated from the MWI data. Using these novel atlases, we then created maps of each ROI-to-ROI combination in each network that allowed us to extract the corresponding FA, MD and MWF values for each combination. For FC, a pre-existing functional atlas was used to extract the corresponding FC values from the same ROI combinations, based on spontaneous blood oxygen level-dependent changes as measured using resting-state fMRI. For SC-FC relationships, we tested whether each SC measure (FA; MD; MWF) was correlated with FC between the same functional regions and across subjects. Certain ROI-to-ROI combinations in each network were identified as having strong SC-FC correlations, and patterns emerged among the most highly correlated regions within each network, suggesting their potential roles as network hubs. Finally, we established normal SC-FC relationships within these networks, thus allowing us to establish a baseline for future clinical studies involving abnormal relationships in patient populations.

Title: Diffusion MRI in the non-human primate at 3T: a direct comparison of multi- vs. single-shell acquisitions

Authors: *M. A. PINSK[1], S. KASTNER[1,2];
[1]Princeton Neurosci. Inst., [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: In recent years diffusion MRI (dMRI) studies have advanced from relatively few number of gradient directions acquired with a single diffusion weighting to more complex multi-shell acquisition schemes and reconstruction methods (Tuch 2004; Tournier et al. 2004; Behrens et al. 2007; Wedeen et al. 2008; Aganj et al. 2010; Jbabdi et al. 2012). Here we asked whether a multi-shell scheme can improve accuracy of tractography through complex white matter architecture in the *in-vivo* non-human primate (NHP) model compared to a single-shell scheme with a similar density coverage and acquisition time.
Initial datasets were acquired at a Siemens MAGNETOM 3T Prisma scanner in the same animal under anesthesia with a 5-channel transmit/receive coil system using single-shell and 3-shell acquisition schemes (270 directions, b= 1000 s/mm^2 versus 90 unique directions per shell, b= 1000, 2000, 3000 s/mm^2). All other acquisition parameters were kept identical (TR= 9500ms; TE= 86ms; IPAT= 2; in-plane resolution= 0.8mm; slice thickness= 0.8mm). Recommendations provided by the Human Connectome Project (Sotiropoulos et al. 2013) were followed closely (e.g. interleaved acquisition schemes, polarity reversed slice select gradients for fat suppression, left-right and right-left phase encode directions to eliminate susceptibility distortions, monopolar diffusion encoding to reduce TE). Data were acquired twice under reversed phase-encoding to correct for susceptibility-induced distortions with FSL's topup tool (Andersson et al. 2003), and corrected for eddy current-induced distortions with FSL's eddy tool (Andersson & Sotiropoulos 2016). Both datasets were reconstructed with FSL's bedpostx tool ("zeppelin" axially symmetric tensor model with 3 fiber populations per voxel) (Sotiropoulos et al. 2015 ISMRM). Reconstructed datasets were imported to DSI-Studio (http://dsi-studio.labsolver.org) for

streamline tractography or FSL's probtrackx for probabilistic tractography.
Preliminary results suggest that the reconstructions of both the high-density single-shell dataset and the multi-shell dataset successfully modeled voxels with 2-fiber crossings throughout much of the white matter. However the multi-shell scheme allowed for detection of more voxels whose diffusion signal could be accounted for by 3 fiber orientations. Most of these voxels were found, as expected, in the centrum semiovale of the white matter, but remained quite sparse. Future plans include performance of tractography through the region as well as further improvements in acquisition (e.g. denser multi-shell coverage over longer periods of scan time).

Title: Detecting multivariate cross-correlation structure between brain regions

Authors: *J. RODU, N. KLEIN, Y. YANG, E. AMINOFF, M. J. TARR, R. E. KASS; Carnegie Mellon Univ., Pittsburgh, PA

Abstract: When recordings from multiple electrode arrays, ECoG, EEG, or MEG are used to establish functional connectivity across two or more brain regions, multiple signals within each brain region must be combined. If, for example, signals across multiple electrode arrays in each of two regions are examined, the problem is to describe the multivariate relationship between all the signals from the first region and all the signals from the second region, as it evolves across time, during a task. While it is possible to take averages across signals, or across numerical summaries of pairwise interactions, this averaging may lose important information. We have investigated an alternative approach, which is capable of finding multivariate interactions among signals that are highly non-stationary due to stimulus or behavioral effects. For a single stationary time series in each of two brain areas statistical tools such as cross-correlation and Granger causality may be applied. On the other hand, to examine multivariate interactions at a single time point, canonical correlation, which finds the linear combinations of signals that maximize the correlation, may be used. However, an implementation of vanilla canonical correlation analysis to multivariate signals across time points inevitably fails to regard time as a special variable. The method we have developed produces interpretations much like these

standard techniques and, in addition, (a) extends the idea of canonical correlation to 3-way arrays with one dimension indexed by time (and the others by number of signals given and number of trials), (b) allows for non-stationarity, (c) also allows for nonlinearity, (d) scales well as the number of signals increases, and (e) captures predictive relationships, as is done with Granger causality. We demonstrate the effectiveness of the method through simulation studies and illustrate with MEG data.

Title: Detection of predictive spike patterns with products of generalised linear models

Authors: ***T. HAYAKAWA**, T. FUKAI;
RIKEN BSI, Wako Saitama, Japan

Abstract: How neuronal circuits encode information into spikes has been a central question in neuroscience. It has been hypothesized that not only firing rates of single neurons but also spatiotemporal spike patterns possess information. Experimental studies have reported repeatedly observed spike patterns both in vitro and vivo. Computational studies have proposed candidate mechanisms underlying those spike patterns. The statistical significance of those spike patterns has often been quite controversial, however, and their functional role is still elusive. This is partly because there is a technical difficulty in identifying a combination of spikes whose coincidence has a large predictive value. This difficulty arises from the fact that the number of candidate combinations grows exponentially with respect to the number of the observed neurons and the length of the examined time interval.To address this issue, we consider products of generalised linear models. In this model, each basis function represents a predictive value of a spike of a specific neuron at a specific timing and hence products of these functions represent that of coincident spikes. Although estimation of parameters in this model is a highly non-convex problem, we derive a convex algorithm for this estimation. Then, under a suitable

assumption of sparseness, we prove that the estimated values of the parameters converge to the optimal values as the amount of the observed spike train is increased. We also show numerically that the proposed algorithm successfully detects predictive spike combinations.

Title: Quantifying network structure during state changes in functional brain networks

Authors: ***M. VAIANA**[1], S. E. F. MULDOON[2];
[1]Mathematics, Univ. At Buffalo, Amherst, NY; [2]Mathematics and CDSE Program, Univ. at Buffalo, Buffalo, NY

Abstract: Dynamic neural information can be encoded in functional brain networks but these dynamics can change with time, task, and brain state. Multilayer networks form a novel framework for encoding time dependent information and can be used to monitor and track evolving network structures. Recently it has been shown that community detection (or clustering) with a generalized multilayer modularity function is possible, but the results of such clustering are highly parameter dependent. Due to this sensitivity with respect to the parameters of the clustering algorithm, one must question how to optimize the choice of parameters for a given data set. This concern is particularly salient in data in which state changes are present, as would be expected in neural systems, since an abrupt change in system dynamics can result in a change in network structure. In order to address this concern, we use synthetic neural data to investigate the sensitivity of this method to the presence of noise and state changes in functional brain networks. We present results detailing the performance of the clustering algorithm with respect to the choice of parameters and provide recommendations for how to choose algorithm parameters to best represent community structure in noisy data in which state changes are present.

Title: Momentum: a new approach to signal detection

Authors: *N. Z. BIELCZYK, J. GLENNON, C. BECKMANN;
Donders Institute, Radboud Univ. Nijmegen Med., Nijmegen, Netherlands

Abstract: Gaussian white noise is highly prevalent in human environment, from telecommunication to synaptic transmission in the brain. Detection of signal against white noise is typically based on measures of non-Gaussianity such as skewness or kurtosis of the samples' distribution. These measures for non-Gaussianity are particularly useful in the context of Independent Component Analysis for fMRI data. The success in unraveling the ICA mixing matrix depends on the match between the type of non-Gaussianity incorporated in the ICA algorithm, and the non-Gaussianity in the data. In this work, we propose 'Momentum': a novel approach to non-Gaussianity, based on a combination of all central moments of the samples distribution. We argue that this is an efficient method for signal detection in case we have no prior information about the spectral properties of the signal. If we do not know the frequency content of the hypothetical signal, time order of the samples does not matter to the signal detection, and the only information which can be used to answer the question is the statistical properties of the samples' distribution. Furthermore, the Gaussian white noise has a *unique characteristics* in terms of the central moments. Let us assume the noise time series is normalized. Then, its first moment (the mean) is equal to zero, second moment (variance) is equal to one, third moment (skewness) is equal to 0 etc. All the higher central moments of the Gaussian distribution are also fixed and can be easily obtained analytically. Therefore, aggregating higher order central moments together as one measure of nonGaussianity (or, in other words, measure of aberrance from Gaussianity) can bring high discriminability for the noisy signal.
In order to evaluate the method against the other methods for signal detection, we sampled a few types of signals often encountered in the environment: (a) a number of single events (governed by a Poissonian process); (b) a train of on- and off- states (governed by a Poissonian process); (c) a sinus function; (d) a mixture of sinus functions of a few frequencies**.** For each signal in our testing set, we compared the results against the null distribution. Our results suggest that for the selection of tested signals, Momentum is the most sensitive detection method. We conclude that Momentum is a powerful method for the signal detection, and the optimal method in case we do not have a prior information about the power spectrum of the signal. It is not only a promising

improvement to the ICA algorithms, but can also have implications to a broad variety of disciplines, from telecommunication to seismology.

Title: Light-sheet microscopy of brain vascular image enhancement based on gradient adjust with split bregman

Authors: H. HUI, X. LIANG, D. DONG, X. YANG, *J. TIAN;
Key Lab. of Mol. Imaging, CAS, Beijing City, China

Abstract: Light Sheet Microscopy (LSM) is a high-resolution fluorescence microscopic technique which enables to observe the mouse brain vascular network clearly with immunostaining. However, micro-vessels are stained with few fluorescence antibodies and their signals are much weaker than large vessels, which make micro-vessels unclear in LSM images. In this work, we developed a vascular image enhancement method to enhance micro-vessel details which should be useful for vessel statistics analysis. Since gradient describes the edge information of the vessel, the main contribution of our method is to increase the gradient values of the enhanced image to make the micro-vessels contrast. Meanwhile, an optimum problem whose solution was the final enhanced image with increased gradient values was formulated by designing an energy function. Our method contained two steps: 1) calculate the gradient image of LSM image, and then amplify high gradient values of the original image to enhance the vessel edge and suppress low gradient values to remove noises. Then we formulated a new L1-norm regularization optimization problem to find an image with the expected gradient while keeping the main structure information of the original image. 2) The split bregman iteration method was used to deal with the L1-norm regularization problem and generate the final enhanced image.

The main advantage of the split bregman method is that it has both fast convergence and low memory cost. In order to verify the effectiveness of our method, we applied our method to a series of mouse brain vascular images acquired from a commercial LSM system in our lab. The experimental results showed that our method could greatly enhance micro-vessel edges which were unclear in the original images.

Title: Hippocampal neural events predict ongoing brain-wide BOLD activity.

Authors: *M. BESSERVE[1,3], N. K. LOGOTHETIS[2,4];
[2]Cognitive Neurophysiol., [1]MPI for Biol. Cybernetics, Tuebingen, Germany; [3]MPI for Intelligent Systems, Tuebingen, Germany; [4]Ctr. for Imaging Sciences, Biomed. Imaging Inst., The Univ. of Manchester, Manchester, United Kingdom

Abstract: Transient Local Field Potential (LFP) activity exhibits a wide variety of patterns, reflecting local antagonistic or synergistic neural activity changes in the recorded structure. Among them, “events” with a characteristic time-frequency profile can be identified, which may occasionally reflect transient large-scale interactions with other brain structures. Such an event-related multistructure activity can be studied using concurrent fMRI and LFP recordings in an experimental design dubbed as Neural Event Triggered (NET)-fMRI (Logothetis et al, 2012). Recently we used NET-fMRI to describe the brainwide up and down modulation of neural activity associatiated with hippocampal ripples. Here we examine how much the BOLD changes associated with these events can describe the fMRI time series along the entire data acquisition period. To address this question, we develop a generative model of the ongoing neural activity including both hippocampal LFP recordings and BOLD signals in the whole brain.
The model was based on 6 types of oscillations detected in the hippocampus: Sharp-waves, ripples, gamma, beta, sigma and low frequency events. We first estimated the time course of the BOLD signature of neural events across brain structures by learning a dictionary of responses using the kSVD algorithm, and performed statistical analysis to extract significantly activated voxels for each neural event. Based on a convolutive model of the LFP-BOLD relationship, we corrected the effects of overlap between successive neural events on the BOLD response by estimating the autocorrelation function of the neural events and used it to obtain deconvolved

BOLD signatures, describing the contribution of a single event to the BOLD signal. Preliminary results on 3 sessions show the BOLD signature of each event can be well captured by two dictionaries elements: one with a short response latency (peak response at 2.6s) in a wide range of subcortical and cortical structures, and a long latency (peak response at 5.1s) response restricted to sensory and associative cortical areas. This model enables us to estimate the contribution of hippocampus-related activity to fMRI time series in the whole brain. We thus estimated the overall ongoing single trial fMRI activity averaged across all brain structures at each time point using the model and LFP event time stamps only. The average correlation coefficient between the true fMRI signal and the event based reconstruction was .313, showing that hippocampal neural event carry rich information about global brain dynamics and suggesting that global brain dynamics could in turn be used to infer electrical activity non-invasively.
