Abstract: BACKGROUND: Critical decisions are made daily about whether to bench athletes who might have suffered mild traumatic brain injury (mTBI). Unfortunately, the low-level, diffuse damage underlying sport-related mTBI has proven difficult to measure, especially on the sidelines where initial decisions must be made quickly. Other than self-reported symptoms, the most widely used tool for diagnosing and tracking sports-related mTBI is the ImPACT test, a neuropsychological battery. This test is not viable as a rapid sidelines test because of its length (30 minutes) and the need for a controlled testing environment. It is also susceptible to motivational factors. The ideal instrument would be a) sensitive to low-level diffuse damage, b) easily and rapidly administered on the sidelines, and c) unaffected by human bias. Based on a body of research documenting the sensitivity of ocularmotor performance (e.g., eye movements such as saccades and smooth pursuit) to mTBI damage, we have built five Sideline Eye Trackers and are evaluating their clinical utility as a rapid, objective, and accurate sidelines test of sport-

related concussion/mTBI. METHODS: The Sideline Eye Tracker contains a 7" computer screen, works in direct sunlight, and is highly portable (e.g. fits in a backpack and is battery powered). Our current enrollment is over 1000 athletes, including the entire IU varsity athletic department, two high schools, a middle school and youth hockey and lacrosse teams. Subjects perform a six-minute ocular-motor exam consisting of two saccade tasks, two pursuit tasks, and an ocular following task. Balance data is collected simultaneously with a portable balance board. All athletes complete a baseline exam prior to the onset of their sport season. Anyone suspected of having a concussion is studied a minimum of 3 additional times: 1) immediately post-injury (minutes to within an hour), 2) at the time of being cleared for return-to-play, and 3) as far out post-injury as possible (~4-9 months). To provide two separate measures of test-retest variability, two control groups are also being studied, namely: 1) a within-sport and season-matched control group, and 2) non-concussions prone cross-country athletes. RESULTS: Preliminary results suggest that concussed athletes show significant deficits compared to their baseline measures in both saccades and pursuit. While data collection is ongoing, measuring ocular-motor deficits with our portable eye tracker and a 6 minute exam appears a promising method for diagnosing and tracking sport-related mTBI. Further data is needed in order to ascertain the specificity and sensitivity of our measures.

Title: Natural viewing and pursuit behavior in marmosets performing foraging tasks

Authors: ***J. F. MITCHELL**[1], S. U. NUMMELA[2], C. T. MILLER[2];
[1]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [2]Psychology, UCSD, La Jolla, CA

Abstract: Pursuit eye movements allow primates to stabilize high acuity central vision on slow moving targets. In natural conditions, this provides valuable visual information to guide

movements to those targets, for example to capture moving insects or to track conspecifics. In the laboratory, pursuit has been one of the best studied behaviors for understanding the feedback loop between sensory processing, target selection, and motor control. Recently we found that the small bodied New World primate, the common marmoset (Callithrix jacchus), shares core features of the pursuit behavior seen in humans and macaques (Mitchell, Priebe, and Miller, 2015). Because cortical areas crucial to pursuit (MT, MST, and FEF) are accessible at the surface of marmoset's smooth brains, and not buried in sulci, there are several potential advantages for recording and imaging in this species. However, the work ethic of marmosets is not the same as macaques, particularly for tasks where trials must be initiated from central fixation and where targets must be tracked over stereotyped trajectories to obtain reward. Here we instead examined pursuit behavior in the context of two foraging tasks that naturally engage marmosets to work for longer periods. In the first task, marmosets free viewed high resolution videos of other marmosets chasing each other in their home cages. We find that marmosets routinely pursue marmosets in these videos and that their pursuit shows visual selection of the target motion that is robust to competing background motion signals generated by eye movement. In a second task, marmosets actively tracked Gaussian windowed face images that moved along semi-random linear trajectories. In this task it is possible to manipulate the position and motion of appearing face targets based on the current eye position, providing greater control over sensory conditions. These foraging tasks will be of value for obtaining sufficient repetitions in marmosets, but more critically, may lead to a new understanding of how mechanisms of visual selection generalize to more dynamic natural viewing conditions.

Title: Female sex steroid dynamics may modulate retinal-based horizontal smooth pursuit pathways

Authors: *E. CURRIE[1], M. F. WESNER[2];
[2]Psychology, [1]Lakehead Univ., Thunder Bay, ON, Canada

Abstract: Despite the existence of female sex-steroid receptors throughout the CNS including lower brainstem areas associated with oculomotor functioning, little is known about the non-reproductive effects of cycling sex steroids on CNS pathways. Given that there is converging evidence for depressive and cyclic hormonal influences on various eye movements in females, we decided to measure retinal-based smooth pursuit eye movements (SPEM) with the specific intent of localizing real-time tracking and tracking perseverance effects (i.e., extrapolated trajectories after target termination). Women underwent SPEM measurements during their late follicular (LF) and late luteal (LL) menstrual phases, where estradiol (progesterone) levels are known to be high (low) and low (high) respectively. To narrow down specific steroid effects, three groups of women were used who were (pro)retrospectively screened as either non-symptomatic, non-contraceptive users (Controls; N = 23), as having premenstrual syndromes (PMS; N = 22), or as using a monophasic contraceptive (Alesse™ users; N = 21). Based on salivary immunoenzymometric assay, our PMS and Alesse™ users showed stable estradiol levels across LL and LF phases with the latter also showing progesterone stability. Thus, certain group differences logically revealed estradiol- or progesterone-based manifestations on SPEM. Horizontal, sinusoidal tracking was done with a 60-Hz infrared eye tracker. Target excursion was ±13.3° from fixation moving at 0.25, 0.5 or 1.0 Hz. We found significant between-group deviations from nominal sinusoidal movements where PMS and Alesse™ users showed greater lag, amplitude excursions, and left-to-right excursion bias (greater average right than left amplitude). Our extrapolated measures showed shorter persistence for the PMS and Alesse™ users (defined as duration of movement that statistically followed an extrapolated track) with fitted decay functions revealing slopes that were steeper for the 0.5- and 1.0-Hz conditions compared to Controls. For the 1.0 Hz condition, Controls showed a periodic SPEM pattern that lasted until the end of a 2-sec recording. Also, there was an overall phase trend where LL showed steeper fitted decay slopes than LF. Because we found no direct menstrual phase effects outside of our assays, it is not clear whether estradiol or progesterone directly modulates SPEM circuits. However, based on our group differences, it is possible that neuroendocrine circuits in the CNS that invoke stable ovarian estradiol also modulate brainstem pathways that command SPEM maintenance such as those areas where estradiol has been shown to exert molecular effects.

Title: Conjugate eye movements to monocularly-visible and cyclopean targets

Authors: *J. S. DECKER, C. AURA, K. SCHULTZ, P. GAMLIN;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Saccades and smooth pursuit either shift or maintain gaze on objects of interest so that the image of the object is, respectively, either brought to or maintained on the fovea. Most previous studies have characterized these eye movements using monocularly-visible targets. However, eye movements can also be generated to stimuli that are purely cyclopean, i.e., visible only with binocular viewing and devoid of local contrast or other monocular cues. For future imaging or electrophysiological studies, we hypothesize that the use of cyclopean targets in addition to monocularly-visible targets will permit more effective dissection of the sensorimotor pathways involved in conjugate eye movement control. Therefore, the purpose of the present study was to test the feasibility of this approach by characterizing the metrics and dynamics of saccades and smooth pursuit to cyclopean targets and comparing these parameters to those for monocularly-visible targets. A custom-made stereoscopic visual display was used to present visual stimuli. Four participants performed horizontal saccades to targets at ±5° and ±10° and horizontal smooth pursuit eye movements over a range of 10° or 20° at 0.2 - 0.8Hz. Two types of monocularly-visible targets were used. One was a white cross subtending 1° on a dark background. The other was a 5° circular random dot stereogram (RDS) with +0.5° relative disparity with respect to a correlated dynamic RDS (DRDS) background. The cyclopean target was a 5° circular patch of DRDS with +0.5° relative disparity with respect to the DRDS background. This target was identical to the latter monocularly-visible target, apart from being redrawn in sync with the background redraw rate. Binocular eye positions were recorded using a 240 Hz eye tracking system (ISCAN). We found that saccadic gain was comparable for all target types; however, saccadic latency depended on target type. Shorter latencies were found for the non-RDS target; longer latencies were found for both the monocularly-visible RDS and cyclopean DRDS targets. For smooth pursuit at low frequencies, gain was near 1.0 and phase lag was minimal for all target types. At higher frequencies, gain was reduced for all target types, and phase lag was greater for the cyclopean targets. We conclude that humans are able to perform conjugate voluntary eye movements to cyclopean targets with dynamics and metrics qualitatively similar to those observed for movements to monocularly-visible targets. Therefore, cyclopean targets may be used in future experiments as a way to probe the neural circuitry underlying target selection and the sensorimotor transformations underlying eye movement control.

Title: A computational model for feature integration across saccadic eye movements

Authors: *Y. MOHSENZADEH[1], J. CRAWFORD[2];
[1]Ctr. For Vision Research, York U, Toronto, ON, Canada; [2]Ctr. For Vision Research, York Universiy, Toronto, ON, Canada

Abstract: Humans have a continuous visual perception of the world despite the fact that eyes collect visual information as discrete snapshot-like images across saccades. This raises several questions about human visual system. How does the brain make use of this temporally and spatially separated visual information to make a unified internal perception of the world? How does the visual system succeed in retaining, updating and integrating the visual feature information across saccades? The integration of visual information collected across saccadic eye movements is well known as trans-saccadic feature integration in the vision sciences literature. Here, we present a dynamic computational model to account for the mechanism of trans-saccadic feature integration across gaze shifts. The proposed model is a cyclic process consists of three phases: prediction, updating and fusion. We modeled short term memory as the stored internal representation of the most salient or task-relevant features in the visual scene. A prediction about the stored feature information at the time of the upcoming gaze position is then made based on efference copy signals (intended eye displacement, eye velocity, and eye position), so that the stored features are updated to be matched and consistent with the new gaze position. Afterwards, the spatially updated visual information is fed back to the fusion phase. The fusion phase also receives new visual feature information collected at the new gaze position and produces the desired fused (or integrated) feature information after the eye movement. Finally, the integrated output enters to the memory and updates the visual feature information stored in the memory. In the future, we are planning to make a neurally plausible version of this model to predict and interpret the neural mechanisms and underlying trans-saccadic integration. Title: Fmri targeted electrophysiology of a cyclopean stereomotion-in-depth region in rhesus monkeys

Authors: *K. SCHULTZ[1], M. WARD[2], M. BOLDING[2], P. GAMLIN[2];
[1]Univ. Alabama-Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The perception of motion in depth in primates arises not only from the changing disparity of the images in the two eyes, but from a variety of monocular cues. To eliminate these cues, dynamic random dot stereogram (DRDS) stimuli can be used. These generate what appears to be random noise in either eye alone but, when binocularly fused, they generate the percept of a target with a given disparity. By systematically changing the disparity of the DRDS shown to the two eyes, one can produce the perception of cyclopean stereomotion in depth (csMID). In humans, a csMID region has been reported within hMT+ (Rokers et al., 2009) as well as immediately anterior to hMT+ (Likova and Tyler, 2007). To examine the neural processing underlying csMID perception in the rhesus monkey, we used fMRI to identify candidate regions. By interleaving csMID trials with trials using stimuli at fixed disparity planes, and by also comparing the results with the areas of activity related to eye movements in the same animal, we identified a region related to csMID in the superior temporal sulcus of two monkeys. Subsequently, recording chambers for electrophysiology were implanted and the position of these chambers was imaged using MRI, allowing us to target the csMID region for single-unit recording. Data (43 cells) from one animal has been collected to date. In order to differentiate cell activity for the fixed disparity plane versus motion-in-depth, we compared firing of the cells during near-to-far and far-to-near, as well as to different fixed disparity planes. Cell behavior was also characterized for conjugate smooth pursuit; saccades; dot field movements in multiple directions; dot fields shown to only one eye; uncorrelated dot fields; and dot fields that did not randomly refresh (monocular cues present). Consistent with the fMRI results, we encountered

some cells, generally deeper in the targeted area, that modulate their activity for csMID alone. In addition, the activity of other cells within the targeted area was modulated by vergence eye movements as well as by csMID. In the region superior to the csMID area, we encountered cells that modulate their activity in relation to vergence eye movements. Overall, we found that while cells in the targeted area code for cyclopean motion-in-depth, the activity of many are also modulated by disparity and eye movements. As expected from the overlapping areas of activity for eye movements and csMID in fMRI, the cells found in and around the targeted area have complex visual and oculomotor properties that warrant further investigation.

Title: External directed high intensity focused ultrasound for migraine treatment in rodents

Authors: *J. G. PILITSIS[1], L. GEE[2], G. GHOSHAL[3], I. WALLING[4], C. E. BURDETTE[3]; [1]Neurosurg., [2]Ctr. for Neurosci. and Neuropharm., Albany Med. Col., Albany, NY; [3]Acoustic MedSystems Inc, Savoy, IL; [4]Dept. of Neurosurg., Albany Med. Ctr., Albany, NY

Abstract: Chronic migraine affects over 37 million people in the US and up to 15% are refractory to medical treatment. Interestingly, 70% of patients exhibit allodynia, an increased sensitivity to non-painful stimuli, which we can study using a validated rodent model of chronic migraines (CM) which also causes allodynia in the peri-orbital region. We investigate a novel external high intensity soft focused ultrasound system (HI-SFUS) on allodynia in a rodent model of headache. Using epidurally infused inflammatory media for 15 applications, we induce a chronic migraine state in Sprague Dawley rats. We use a unique HI-SFUS external applicator to deliver 3-6 watts of acoustic energy to the occipital region of the rats, an area that is frequently blocked or stimulated in patients for temporary control of migraines (Fig 1). Our device allows directed high frequency ultrasound ablative energy to be directed specifically at the occipital nerves non-invasively setting it apart from other therapies. Mechanical thresholds of the peri orbital region were assessed using vonFrey filaments. We found a significant reduction in mechanical thresholds after inducing the CM state in rodents (n=4, p=0.02). Immediately after HI-SFUS, thresholds were significantly increased and remained increased significantly at 1 day post treatment (Fig 2, p=0.048). Thresholds remained elevated for the first 6 days following

ultrasound therapy. We demonstrate proof of principle of externally applied high intensity soft focused ultrasound therapy in a rodent migraine and demonstrate significant improvement of allodynia following HI-SFUS administration. We are currently performing a dose response study to assess the optimal, safe dose of energy to administer to improve allodynia. Further device customization will allow preferential targeting of the nerve at the exact depth and location to illicit optimum response.

Figure 1. External HIFU applicator device

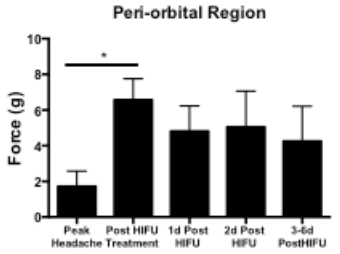

Figure 2. Mechanical thresholds in peri-orbital region. Thresholds increased significantly after HIFU treatment (p=0.048) and remained elevated up to 6 days afterwards

Title: Chronic peripheral nerve injury produces phase-selective suppression of voluntary wheel activity in rats consistent with the duration of bilateral sensory allodynia

Authors: *R. WHITEHEAD[1], M. S. SUN[2], J. J. SANCHEZ[2], H. MARTIN[2], E. MILLIGAN[2]; [1]Univ. of New Mexico, Santa Fe, NM; [2]Univ. of New Mexico, Albuquerque, NM

Abstract: Peripheral neuropathies such as heightened sensitivity to light touch (clinically referred to as allodynia) are an underlying cause of many types of chronic pain arising from aberrant glial and neuronal signaling. One method commonly used to detect allodynia in rodent models of peripheral neuropathy is the von Frey test (VF), which utilizes a series of calibrated monofilaments applied to the hindpaw eliciting a paw withdrawal response. One widely applied rodent model of peripheral neuropathy is unilateral sciatic nerve chronic constriction injury (CCI) that generates reliable allodynia. Complementary non-reflexive physical-activity measures such as voluntary wheel running (VWR) may be useful to assess function, as reduced activity is a common feature in clinical neuropathic pain. Here, we aimed to determine whether VWR would reveal a reduction in physical activity (distance traveled) under peripheral neuropathic conditions. Three experimental groups were assigned to running wheels (RW) at the onset of the rat's light cycle: (1) CCI with unrestricted access to in-cage RWs, (2) sham surgery with unrestricted access to in-cage RWs, and (3) CCI with unrestricted access to locked in-cage RWs. An additional group was run to determine the effects of CCI on VWR at the onset of the rat's dark cycle. Seven & 3 days prior to surgery, RW activity levels and baseline (BL) paw withdrawal thresholds (VF test), respectively, were obtained. Daily RW activity levels (1 hr) were obtained each 24 hr for 7 days prior to surgery. After surgery, hindpaw thresholds followed by RW activity (1 hr) were re-assessed 3, 10, 14, and 18 days after surgery, with an extra VF timepoint collected on Day 16. RWs were connected to an automated data system that recorded the absolute values of distance traveled (meters). Rats were monitored continuously during the 1-hr RW exposure. Data were acquired every second allowing for analyses of binned 20-min profiles: Phase I, II and III within the 1 hr period. We observed similar allodynia profiles between wheel-locked and RW groups, suggesting that 1 hr WR exposure does not alter the VF thresholds during peripheral neuropathy. Compared to sham controls, robust decreases in RW activity was observed on days 3, 10 & 14 post-surgery in CCI rats, while allodynia remained significant at all timepoints. The most pronounced decrease in RW activity was observed during Phase II, with similar decreases observed in rats expose to WR during the dark cycle, with about 50% greater overall activity levels than light-cycle activity levels. VWR may serve as a complementary assay of peripheral neuropathy in rats, which could be useful in providing a screen for novel pain therapeutic drugs.

Title: Donepezil completely reverses fibromyalgia-like pain in intermittent cold stress model mice

Authors: *H. NEYAMA, T. MUKAE, H. UEDA;
Nagasaki Univ., Nagasaki-Shi, Japan

Abstract: We have started to search for therapeutic candidates to cure experimental fibromyalgia-like pain disease. Our strategy is to use intermittent cold stress model to cause fibromyalgia-like pain in mice. The model mouse shows chronic pain (thermal, mechanical, chemical and electrical) for over 3 weeks, female-predominant gender difference, lack of morphine analgesia, but sensitive to pregabalin (i.c.v.) and antidepressants (i.t.). However, constant cold stress showed only a transient pain, which completely disappears 5 days after the stress. Based on clinical evidence that fibromyalgia often accompanies the symptoms, dry-eye and dry-mouth, we started pilocarpine to treat this chronic pain disease. Following successful results and identification of brain-specificity, we further observed that efficiently brain-penetrable donepezil could completely cure this pain disease even after repeated treatments. In the present study we will discuss the newly produced pain-inhibitory mechanisms following repeated donepezil treatments in terms of brain loci and related genes.

Title: AAV6 based delivery of zeta inhibitory peptide to dorsal root ganglion neurons and its effect on nerve-injury induced neuropathic pain

Authors: *G. FISCHER[1,3], Z. LIU[4], Q. HOGAN[3,2], H. YU[1,3];
[1]Anesthesiol., [2]VAMC, Milwaukee, WI; [3]Anesthesiol., [4]Med. Col. of Wisconsin, Wauwatosa, WI

Abstract: Protein Kinase C-zeta and Protein Kinase M-zeta (PKCζ and PKMζ) are atypical PKC (aPKC) isoforms with demonstrated roles in altering synaptic strength in learning and memory. Evidence also exists that aPKCs have similar effects on nociceptive pathways in chronic pain states. Bulk administration of the selective PKC/Mζ pseudosubstrate inhibitor zeta inhibitory peptide (ZIP) to multiple sites in the central nervous system has shown efficacy in preventing or reversing increased sensitivity after peripheral inflammation or nerve injury. PKMζ is highly enriched in sensory neurons in the dorsal root ganglion (DRG), but the role of aPKCs in peripheral sensory neurons remains relatively unexplored. We determined whether inhibition of PKC/Mζ activity in primary sensory neurons had an effect on ongoing neuropathic pain. Using an adenoassociated virus (AAV 2/6) encoding ZIP linked to GFP (AAV6 GFP-ZIP) injected into fourth and fifth lumbar DRG, we examined whether inhibition of PKC/Mζ affected the evolution of neuropathic pain after tibial nerve injury (TNI) compared to controls. Tissue was histologically examined to characterize sensory neuron transduction, and to determine if aPKC inhibition had effects on phenotypic changes in DRG neurons typical of nerve injury. Vector injection into L4 and L5 DRGs resulted in efficient and persistent transduction of a wide phenotypic range of sensory neurons, and revealed transgene expression that extended to the central terminals in the spinal cord dorsal horn. Although nerve injury did not alter total expression of PKC/Mζ in DRG neurons, enzyme inhibition reduced the expression of pain-related behaviors four weeks after injury. This could reflect an effect on changes in synaptic transmission that endure after the response to the initial insult had subsided. These findings suggest that PKC/Mζ are an important component of processes governing the response of neurons to stimulation, and that aPKCs may present a potential therapeutic target for modifying the evolution of chronic pain and other disorders of neuronal and synaptic function.

Title: The antinociceptive effect of light emitting diode irradiation on incised wound is via inhibition of cyclooxygenase-2 and prostaglandin E2

Authors: *P.-H. TAN[1], C.-C. LIU[2];
[1]Dept. of Anesthesiology, E-Da Hospital/I-Shou Univ., Kaohsiung, Taiwan; [2]Dept. of Biol. Sciences,, Natl. Sun Yat-Sen Univ., Kaohsiung, Taiwan

Abstract: Introduction: Light emitting diode (LED) phototherapy has attracted attention for reducing pain and inducing tissue repair through several mechanisms. Optimal postsurgical pain therapy remains a challenge for physicians. The analgesic effect of LED on incised wound has never been examined. In this study, we examined the analgesic effect on incised pain and the change of cyclooxygenase 2 (COX-2) and prostaglandin E2 (PGE2) after LED therapy. Methods: The animal protocols were approved by the Institutional Review Board of I-Shou University, Kaohsiung, Taiwan. The rats were randomly assigned to the following groups. Rats received LED therapy on incised skin 6 days before incision (LI group) or 6 days after incision (IL group) or from 3 days before incision to 3 days after incision (LIL group) and skin incision only (I group). Thermal hyperalgesia and mechanical allodynia were tested 1 day after incision in LI and I groups or after LED therapy in the other groups; skin tissues were collected for RNA and protein analysisof COX-2 and PGE2 (n = 6 each group) after behavior test. The RNA and protein analysis are performed by real time quantitative PCR and western blot. Results: Significant thermal hyperalgesia (lower thermal withdrawal latency) was noted in I group compared with the other three LED-treated groups. The expression of COX-2 and PGE2were significantly decreased in the three LED-treated groups compared with I group. Concludions: We concluded LED therapy could relieve thermal hyperalgesia on incised wound and the analgesic effect is possibly produced by inhibiting the expression of COX-2 and PGE2.

Title: Intrathecal bone marrow stromal cells inhibit neuropathic pain via TGF-β secretion and target dorsal root ganglia via CXCL12

Authors: *G. CHEN, C.-K. PARK, R.-G. XIE, R.-R. JI;
Sensory Plasticity Laboratory/Department of Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Neuropathic pain remains a pressing clinical problem and there are still no drugs that can treat neuropathic pain in a complete and definitive way. Bone marrow stromal cells (BMSCs) are a population of progenitor cells of mesodermal origin and present in the bone marrow of adults, emerging as a major source for cell-based therapies for clinical applications. BMSCs were originally conceived as stem/progenitor cells to rebuild diseased or damaged tissues. However, systemically infused BMSCs have been shown to exert therapeutic effects through the release of cytokines/trophic factors that act on local, or perhaps distant, target tissues. Through this paracrine modulation, it has been discovered that BMSCs are potent modulators of immune responses in humans and animals. Here we report that a local injection of BMSCs, via intrathecal route following lumbar puncture, can prevent and reverse neuropathic pain symptoms (allodynia and hyperalgesia) in mice for several weeks following nerve injury (chronic constriction injury, CCI). Intratehcal BMSCs also reduced CCI-induced ongoing pain as measured by conditioned place preference. Furthermore, this BMSCs treatment protected dorsal root ganglion (DRG) neurons from nerve injury and inhibited neuroinflammation in DRGs and spinal cords. Interestingly, BMSCs secreted TGF-β1 to CSF, and the analgesic effect of BMSCs was reversed by neutralization of TGF-β1 but not IL-10. Conversely, intrathecal administration of TGF-β1 potently inhibited neuropathic pain. TGF-β1 is a powerful neuromodulator and rapidly (within minutes) suppressed CCI-evoked spinal synaptic plasticity and DRG neuronal hyperexcitability via TGF-β receptor-1-mediated non-canonical signaling. CCI also upregulated CXCL12 in lumbar L4-L6 DRGs, and this up-regulation caused migration of intrathecally injected BMSCs to L4-L6 DRGs through CXCR4 expressed on BMSCs. These migrated BMSCs

survived in DRGs for more than two months and eventually disappeared. Finally, intrathecal BMSCs also effectively reduced neuropathic pain after spared nerve injury. Our findings support a paracrine mechanism by which intrathecal BMSCs target the CXCL12-producing DRGs via to elicit neuroprotection and sustained neuropathic pain relief via TGF-β1 secretion. Key words: bone marrow stromal cells, intrathecal injection, TGF-β1, CXCL12, CXCR4, neuropathic pain

Title: Co-adminstration of melatonin attenuates morphine tolerance and preserves morphine's antinociceptive effect in spinal nerve ligation rats

Authors: *J.-H. KAO[1,3], C.-S. WONG[2];
[1]Dept. of Med. Res., [2]Dept. of Anesthesiol., Cathay Gen. Hosp., Taipei, Taiwan; [3]Dept. of Pharmacol., Natl. Def. Med. Ctr., Taipei, Taiwan

Abstract: Opioids possess strong antinociceptive effect on various types of pain in clinical; however certain types of pain are difficult to control with opioids. For example, neuropathic pain, caused by nerve injury, is poorly responded to morphine at regular dose. Recently, pineal hormone melatonin was demonstrated to exert antinociceptive effect in animal models, including neuropathic pain models. However, the effects of chronic melatonin treatment and the combination effect of melatonin with morphine are still unclear. In the present study, we explore the combined effect of melatonin with morphine on neuropathic pain and the underlying mechanisms. Spinal nerve ligation or sham operation was performed in adult male Wistar rats. Melatonin (10 mg/kg, i.p.) was co-administrated with morphine (5 mg/kg, s.c.) 1 day after surgery for 14 days. Anti-allodyniic and anti-hyperalgesic effects were assessed by von Frey test and plantar test before and after drug treatment. The L5 spinal cord was removed for western blot, immunohistochemistry or cytokine assay after all the behavioral tests. Our data show that chronic morphine treatment induced tolerance not only in rats underwent sham operation but also in rats with neuropathic pain. Co-administration of melatonin prevents morphine-induced tolerance and increase morphine's antinociceptive effect in spinal nerve ligation rats. We

conclude that co-administration of melatonin with morphine could be a future therapeutic paradigm for the management of chronic neuropathic pain.

Title: Analgesic and neuro-protective effect of acrolein-scavenger of phenelzine for rats with spinal cord injury

Authors: ***Z. CHEN**[1], J. PARK[2], G. GLEN[2], R. TIAN[2], S. VEGA-ALVAREZ[2], P. CAO[3], R. SHI[2];
[1]Med., Shanghai Jiao Tong Univ. Sch. of Med., Shanghai, China; [2]Basic Med. Sci. and Biomed. Engin., Col. of Vet. Med. and Weldon Sch. of Biomed. Engineering, Purdue Univ., West Lafayette, IN; [3]Orthopedics, Dept. of Orthopedics, Rui-Jin Hospital, Sch. of Medicine, Shanghai Jiao-tong Univ., Shanghai, China

Abstract: Acrolein, an aldehyde and endogenous byproduct of lipid peroxidation, is reported to play an important role in neuropathic pain (NP) and neuro-tissue damage after spinal cord injury (SCI). In addition, hydralazine, a known acrolein scavenger, has been shown to suppress acrolein and mitigate sensory hypersensitivity post-SCI. We have found that systematic administration of phenelzine, another known acrolein-scavenger with a chemical structure distinct of that of hydralazine, also has the ability to alleviate NP when administered either immediately post injury, with a delay of three weeks, or a further delay of two months post SCI. Consistent with its neuroprotective effect, the application of phenelzine was also effective in ameliorating motor deficits and preserving neuro-tissues after SCI. In fact, phenezline produced a higher efficacy of analgesic effects compared to hydaralzine when both were used at a maximal safe level. We also show that acrolein-adducts were reduced due to phenelzine application in spinal cord tissue based on immunoblotting techniques. This is in good agreement with the reduction of 3-

hydroxypropyl mercapturic acid (3-HPMA), a metabolite of acrolein in urine, following the application of phenelzine. Furthermore, phenelzine application has also resulted in the reduction of post-SCI elevation of TRPA1 mRNA in central and peripheral locations. Taken together, we have shown that phenelzine is capable of mitigating NP by neutralizing excessive acrolein accumulated post-SCI and also reducing the expression of TRPA1 mRNA. Considering its longer half-life *in vivo* (11 hrs) compared to hydralazine (1 hr), and higher efficacy in mitigating pain, phenelzine is likely a viable, alternative acrolein scavenger in reference to hydralazine that can provide neuroprotection and analgesic effects post SCI.

Neurosciences, [6]Dept. of Neurol., Geneva Univ. Hosp. and Fac. of Med., Geneva, Switzerland

Abstract: Introduction: Complex regional pain syndrome (CRPS) is a chronic painful condition that remains poorly understood and difficult to treat. Recent work has applied insights from the neuroscience of embodiment and body ownership to moduale pain perception and showed that inducing body ownership for artificial body parts results in analgesia for experimentally-induced pain in healthy subjects. Here we adapted the existing research protocole and translated it to the study of chronic pain in patients suffering from CRPS. Methods: 14 patients with CRPS following upper limb trauma were tested. We used physiologically-enhanced virtual reality and exposed patients to cardio-visual stimulation, in which we presented participants with a virtual

hand flashing in synchrony (or in asynchrony in the control condition) with respect to their own online-detected heartbeats. Prior and after each experimental condition, we assessed pain, grip strength, and embodiment measures. Results: Preliminary results demonstrated that the large majority of CRPS patients well supported the entire procedure and embodied the virtual hand, independently of stimulation condition. However, reduction of pain ratings was stronger in the synchronous as compared to the control (asynchronous) condition. Importantly, grip strength increased after exposure to the synchronous condition probably through the embodiment analgesic effect. Conclusion: This study describes a novel approach to achieve pain relief in patients with chronic pain through the use of physiologically-enhanced virtual reality. These preliminary data show that exposure to specific patterns of cardio-visual illumination of a virtual hand, with related effects of embodiment, can be used to treat CRPS symptoms, potentially leading to new non-invasive, analgesic rehabilitation programs for different pain conditions.

Title: miRNA-132-3p plays a role in chronic neuropathic pain

Authors: *M. LEINDERS[1], N. ÜÇEYLER[1], C. SOMMER[1], L. SORKIN[2];
[1]Dept. of Neurol., Univ. of Würzburg, Wuerzburg, Germany; [2]Anesthesia Res. Labs., Univ. of California San Diego, UCSD, San Diego, CA

Abstract: Chronic pain is a frequent and serious condition that reduces quality of life and is often resistant to treatment. MicroRNAs (miRs) are master-regulators of multiple intracellular pathways that are implicated in the pathophysiology of pain. In particular, miR-132 seems to be an interesting candidate, based on preliminary findings in patients with painful polyneuropathies. We therefore assessed miR-132 expression in an animal model of neuropathic pain, and furthermore, studied its functional relevance in spontaneous and evoked pain behavior, including the place escape avoidance paradigm (PEAP). We systematically assessed miR-132-3p and miR-132-5p isoform expression throughout the neuraxis of male Sprague-Dawley rats before and after spared nerve-injury (SNI) in comparison to sham-operated littermates. An intrathecal (i.th.)

LNA-miR-132-3p inhibitor was used to assess the functional role of miR-132, 10 days after SNI. Tests for pain and avoidance behavior were performed prior to, and after SNI and/or followed by i.th. injections by assessing paw withdrawal thresholds with von Frey filaments and with the PEAP. MiR-132-3p expression was higher in the ipsi- but not contralateral L4/5 spinal cord and dorsal root ganglia (DRG) of SNI rats showing pain behavior compared to samples from sham controls (2.4 fold change; $p<0.05$ for both). In contrast, miR-132-5p did not show any difference in expression. I.th. administration of the miR-132-3p antagonist reduced SNI-induced spinal and DRG expression of miR-132 (10.8 fold change $p<0.01$), whereas scr-mismatch control had no effect. Animals that received anti-miR-132-3p showed dose-dependent reduction of mechanical hyperalgesia lasting for up to 7 days after the last (3rd) daily bolus injection ($p<0.001$), compared to animals treated with scr-mismatch control. In the PEAP test, SNI animals spent significantly more time in the light chamber when time in the dark chamber was matched with stimulation of their SNI paw, however animals given the miR-132 inhibitor spent significantly more time in the dark chamber under the same experimental conditions ($p<0.001$), indicating that they no longer found the dark chamber aversive. We found evidence for elevated spinal and DRG miRNA-132-3p expression and its involvement in pain behavior. We identified miRNA-132-3p but not -5p as being involved in not only evoked pain but also pain-aversion. Further studies will unravel downstream mechanisms and pathophysiological significance of miR-132 in chronic pain.

Title: Carbamazepine potentiates the effectiveness of morphine in a rodent model of neuropathic pain

Authors: A. L. RANDOLPH[1,3], M. S. RIPSCH[1,3], Y. M. ALLETTE[1], M. R. DUE[1], Y. KIM[1], C. ALBANY[2], *F. A. WHITE[4,3];

Abstract: Approximately 60% of morphine is glucuronidated to morphine-3-glucuronide (M3G) which may aggravate preexisting pain conditions. Accumulating evidence indicates that M3G signaling through neuronal Toll-like receptor 4 (TLR4) may be central to this proalgesic signaling event. These events are known to include elevated neuronal excitability, increased voltage-gated sodium (NaV) current, tactile allodynia and decreased opioid analgesic efficacy. Using an *in vitro* ratiometric-based calcium influx analysis of acutely dissociated small and medium-diameter neurons derived from lumbar dorsal root ganglion (DRG), we observed that M3G-sensitive neurons responded to lipopolysaccharide (LPS) and over 35% of these M3G/LPS-responsive cells exhibited sensitivity to capsaicin. In addition, M3G-exposed sensory neurons significantly increased excitatory activity and potentiated NaV current as measured by current and voltage clamp, when compared to baseline level measurements. Using a known inhibitor of several NaV currents, carbamazepine (CBZ), we then compared the efficacy of CBZ and morphine as independent agents to the combined treatment of both drugs simultaneously in a variant of the spared nerve injury model of neuropathic pain; tibial nerve injury (TNI). The potent anti-nociceptive effects of morphine (5 mg/kg, i.p.) were observed in TNI rodents at post-injury day (PID) 7-14 and absent at PID21-28, while administration of CBZ (10 mg/kg, i.p.) alone failed to produce anti-nociceptive effects at any time following TNI (PID 7-28). In contrast to either drug alone at PID28, the combination of morphine (1 or 5 mg/kg, i.p.) and CBZ transiently reversed tactile hyperalgesia in the rodent TNI model. Taken together, our observations demonstrate a potential therapeutic use of morphine and CBZ as a combinational treatment for neuropathic pain conditions. An open-label, single arm, Phase Ib dose escalation study of oxcarbazepine (structural derivative of carbamazepine)with morphine in patients with chronic pain is currently evaluating the safety and toxicity of the combination of these two FDA-approved drugs (https://clinicaltrials.gov/ct2/show/NCT02078089). The secondary endpoints are improving pain control, reduce morphine use and improve the quality of life.

Title: Spinal manual therapy effects on experimental pain

Authors: *S. M. ONIFER[1], W. R. REED[1], R. S. SOZIO[2], C. R. LONG[3];
[1]Associate Professor, [3]Professor, [2]Palmer Ctr. For Chiropractic Res., Davenport, IA

Abstract: Neuromusculoskeletal pain is often managed clinically by non-pharmacologic complementary and integrative health manual therapies. Optimizing pain relief resulting from manual therapies requires studies that determine their biologic effects and mechanisms of action. Essential to these studies are experimental pain models wherein simulated manual therapies are administered and their effects on nociceptive events are assessed by established methods. Short-term, remote pain relief occurs after a single spinal manual therapy treatment. We simulated a spinal manual therapy passive lumbar flexion technique in adult male Sprague Dawley rats and investigated the duration of anti-nociceptive effects following a single treatment on nociceptive behavior during the hindpaw formalin test. Nociceptive events in this model of peripheral pain occur during a rapid-onset, brief acute phase and a persistent phase separated by a quiescent interphase. Dilute formalin was injected subcutaneously at the plantar surface of the hindpaw. Nociceptive behavior during the acute phase was video-recorded for 5 minutes. Ten minutes of cyclic 20º passive flexion was administered with a custom-made device at the lumbar (L5) vertebra of isoflurane-anesthetized experimental rats (n=12) beginning 10 minutes after formalin injection. Nociceptive behavior during the persistent phase was video-recorded for 60 minutes beginning 5 minutes after treatment ended. Control rats (n=12) underwent the same methods except the passive lumbar flexion. The mean times spent licking the formalin-injected hindpaw of both groups during 1-5 minutes following formalin injection, and prior to passive lumbar flexion, were not different. The mean licking times of experimental rats during the first 20 minutes after passive lumbar flexion were significantly less than that of control rats ($p<0.001$). The mean licking times of both groups during the second and third 20 minutes following passive lumbar flexion were not different. These findings are similar to the short-term, remote pain relief reported clinically after a single spinal manual therapy treatment. Thus, this simulated manual therapy technique and experimental pain model can be used for investigations of peripheral and central mechanisms of action that are needed to optimize the clinical efficacy of non-pharmacologic complementary and integrative health interventions.

Title: Field stimulation of the dorsal root ganglion reduced noxious stimulation-induced cortical activation

Authors: C. PAWELA, Z. LI, A. KACZMAROWSKI, *Q. H. HOGAN;
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Spinal cord stimulation is a well-established treatment option for chronic pain that electrically activates predominantly Abeta sensory neuron fibers in the dorsal columns. An alternative pain treatment approach is being developed that uses electrical field stimulation of the dorsal root ganglion (ganglionic field stimulation - GFS), where nociceptive neurons may also be activated. This has shown initial success in clinical trials. We have developed a rat model of GFS, and here test its efficacy against acute noxious stimulation using function magnetic resonance imaging (fMRI) imaging to gauge it effect on pain-related activation of brain regions. Male rats (160-260g) were anesthetized with dexmedetomidine (0.05mg/kg/hr) and pancuronium (2mg/kg/hr), mechanically ventilated, and subjected to noxious electrical stimulation of the hind paw (3ms pulses at 10Hz, 5mA), which activated brain centers including hindlimb primary somatosensory cortex (S1HL), anterior cingulate cortex, insular cortex, thalamus, and caudate/putamen. Subsequent presentation of the same noxious stimulation during GFS (20Hz, 0.3ms, current at a level determined to be subthreshold for motor activation; n=9) delivered by a bipolar electrode (1mm separation) previously placed into the intervertebral foramen such that it was adjacent to the L4 DRG, showed reduced activation of S1HL, thalamic ventral posterolateral nucleus (VPL), and anterior cingulate. In contrast, a repeated presentation of the noxious stimulation without GFS (n=4) showed no changes from the initial noxious stimulation. GFS alone (without noxious paw stimulation; n=11) showed no discernable fMRI activation when delivered at the therapeutic level, but increasing GFS intensity (5mA) resulted in patterns comparable to noxious paw stimulation - which together show that the treatment level was sub-nociceptive. We conclude that GFS is antinociceptive, but does not produce a simple afferent blockade. Rather, GFS selectively inhibits activation of S1HL and VPL (sensory-discriminative function) and anterior cingulate (affective-motivational), while other centers activated by noxious stimulation are not affected.

Title: Creation of a brain-penetrant peptide-neurotensin(8-13) conjugate exerting analgesic activities after systemic administration

Authors: ***J. COTE**[1], M. DEMEULE[2], N. BEAUDET[1], A. REGINA[2], K. BELLEVILLE[1], A. LAROCQUE[2], J.-M. LONGPRÉ[1], J. LACHOWICZ[2], J.-P. CASTAIGNE[2], P. SARRET[1]; [1]Pharmacol. and Physiol., Univ. De Sherbrooke (FMSS), Sherbrooke, QC, Canada; [2]Angiochem Inc., Montreal, QC, Canada

Abstract: Neuropeptides play a crucial role in brain functions, and peptide receptors hold great promise in advancing structure-based drug discovery for the treatment of brain disorders. However, one of the major remaining challenges in the development of peptides as potential drugs is to achieve therapeutic brain concentrations after systemic delivery, the blood-brain barrier (BBB) preventing entry of molecules from cerebral capillaries into surrounding brain tissue. In the present study, we conjugated the biologically active neurotensin fragment (NT(8-13)), which produces strong analgesia when injected directly into the brain, to the Angiopep-2 peptide (An2), a proprietary 19-amino acid peptide that crosses the BBB by LRP1 receptor-mediated transcytosis. The brain uptake of this new chemical entity, An2-NT(8-13), was first determined using positron emission tomography coupled to computed tomography (PET/CT) imaging. For this purpose, we acquired dynamic PET scans over 60 min followed by a CT scan and quantified brain distribution of 64Cu-radiolabeled An2-NT(8-13) with or without pre-blockage of LRP1 receptors with an excess of unlabeled An2. These experiments showed that An2-NT(8-13) accumulates more efficiently in the brain when pre-blockage is not performed, thus demonstrating transcytosis through a LRP1-dependent mechanism. We next investigated whether the An2-NT(8-13) conjugate exhibited potent analgesic activity in different pain models. In rats, An2-NT(8-13) administered intravenously (i.v.) attenuates the stereotypical nociceptive

behaviors observed following intraplantar injection of formalin into the right hind paw (formalin tonic pain model). At a dose of 0.05 mg/kg, An2-NT(8-13) was also effective in reversing the pain behaviors induced by chronic constriction injury of the sciatic nerve (neuropathic pain). Finally, we found that i.v. An2-NT(8-13) significantly reversed the allodynic state induced by the femoral inoculation of MRMT-1 rat breast cancer cells (bone cancer pain). Altogether, these results demonstrate that the An2-NT(8-13) derivative penetrates the BBB efficiently after systemic administration and mediates relief of chronic pain, thus supporting the potential of An2-NT(8-13) as a first-in-class NT-based chronic pain therapeutic.

Title: Depletion of heat sensitive TRPV1 positive cutaneous nociceptors by infrared light

Authors: M. I. NEMENOV[1,2], *F. L. RICE[3];
[1]Lasmed LLC, Mountain View, CA; [2]Anesthesiol., Standord Univ., Palo Alto, CA; [3]Integrated Tissue Dynamics LLC, Rensselaer, NY

Abstract: Painful peripheral neuropathy (PPN) can have a variety of causes, including diabetes, HIV, herpes zoster, and chemotherapy. PPN poses a considerable challenge to physicians because it is difficult to diagnose and current treatments are usually inadequate with fewer than one third of patients achieving no more 50% pain relief. Most therapeutics target purported pain mechanisms in CNS producing unwanted side effects. Some alternative strategies attempt to reduce or eliminate demonstrated pathological hypersensitivity of cutaneous sensory endings of peripheral nociceptive neurons. Capsaicin is a TRPV1 agonist which, when applied to the skin, has been shown to deplete sensory endings in the epidermis that are postulated to express TRPV1 and one of the main sources of neuropathic pain. Unfortunately, the half-life of capsaicin in the skin is ~ 24 hours and can therefore lead to prolonged inflammatory pain after treatment. This post treatment pain together with non-specific chemotoxicity limit the use of high concentration capsaicin patches even for FDA approved treatment of some types of PPN. However, heat also acts as physical agonist of TRPV1 channels. Subsequently, we have shown that diode laser (DL) pulses can selectively activate TRPV1 positive neurons *in vitro* and *in vivo*. In this study we provide preliminary evidence from punch biopsies of pig skin, that 4 Watt DL pulses deplete sensory endings immunoreactive for PGP9.5, a widely (and clinically) used cross-species marker of cutaneous innervation. As much as 80% of the sensory innervation to the epidermis has been shown to co-express TRPV1 immunoreactivity in healthy subjects and patients with DPN. Moreover, TRPV1 is also expressed in keratinocytes whose stimulation may in turn activate epidermal endings that lack direct expression of TRPV1. The punch biopsies were taken at seven days after repetitive DL pulses and show that this depletion is dose-dependent in that 10 pulses did not reduce innervation density over control tissue but 25 pulses produces a substantial decrease. Importantly, the higher dose caused no obvious damage or inflammation (e.g., macrophages) as assessed sections stained for hematoxylin and eosin (H&E), a standard histological preparation for examining damage and inflammation of skin.

Title: Amount of exercise is not related to exercise-induced analgesia in a rat model of persistent inflammatory pain

Authors: *F. TARUM[1], M. PITHCER[2], R. IMRAN[2], M. BUSHNELL[1];
[1]NCCAM, [2]NCCIH, NIH, Bethesda, MD

Abstract: Aerobic exercise is widely accepted to confer positive therapeutic effects in persistent pain states. However, it is unclear if the amount of exercise determines the degree of beneficial outcome. Here, we tested whether or not the amount of running exercise is related to the level of exercise-induced analgesia and stress reduction in a rat model of persistent inflammatory pain. Rats (n=12/group) were either sedentary or given access to a running wheel for three weeks (2hrs/day, 4days/wk) following intra-articular injection of Complete Freund's Adjuvant (CFA) or sham injection. We assessed weight bearing capacity of ipsilateral and contralateral hind paws, plasma corticosterone and the level of running exercise. At three weeks post-inflammation, sedentary rats continued to exhibit significant hypersensitivity, with 58.4±6.8% less weight bearing capacity compared to baseline ($p<0.001$), as well as significantly elevated corticosterone levels (1931±421.5pg/ml vs. 838±121.4pg/ml in sham rats; $p<0.05$). On the other hand, access to exercise prevented CFA-induced weight-bearing deficits (97.6±7.4% weight bearing capacity compared to baseline) and maintained plasma corticosterone at sham levels (875±127.7pg/ml vs. 838±121.4pg/ml in sham rats). While the average weekly running distance ranged between 1000-3500m in the CFA-injected group, the amount of exercise was not associated with either weight bearing capacity or corticosterone levels. Our findings suggest that simply engaging in regular exercise, regardless of the level, may be an effective approach to reduce hypersensitivity and stress in persistent pain states.

Abstract: Spinal cord stimulation (SCS) with high frequency pulse trains (~10 kHz) has emerged as a potential treatment for chronic neuropathic pain. However, the effects of kilohertz-frequency stimulation on spinal dorsal column axons and its mechanisms of action remain unknown. The objectives of this work were to quantify the effects of kilohertz-frequency epidural stimulation on action potential conduction of dorsal column axons and to identify thresholds for activation and block of axonal conduction. Male Sprague-Dawley rats were anesthetized with urethane (1.2g/kg) and the spinal cord was exposed at the T10 and T13 vertebrae. A custom platinum electrode was inserted epidurally at T13 to deliver bipolar constant-current stimulation at 10 kHz, using either sinusoidal or biphasic rectangular (24 μs per phase) waveforms. A second pair of contacts on the electrode delivered biphasic 100 μs test pulses to evoke compound action potentials (eCAPs) in the dorsal columns, caudal to the site of SCS. The motor threshold (MT) was identified for each type of SCS, then rats were paralyzed and a recording electrode was placed at T10 to record eCAPs from the dorsal columns before, during, and after 30 second trials of SCS (0.1 mA to 4 mA). MT was 1.0±0.3 mA for sinusoidal and 1.5±0.3 mA for biphasic 10 kHz SCS. Sinusoidal stimulation at 10 kHz significantly reduced eCAP amplitudes beginning at 0.5 mA (0.94-fold below baseline, $p=0.001$) and continuing through 4 mA (0.58-fold below baseline, $p<0.0001$). The reduction in eCAP amplitude at 0.5 mA suggests that conduction block in dorsal column axons began at about 50% MT. Biphasic 10 kHz stimulation from 0.6 to 0.8 mA increased eCAP amplitudes (1.05 to 1.07-fold over baseline $p<0.001$), and eCAP amplitudes did not decline until the SCS amplitude reached 1.5 mA or higher (0.88 to 0.61-fold below baseline $p\leq0.002$). These results support recent reports suggesting that biphasic 10 kHz SCS, which is closer than sinusoidal stimulation to the clinically applied waveform, likely does not attenuate neuropathic pain by blocking dorsal column fibers, because SCS is not administered at the supra-MT amplitudes where block occurred. However, fiber activation or potentiation of firing may occur during 10 kHz SCS, a possibility that warrants further investigation. By establishing thresholds for fiber activation and block in the rat dorsal columns, this work lays the foundation for further *in vivo* investigation of the mechanisms underlying the effects of kilohertz-frequency SCS.

Title: Transcranial static magnetic field stimulation for chronic neuropathic pain modulation

Authors: *B. NANDAKUMAR[1], G. H. BLUEMENTHAL[1], A. GRAZIANO[2], G. FOFFANI[3,5], A. OLIVIERO[4], K. A. MOXON[1];

Abstract: Chronic neuropathic pain (CNP) often arises due to nerve lesion or injury accompanied by maladaptive changes in the peripheral and central nervous system. Chronic neuropathic pain is associated with aberrant cortical reorganization, accompanied by increased excitability in the associated somatosensory-motor cortical representation along with the development of tactile allodynia. Reversal of this maladaptive reorganization using sensory feedback and restoration of defective intracortical inhibition through pharmacological strategies may reduce pain in some patients. However these approaches are often invasive, expensive and accompanied by adverse side effects. It was recently found that that cortical excitability can be modulated in a noninvasive, reversible manner using localized moderate-intensity static magnetic fields generated by Neodymium NdFeB magnets. Transcranial static magnetic field stimulation (tSMS) with exposure of 120 to 200mT over sensorimotor cortical representations transiently reduced the cortical excitability in healthy human subjects. In this study, we assessed the effects of tSMS on pain modulation in a rodent model of chronic neuropathic pain induced by a peripheral nerve injury. Methods: Male Sprague Dawley rats underwent spared nerve injury (SNI) followed by a chronic implant surgery. All these animals either received NdFeB magnet implant (SNI-magnet) or an identical non-magnetic sham implant (SNI-sham) onto the skull. The

implants were placed over the bilateral hind paw representation of somatosensory and motor cortex. Computational finite element modelling was used to estimate the field geometry and design specs of the NdFeB implant based on the field strength requirement of 120mT exposure over the hind limb area. Tactile allodynia was assessed using Von-Frey hair filaments over a period of 4 weeks including a pre-surgical baseline. Result: As expected, animals that received sham magnet treatment developed chronic neuropathic pain as demonstrated by an immediate and severe drop in withdrawal threshold. This drop in withdrawal threshold was attenuated for animals that received magnet therapy. ($F=14.876$, $p<0.05$, $\eta 2=0.788$) Conclusion: These data suggest that tSMS may prevent the onset of the development of CNP after severe nerve injury.

Title: Small molecule inhibitors of protein-protein interactions as novel analgesics

Authors: *W.-H. LEE[1,2], Z. XU[3], N. ASHPOLE[4], A. HUDMAN[4], P. KULKARNI[5], G. THAKUR[5], Y. LAI[3], A. HOHMANN[3,6,2];

Biol., Indiana Univ. Sch. of Med., Indianapolis, IN; [5]Dept. of Pharmaceut. Sci., Northeastern Univ., Boston, MA; [6]Gill Ctr. for Biomolecular Sci., Bloomington, IN

Abstract: Abnormal NMDAR activity is linked to central sensitization and chronic pain. This process involves activation of the enzyme neuronal nitric oxide synthase (nNOS) and generation of the signaling molecule nitric oxide (NO). Because the scaffolding protein postsynaptic density 95kDA (PSD95) tethers nNOS to NMDARs, the PSD95-nNOS complex represents a therapeutic target due to its role linking NMDAR activity to NO production. We used a solution binding

assay, AlphaScreen, to quantify potency and efficacy of putative small molecule inhibitors of the PSD95-nNOS complex (i.e. IC87201 and ZL006) in disrupting binding between purified PSD95 and nNOS proteins *in vitro*. We characterized the specificity of PSD95-nNOS disruption by examining abilities of the small molecules to disrupt binding in PSD95-ErbB4 protein pairs. We evaluated the neuroprotective effects of these small molecule inhibitors using a glutamate-induced cell death assay in primary cortical neuronal cultures. We also used inflammatory and a toxic neuropathy models to characterize the antinociceptive efficacies of these small molecules. IC87201 (EC5O: 23.94 μM) and ZL006 (12.88 μM) inhibited PSD95-nNOS binding without altering binding of PSD95 to ErbB4. Thus, IC87201 and ZL006 specifically disrupt PSD95-nNOS interactions but not other PDZ containing protein-protein interactions. Both nNOS-PSD95 inhibitors suppressed glutamate-induced cell death with efficacy comparable to the NMDAR antagonist MK-801. IC87201 and ZL006 preferentially suppressed phase 2A of nociceptive responding in the formalin test and suppressed allodynia induced by intraplantar administration of complete Freund's adjuvant. IC87201 and ZL006 suppressed mechanical and cold allodynia induced by the chemotherapeutic agent paclitaxel (ED50s: 2.47 and 0.93 mg/kg i.p. for IC87201 and ZL006, respectively). However, motor ataxic effects were induced by MK-801 but not by ZL006 or IC87201. Finally, MK-801 produced hyperalgesia in the tail-flick test whereas IC87201 and ZL006 did not alter basal nociceptive thresholds. Our studies establish the utility of using AlphaScreen and purified protein pairs to establish and quantify disruption of protein-protein interactions. Our results demonstrate previously unrecognized antinociceptive efficacy of ZL006 and establish, using two small molecules, a broad application for PSD95-nNOS disruption for treating neuropathic and inflammatory pain. Collectively, our results demonstrate that disrupting PSD95-nNOS protein-protein interactions is effective in attenuating pathological pain without producing motor ataxia associated with NMDAR antagonists.

Title: The electrophysiological property and anti-hyperalgesic activity of sophoraflavanone G and 6-prenylnaringenin, novel T-type calcium channel blockers

Authors: *S. ONO[1], M. ICHII[1], S. YAMAOKA[1], F. SEKIGUCHI[1], T. FUJITA[1], T. DEGUCHI[1], M. TSUBOTA[1], H. NISHIKAWA[1], S. YOSHIDA[2], K. MURATA[1], H. MATSUDA[1], N. TOYOOKA[3], T. OHKUBO[4], A. KAWABATA[1];

Abstract: Among three isoforms of T-type calcium channels (T-channels), $Ca_v3.2$ is targeted by hydrogen sulfide, and plays a crucial role in processing of somatic and visceral pain. Selective T-channel inhibitors are thus considered useful for treatment of intractable inflammatory and neuropathic pain. In the present study, we found T-channel inhibitory activity of sophoraflavanone G (SG) purified from SOPHORAE RADIX (SR), a herbal medicine, and also of its analogue, 6-prenylnaringenin (6-PNG), by a patch-clamp assay using HEK293 cells transfected with human $Ca_v3.1$ or $Ca_v3.2$. The IC_{50} values (μM) of SG and 6-PNG were 1.413 and 1.046 for $Ca_v3.1$, and 0.752 and 0.423 for $Ca_v3.2$, respectively, while naringenin, a common core structure of SG and 6-PNG, exhibited no inhibitory activity. In the $Ca_v3.2$-expressing HEK293 cells, SG, but not 6-PNG, shifted the activation curve toward more positive potentials, and 6-PNG, but not SG, shifted the steady-state inactivation curve toward more negative potentials. In the differentiated NG108-15 cells that express high voltage-activated (HVA) calcium channels, SG and 6-PNG at relatively high concentrations suppressed the HVA-currents, the IC_{50} values being 2.4-fold and 3.8-fold higher than those for T-currents in $Ca_v3.2$-expressing HEK293 cells, respectively. SG and 6-PNG even at high concentrations did not suppress high-K-induced contraction in rat aortic smooth muscle preparations. In mice, oral or i.p. administration of SR-extract at 200 mg/kg or intraplantar (i.pl.) administration of SG and 6-PNG at 10 pmol/paw abolished the $Ca_v3.2$-dependent mechanical hyperalgesia/allodynia caused by i.pl. NaHS, a donor of hydrogen sulfide, as assessed by the von Frey test. SG, when administered i.pl. at 10 pmol/paw or i.p. at 2.5-10 mg/kg, suppressed the neuropathic hyperalgesia/allodynia in mice subjected to partial sciatic nerve ligation. SG and 6-PNG, administered i.p. at 10 mg/kg, also suppressed the neuropathic hyperalgesia/allodynia caused by i.p. administration of oxaliplatin, an anti-cancer drug, in mice. Collectively, SG and 6-PNG, novel T-channel inhibitors, appear to have distinct electrophysiological characteristics, and are considered therapeutically applicable to neuropathic pain.

Title: Interfering with chronic inflammatory pain: the case of Dicer-substrate siRNAs targeting the CCL2/CCR2 chemokine system

Authors: *M.-A. DANSEREAU[1], A. M. JACOBI[2], S. S. ROSE[2], M. A. BEHLKE[2], J.-M. LONGPRE[1], P. SARRET[1];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Integrated DNA Technologies Inc., Coralville, IA

Abstract: New developments in the field of small interfering RNA provide neuroscientists with alternative tools to pharmacological agents and genetically modified animals. This may prove especially useful when working with a complexly interacting system such as the highly redundant chemokine family, for which the design of antagonists acting selectively on one receptor target is difficult to achieve. In the current study, we evaluated the efficiency of 27-mers double-strand Dicer substrate small interfering RNA (DsiRNA) targeting the chemokine CCL2 or its main receptor, CCR2, to counteract the nociceptive behaviors associated with the development of chronic inflammatory pain. This animal pain model was used because CCL2 is described as a major mediator of inflammation and pain. DsiRNAs exhibiting different patterns of methylation (either 7 methylation or S3/AS12 methylation) in order to reduce their ability to trigger an innate immune response were first screened *in vitro* for their ability to knockdown CCL2 or CCR2. Real-time quantitative PCR were performed on the RG2 rat glioblastoma cell line, endogenously expressing CCL2 or on HEK cells stably expressing CCR2. The two best leads for CCL2 and CCR2 were then injected intrathecally (i.t.) twice before (-24h and -1h) or after (+1h and +24h) intraplantar administration of complete Freund adjuvant (CFA) into the right hind paw. Mechanical and thermal hypersensitivity, hind paw edema and dynamic weight distribution on each limb were assessed in male Sprague-Dawley rats at days 1, 3, 5 and 7 post-CFA administration. CFA induced a painful hypersensitivity to mechanical and thermal stimuli, a reduction in the weight bore on the ipsilateral hind paw and a major local edema that were all slightly increasing through the experimental period. DsiRNA targeting either CCL2 or CCR2 were able to reduce mechanical hypersensitivity when administered post-CFA. This action was sequence-specific, as one CCL2 duplex failed to reduce painful hypersensitivity, but methylation-independent, as different methylation patterns of the same sequence yielded identical results. Both CCL2 and CCR2 targeting DsiRNA were however unable to prevent any of the pain-associated symptoms measured when administered prior to CFA. In conclusion, we

report that DsiRNAs targeting CCL2 or CCR2 reduce the mechanical hypersensitivity associated with the development of inflammatory pain, and thus constitute promising tools to expand our knowledge of the mechanisms by which the different family of chemokines contributes to chronic pain.

Title: Inhibition of spinal microglia and astrocytes contributes to the anti-allodynic effect of electroacupuncture in neuropathic pain induced by spinal nerve ligation

Authors: ***L. YI**[1], J. DU[1], Y. QIU[2], J. FANG[1], J. LIU[1,2], J. ZHU[3], J. FANG[1];
[1]Dept. of Neurobio. and Acupuncture Res., Zhejiang Chinese Med. Univ., Hangzhou, China; [2]Dept. of Acupuncture and Rehabil., Xixi Hospital of Hangzhou, China; [3]Dept. of Med. Lab., The Third Affiliated Hosp. of Zhejiang Chinese Med. Univ., Hangzhou, China

Abstract: Besides neurons, activated microglia and astrocytes in the spinal cord dorsal horn (SCDH) contribute to the pathogenesis of chronic pain. Electroacupuncture (EA) has been used widely to treat various chronic pain diseases, however, the underlying mechanisms of EA are still not fully understood. Part 1: Male Sprague-Dawley rats were divided randomly into 4

groups, including an untreated healthy Control group, a True-SNL group that underwent spinal nerve ligation (SNL) and remained untreated, a True-SNL+EA group that underwent SNL followed by EA treatment and a Sham-SNL group that underwent sham surgery and remained untreated. SNL was performed unilaterally at L5 spinal nerve ligation and EA was applied to ST36 and BL60 bilaterally once per day. Part 2: Male SD rats were cannulated for SNL-induced neuropathic pain, and then were randomly divided into dimethyl sulfoxide (DMSO), EA plus DMSO, 4-(4-fluorophenyl)-2-(4-methylsulfonylpheny)-5-(4-pyridyl)-1H-imidazole (SB203580) and EA plus SB203580 groups. SB203580 (30 nmol/L) was administered 5 min prior to EA treatment. Paw withdrawal thresholds (PWTs) were measured ipsilaterally at different timepoints after ligation. Activation of microglia and astrocytes as well as p38 MAPK phosphorylation (p-p38 MAPK) in the SCDH were examined bilaterally by immunofluorescence staining and concentrations of interleukin-1β (IL-1β) and interleukin (IL-6) were measured in the ipsilateral SCDH by ELISA. SNL significantly decreased PWTs and activated glial cells in the superficial laminae of the ipsilateral SCDH. In rats with SNL, GFAP immunoreactivity peaked at 7d and was maintained until 14d post-ligation, while OX-42 immunoreactivity peaked at 3d and declined gradually. EA significantly alleviated SNL-induced mechanical allodynia. Furthermore, EA reduced microglial activation (OX-42 positive ratios) in the lumbar SCDH at 3d post-ligation and suppressed astrocyte activation (GFAP positive ratios) at all time points observed. Spinal p-p38 MAPK was only co-localized with OX-42 in our study. Intrathecal injection of low dose SB203580 had no influence on PWTs, but inhibited the expression of OX-42 positive cells in bilateral SCDH. EA plus SB203580 synergistically increased PWTs and reduced the expression of bilateral spinal OX-42 near to the normal level. EA stimulation alleviates SNL-induced neuropathic pain, at least in part through inhibition of spinal glial activation. Moreover, inhibition of spinal microglia activation may contribute to the immediate effects of EA analgesia which may be partially associated with the reduced expression of p-p38 MAPK.

Title: Mechanical hypersensitivity reversal with drug-loaded nanoemulsion in a CCI model

Authors: *M. SALEEM[1,2], K. VASUDEVA[1,2], S. K. PATEL[3,2], K. T. HITCHENS[4], A. STEVENS[1,2], J. M. JANJIC[3,2], J. A. POLLOCK[1,2];
[1]Biol. Sci., [2]Chronic Pain Res. Consortium, [3]Mylan Sch. of Pharm., Duquesne Univ., Pittsburgh, PA; [4]Pittsburgh NMR Ctr. for Biomed. Res., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Chronic pain is an inadequately managed condition in the clinic. Current treatments are not yet targeting underlying pain mechanisms. We sought to target the neuroinflammatory component in the chronic constriction injury (CCI) rat model of neuropathic pain. The chromic gut used to ligate the sciatic nerve in this model causes inflammation. We have previously reported the targeting and imaging of CCI inflammation with a dual labeled perfluorocarbon (PFC) nanoemulsion. This serves as a tool to label circulating macrophages that accumulate at the site of injury, which can be imaged by Near IR fluorescence of live animals or 19F MRI. Histological studies have confirmed the accumulation of macrophages and inflammatory mediators at the site of injury (Vasudeva et al., 2014. PLoS ONE 9(2). In a related study we have demonstrated that macrophages accumulate the drug loaded nanoemulsion *in vivo* at the site of inflammation leading to changes in macrophage infiltration levels indicating anti-inflammatory effects as measured by molecular imaging (NIR and 19F MRI) (Patel et al., 2015. Clinical Immunology). In the current study, the nanoemulsion was loaded with an anti-inflammatory drug and injected intravenously. In this study, tactile allodynia behavioral testing using Von Frey filaments was utilized and paw-withdrawal thresholds were calculated. This measure infers hypersensitivity to stimuli. Inflammation was assessed by imaging the NIR fluorescence of the accumulated nanoemulsion in live animals and separately in post-mortem histological studies. Drug delivered in the infiltrating immune cells results in a significant relief from hypersensitivity associated with tactile allodynia. Drug delivered independently of the nanoemulsion (free drug) has no such effect. These findings demonstrate that PFC nanoemulsion therapy targeted to the inflammatory components of pain is an effective theranostic tool: one that can track and reverse inflammation, resulting in chronic pain relief.

Title: Adult-onset deletion of Nav1.7 in conditional knockout mice

Authors: *S. D. SHIELDS, R. M. REESE, L. DENG, K. SCEARCE-LEVIE, D. H. HACKOS; Neurosci., Genentech, South San Francisco, CA

Abstract: Human genetics strongly implicates the voltage-gated sodium channel Nav1.7 in the function of nociceptors of the peripheral nervous system: loss-of-function mutations in the scn9a gene that encodes Nav1.7 result in congenital insensitivity to pain (CIP), a serious condition in which affected individuals report no experience of pain of any kind in any part of the body and often suffer severe injuries as a result of the loss of pain's protective function. Because null mutation of scn9a in mice results in neonatal lethality, preclinical animal models to study Nav1.7 function have depended heavily on conditional knockout lines in which Cre recombinase, under the control of various promoters, has been used to delete Nav1.7 from different neuronal subpopulations. In many of these cases, incomplete deletion of Nav1.7 from dorsal root ganglion (DRG) neurons has resulted in residual sensitivity to noxious stimuli. Moreover, in both human CIP individuals and knockout mice, deletion of the channel is constitutive beginning during embryonic development. As a result, it has been difficult to predict the expected action of a drug that inhibits Nav1.7 when taken in adulthood by pain patients. A number of important questions still remain: 1) Are all modalities of acute pain affected by complete loss of Nav1.7 in animal models? 2) If Nav1.7 function is interrupted in adulthood, is the effect on pain the same as when it is deleted throughout development? 3) In the setting of established chronic pain, what is the effect of removing Nav1.7? To address these questions, we generated mice with a tamoxifen-inducible deletion of Nav1.7, namely pCAGG-CreERTtg/- x scn9aloxP/loxP (Nav1.7 cKO) mice. We report that both scn9a mRNA and Nav1.7-like immunoreactivity are reduced to undetectable levels in DRG of tamoxifen-dosed Nav1.7 cKO mice, indicating the completeness of deletion in primary afferent somatosensory neurons. After tamoxifen administration, Nav1.7 cKO mice perform similarly to control littermates in a battery of neurological assessments. However, tamoxifen-dosed Nav1.7 cKO mice develop a profound insensitivity to acute noxious stimuli that encompasses heat, mechanical, and chemical stimuli, and both cutaneous and visceral afferents. Our evidence suggests that Nav1.7 is necessary for the ongoing function of the pain sensory nervous system in adulthood, and that drugs that selectively inhibit this channel are likely to be effective in multiple modalities of pain.

[1]Anesthesiol., Washington Univ. In St Louis, Saint Louis, MO; [2]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Sch. of Materials Sci. and Engin., Seul, Korea, Republic of

Abstract: Chronic pain is a debilitating condition that is poorly managed by current therapeutics due to a lack of efficacy and a multitude of side effects. New approaches to manage chronic pain are desperately needed. Optogenetics affords the opportunity to nonpharmacologically control neuronal activity in pain pathways using light. Implementation of optogenetics for pain control in a clinical setting will require both a light-activateable ion channel and a light source that is small and compatible with biological tissues. Hence, we have developed a fully implantable, wirelessly powered, microscale-LED (mLED) devices for targeted light delivery to primary afferent fibers at the level of the sciatic nerve and spinal cord, to illuminate opsin-expressing sensory neurons. We hypothesize that optical stimulation of conditionally expressed opsins modulates the activity of nociceptive fibers and is sufficient for a modified nocifensive response to a noxious stimulus.

To test our hypothesis, we characterized two transgenic mouse lines expressing the excitatory ion channel Channelrhodopsin (ChR2-EYFP) in specific subsets of Advillin-Cre+ and TRPV1-Cre+ primary afferent fibers. We performed immunohistochemistry to confirm selective expression of opsins in nociceptors and patch-clamp electrophysiology to assess the modulation of neuronal activity *in vitro* as a result of photostimulation. We also performed behavioral assays using our implantable mLED devices and found that optical stimulation of primary afferent fibers expressing ChR2-EYFP is sufficient to induce nocifensive behaviors. With this novel wireless technology, mice expressing ChR2-EYFP exhibited aversion to optical stimulation as demonstrated by using a real-time place aversion assay. The development and implementation of these tools will allow us to further dissect the specific roles of molecularly defined sensory fibers, which could lead to novel optogenetic treatments for chronic pain.

Title: Non-reflexive measures of persistent pain in mice

Authors: ***T. SHEAHAN**, E. R. SIUDA, R. W. GEREAU, J. P. GOLDEN;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Chronic pain represents an immense clinical problem, with over 100 million Americans afflicted and an annual price tag exceeding half a trillion dollars. One of the major

hurdles to effective translation of pain research findings is the lack of research that directly translates from animal models into human studies. There has recently been some discussion regarding the validity of using only reflex/withdrawal measures of pain in animal studies, as these endpoints may not adequately model the complexities of human pain. The development of non-reflexive assays that measure non-evoked pain, as well as the affective components of pain, is therefore an important goal that may be useful in increasing the broad translatability of preclinical findings. Voluntary wheel running has recently been demonstrated as a sensitive and reliable endpoint for evaluating inflammation-induced pain. Further, pain has been shown to alter social interactions in rodents. We tested the utility of voluntary wheel running and social interaction assays as non-reflex/withdrawal measures of pain in the context of inflammatory and nerve injury induced-pain on adult C57BL6/J male mice. We report that inflammatory but not nerve injury-induced pain depresses both voluntary wheel running and social interactions compared to control mice, suggestive that these non-reflex/withdrawal assays are most reliable in the context of inflammation-induced pain.

Title: The role of the lateral habenula in the affective dimension of pain

Authors: *M. M. WHITE, S. A. MORRIS BOBZEAN, C. A. SALCIDO, L. I. PERROTTI, P. N. FUCHS;
Univ. of Texas At Arlington, Arlington, TX

Abstract: The lateral habenula (LHb) integrates input from cortical affective regions to aid in decision-making. Additionally, the LHb constitutes an important relay center in a descending pain modulatory circuit involving both the nucleus accumbens and periacqueductal gray. These two functions of the LHb indicate its importance in decision-making during heightened states of arousal (i.e., pain). Here, we tested the hypothesis that cells of the LHb become activated during the Place Escape/Avoidance Paradigm, a test of pain affect in which animals must decide to avoid or withstand painful stimuli. 144 adult experimentally naïve female Sprague-Dawley rats were randomly assigned to one of four test conditions: a no test control group, a mechanical paw withdrawal threshold (MPWT) test group, a Place Escape/Avoidance (PEAP) test group, and a

group that underwent both MPWT and PEAP tests. Additionally, animals within those four conditions were further randomly assigned to receive subcutaneous injections into the left hindpaw of one of three solutions: 0.5% or 2% carrageenan dissolved in 0.9% saline or an equivalent volume saline. Behavioral testing occurred three hours after injection in accordance with previously established maximum behavioral responding. Animals were sacrificed at the conclusion of testing via intracardiac perfusion and brains sectioned and stained via immunohistochemical methods for cFos to evaluate neuronal activity in the LHb. Overall, behavioral results indicated that animals injected with both doses of carrageenan (0.5% and 2%) had significantly lower pain thresholds compared to animals injected with saline. Additionally, pain thresholds in the 2% carrageenan group were significantly lower than in the 0.5% group. Moreover, during PEAP testing, animals injected with carrageenan actively escaped and avoided stimulation to the inflamed left hindpaw significantly more than saline controls. However, no significant difference in avoidance behavior was observed between the carrageenan treatment groups (0.5% and 2%). Preliminary results of immunohistochemical analyses indicated that carrageenan treatment (0.5% and 2%) increased the number of cFos positive cells in the LHb as compared to saline controls. The aim of this study was to assess neuronal activation in the LHb during affective tests of pain in comparison to more basic sensory testing. While the assertion has been made that the LHb is involved in the affective component of pain, this claim has not been directly tested. This research holds importance because it offers further insight into the mechanisms that underlie the pain experience.

Title: Assessing contending motivational drives of hunger and pain in an operant multi-approach avoidance paradigm

Authors: *C. A. SALCIDO[1], A. L. HARRIS BOZER[1], C. T. MCNABB[3], M. M. WHITE[1], P. N. FUCHS[2];
[1]Psychology, [2]Psychology and Biol., Univ. of Texas at Arlington, Arlington, TX; [3]NIH, Bethesda, MD

Abstract: Pain has been described as a homeostatic emotion that motivates an organism to maintain internal stability. In small amounts, pain can be beneficial and provides critical feedback about bodily functioning. However, when pain is inescapable, it begins to contend with other homeostatic drives, like hunger. To test the hypothesis that pain contends with satiation and attention, we developed a series of experiments that allowed a rat to either satisfy hunger or avoid noxious stimulation in a novel operant approach-avoidance paradigm. In the first experiment, animals were presented with a two lever operant conflict where in order to receive food, they had the choice to press a lever associated with stimulation to a paw with painful inflammation by carrageenan injection or neuropathy by L5 nerve ligation. Results revealed there was no preference for levers/paw stimulation and there was an overall suppression of reward seeking behavior. In addition, control animals with only one pain condition also did not indicate a preference. Due to a possible generalization affect due to spatial proximity of the levers, levers were moved to opposite sides of the chamber for experiment two. Results also suggested that on day one, the generalization effect remained. On day two, there was an emerging preference for stimulation in the non-noxious paw. It was hypothesized that the paradigm may be too complex to allow rodents to indicate their preferences. Therefore, in experiment three, the paradigm was reduced to a single lever, single paw pain inflammation model. There were significant differences between carrageenan and saline groups in mean latency to lever-press, as well as the percentage of trials yielding lever-presses. Even more, when animals were presented with only one pain condition and one lever, this suppression of reward seeking behavior suggested that motivation to avoid pain superseded the motivation to alleviate hunger. Therefore, the results of these studies revealed that suppression of reward seeking behavior occurred only when animals successfully differentiated lever pressing with noxious paw stimulation, and this suppression revealed pain was the most averse contending motivational drive. Future research should be conducted to elucidate the complexity of motivational drives that influence decision-making when pain is present and to investigate the neural mechanisms underlying approach-avoidance conflicts. Utilization of approach-avoidance paradigms such as this can allow researchers to unravel the complexities of the pain experience with the goal of enhancing translation to clinical efficacy.

Abstract: We have developed an ovine model of neuropathic pain intended for use in investigating the analgesic efficacy and possible mechanisms of spinal cord stimulation (SCS). Data were collected from three adult female Polypays sheep. Chronic constriction, i.e., 25% reduction in diameter, of the peroneal nerve produces quantifiable behavioral and neurophysiological responses, without the deficits associated with complete ligation, which seem to be modulated by SCS. In particular, we observed that epidural stimulations from 0.1 to 0.5 V result in an apparent increase in tolerance to von Frey filaments applied to the affected limb and recovery to near-normal gait characteristics during treadmill ambulation. Preliminary evidence from gait analysis suggests an acclimation to the stimulation signal within < 150 steps on the treadmill. In parallel with this, we have developed neurophysiological methods for obtaining single unit recordings from dorsal horn neurons in order to characterize the effects of chronic pain and SCS on spontaneous activity. The development of a large-animal model of neuropathic pain and spinal cord stimulation is a crucial step towards improving clinical care.

Title: A novel platform for genetic dissection of nociceptive sensitization to cold

Authors: *H. N. TURNER[1,2], E. SUMNER[1,3], C. LANDRY[4], M. GALKO[1];
[1]Genet., MD Anderson Cancer Ctr., Houston, TX; [2]Neurosci. Program, Univ. of Texas Grad. Sch. of Biomed. Sci. at Houston, Houston, TX; [3]Univ. of Texas Grad. Sch. of Biomed. Sci. at Houston, Houston, TX; [4]ProDev Engin., Missouri City, TX

Abstract: Organisms from flies to mammals utilize thermoreceptors to detect and respond to ambient and noxious thermal stimuli. Numerous clinical conditions disrupt the sensory machinery, such as in patients suffering from tissue damage (from a wound or sunburn), or damage to the peripheral nerves, common in patients undergoing chemotherapy treatment, or suffering from neurodegenerative disorders. Our goal is to dissect the mechanisms underlying nociceptive sensitization using the genetically tractable *Drosophila* species, as a model. Larvae respond to a high temperatures and harsh mechanical stimuli with a 360° lateral body roll (BR) through class IV multiple dendritic peripheral sensory neurons that innervate the epidermis along the entire body length of the larva. This behavior sensitizes to heat after UV damage to the larval epidermis. Here we show that larvae are also sensitized to cold stimuli after similar epidermal injury. Using a novel "cold probe" assay we found that *Drosophila* larvae produce a mutually exclusive set of primary reactive behaviors, distinct from the commonly reported aversive "corkscrew" behavior seen in response to the high temperature probe. These behaviors include a posterior raise (PR), a combined head and tail raise into a U-Shape (US), and a full-body contraction (CT) behavior. These behaviors are cold specific, occurring in 60% of larvae below 12º C, and require sensory neurons different from those required for responding to heat. After UV exposure, larvae exhibit an increase in the US and also exhibit the typically heat-evoked aversive rolling behavior in response to the cold probe. Larvae simultaneously show a decrease in the CT and TR responses. We see similar results when the epidermis is injured via a pinch wound, which damages the epidermal cell layer and nociceptive neurons while leaving the underlying cuticle intact. These findings suggest a switch in the motor program selected to respond to a cold stimulus after epidermal injury. We have established the first system to study noxious cold responses and cold nociceptive sensitization in *Drosophila*. Our unique tools and assays should allow us to further uncover the conserved molecular and genetic bases of cold nociceptive sensitization, including the cells and channels required for this process.

Title: Persistent thermal allodynia evoked by nerve growth factor (NGF) is mediated by TRPV1 and oxidative mechanisms

Authors: *M. ESKANDER[1], S. RUPAREL[1], P. CHEN[1], X. GAO[2], K. HARGREAVES[1]; [1]Endodontics, [2]Biochem., UTHSCSA, San Antonio, TX

Abstract: Chronic pain management remains a major health care problem due to an incomplete understanding of mechanisms involved in the transition to persistent pain states. Nerve growth factor (NGF) is a sufficient stimulus in humans to trigger persistent pain, but the mechanisms mediating this transition are unknown. We have tested the hypothesis that NGF evokes a persistent nociceptive state via increased TRPV1 activity and oxidative mechanisms. Using blinded observers, rats received NGF (30 μg/kg, s.c.) for 5d and then tested for thermal allodynia using the radiant heat test. NGF evoked a persistent thermal allodynia that extended up to 11d. Thermal allodynia was significantly and dose-dependently reversed by intraplantar (i.pl.) injection of the TRPV1 antagonist capsazepine (CPZ), the cytochrome p450 (CYP) and lipoxygenase (LOX) inhibitor and antioxidant nordihydroguaiaretic acid (NDGA), and the phospholipase A2 (PLA2) inhibitor bromoenol lactone (BEL), suggesting that persistent allodynia is mediated by TRPV1, oxidation, and PLA2-mediated release of free fatty acids. NGF treated animals showed increased nocifensive responses to intraplantar capsaicin (1μg, $p<0.001$), therefore we utilized whole cell patch clamp to conduct a capsaicin concentration response in acutely cultured lumbar DRG cell bodies. Maximal current density (pA/pF) was enhanced after NGF treatment ($p<0.05$) with no change in EC50 values, suggesting increased membrane density of TRPV1. Similarly, maximal capsaicin-evoked calcitonin gene related peptide (CGRP) release

from hind paw skin was enhanced after NGF ($p<0.05$) with no change in EC50 values, suggesting similar effects on TRPV1 between DRG cell bodies and nerve terminals in skin. Finally, we used HPLC/MS to demonstrate that NGF significantly increased concentrations of oxidized TRPV1-active lipids in skin, which were attenuated by i.pl. injections of NDGA and BEL. Collectively, these data support the hypothesis that NGF-induced persistent nociception is mediated by PLA2-dependent generation of oxidized lipids leading to activation of TRPV1. Since NGF is implicated in many chronic pain disorders, increased understanding of the oxidative mechanisms mediating persistent nociception may advance the development of novel analgesics.

Title: Psychosocial stress and susceptibility to chronic postsurgical pain in the rat

Authors: *V. ARORA, C. E. MORADO-URBINA, C. ASCHENBRENNER, K. HAYASHIDA, T. J. MARTIN, J. C. EISENACH, C. M. PETERS;
Dept. Of Anesthesiol., Wake Forest Univ. Sch. of Hlth. Sci., Winston Salem, NC

Abstract: Chronic postsurgical pain (CPSP) is a frequent and often disabling complication of many surgical procedures. Identification of patients at risk of developing CPSP remains inadequate. Analysis of predictive and pathologic factors is important to develop rational strategies to prevent development of CPSP. Clinical studies have suggested that psychosocial and socio-environmental factors are associated with the development of CPSP, however few animal studies have examined this relationship. The goal of this study was to investigate the impact of preoperative psychological stress on postoperative recovery following surgery in the rat. Psychosocial stress was induced in male Sprague-Dawley rats by two weeks of repeated social defeat (10 sessions) using the resident intruder paradigm. Rats exposed to social defeat

had reduced weight gain and reduced plasma corticosterone levels compared to non-defeated rats. Behaviorally defeated rats did not display anxiety like behavior based on the elevated plus maze and open field test but did show increased immobility time on the forced swim test indicating depression like behavior. Social defeat stress also induced a transient mechanical hypersensitivity and spinal microglial activation compared to non-defeated rats. Three days after the last session of social defeat, rats had plantar incision surgery. Mechanical withdrawal thresholds were measured for several weeks using von Frey filaments and individual postoperative trajectories were ¬modeled using mixed growth curve analysis. Preoperative psychosocial stress significantly delayed resolution of mechanical hypersensitivity for several weeks following surgery evident as a reduced slope of recovery. Preoperative measures of affective distress including stress induced hypersensitivity, immobility time during FST, plasma corticosterone levels were correlated to postoperative outcomes to identify potential predictors of impaired recovery. The results indicate that the stress of social defeat can produce physiological and behavioral outcomes which reflect aspects of risk for the development of CPSP. Future studies will investigate mechanisms behind the association between affective distress and chronic pain after surgery and test targeted interventions based on these mechanisms.

Title: Effects of chronic pain on hippocampal microglia and development of depressive-like behaviors

Authors: M. CARDER, B. LAMB, L. SEMKE, M. LEONG, M. LENDE, L. YUAN, *V. DURIC;
Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: Clinical reports indicate that many chronic pain patients also develop symptoms of mood disorders, especially major depressive disorder (MDD); however, the underlying neural mechanisms linking chronic pain conditions and depressive behaviors are still poorly understood. Our previous studies have demonstrated that rodent models of chronic pain mimic some of the stress-like alterations in intracellular signaling and cellular architecture (e.g., decreased MAPK

signaling and reduced rate of neurogenesis) within the hippocampus, a limbic brain region involved in regulation of mood. Thus, in this study, we examined the effects of persistent pain on activation of immune-inflammation processes in the hippocampus. Male rats were initially exposed to either injection of complete Freund's adjuvant (CFA; model of chronic inflammatory pain) or spared nerve injury (SNI; model of chronic neuropathic pain). Both pain models produced robust mechanical hypersensitivity throughout the 42 day period, accompanied by depressive-like phenotype. In parallel with the behavioral effects, exposure to pain also induced changes in expression of proteins involved in activation of interlukin-1-beta (IL-1ß)-mediated inflammatory mechanisms, as well as negative regulation of MAPK signaling. These results resemble previous findings linking stress-induced IL-1ß up-regulation and suppression of neurogenesis in the adult rat hippocampus and, thus, may present novel factors contributing to the depressive-like behaviors observed in chronic pain models. Furthermore, studies are currently underway to characterize pain-mediated alterations on the microglial cell number, size and activation level within the hippocampus. Together these studies may ultimately contribute towards the identification of new treatment targets and the development of novel clinical strategies to diminish the mental health consequences of chronic pain.

Title: Comparison of the analgesic effects of amphetamine and caffeine on tail-flick nociception following repeated forced exercise

Authors: S. PIERCE, L. PEREZ, L. MININBERG, *J. A. SCHROEDER;
Dept Psychol, Connecticut Coll, New London, CT

Abstract: Caffeine and amphetamine have been used by athletes to enhance performance and resist fatigue. Both stimulants have also been shown to be an effective analgesics or analgesic adjuvants. In the current study, for ten consecutive days, rats received caffeine (5, 10 or 20 mg/kg, ip), amphetamine (1.0, 2.5 or 5.0 mg/kg, ip) or saline 5 minutes prior to being subjected to a 10 minute forced swim or no exercise. Tail flick nociception was measured at 15 (immediately post-swim), 30 and 45 minutes post injection. Both stimulants significantly

enhanced active swim time vs. passive floating. Exercise alone significantly enhanced analgesia following forced exercise, however the effect dissipated by 15 minutes following exercise. Caffeine alone at all doses did not produce an antinociceptive effect, however 10 or 20 mg/kg caffeine administered prior to forced swimming significantly enhanced exercise-induced analgesia. Amphetamine alone produced a dose dependent analgesic effect and similar to caffeine, significantly enhanced exercise-induce analgesia. Tolerance to either drug's effects on exercise-induced analgesia was not observed. These results suggest that repeated forced exercise alone is antinociceptive, an effect that is enhanced by psychostimulants with separate pharmacologic profiles.

Title: Pain-related behaviors in nonhuman primate models of knee osteoarthritis

Authors: ***S. NEMOTO**[1], S. OGAWA[2], Y. AWAGA[2], M. TAKASHIMA[2], K. SUEHIRO[2], T. KAMADA[2], A. HAMA[2], A. MATSUDA[2], H. TAKAMATSU[2], K. UMEMURA[3];
[1]Contract Res. Dept., Hamamatsu Pharma Res. Inc., Hamamatsu, Japan; [2]Hamamatsu Pharma Research, Inc., Hamamatsu, Japan; [3]Pharmacol., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: The social and economic burdens of osteoarthritis (OA) are expected to rise as the global population ages. Treatments to reverse tissue damage as well as to alleviate pain are needed. Much of the pathophysiology of OA has been derived from preclinical rodent OA models, but a potential limitation is their phylogenetic distance from humans. Thus, nonhuman primate (NHP) models of OA were developed. Methods designed specifically for the NHP were also developed to quantify pain-related behaviors, including weight bearing, gait disturbance and knee pressure threshold. Following intraarticular injection of monoiodoacetate (MIA), increased knee joint skin temperature and knee joint diameter were observed, suggestive of inflammation. While knee joint temperature remained elevated, knee joint diameter diminished over time. After MIA-injection, significantly decreased weight bearing of the ipsilateral limb, gait disturbance, characterized by diminished mobility of the ipsilateral limb, and decreased pressure threshold, suggestive of pressure "hyperalgesia," were observed over time in the ipsilateral but not

contralateral knee joint. Daily treatment with diclofenac prevented the full expression of pain-related behaviors following MIA injection over time compared to vehicle-treated controls. At 36 days post-MIA injection, an acute injection of morphine transiently reversed pain-related behaviors. Following ipsilateral medial meniscectomy (MMx), weight bearing and knee pressure threshold were normal. Gait disturbance was not observed. However, following an exercise schedule, decreased weight bearing, gait disturbance and pressure hyperalgesia emerged. An analgesic dose of morphine decreased pain-related behaviors. Cartilaginous erosion was observed with magnetic resonance imaging in the ipsilateral knee. Interestingly, pain and decreased functioning are seen with activity but not during periods of inactivity following MMx, similar to clinical OA. The current NHP OA models demonstrate clinical symptoms of knee OA and could highly useful in further elaborating disease mechanism and testing treatments that both ameliorate symptoms and reverse disease.

Title: Spinal dopamine / morphine interactions in the D3 receptor knockout animal model of Restless Legs Syndrome (RLS)

Authors: A. P. YLLANES[1], S. SAMIR[1], K. L. BREWER[2], *S. CLEMENS[1];
[1]Physiol., [2]Emergency Med., East Carolina Univ., Greenville, NC

Abstract: Restless Legs Syndrome (RLS) is an aging-related sensorimotor disorder characterized by abnormal limb sensations that worsen at rest and that severely disrupts sleep. Primary treatment is directed at CNS dopamine (DA) systems that activate D2-like receptors (in particular, D3 and D2). However, long-term therapy directed at these receptors can lead to augmentation, which then routinely leads to a switch to an opioid treatment plan. We recently reported that a dysfunction of the D3 receptor (D3R) system was associated with a lack of responsiveness to morphine as well as increases in D1 receptor (D1R) protein levels in the spinal cord, and that block of D1Rs can reduce spontaneous locomotor activity. As D1Rs and D3Rs can form functional heterodimers, we hypothesized that a modulation of the D1R system might provide a novel means by which to prevent the development of D3R agonist-induced augmentation and the lack of responsiveness to morphine. We tested thermal pain withdrawal latencies over the 2-year life span of male wild type (WT) and D3R knockout mice (D3KO) with varying dosages and/or combinations of morphine, D3R agonist, and D1R antagonist. After establishing baseline withdrawal latencies, animals were treated with morphine (2 mg/kg and 5 mg/kg, respectively), D3R agonist (0.5 mg/kg), D1R antagonist (0.1 mg/kg), and morphine-D1R antagonist combinations (2 mg/kg + 0.1 mg/kg and 5 mg/kg + 0.1 mg/kg, respectively). We found that application of the D3R agonist increased withdrawal latencies in WT but had no effect in D3KOs. Low morphine increased pain withdrawal latencies in young and old WT animals, but had no effect in young or old D3KO. In contrast, high morphine increased withdrawal latencies in both 2 months- and 2 years-old animals. Blocking D1R function alone did not alter responses in young or old WT, or old D3KO; however, it increased withdrawal latencies in young D3KO. Combination treatments of D1R block with low morphine increased latencies in young and old WT, and young but not old D3KO. Interestingly, combination of D1R block and high morphine increased latencies in young and old WT and D3KOs. These data suggest that D1R-D3R interactions mediate morphine responsiveness in an aging-dependent manner, and that block of D1R function can restore opioid sensitivity in an animal model of RLS with D3R dysfunction.

Title: Validation of the kaolin/carrageenan model as an experimental model of osteoarthritis in rats

Authors: *F. PINTO-RIBEIRO[1,2,3], D. AMORIM[3,2], A. DAVID-PEREIRA[3,2], A. LIMA[3,2], R. NOGUEIRA[3,2], N. SEVIVAS[3,2], A. ALMEIDA[3,2];

Abstract: Introduction: Human osteoarthritis (OA) is a chronic degenerative disorder affecting joints, most frequently the knee. Many experimental models have been developed in several species attempting to reproduce features of the human OA but so far the available models correlate poorly with the human pathogenesis in terms of anatomy, functionality and cartilage thickness and repair. Recently, the kaolin and carrageenan (K/C) model was shown to mimic the acute inflammatory phase of OA, reproducing the main features of the onset and initial stages of human OA. Nonetheless, no study has yet shown the time-dependent changes observed in articular structures after the induction of this experimental model. Purpose: To evaluate changes in nociceptive behaviour and gait in male and female rats with experimental OA through a period of six weeks; and to perform a time dependent characterization of knee joint pathophysiological and radiological alterations. Materials and Methods: Hence, in the work herein, right knee K/C-induced OA in adult male and female wistar han rats was evaluated through a period of six weeks in terms of nociceptive behaviour, gait and radiological and histological alterations of articular structures.Comparisons between groups were performed using unpaired t-tests or the non-parametric Mann-Whitney test. A two-way ANOVA was used to assess changes in weight gain between experimental groups. Comparisons between the results of the OA grading scale were performed using Pearson analysis and data reliability was evaluated using the Cronbach alpha test. Results: Our data showed increased ipsilateral oedema and mechanical hyperalgesia in arthritic rats. Radiological and histological findings demonstrated a significant narrowing of the articular space, the development of osteophytes, bone remodelling and chondrocyte hypertrophy and disorganization. Discussion and Conclusions: Our findings support the use of the K/C model as a valid animal model for the preclinical study of OA as its shares important time-dependent homologies in what concerns nociception, gait and articular degeneration with the human pathology.

Title: Effects of chemotherapy exposure on pain sensitivity in the developing rat

Authors: *K. A. SCHAPPACHER, M. L. BACCEI;
Anesthesiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Recent work points to an age-dependent effect of peripheral nerve damage on pain sensitivity, as neonatal rodents display a significantly delayed onset of mechanical hypersensitivity compared to adults. While high dose chemotherapy consistently evokes neuropathic pain in adults, the degree to which pediatric chemotherapeutic regimens influence nociceptive processing throughout development remains unknown, in part due to the lack of an established animal model of chemotherapy-induced neuropathy during early life. Therefore, the present study investigated the effects of early exposure to vincristine (VNC), commonly used in the treatment of pediatric cancers, on mechanical and thermal pain sensitivity in the developing rat. Sprague Dawley rats received daily i.p. injections of 25, 50, 75, or 100 μg/kg VNC, or equivalent volumes of saline, with a five-day on, two-day off schedule starting on postnatal day (P)10 for a total of 10 injections. Mechanical reflex withdrawal thresholds were measured prior to each injection and then at weekly intervals until eight weeks of age. Withdrawal latencies in response to radiant noxious heat were evaluated weekly starting on P26 until eight weeks of age. VNC at 25 and 50 μg/kg did not significantly alter mechanical or thermal thresholds at any time point compared to saline-treated littermate controls. Since daily administration of 75 and 100 μg/kg VNC resulted in death following the third dose, we modified our dosing protocol and administered 5 i.p. injections of 100 μg/kg vincristine (or saline) every other day starting at P10. Body weights were monitored and mechanical and thermal withdrawal thresholds were measured as described above until eight weeks of age. Although rats routinely survived this VNC dose, both male and female VNC-treated rats had significantly reduced weight gain compared to control groups starting at P33. In both sexes, mechanical and thermal reflex sensitivity in the VNC-treated and saline-treated groups were similar throughout the time period examined. Overall, the present results suggest that the administration of high doses of vincristine during the early postnatal period fails to evoke common signs of neuropathic pain in the developing rat.

Title: An over ground testing apparatus for evaluation of spinal cord injury associated neuropathic pain

Authors: *E. A. DUGAN, J. SAGEN;
Neurolog. Surgery, Univ. of Miami, Miami, FL

Abstract: Spinal cord injury (SCI) is associated with both locomotor deficits and sensory abnormalities that include the development of neuropathic pain. Preclinical research for associated neuropathic pain has depended on the use of behavioral testing that is reflexive in nature, however, there is a growing need for the inclusion of testing paradigms that include a cognitive component to the response. We have designed a locomotor over ground apparatus that has exchangeable floors for examination of developed pain behaviors in response to cold (thermal) and rough (tactile) stimulation. Male SD rats are pre-trained for 4 weeks to cross three different over ground surfaces (standard, cold and rough) at a consistent walking pace for a food reward. To further encourage the rodents to cross the walkway, a light was placed at the start of the runway with a dark box at the other end to take advantage of the innate photophobia in rodents. The outcome measures we examined where 1) time spent in the lighted start chamber prior to initiating the crossing (animals were removed after 3 minutes and the crossing was marked incomplete), 2) time to cross the over ground surface, and 3) number of completed crossings out of the number of attempted crossings. All three surfaces were used during pre-training and testing for this experiment. Crossing times for control animals did not differ on any of the three surfaces. We found an increase in crossing speeds for the cold over ground compared to pre-SCI times which was inversely correlated with the development of cold allodynia (acetone testing). We did not see a change in the number of completed crossing or time spent in the start chamber suggesting the animals choose to cross the apparatus at a faster speed, which did not result in a food reward. We found a decrease in crossing speeds at 2, 6, 7, 10 and 12 weeks post SCI for the rough over ground compared to pre-SCI times which was inversely correlated with the development of mechanical allodynia (Von Frey testing). We also show an increase in the time spent in the start chamber with many animals “timing out” and not attempting to cross the rough surface at post SCI weeks 4-12. We did not see differences in the pre- and post-SCI crossing times for SCI animals on the standard over ground surface suggesting that locomotor deficits are not associated with the changes in crossing speeds observed with cold and rough over ground surfaces. This over ground testing apparatus provides a rapid additional screening test that is easy to establish in animal models for the development of cold and mechanical allodynia.

Title: A novel method to study oral cancer pain

Authors: *L. CHODROFF[1], M. BENDELE[2], M. HENRY[2], S. RUPEREL[2];
[1]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Pain is the primary symptom reported by oral cancer patients. Most patients require NSAIDs and opiates that are either only partially effective or develop tolerance and side effects. Because pain occurs even when the tumor is still quite small in size, it is likely that oral cancer cells control the activities of surrounding nociceptors at the site of the tumor. Therefore, it is crucial to understand the mechanisms of tumor-nerve interactions in order to develop more effective ways of treating oral cancer pain. The current study developed a novel tongue cancer pain model that includes *in vivo* nociceptive behavior assays as well as anatomical and expression studies, to study mechanisms of oral cancer pain. The human oral squamous cell carcinoma (OSCC) cell line HSC2 (3.5 x 10^5 cells) or normal cells was injected (50 uL) in the ventral side of the tongue of athymic male mice and after allowing time for growth, nociceptive behavior was measured. Mechanical allodynia was assessed by measuring changes in feeding as well as by application of von Frey filaments to the vibrissal pad. Higher order responses to spontaneous nociception was assessed using a conditioned placed preference (CPP) test where animals were paired with morphine 3mg/.kg for 3 days and then tested for chamber preference on the 4th day. Data were analyzed by ANOVA. Immunohistochemistry was performed on tongue-tumor sections as well as trigeminal ganglia (TG) to anatomically characterize the model. Our results showed that HSC2 mice, but not normal mice, presented reduced feeding by day 7 post-inoculation that was reversed by indomethacin 5mg/kg ($p<0.05$). Similarly, tumor-grown mice showed mechanical hypersensitivity compared to normal mice that was also reversed by indomethacin. CPP testing revealed that HSC2 mice showed increased preference to the morphine-paired chamber compared to normal mice. Additionally, we observed no difference in ATF3 expression in TG of normal and tumor-growing mice suggesting that the tumor did not induce nerve-damage. However, we observed significant CGRP positive innervation within the tumor-tongue sections. In conclusion, the study characterizes a novel oral cancer pain model that

can be used to study the effect of novel analgesics for the treatment of oral cancer pain as well as determine mechanisms by which oral tumor activate the pain transduction pathway.

Title: Activation of membrane estrogen receptors rapidly attenuates opioid receptor-like 1 (ORL1) receptor-mediated modulation of nerve injury-induced hypersensitivity in the rat spinal cord

Authors: *D. M. HECKARD, S. S. MOKHA;
Meharry Med. Col., Nashville, TN

Abstract: Numerous studies report that women have a higher prevalence of chronic pain disorders than men. We have previously shown that estrogen attenuates opioid receptor like -1 (ORL1) receptor mediated thermal antinociception in females [Claiborne et al. J Neurosci. 26:13048-53, 2006]; and down regulates the ORL1 gene expression [Flores et al. Neurosci. 118:769-78, 2003]. Recently, we have shown that estrogen activation of membrane estrogen receptors (GPR30, Gq-mer, ER α, but not ER β) abolishes ORL1-mediated acute thermal antinociception via an ERK2-dependent non-genomic mechanism [Small et al. Neurosci. 255:177-190, 2013]. However, the role of membrane estrogen receptors (mERs) in modulating opioid receptor -mediated attenuation of neuropathic pain is unknown. Thus, the present study investigated whether activation of mERs attenuates ORL1-mediated modulation of nerve injury-induced mechanical hypersensitivity. We employed the spared nerve injury (SNI) model as previously described by Decosterd and Woolf [Pain. 87:149-58, 2000] to induce mechanical hypersensitivity in male and OVX female Sprague Dawley rats. Paw withdrawal thresholds (PWTs) were recorded using an automated dynamic plantar aesthesiometer. After a 7-day recovery period, sham and SNI rats were intrathecally administered E2BSA, a membrane impermeable analog of estradiol (E2BSA), or a selective mER agonist immediately followed by

OFQ, the endogenous ligand for the ORL1 receptor, into the lumbosacral spinal cord of rats through an implanted PE-10 cannula. SNI significantly reduced PWTs in both males and OVX females. Intrathecal administration of OFQ significantly increased PWTs in both males and OVX females. E2BSA as well as selective mER activation abolished OFQ-induced increase in PWTs. Thus, we conclude that activation of mERs rapidly attenuates ORL1-mediated modulation of nerve injury-induced mechanical hypersensitivity which provides evidence of a biological mechanism that increases female vulnerability to the development of chronic pain disorders.

Title: Connotative meaning of the concepts of lumbago and sciatica in patients with chronic lumbar pain through a model of Natural Semantic Network

Authors: R. CORONADO-ZARCO[1], E. CRUZ-MEDINA[2], *I. ZARCO DE CORONADO[4], S. I. MACÍAS-HERNÁNDEZ[3];
[1]Rehabilitación Ortopédica, [2]Rehabilitación ortopédica, [3]rehabilitación ortopédica, Inst. Nacional de Rehabilitación, México, Mexico; [4]UNAM, Mexico DF, Mexico

Abstract: A Natural semantic network (RSN)is a series of processes that a person integrate about words, verbal symbols, meanings and references to create productive and generative concepts that should modify individual´s behavior. Patients with low back pain require not only knowledge but also acceptance of their condition in order to comply with treatment, so we considered the identification of the connotative meaning of "lumbago" and "sciatica" with a RSN in patients with lumbar spine pathology. Design: Cross sectional study. Setting: Spine Rehabilitation Service, Mexico City. Participants: A total of 203 surveys were applied to the service patients, 111 women, 93 men with a mean age of 44.4 years. Main Outcome Measures: In the survey were provided in The stimulus "lumbago" and "sciatica" words, and asked patients to relate to other 5 words from arbitrary form and then rank them in order of importance. Frequency of mention (J) was determined, group consensus (C10), semantic memory association, semantic weight (M) and percentage of defining words. **Results**: Value J: 164 for lumbago, 195 for sciatica; C10: 33.1for lumbago and 26.9 for sciatica; Value M: lumbago (Pain 1793, spine

623, back 466, discomfort 405lumbar 264) Sciatica (Pain 1573, nerve 947, leg 560); Median: 14.6 lumbago 18.0/sciatica; Range:9.2-88.2 lumbago / Sciatica 14.7-119 (p = 0.315, u = 36). Lumbago PV / S (Median 14.4/13.8, Rank 10.8-88.3/8.9-86.6 (p = 0.684;U = 44) Sciatica PV / S (Median 7.4/6.9, Rank 8.1-46.1/5.1-42.1 (p =0.436 , U = 39).**Conclusion**: There is no difference in the conceptualization of the terms. Therefore it is necessary to emphasize patient´s education with the modification of these concepts to promote behavioral changes that improve adherence to treatment

Title: Post-ganglion spinal nverve injury causes more severe radiculopathy: from humans to animal studies

Authors: *J.-H. LIN[1,3,2,4,5], Y.-W. YU[3], C.-C. CHEN[4,5], Y.-H. CHIANG[3,2];
[2]Dept. of Neurosurg., [1]Taipei Med. Univ. Hosp., Taipei, Taiwan; [3]Grad. Inst. of Neural Regenerative Med., Taipei Med. Univ., Taipei, Taiwan; [4]Inst. of Biomed. Sciences, Academia Sinica, Taipei, Taiwan; [5]Taiwan Mouse Clinic- Natl. Comprehensive Phenotyping and Drug Testing Ctr., Academia Sinica, Taipei, Taiwan

Abstract: Introduction: Lumbar spinal stenosis (LSS) resulting in lumbar radiculopathy can be anatomically classified as central lumbar spinal stenosis (CLSS) and lateral lumbar spinal stenosis (LLSS). CLSS comprises the preganglion part of the spinal nerve, while LLSS comprises the ganglionic and postganglionic parts. Lumbar radiculopathy has been reported much more severe in LLSS than in CLSS. Accordingly, we argued it is the site of nerve injury that determines the severity of lumbar radiculopathy. The aims of this study is to compare the sensory phenotype and pain scores between patients with CLSS or LLSS and to compare the pain behaviors between animals with the pre- or post-ganglionic spinal nerve injury. Materials & methods: The clinical study prospectively included patients who had degenerative spinal disorders on L4/5 or L5/S1 levels with/without unilateral L5 radicular pain. The compressing pathologies on L5 nerve root were divided into 2 categories: central spinal stenosis, or lateral spinal stenosis. The sensory examination included warm, cold, static mechanical, vibration, and

dynamic mechanical sensation on the foot dorsum ipsilateral to the pathology, and the foot dorsum contralateral to the pathology on the images served as the control. The association between the sensory examination and the compression sites was analyzed. Then, we established two animal models of lumbar radiculopathy- pre-ganglion and post-ganglion injury to identify the differences between in terms of von Frey filament test, and incapacitance test for assessing mechanical hyperalgesia and spontaneous pain, respectively. Results: Forty-eight patients met the inclusion criteria. The incidences of compressing pathology were 42% (20/48) with central spinal stenosis and 58% (28/48) with lateral spinal stenosis. There were 54% (26/48) patients with impaired warm sensation, 45% (22/48) with impaired cold sensation, 27.78% (10/36) with impaired static mechanical stimuli, and 39.58% (19/48) with impaired dynamic mechanical stimuli. The presence of sensory deficit was highly associated with lateral spinal stenosis ($p=0.0023$) with 78.5% sensitivity and 65% specificity. In animal study, the postganglion group showed more severe and persisted course of hypersensitivity both in von Frey test and incapacitance test. This phenomenon last at least for 12 weeks. Conclusion: The results of the present study showed patients with LLSS had more severe lumbar radiculopathy. In similarity, our results of animal study also showed animals with post-ganglion injury had more severe hypersensitivity. As a result, the post-ganglionic spinal nerve injury may cause more severe lumbar radiculopathy.

Title: Assessment of gait deficiencies to provide a functional endpoint in the spinal nerve ligation model and spared nerve injury model in rats

Authors: A. NURMI, *L. TOLPPANEN, T. HEIKKINEN, R. HODGSON, A.-M. ZAINANA; Charles River Discovery Services, Kuopio, Finland

Abstract: Nerve compression, damage to peripheral nerves or damage to spinal nerves often results in chronic neuropathic pain. There are multiple rodent models to model neuropathic pain, which are widely used in research and drug development to understand the biology/pathology of this condition and also to develop novel therapies to improve quality of life. Two rodent models used for neuropathic pain research, spinal nerve ligation (SNL) and spared nerve injury (SNI),

produce heightened sensitivity to painful stimuli. However, there has been relatively little that has been done to determine the extent to which SNL and SNI impair motor function in rodents. In this presentation we show how tactile and thermal stimuli are observed in these models over chronic follow-up period and how these symptoms respond to clinically used therapies against neuropathic pain. Since we have previously seen and reported gait changes in another type of model containing neuropathic pain symptoms, in neuritis model, we sought to characterize potential gait related changes and phenotypes for both of the models by using kinematic fine motor analysis. Sprague-Dawley rats were subjected to SNL and SNI according to previously described methods. In both models, the rats were allowed to recover from the surgery and were assessed for tactile and thermal allodynia symptoms over an 8-week follow-up period. Morphine, pregabaline and amitriptyline were dosed and tested for their efficacy to alleviate the symptoms in the end of chronic follow-up period. During the follow-up period, fine motor gait analysis was performed on the models to understand how spontaneous gait properties are affected in the models and what additional information they provide from the model besides classical stimulated sensory responses. In both of the models, SNL and SNI, models showed clear tactile allodynia. Thermal responses were found to be either transient or more variable than tactile allodynia seen in the model. Pharmacological treatments with morphine, pregabaline and amitriptyline showed expected reversal of the tactile allodynia. Results from the thermal allodynia were more variable in tests, both in the magnitude of thermal allodynia over time as well as responses to pharmacological treatments. When both models were assessed in fine motor gait analysis, we saw clearly altered gait parameters in rats subjected to SNL and SNI. These data provide more in depth insight to neuropathic pain models. Moreover, the use of gait as an endpoint provides a functional endpoint that significantly increases the utility of the model in its application to research and drug development.

Title: A novel model of spontaneous pain behaviors in rats generated by controllable electrical stimulation of the peripheral nerve

Authors: ***A. HARRIS**[1,2], A.-L. LI[3], M. M. KAJUMBA[2], J. N. STRAND[2], P. N. FUCHS[2], Y. B. PENG[2];
[1]Psychology, Tarleton State Univ., Fort Worth, TX; [2]Psychology, Univ. of Texas at Arlington, Arlington, TX; [3]Anesthesiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Neuropathic pain patients have described experiencing spontaneous pain attacks with shooting, stabbing, and burning qualities (Campbell & Meyer, 2006). Rodent models are either acute (inflammation by formalin) or cannot be manipulated *in vivo* by the experimenter during an experiment (nerve injury). We propose a novel model of spontaneous pain in rodents that can be manipulated throughout the course of an experiment; the cuff stimulating electrode model. Two soft implantable wires were unilaterally implanted at the L5 spinal nerve location in 15 Sprague-Dawley rats. Seven animals were excluded due to nerve damage. After recovery, our custom-built wireless stimulating device (Zuo et al, 2012) was attached to the wires to deliver variable stimulations to the nerve in freely moving animals. A repeated measures ANOVA of data from the mechanical paw withdrawal threshold test of hypersensitivity confirmed that there was no hypersensitivity created by the surgical implant. A test of spontaneous pain behaviors was applied using the formalin scoring method (up, down, & lick) during stimulation. Stimulations were applied for 10 seconds with 1 minute of rest over 10 trials. Higher stimulation parameters yielded a significant increase in spontaneous pain behaviors ($p<.05$) while low parameters did not. Even further, high parameter stimulation resulted in spontaneous pain behaviors that persisted into the 5 minute resting period when no stimulation was applied. A modified Place Escape Avoidance Paradigm was used to measure the unpleasantness of stimulation. Stimulations were administered every 15 seconds for a 30 minute period: high electrical stimulations (100Hz, 1V, 10sec) were delivered while animals were on the dark, naturally preferred half of a testing chamber and low stimulations (50 Hz, .5V, 10sec) were applied while animals were on the light side. Repeated measures ANOVA indicated that while animals did not spend increasingly more time choosing to receive lower stimulation, the average time spent on the light side of the chamber was consistent with previously published results for animals with a pain model. We conclude that our model can be used to study spontaneous pain behaviors in freely moving rodents when stimulation is administered at the high parameter (100 Hz, 1V). Benefits of the model include: (1) the ability of the experimenter to manipulate spontaneous input to investigate spontaneous pain behaviors (2) reduce the number of animal controls that are needed because varying degrees of pain can be studied within the same animal and (3) to investigate the complex relationship between peripheral input and brain activity to create dynamic response profiles.

Title: NeuroDigm GEL(TM) model of neuropathic pain in rats: a nonsurgical model with an analgesic profile as seen in man

Authors: *D. A. FITTS[1], J. L. BRYANT[2], M. R. HANNAMAN[3];
[1]Univ. Of Washington (retired), Arlington, WA; [2]Inst. of Human Virology, Univ. of Maryland, College Park, MD; [3]NeuroDigm Corp., Colorado Springs, CO

Abstract: A percutaneous placement of a physiologic gel near a peripheral nerve gradually induces known neuropathic pain behaviors. Rats were given gel injections in the tibial nerve tunnel on the left (ipsilateral) lower leg (GEL group, n = 14), injections of physiologic Ringer's Lactate Ph 7.4 on the same side (Sham group, n = 8) or no injection (Control group, n = 11). Paw-withdrawal responses to application of 3 von Frey fibers, a sable brush, and pinprick were tested on both hind paws on 4 pretreatment baseline days and periodically on 36 days between the treatment day 0 and post-treatment day 149. An increase in paw withdrawals to the chosen stimuli is considered neuropathic pain behavior. There were 3 time periods of screening in the 5 months with the same 4 analgesics: morphine sulfate 3 mg/kg, celecoxib 10 mg/kg, gabapentin 25 mg/kg, or duloxetine 10 mg/kg. Static (von Frey fibers) and dynamic (brush) mechanical allodynia and mechanical hyperalgesia (pinprick) emerged in the GEL group after 23 days on the ipsilateral side and to a lesser extent and after 72 days on the contralateral side. The paw-withdrawal response to pinprick was robust, occurred in every Gel-injected animal, and persisted throughout the 149 days. Morphine was effective in reducing paw withdrawal responses early but not late in the post-treatment period. Celecoxib was ineffective. Gabapentin and duloxetine were both effective throughout the post treatment period. The pattern of development of ipsilateral and contralateral symptoms, the persistence of symptoms for months, and the analgesic profiles of response and dosage closely model human neuropathic pain.

Abstract: In this prospective multi-center validation study the burrowing paradigm was validated across 8 centers in Europe, USA and Japan using a standardized protocol in a Complete Freund's Adjuvant model (CFA) for inflammatory pain. Burrowing is an ethologically relevant rodent behavior, suppressed by pain and other conditions, and considered an important non-evoked readout for ongoing pain. Methods: Participating labs followed a standardized burrowing protocol designed according to ARRIVE Guidelines. Burrowing performance was measured by the weight of substrate left in a hollow tube after 60 minutes exposure. Male rats were given daily burrowing sessions for 2-4 days in pairs after which individual baseline burrowing scores were taken (2-3 days). Following baseline, animals where randomly allocated to one of three

groups: Naïve (untreated), Sham (vehicle -100 µl 0.9% saline i. pl.), or CFA (100 µg (100 µl @ [1 mg/ml]) i. pl.). Burrowing was tested on post treatment days 1, 2, 3, 7 and 10. Data were centrally captured, monitored and checked, including minor protocol variations permitted for local expediency. Data were analyzed by a restricted maximum likelihood (REML)-based mixed model for repeated measures (MMRM) approach. Results: 11 studies at 8 different laboratories were included, with a total of 104 CFA treated rats, 96 sham treated and 49 naïve. The analyses of change from baseline over time in burrowing score provided a consistent picture (including and excluding Lab ID as explanatory factor). In all analyses there was a significant difference between CFA and control (sham or naïve) in change in burrowing score at day 1 after injection and the CFA difference decreased over time. Lab ID was statistically significant when included in the model, but when adjusted for Lab ID, the estimates of change from baseline showed similar patterns in both analyses, suggesting the burrowing effect seen in the CFA model is robust across laboratories. The baseline score-by-time interaction was not significant, while all other fixed effects contributed statistically significantly. In addition, burrowing scores have been investigated for the most important explanatory factors based on descriptive statistics, as no statistical hypothesis testing was possible due to study design. Conclusion: A robust and positive replication of the CFA effect on burrowing behaviour across centres was observed and the timescale of effects is compatible with what is known of biology of CFA effects. In preclinical settings this multi-center validation approach is unique, in contrast to the usual ad-hoc replication which is haphazard and subject to publication and single center bias.

Title: Meningeal application of low pH, IL-6 and allyl isothiocyanate produces migraine-related behavior in mice

Authors: ***C. C. BURGOS-VEGA**[1], G. TREVISAN[3], L. QUIGLEY[2], T. PRICE[2], G. DUSSOR[2];

[2]Brain & Behavior Sci., [1]UT DALLAS, Dallas, TX; [3]Federal Univ. of Santa Maria, Santa Maria, Brazil

Abstract: Migraine headache is the most prevalent neurological disorder but the pathophysiology contributing to the development and progression of the condition is not well understood. Current pharmacological treatments are inadequate at managing the complex symptomology experienced by migraine sufferers and thus new therapeutics are needed. Increasing amounts of evidence suggest that nociceptor activation in the meninges plays a role in migraine pain. Identification of mechanisms leading to activation/sensitization of these neurons may provide targets for novel migraine therapeutics. Previous work in rat models of migraine pain has found that stimulation of the dura produces afferent input to the central nervous system leading to headache-like behaviors (cutaneous allodynia). However, development of a mouse model of headache using dural stimulation would allow the use of genetic tools for target identification that do not exist in rats. The intent of these studies was to determine whether exposure of mouse dura to stimuli that have been shown to produce headache behaviors in rats (low pH, IL-6, and 10% Allyl isothiocyanate (AITC)) produce similar responses in mice. Male ICR mice were acclimated to testing chambers for 2-3 days for approximately 2 hours a day. Prior to injection, baseline facial and hindpaw thresholds were recorded for each animal. The junction of the saggital and lambdoidal sutures was identified and this junction was used for injection of solutions onto the dura using a 0.5 mm injector designed to penetrate the skull but not damage the dura. The mice were under light isofluorane anesthesia for less than 2 minutes and injections of 5 µl were administered onto the dura. The animals were then returned to the testing boxes. Following administration, facial and hindpaw thresholds were measured at 1,3, 5 and 24 hours post-injection using the Von Frey up down method of testing. Dural application of pH 6.0, IL-6, and 10% AITC produced facial and hindpaw allodynia, lasting up to 24 hours, that was not present in animals given vehicle injections. These data show that stimulation of dural afferents in mice with pH 6.0, IL-6, and AITC produce headache-like behaviors similar to those previously demonstrated in rats. Further, they suggest that mice are a suitable species for behavioral testing of headache following stimulation of the dura mater.

Title: EEG analysis of a rodent headache model

Authors: A. MELO-CARRILLO[1], R. NOSEDA[1], F. J. FLORES[2], R. BURSTEIN[1], *A. M. STRASSMAN[1];
[1]Dept. Anesthesia, Beth Israel Deaconess Med. Ctr., Boston, MA; [2]MIT, Cambridge, MA

Abstract: In a new behavioral model of ongoing headache pain, Melo-Carrillo and Lopez-Avila found that application of inflammatory mediators to the cranial dura in rats produced a decrease in total exploratory behavior and a concomitant increase in resting behavior, during a 45-min. observation period, compared to saline control animals (Cephalalgia 33:1096, 2013). In the present study, we used EEG recording in this model to investigate whether the resting behavior of the stimulated animals differed from that of the control animals, despite being indistinguishable with video analysis. We hypothesized that, if the resting behavior of the stimulated animals represents a behavioral correlate of headache, then it constitutes a different behavioral state than the resting behavior of control animals. Specifically, we hypothesized that the EEG would lack the increased slow wave activity that would be expected during normal resting and transition to sleep, and would instead display signs of arousal that do not normally accompany periods of behavioral quiescence in control animals. Following a 5-day pre-surgery habituation period, male Sprague-Dawley rats (250-300g) maintained on an inverted light-dark cycle were chronically implanted with a cannula sterotaxically positioned over a 1-mm diameter craniotomy in the frontal bone, as well as EEG electrodes. After a 2-day recovery, 2ul of a mixture of inflammatory mediators (histamine, serotonin, bradykinin 1mM, and prostaglandin E2 0.1mM) was delivered to the dura through the cannula. Control rats received saline. Video and EEG recordings were made for 15 min. before and 45 min. after the dural infusion. As observed previously, animals that received inflammatory mediators displayed more resting behavior than control animals. In both stimulated and control animals, the resting periods were accompanied by an increase in delta activity compared to the intervening periods of exploratory behavior, and this delta activity tended to increase over the course of each individual rest period. Preliminary analysis indicates that the resting behavior in the stimulated animals was accompanied by a similar level of slow wave activity, but an increased amount of activity in a band extending from the upper delta to the theta range, as compared to resting behavior in the control animals. Such a difference would be consistent with findings of EEG studies in human pain patients, and would support the hypothesis that the periods of behavioral quiescence in the stimulated animals represent a different state than the resting periods exhibited by control animals.

Title: Development of a conditioned place preference model to evaluate post-TBI headache in rats

Authors: *J. SAGEN[1], S. JERGOVA[1], D. HOPMAN[1,3], J. MATOS[2], O. FURONES-ALONSO[1], H. BRAMLETT[1], S. IZENWASSER[2];

Abstract: Headache pain is a common symptom following traumatic brain injury (TBI), with a significant patient population continuing to experience recurring or persistent headaches for years. Although widely accepted rodent models for TBI exist, they have not been utilized in evaluation of headache pain or exploration of effective treatment strategies. Therefore the goal of this study was to establish a predictive rat model for evaluating post-TBI headache. A novel conditioned place preference (CPP) model was established to reflect headache pain as experienced by the patient, utilizing common headache triggers such as bright light. Behavioral manifestation of headache like symptoms in the form of facial allodynia also was evaluated. The fluid percussion injury model is widely accepted as a clinically relevant model for TBI in that it produces cognitive and motor deficits consistent with TBI injury severity and clinical observations. The right parietal cortex was partially exposed by craniotomy in male rats and a fluid percussion device was used to induce moderate TBI. Sham rats underwent the same procedures omitting the injury. Two weeks post TBI/sham surgery animals were evaluated for the presence of headache-like behavior by a CPP setup. Cages with white walls on one side and striped black and white walls on the other side were used with a bright light over the white side of the cage. The time spent on each side was measured over a 20 minute period (pretest). Next a divider was inserted in the middle of the cage and animals were conditioned for the dark side

with no food, and the light side with food. After 5 days of conditioning, the divider was removed and the same conditions as during the pretest were used to evaluate time spent on each side (posttest). Sham animals spent significantly more time in the white side of the cage with bright light on during the posttest as compared to pretest and compared to TBI animals, indicating development of CPP. TBI rats preferred to stay in the dark side. However, when the posttest was run with the light off, TBI rats showed a preference for the side originally paired with food, suggesting that the light was aversive. Pre-treatment with sumatriptan, a drug used clinically for treatment of migraine headaches, reversed bright light avoidance in TBI animals. Facial allodynia was evaluated in animals after 30 min of exposure to light. Most of the TBI animals that developed light aversion also were sensitive to nonnoxious stimulation with Von Frey hairs in the periocular and forehead region. These results suggest that TBI may induce headache-like behavior and that our model of CPP may be suitable for future studies of experimental treatment of post-TBI headache.

Title: Optogenetic investigation of the MRGPRD nociceptors in behaving transgenic mice

Authors: *I. DAOU, A. R. ASE, P. SEGUELA;
Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Primary afferents consist of a heterogeneous population of peripheral neurons. Nociceptors represent a subset of sensory neurons responsible for detecting and transmitting pain signals from the periphery to the central nervous system. The molecular profiling of nociceptors

classifies them into smaller subpopulations associated with a variety of sensory functions and modalities. The Mas-related G protein-coupled receptor D (MRGPRD) is expressed in a population of nociceptive non-peptidergic polymodal C-fibers that largely overlaps with fibers expressing the purinoceptor P2X3. MRGPRD neurons are implicated in the detection of mechanical pain under normal and inflammatory conditions. The β-alanine-responsive subset of these neurons is also heat-sensitive and produces itch in response to β-alanine. Using the MRGPRD-CreERT2 mouse line (Wenqin Luo, U. Penn), we selectively delivered the excitatory opsin ChR2-EYFP to adult MRGPRD neurons by inducing its expression postnatally to overcome any developmental regulation of MRGPRD. This optogenetic approach allows us to manipulate this neuronal population with high spatio-temporal precision. EYFP fluorescence revealed efficient and selective expression of the transgenic opsin in dorsal root ganglia (DRG), trigeminal ganglia, sciatic nerve, glabrous skin and dorsal horn of the spinal cord. EYFP-labeled projections to the dorsal horn targeted lamina II, consistent with previous reports showing monosynaptic input from IB4-labeled MRGPRD+ afferents to second-order neurons in lamina II. Electrophysiological recordings on cultured DRG neurons showed blue light-evoked inward photocurrents with typical ChR2 kinetics, leading to reliable generation of action potentials. EYFP-expressing DRG neurons were also responsive to the P2X3 agonist αβmeATP, confirming the specific expression of ChR2 in non-peptidergic neurons. *In vitro* validation data translated *in vivo* into nocifensive behaviors as transdermal stimulation with acute blue light evoked hind paw withdrawal and licking. Further evaluation of this model is underway to investigate the role of the MRGPRD neuronal population in different sensory modalities and under chronic pain conditions. This work will contribute to expanding our knowledge on the functional diversity of somatosensory pathways and their involvement in nociceptive transduction and pain processing.

Title: Optogenetic inhibition of specific populations of sensory neurons mediating bladder nociception

Authors: *A. D. MICKLE[1], V. K. SAMINENI[2], S. PARK[3], M. PULLEN[2], J. GRAJALES-REYES[2], C. D. MORGEN[1], J. RODGERS[3], R. W. GEREAU, IV[2];

Abstract: Bladder pain is a cardinal sign of interstitial cystitis/bladder pain syndrome (IC/BPS); however, its pathophysiology is poorly understood. A greater understanding of the neuronal populations underlying IC/BPS would be greatly beneficial in the development of new treatments. Here, we used an optogenetic strategy to inhibit different populations of bladder afferents and characterize the influence that inhibition has on bladder nociception. We characterized two transgenic mouse lines expressing the light-activated proton pump, Archaerhodopsin (Arch), fused to EYFP. One line expressed Arch in Advillin+ neurons (all sensory neurons) and the other expresses Arch in Nav1.8+ neurons (nociceptors). Histological studies confirmed the expression of Arch-EYFP in the bladder-projecting sensory neurons. Electrophysiological analysis of sensory neurons from these mouse lines confirmed robust light-induced inhibition of action potential firing in cells expressing Arch-EYFP. To study the impact of optogenetic inactivation of these neuronal populations on bladder nociception, we assessed the visceromotor response (VMR) during graded bladder distension (20-60 mmHg), both prior to and during 532nm green laser stimulation of the bladder. In our preliminary studies, activation of Arch in both Advillin+ and Nav1.8+ bladder neuron populations decrease the visceromotor response (VMR) during graded bladder distension, suggesting activation of Arch in the subpopulation of Nav1.8+ expressing neurons causes a decrease in bladder sensitivity to nociceptive stimulation. Further studies utilizing this approach will help to elucidate the cellular basis of bladder pain in chronic bladder pain syndromes. This work is supported by an NIH Director's Transformative Research Award (TR01 NS081707) to RG and JR.

Title: Optogenetic inhibition of the corticalstriatal circuit intensifies sensory and affective symptoms of chronic neuropathic pain

Authors: *R. YANG, H. LIN, J. WANG, C. SU, T. R. MANDERS;
Anesthesiol., NYU Med. Sch., New York, NY

Abstract: Cortical mechanisms that regulate acute or chronic pain remain poorly understood. Optogenetic activation of the prefrontal cortex (PFC) has been shown to alleviate both sensory and affective effects of chronic pain (Lee et al. 2015). Furthermore, projections from the PFC to the nucleus accumbens (NAc) have been shown to mediate these pain-relieving effects. Thus, this corticostriatal circuit plays an important pain modulatory role. However, it is unclear whether this circuit is endogenously involved in pain regulation. To answer this question, we disrupted this circuit using an optogenetic strategy. We used halorhodopsin, a light activated chloride channel, to optogenetically inhibit the PFC and then selectively inhibit the axonal projection from the PFC to the NAc in rats that have chronic neuropathic pain. Our results reveal that inhibition of the PFC or its projection to the NAc heightens both sensory and affective symptoms pain. Thus, these results suggest that the corticostriatal circuit likely plays an important role in endogenous pain regulation.

Title: A mouse model of oxaliplatin-induced neuropathic pain

Authors: *T. T. AHTONIEMI, A.-M. ZAINANA, L. KOISTINEN, R. HODGSON, A. NURMI;
Charles River Discovery Res. Services, Kuopio, Finland

Abstract: Neuropathic pain is globally a significant factor resulting in decreased quality of life. Causes as well as symptoms of neuropathic pain are diverse ranging from numbness to tingling, touch sensitivity and sensitivity to cold or warm temperatures. As many of the chemotherapeutic drugs such as platin-based compounds are also neurotoxic, they are often associated with neuropathic pain during and after therapy. To model platin-based chemotherapy induced neuropathic pain in rodents we established and validated a sustained chronic model of oxaliplatin-induced neuropathic pain in mice which suffer from cool/cold allodynia. Mice were treated withoxaliplatin (3 mg/kg; i.v.) or vehicle every 3 days for 27 days. After a stabilization period of one week after discontinuation of the oxaliplatin the mice were tested weekly for their sensitivity for cool/cold allodynia until 110 days after the induction of the model. A tail flick test was performed by submerging the tail in +15°C water and measuring the flick response latency. An acetone test was performed during the follow-up period by measuring response (flicking, shaking and licking) duration when cool stimulus (acetone drop) was placed on dorsal side of the hind paw. Pregabaline, an antiepileptic drug and duloxetine, a selective noradrenaline reuptake inhibitor (SNRI), were tested for their ability to alleviate the cool allodynia symptoms. At the baseline, mice showed normal responses to cool/cold stimuli. Oxaliplatin challenge induced both acute and chronic cool allodynia symptoms during and after the induction phase. Cool allodynia was seen in tail flick and acetone tests and was persistent until 110 days. Pregabaline (20, 40 and 80 mg/kg) and duloxetine (1, 3 and 10 mg/kg) were effective in the acetone test, but in the tail flick test results were more variable or not significantly analgesic. These data demonstrate the utility of oxaliplatin treatment as a model of chemotherapy-induced neuropathic pain with the presentation of cool/cold allodynia symptoms. Moreover, the duloxetine and pregabaline demonstrate the utility of this model for the development of novel treatments.

Title: Short-term sleep disturbance-induced stress does not affect basal pain perception, but does delay postsurgical pain recovery

Authors: *Y. TAO, P.-K. WANG, J. CAO, L. LIANG, B. M. LUTZ, A. BEKKER;
Dept. of Anesthesiol., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Chronic sleep disturbance-induced stress is known to increase basal pain sensitivity. However, most surgical patients frequently report short-term sleep disturbance/deprivation during pre- and post-operation periods and have normal pain perception pre-surgery. Whether this short-term sleep disturbance affects postsurgical pain is elusive. We here reported that pre- or post-exposure to rapid eye movement sleep disturbance (REMSD) 6 h daily for 3 consecutive days did not alter basal responses to mechanical, heat, and cold stimuli, but did delay recovery in incision-induced reductions in paw withdrawal threshold to mechanical stimulation and paw withdrawal latencies to heat and cold stimuli on the ipsilateral side of male or female rats. This short-term REMSD led to stress evidenced by an increase in swim immobility time, a decrease in sucrose consumption, and an elevation in the level of corticosterone in serum. Blocking this stress via intrathecal RU38486 or bilateral adrenalectomy abolished REMSD-caused delay in recovery of incision-induced reductions in behavioral responses to mechanical, heat, and cold stimuli.

Title: Endothelin-type A receptors are necessary for pain hypersensitivity in a mouse model of Sickle Cell Disease

Authors: *B. LUTZ, Y.-X. TAO;
Anesthesiol., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: Sickle Cell Disease (SCD), a hemoglobinopathy resulting in a mutated β globin gene, is associated with acute painful episodes and persistent intractable pain. Both adults and children report chronic pain symptoms that are severe enough to require long-term opioid therapy. Endothelin-1, a known pain inducer, is elevated in the blood plasma of both SCD patients and SCD mouse models. Endothelin-1 binds to Endothelin-type A receptors and Endothelin-type B receptors. In dorsal root ganglion (DRG), ETA receptors are found in the neurons, while ETB receptors are found in the surrounding satellite cells. We hypothesize that ET-1 binding to ETA receptors on peripheral nerve terminals initiates nociceptor sensitization which contributes to chronic pain in a mouse model of SCD. Mechanical, thermal, and cold sensitivity were assessed in 6 months old HBSS-BERK (SCD) and HBAA control mice before and after exposure to hypoxia with and without the addition of the ETA receptor antagonist, ABT-627. Additionally, a DRG-specific genetic knockout of ETA receptors underwent total body irradiation and bone marrow transplantation (BMT) using HBSS and HBAA bone marrow. The resulting ETA receptor knockout mice expressed human sickle β globin (HBSS marrow recipients) or normal human β globin (HBAA marrow recipients). Pain behavior was assessed in these mice before BMT, after BMT, and after hypoxia. Our results show that HBSS mice possess basal pain hypersensitivity that is exacerbated after 3 hours of exposure to a hypoxic environment. Subcutaneous injection of ABT-627 attenuated basal and hypoxia-exacerbated pain hypersensitivity in HBSS mice. Additionally, DRG ETA receptor knockout mice transplanted with HBSS bone marrow showed less basal and hypoxia-induced pain hypersensitivity compared to ETA $^{flox/flox}$ mice transplanted with HBAA bone marrow. Our findings indicate that ETA receptors are necessary for pain hypersensitivity observed in SCD mice.

Title: Continuous home cage monitoring of wheel-running in male and female rats: A clinically relevant method to assess nociception

Authors: *R. KANDASAMY[1], J. J. CALSBEEK[2], M. M. MORGAN[2];
[1]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA; [2]Psychology, Washington State Univ. Vancouver, Vancouver, WA

Abstract: Failures in analgesic drug development have raised concern over the translatability of nociceptive research in animals. Part of the problem is that a decrease in activity is often used to evaluate pain in patients, whereas nociception in animal studies is commonly assessed with acute noxious stimuli such as the hot plate and tail flick tests. Such pain-evoked tests do not mimic the disruptive effects of pain on daily life, thus pain-depressed tests have been developed to address this issue. The present study expands on this approach by examining depression of wheel-running. Wheel-running is a natural rodent behavior that can be assessed in the rat's home cage (a low-stress environment) 24 hours a day. If depression of wheel-running mimics the effects of pain in humans, then the induction of inflammatory pain should depress wheel-running, and this reduction should be greater in female compared to male rats (human data reveal a greater prevalence of chronic pain in women). Male and female rats were group housed by sex until at least age 50 days prior to the experiment. Rats were transferred to individual cages with a running wheel where they remained for the rest of the experiment. Rats were allowed free access to the wheel 23 hours/day for either 3 or 8 days prior to the induction of hindpaw inflammation. Wheel-running during the 23 hours immediately prior to induction of inflammation was used as the baseline. Inflammation was induced with an intraplantar injection of Complete Freund's Adjuvant (CFA; 0.1 mL) into the right hindpaw. Rats were removed from the home cage for one hour each day to assess nociception using mechanical and thermal pain-evoked tests (von Frey and Hargreaves, respectively). Baseline wheel-running was greater in female (2609 revolutions) compared to male rats (824 revolutions), and following 8 compared to 3 days of prior exposure to the wheel (2268 vs. 1627 revolutions). CFA almost completely inhibited wheel-running in male and female rats in the 23 hours following administration. Wheel-running recovered to near baseline levels by Day 3 in male rats, whereas recovery of wheel-running took 4 days in female rats. Withdrawal thresholds for the mechanical and thermal evoked tests were low across the entire 4 days of testing. These data demonstrate that depression of wheel-running mimics the effects of pain in humans in two important ways: Induction of inflammatory pain reduces daily activity, and this depression of behavior is enhanced in females compared to males. Taken together, our results suggest that continuous monitoring of wheel-running activity provides a novel, simple, and reliable way to assess nociception in male and female rats.

School, Rutgers, Newark, NJ; [4]Anesthesiol. and Critical Care Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [5]Anat., Col. of Basic Medicine, Zhengzhou Univ., Zhengzhou, China

Abstract: It has been reported that chronic stress increases basal pain sensitivity and/or exacerbates existing persistent pain. Nevertheless, the majority of surgical patients are under normal physiological and psychological conditions and have normal pain perception before surgery although they have short-term stress during perioperative period. Whether or not this short-term stress affects persistent postsurgical pain is unclear. We reported here that pre- or post-exposure to immobilization or forced swimming 6 h daily for 3 consecutive days did not change basal responses to mechanical, heat, and cold stimuli, but did exacerbate postsurgical pain evidenced by delaying recovery in incision-induced reductions in pain withdrawal threshold to mechanical stimulation and paw withdrawal latencies to heat and cold stimuli on the ipsilateral side of male or female rats. This short-term immobilization produced stress demonstrated by an increase in swim immobility time, a decrease in sucrose consumption, and an elevation in the level of corticosterone in serum. Attenuating this stress via intrathecal a selective glucocorticoid receptor antagonist RU38486 or bilateral adrenalectomy abolished stress-caused delay in recovery of incision-induced reductions in behavioral responses to mechanical, heat, and cold stimuli. Our results indicate that short-term stress during perioperative period worsens postoperative pain although it does not affect basal pain perception. Prevention of short-term stress may help the recovery of postoperative pain in patients.

Title: Intense and mild stress can cause stress-induced analgesia on the formalin pain test two weeks after MRI restraint training

Authors: *L. A. LOW, L. C. BAUER, I. RAUF, L. HYSON, C. BUSHNELL;
Natl. Ctr. for Complementary and Integrative Hlth., Natl. Inst. of Health/NCCIH, Bethesda, MD

Abstract: Aim Functional MR imaging of awake rodents is beginning to be utilized in pain research, but the training involves repeated physical restraint and can be stressful, potentially causing lasting effects on behavior and brain function. In this study, we replicated previously published fMRI restraint training protocols and investigated responses to the formalin pain test 12 days later. Methods: Male Long Evans rats (n=12 per group) were subject to one of the following treatments for 30 minutes per day on 3 consecutive days: 1) physical restraint plus loud (~90dB) MR scanner noise (R); 2) exposure to restraint equipment plus quiet (15dB) scanner noise, performed in the same testing room as rats were previously restrained (NR); or 3) no restraint, no scanner noise (Control, C). On the third day, a noxious heat stimulus was applied via thermode to the left hind paw of R and NR rats (4 x 48°C for 32s, 36s ISI). Blood samples were taken at baseline, every day after restraint, and 24 hours post-restraint, and plasma corticosterone levels quantified by ELISA. Twelve days after the final restraint/handling session rats received 1% formalin (50µl) s.c. injection to the hindpaw and behavior was observed for 60 minutes. Pain behavior was quantified by calculation of a weighted pain score. Results: Restrained rats showed the highest corticosterone response after restraint compared to non-restrained and control animals (R = 189% of baseline, NR = 146% of baseline, C = 125% of baseline, $p<0.0001$). All animals showed an increase in stress hormone after brief restraint and thermode application on day 3 (R = 256% of baseline, NR = 206% of baseline, C = 171% of baseline, $p<0.0001$). When subject to the formalin pain test 12 days after the final restraint, both R and NR groups showed significantly lower weighted pain scores on the formalin test compared to controls (R= 0.23, NR = 0.23, C = 0.47; $p<0.0001$). Conclusions: Restraint causes increases in stress hormones. However, an increase is also seen in non-restrained animals exposed to olfactory cues from stressed animals. An acute nociceptive stimulus causes increases in stress hormones in all animals. Two weeks after restraint, previously restrained and non-restrained animals both show similar reductions in pain behaviors on the formalin test relative to controls,

suggesting a long-lasting form of stress-induced analgesia. Researchers studying nociception should be aware that both intense and mild stressors can have pronounced and lasting effects on pain behaviors.

Title: Evaluation of the antinociceptive and anti-inflammatory effect and gastric safety of the combination of docosahexaenoic acid and naproxen in rats

Authors: *A. G. ARROYO LIRA, E. A. PINEDA PEÑA, A. E. CHÁVEZ PIÑA; ESCUELA NACIONAL DE MEDICINA Y Homeopatía DEL INST, Mexico, Mexico

Abstract: Naproxen is a traditional nonselective nonsteroidal anti-inflammatory drug (NSAID) prescribed in the management of pain and inflammatory diseases like arthritis. Nonetheless, like other traditional nonselective NSAIDs cause gastric damage and other side effects. In other hand, the use of combination of analgesics is a common practice intended to achieve one or more therapeutic goals; for example improving efficacy without increasing side effects. The aim of this work was to evaluate the antinociceptive and anti-inflammatory effect of oral administration of naproxen when is administered individually or in combination with docosahexaenoic acid (DHA), and define the gastric safety and pharmacodynamic interaction in the combination. Female Wistar rats were orally administered naproxen (10, 30, 100 and 300 mg/kg), DHA (56.23, 100, 177.83 and 316.23 mg/kg) the antinociceptive effect was evaluated with the formalin test and the anti-inflammatory effect was evaluated inducing the paw edema by carrageenan. Effective dose 30 (ED30) for naproxen and DHA was determined for their antinociceptive and anti-inflammatory effect, then the dose response curve for the combination of compounds in a fixed-dose ratio 1:3 was performed for the antinociceptive effect (6.80, 13.61,

27.21 and 54.42 mg/kg). Also for the anti-inflammatory effect the dose response curve for combination in a fixed-dose ratio 1:3 was performed (4.48, 8.96, 17.93 and 35.85 mg/kg). An isobolographic analysis was performed to characterize the pharmacodynamic interaction between naproxen and DHA. Gastric hemorrhagic lesions were measured for each group of rats. The antinociceptive ED30 values were 27.67±3.80 mg/kg, 134.83±27.72 mg/kg and 33.44±1.90 mg/kg p.o., for naproxen, DHA and the combination respectively; while theoretical ED30 of the combination was 54.42±7.49 mg/kg. Naproxen produced 30.91±5.73 mm2 of gastric damage, while the combination did not induce gastric damage. For the inflammatory effect, the ED30 values were 5.18±1.42 mg/kg, 127.88±12.47 mg/kg, and 12.33±4.61mg/kg p.o. respectively; the value of the theoretical ED30 of the combination was 35.86±3.29 mg/kg. The isobolographic analysis of the theoretical and experimental ED30 of the combination shows a synergistic interaction in the antinociceptive and anti-inflammatory effect. In conclusion, these data suggest that oral administration of naproxen-DHA combination induces a synergistic antinociceptive and anti-inflammatory effect and gastric safety.

Title: Effect of joint immobilization by cast on the pain threshold, the itch sensation and the negative component of pain

Authors: *K. NODA, M. OGATA, H. AKITA, H. ISHIBASHI;
Sch. Allied Hlth. Sci. Kitasato Univ., Sagamihara, Japan

Abstract: Immobilization of joint by cast is commonly used for resting the injured joint, but it often causes the reduction of pain threshold for mechanical stimuli. We have reported that the hyperalgesia induced by intraperitoneal injection of paclitaxel, one of the chemotherapeutic agents clinically used to treat several types of cancer, reduced the negative affective component of pain using a conditioned place aversion test (Noda et al., 2014). However, it remains unclear whether the cast-immobilization affects the emotional component of pain. Furthermore, although itching is a frustrating problem for a person with a cast, little is known about the effect of cast-immobilization on itch-associated response in experimental animals. In this study using rat, therefore, we examined whether the hypersensitivity induced by cast immobilization alters the

pain-induced place aversion and modulates itch sensation. To examine the effects of cast immobilization on pain- and itching-behaviors in rats, one hind limb was wrapped with a wire mesh to keep the ankle joint almost straight for 2 weeks and observation of behavior was conducted after cast removal for 3 weeks. The pain perception threshold to mechanical stimulation was measured by using calibrated von Frey filament test before and after cast immobilization. The joint immobilization elicited the reduction of the paw withdrawal threshold which continued almost over 10 days after cast removal. The serotonin-induced itch-associated response including licking and biting behavior was escalated when compared with sham-operated control rat. Surprisingly, the formalin-induced conditioned place aversion was decreased in the rats with the cast treatment. These results suggest that the joint-immobilization by the cast not only reduce the mechanical pain threshold but also facilitates itch sensation. On the other hand, the cast-immobilization may disturb to form the paired-associate learning between the painful stimulation-induced aversive emotion and the pain-conditioned environment.

Title: Radiculopathy induces spontaneous and reflex pain that is attenuated by meloxicam in a rat model of nerve root trauma

Authors: C. WEISSHAAR[1], B. PHILIPS[1], *B. A. WINKELSTEIN[2];
[2]Bioengineering, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Many rodent pain studies use reflex testing with mechanical and thermal stimuli to evoke pain responses. Yet, these testing methods do not measure aspects of spontaneous pain, particularly in the early time period following injury. The rat grimace scale (RGS) quantifies spontaneous pain after inflammatory, visceral, incision, and orthopedic injuries, incorporating observational ratings based on positioning of the eyes, nose, whiskers, and ears. Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used to relieve inflammatory and post-surgical pain in both human and veterinary patients. However, the effects of NSAIDs on spontaneous pain after radicular injury are unknown. The goal of this study was to evaluate if the NSAID,

meloxicam, alters spontaneous and reflex pain responses in a rat model of cervical radiculopathy. Accordingly, spontaneous pain behavior was quantified using RGS, and mechanical hyperalgesia was measured by reflex testing on the forepaw, after a transient C7 right dorsal nerve root compression (NRC; n=7). A separate group received meloxicam (2mg/kg in 1ml saline) subcutaneously immediately prior to application of the root compression (NRC+meloxicam; n=7). As controls, another group underwent surgery but no compression (sham; n=7). RGS was measured at baseline (before injury), and 3, 6, 24 and 48 hours after injury; ipsilateral forepaw mechanical hyperalgesia was assessed at baseline, and days 1, 3, 5, and 7. The RGS scores of NRC at 6 hours are significantly higher than those for NRC+meloxicam ($p=0.012$) and sham ($p=0.041$). Yet, by 24 hours, the RGS scores for all groups return to baseline, and are not different from each other. Meloxicam also significantly ($p<0.001$) attenuates mechanical hyperalgesia at days 1, 3, and 5 compared to a compression without treatment. Interestingly, despite the fact that RGS scores for all groups returned to baseline by 24 hours, overall mechanical hyperalgesia is significantly reduced by meloxicam treatment ($p<0.001$). Together, these results suggest that pre-treatment with an NSAID reduces both spontaneous and reflex pain behaviors in the early stages of radicular pain and longer-term reflex pain. However, the first 6 hours after injury, and in pain development, may be a critical window in which to capture elements of spontaneous pain by RGS after neuropathic injury. Although additional studies are needed to evaluate long-term spontaneous pain after radicular injury, these findings provide a better understanding of spontaneous pain in a rodent model of radiculopathy and may also offer a foundation for more effective timing in the treatment for radicular pain.

Title: Involvement of opioid or GABA systems in the ventrolateral periaqueductal gray on analgesia associated to tonic immobility

Authors: *A. M. PÁEZ[1,2], P. VÁZQUEZ LEÓN[2], C. CAMPOS-RODRÍGUEZ[2], E. RAMÍREZ SAN JUAN[2];

[1]Azcapotzalco, México D. F., Mexico; [2]Fisiología, Inst. Politécnico Nacional, México D. F., Mexico

Abstract: Ventrolateral periaqueductal gray (VL-PAG) contains key neuronal circuits related to analgesia and integrated defensive behaviors such as immobility response (IR) which is characterized by a reversible state of motor inhibition. One form of IR can be elicited in rat by touch, labyrinthine stimulation and restriction of movements called tonic immobility (TI) specifically immobility by clamping the neck (ICN). It is known that IR induced-analgesia could be elicited by manipulations or drugs acting at different levels of CNS. The aim of this study was assess the role of either opioid or GABA systems in the TI elicited-analgesia, particularly into VL-PAG. In present work, TI induced-analgesia in naive rats was assessed by tail-flick (TF) test, opioid systemically or into VL-PAG and GABAergic involvement into VL-PAG associated to TI induced-analgesia was assessed. We found that TI elicited-analgesia in naive rats, morphine either systemic or within VL-PAG increased both TF latency and TI duration separately and as well in time duration when occurred both responses simultaneously. On the other hand, naloxone injected systemically or locally into VL-PAG blocked significantly TI elicited-analgesia. Microinjection of muscimol into VL-PAG significantly reduced both TF latency and TI duration when occurred simultaneously, and bicuculline increased TF latency showing an analgesic effect when asses only TF, but not modified TI duration time when both responses occurred simultaneously. These data suggest that TI produce analgesia in rat; it is mediated by opioids at different levels of CNS but critically into VL-PAG, mainly by inhibition of intrinsic tonic GABAergic activity. The sum of effects of morphine or bicuculline and TI is unable to upgrade analgesic response or made it greater than likely, means certain upper limit in such conditions.

Abstract: Neuropathic pain (NP) is caused by a primary insult or dysfunction in the peripheral or central nervous system. The main symptoms are mechanical allodynia and hyperalgesia to both mechanical and thermal stimuli. NP often shows insufficient response to classic analgesics and remains a challenge to medical treatment and scientific research. The transcranial direct current stimulation (tDCS) is a non-invasive method of cerebral stimulation and represents a promising resource to pain management since it promotes neuroplasticity in the central system of pain and can be combined with other interventions. The aim of this study was to investigate the effects of tDCS in thermal and mechanical hyperalgesia induced by a NP model and in IL-1β, IL-10, and TNF-α levels in central nervous system structures. The chronic constriction injury (CCI) of sciatic nerve was used for the induction of NP. After the establishment of NP, the animals of treated groups were subjected to a 20 minutes session of anodal tDCS, every afternoon for eight days. The thermal hyperalgesia and mechanical allodynia were assessed by Hot plate (HP) and Von Frey (VF) tests, respectively, and evaluated on baseline, 7 and 14 days after surgery; immediately, 24 hours and 7 days after treatment. The IL-1β, IL-10 and TNF-α cortex, spinal cord and brainstem levels were determined by sandwich-ELISA at 48 hours and 7 days after the end of treatment. CCI model causes thermal and mechanical hyperalgesia until at least 30 days after the surgery; however, the anodal tDCS treatment was able to relieve the nociceptive behavior for up to 7 days after the treatment end. In summary, we showed that anodal tDCS is effective to relieve neuropathic pain and modulate cytokine in CCI rat model, and its effect is observed at long-term. Additionally, we observed an important role of the central immune system in the neuropathic process, which can be involved with the maladaptative neuroplastic changes.

Title: Itch-related scratching and alloknesis elicited by cinnamaldehyde in mice

Authors: *E. E. CARSTENS, M. IODI CARSTENS, T. NGUYEN;
Neurobiology, Physiol. & Behavior, Univ. California Davis, Davis, CA

Abstract: Scratching elicited by many non-histaminergic itch mediators requires coexpression of TRPA1 in pruriceptive nerve endings. The TRPA1 agonist cinnamaldehyde (CA) elicited itch in human skin (Namer et al., Neuroreport 16:955-9, 2005). We investigated if CA elicits itch-related scratching behavior in mice. Using C57BL6 mice, CA (1-40%) suspended in 5% or 10% Tween80 was delivered unilaterally to the cheek via intradermal injection (10 μL) or topical application. Animals were videotaped for 40 min and the number of discrete hindlimb scratch bouts or forelimb wipes directed to the treated cheek, as well as bilateral facial groom bouts, were scored offline by blinded observers. To test for alloknesis, 40% CA was applied to the rostral back (~1 mm2 area). At 5-min intervals, a von Frey monofilamant (0.7 mN bending force) was applied 3 times to mid- and lateral portions of the treated skin, and the occurrences of immediate hindlimb scratch bouts directed to the stimulus were counted to generate an alloknesis score (# scratch bouts/3). We also counted touch-evoked “wet dog shakes”. Intradermal cheek injection of CA elicited a significant ($F=3.2$, $p<0.05$, ANOVA), dose-dependent increase in number of scratch bouts, reaching a plateau at 5%. Scratching peaked at 10-25 min post-CA and then declined. No dose of CA significantly affected the number of forelimb wipes or groom bouts compared to vehicle injections (except reduced grooming at 20% CA). Topical cheek application of CA (30, 40%) did not elicit significant increases in hindlimb scratch bouts or forelimb wipes compared to vehicle treatments (all counts <10 per 40 min). However, mice exhibited significantly fewer groom bouts following 30 and 40% CA compared to vehicle.

Topical application of 40% CA to the rostral back did not elicit scratching per se. There was a trend toward increased alloknesis score ($p=0.077$, paired t-test) and a significant increase in wet dog shakes ($p<0.005$, paired t-test) vs. vehicle application. Touch-evoked wet dog shakes may represent another sign of alloknesis. Vehicle treatment also increased alloknesis scores starting 10 min post-application, but to a lesser extent than CA. CA presumably acts at TRPA1 in cutaneous nerve endings to elicit scratching and alloknesis. Scratching peaked at 5% CA, strikingly similar to the report that 5% CA elicits maximal itch on human skin (Holand et al., Acta Derm Venerol 2015). Another TRPA1 agonist, mustard oil, elicited wiping but not scratching (Spradley et al., Acta Derm Venereol 92:515-20, 2012). This suggests that there is a narrow concentration range over which TRPA1 agonists selectively activate pruriceptors.

Title: Is the chronic constriction injury model in the mouse an adequate screening model for analgesic activity?

Authors: *D. PUSHETT, E. ESNEAULT, C. LE CUDENNEC, B. HELARD, V. CASTAGNE; Porsolt SAS, Le-genest-saint-Isle, France

Abstract: Different models of neuropathies have been established in the rat and their effects after nociceptive stimulations are extensively described in the literature. However, similar murine models may be useful for proof-of-concept studies with transgenic animals or if there is limited availability of test substance. The objective of this study was to establish a neuropathic model in mice and to validate it pharmacologically. Mice were operated according to a modified protocol of the standard chronic constriction injury (CCI)/Bennett (i.e. three tied ligatures in the mouse instead of four in the rat). The mice (n=10) were then subjected to the electronic von Frey test to confirm the presence of tactile allodynia. The mice were subsequently evaluated using 3 additional pain endpoints: thermal and tactile hyperalgesia and thermal allodynia, using the plantar, pinchmeter, and cold plate tests, respectively. Analgesic effects of morphine and tramadol were investigated in this model. In the electronic von Frey test, the force inducing paw withdrawal was significantly decreased in the lesioned paw as compared to the non-lesioned paw and this difference was observed up to 25 days post-surgery. Morphine displayed an analgesic

effect whereas tramadol was inactive. In the plantar test, we observed significant differences between both hindpaws and significant effects of morphine and tramadol, however, we do not consider this test to be a robust enough evaluation in this model. In the pinchmeter test (alternative to the Randall & Selitto test) the force inducing withdrawal was significantly different between both paws. However this difference was not observed to persist for as long as tactile allodynia. Morphine and tramadol displayed analgesic effects against tactile hyperalgesia. In the cold plate test, sciatic nerve ligature resulted in the appearance of paw-withdrawal responses when a cold stimulus was applied to the lesioned paw of vehicle controls, whereas no responses were observed in the non-lesioned paw, indicating cold allodynia. However, neither morphine nor tramadol displayed significant analgesic effects in our experimental conditions. These results suggest that CCI surgery in the mouse clearly induces neuropathic pain and that electronic von Frey and pinchmeter tests can be used as endpoints in this model. The CCI model in the mouse is therefore a good model for screening for analgesic activity measured by tactile allodynia or hyperalgesia, prior to follow-up testing in the rat with additional endpoints.

Bacteriology, Okayama Univ. Grad. Sch. of Medicine, Dent. and Pharmaceut. Sci., Okayama, Japan; [4]Dept. of Orthodontics, Univ. of Florida, Gainesville, FL

Abstract: Many neuropathic pain patients suffer severe pain; however, available therapies are largely ineffective or inadequate. Peripheral nerve injury induces neuropathic pain states and hyperexcitability of neurons within sensory ganglia. Despite the absence of synaptic contacts in adult sensory ganglia, somata of sensory neurons can be transiently depolarized and cross-excited by activation of neighboring neurons within the same ganglion. In our previous *in vitro* study, neurotransmitter release from peripheral sensory ganglia was inhibited by purified botulinum neurotoxin type A (BoNT/A) administration. In the present study, we sought to modulate neurotransmitter release by direct application of BoNT/A to sensory ganglia in an animal model of neuropathic pain. We evaluated the pain behavior and motor behavior after the BoNT/A application. The peripheral neuropathy site was the right sciatic nerve (SNE). A flexible polyethylene cannula was attached to the L3 transverse process with cyanoacrylate adhesive, and the tip of the cannula was so placed to slightly touch the L4 dorsal root ganglia (DRG). BoNT/A was applied to the L4 DRG via this cannula. We measured the thermal stimulus threshold value of pain and the mechanical stimulation threshold to evaluate pain behavior. Thermal sensitivity testing was performed using the Hargreaves apparatus which measures the withdrawal latency from a radiant heat source directed at the proximal half of the plantar surface of each hindpaw. Mechanical sensitivity was assessed using the electronic von Frey hair pressure transducer. Also, we evaluated general motor function effects using a rotor rod apparatus following BoNT/A application. We measured the pain behavior and motor function of the rats before and after neuropathy surgery and BoNT/A administration. The main findings of this study are as follows: (i) SNE decreased the hindpaw withdrawal threshold to mechanical and withdrawal latency to thermal stimulation, and the direct application of BoNT/A to the L4 DRG counteracted these effects; (ii) The direct application of BoNT/A to the L4 DRG did not affect motor function.

Title: A role for neurokinin neurotransmission in forebrain septal region in nociception

Authors: *S. NG, S. KHANNA;
Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The septal region is implicated in affect. In context of nociception, both the medial (MS) and lateral septum (LS) have direct and indirect anatomical connections to cortical and sub-cortical regions, including the hippocampus and amygdala, which are key structures involved in the affective component of pain. Previously, we showed that the MS region mediates changes in the hippocampal pyramidal cell excitability and the nociceptive behaviors evoked on hind paw injection of the inflammatory algogen, formalin. In contrast, the role of LS in nociception is not well studied. Neurokinin-1 receptors (NK1R) are robustly expressed in the soma and dendrites of neurons in both the MS and LS. It is well established that spinal NK1R expressing neurons are critical in facilitating nociception. However, the role of septal neurokinins (NK) in acute and chronic pain remains unexplored. In the present study, we have investigated whether NK neurotransmission in the septal region influences indices of pain in male Sprague-Dawley rats. The role of NKs was inferred by investigating the effects of intraseptal microinjection of the NK1R antagonist, L-733,060 (0.0176 µg/µl and/or 0.176 µg/µl; 0.5 µl), on indices of nociception in the formalin model and the chronic constriction injury (CCI) model of neuropathic pain. In anaesthetized rats, microinjection of L-733,060 in MS, but not LS prevented or reversed formalin-induced suppression of hippocampal pyramidal cell excitability. However, formalin-induced theta activation was not altered by intraseptal L-733,060 in both anaesthetized and awake rats. On the other hand, L-733,060 microinjection in both MS and LS attenuated flinching, but not licking of the injured paw in phase two of the formalin test. In the context of CCI, intraseptal L-733,060 attenuated both mechanical allodynia and thermal hyperalgesia. In addition, L-733,060 administered into both MS and LS suppressed pERK activation in central amygdala that was normally observed in parallel with thermal hyperalgesia. These findings suggest that NK neurotransmission in both MS and LS mediates nociception. Especially, NK neurotransmission in the region sustains neuropathic peripheral hypersensitivity and the reflexive withdrawal of injured paw in the formalin model.

Title: A role for septal glutamatergic network in modulation of nociception

Authors: *K. IBRAHIM, S. KHANNA;
Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The forebrain region medial septum (MS) has been implicated in nociception. Indeed, we have reported previously that the inactivation of neural transmission in the MS led to an attenuation of nociception in the formalin model of persistent inflammatory pain. The MS region has a rich milieu of neurons that includes both intrinsic and projection glutamatergic neurons. The region, in addition, receives glutamatergic afferents. Evidences indicate that glutamatergic terminals in MS synapse with almost all type of neurons in the MS. Thus, the glutamatergic transmission in MS is likely to be ubiquitous. However, the role of the septal glutamatergic transmission in pain still remains unexplored. In the present study, we have investigated whether glutamatergic neurotransmission in the septal region influences nociception in male Sprague-Dawley rats. The role of glutamate was inferred by investigating the effects of intraseptal microinjection of NBQX (2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f]quinoxaline-2,3-dione; 10µg/µl-40µg/µl in 0.5µl), an antagonist at the AMPA glutamate receptor, on indices of nociception in the formalin model and the chronic constriction injury (CCI) model of neuropathic pain. Intraseptal microinjection of NBQX attenuated the hippocampal theta activation in a dose-dependent fashion in both anaesthetized and awake rat. A peak effect of NBQX on formalin (1.25%)-induced power of theta wave activity was observed at dose of 20µg/µl. Characterization in anaesthetized rat indicated that the dose of 20µg/µl was selective insofar it did not affect suppression of CA1 population spike even though it attenuated the power of theta evoked on indirect and direct stimulation of the MS. However, NBQX (20µg/µl) attenuated only flinching, but not licking of the injured paw in both phase 1 and 2 of the formalin test. In addition, the agent also partially attenuated peripheral hypersensitivity in the CCI model. Microinjection of NBQX at a higher dose (40µg/µl), though, affected both flinching and licking in the formalin test and reverse peripheral hypersensitivity in CCI model. These results suggest that glutamatergic neurotransmission in MS is recruited in nociception and sustains the nociceptive drive.

Title: A new pre-clinical animal model for oral ulcer pain following orthodontic wire appliance

Authors: M. ITO, K. ONO, S. HITOMI, K. YAMAGUCHI, T. KAWAMOTO, *K. INENAGA;
Kyushu Dent. Univ., Kitakyushu, Japan

Abstract: Orthodontic appliances frequently cause oral mucosal lesions, resulting in bacterial colonization, gingival inflammation and pain. However, little study has reported about the mechanisms underlying oral ulceration and subsequent pain induction in the orthodontic appliances. In the present study, we developed a new pre-clinical rat model for oral ulcer pain following an orthodontic wire appliance and evaluated ulceration in the oral mucosa and pain-related behavior. Under pentobarbital anesthesia, 8 week-old Wistar rats were installed with an arched orthodontic thick wire of 10 mm length between inferior incisors, soldered to a ligature wire. The sharp tip of the thick wire directly touched the labial fornix region of the oral mucosa. As control, a shorter thick wire (4 mm) was installed similarly without any contacts of the tip on the oral mucosa. Next day (day 1), severe oral ulcer was observed in the model rats and the wire was removed. The wire-induced oral ulcer was cured completely until day 5 after the procedure. In control group, there were no mucosal lesions. To evaluate pain induction in the model, we observed spontaneous mouth rubbing and facial wiping behaviors for 10 min on pre-procedure day and days 1-3 after the procedure. Compared with control group, the both behaviors were significantly enhanced in the oral ulcer model on day 1. The new pre-clinical animal model for orthodontic wire-induced oral ulcer pain can be utilized in evaluations of new drug treatments for oral ulcer pain in dental practices.

Title: Genotype-dependent exacerbation of nerve injury-induced pain, anxiety and depressive behaviour in rats

Authors: E. M. JENNINGS[1,2,3], N. N. BURKE[1,2,3], M. ROCHE[4,3,2], *D. P. FINN[3,1,2]; [1]Pharmacol. and Therapeut., [2]Ctr. of Pain Res., [4]Physiol., [3]Natl. Univ. Ireland, Galway, Galway, Ireland

Abstract: Numerous studies indicate a very high prevalence of chronic pain comorbid with anxiety disorders and depression (Asmundson and Katz, 2009, Bair et al., 2003). The relationship between altered emotional states and chronic pain disorders is complex and the bidirectional interplay between affective disorders and chronic pain is poorly understood. Wistar-Kyoto (WKY) rats are an inbred rat strain that demonstrate hyper-responsivity to stress, a depressive and anxiogenic phenotype, as well as enhanced nociceptive responding to visceral (O'Mahony et al., 2013), mechanical and inflammatory (Burke et al., 2010, Rea et al., 2014) stimuli, compared with Sprague-Dawley (SD) rats. The aim of this study was to investigate if WKY rats, as a model of trait negative affect, exhibit altered nociceptive behaviour and depressive- or anxiety-like behaviour following peripheral nerve injury, compared with SD counterparts. L5 spinal nerve ligation (SNL) resulted in prolonged (up to 30 days) mechanical and cold allodynia in adult male SD and WKY rats as measured by the von Frey and acetone drop tests, respectively. Prolonged SNL-induced heat hyperalgesia in the Hargreaves test was only observed in WKY, but not SD rats. Baseline testing showed that WKY rats displayed increased anxiety-like behaviour (reduced time in centre zone of the open field) compared to the SD rats. Post-SNL, both SD and WKY rats displayed increased anxiety-like behaviour compared to sham counterparts, but levels of anxiety-like behaviour were higher in WKY rats than in SD rats. WKY-sham rats spent more time immobile in the forced swim test versus SD-sham rats, indicating increased depressive-like behaviour. Immobility was greater in the WKY-SNL group versus the WKY-sham group, while no difference in immobility was observed between SD-sham and SD-SNL groups. In conclusion, these data suggest increased sensitivity to noxious heat, and increased anxiety- and depressive-like behaviour following peripheral nerve injury in a genotype (WKY) predisposed to negative affect.

Title: Peripheral serotonin evokes sexually dimorphic and estrous cycle dependent pain behaviors in male and female rats

Authors: W. L. BENTON[1], Y. J. LEE[1], R. H. BESHER[1], *D. L. AVERITT[2];
[1]Biol., [2]Texas Woman's Univ., Denton, TX

Abstract: Many persistent pain conditions occur predominantly in women making pain a major women's health issue. As the majority of pain research has been conducted in males, the mechanisms underlying pain in women are unclear. One theory for the prevalence of pain disorders in females is steroid hormone modulation of pain mechanisms. The monoamine neurotransmitter serotonin (5HT) has been highly implicated in various pain conditions that are more prevalent in women. Our recent studies found that peripheral 5HT (1) evokes pain via a subpopulation of trigeminal nociceptors expressing the transient receptor potential V1 channel (TRPV1) and (2) potentiates capsaicin-evoked proinflammatory peptide release from human tissue during the luteal phase of the menstrual cycle. No studies have yet examined the effect of steroid hormone modulation on 5HT-evoked pain behaviors in female rats. We hypothesized that peripheral 5HT evokes greater pain sensitivity in female rodents during stages of the estrous cycle when steroid hormones are fluctuating. Female Sprague-Dawley rats (250-350 g) from each stage of the estrous cycle (proestrus, estrus, diestrus 1 or diestrus 2) and intact males were acclimated to the testing apparatuses. Vaginal lavages were performed daily to determine the stage of estrous at the time of testing. Rats received an intraplantar hindpaw injection of 5HT (2 μg / 100uL) or saline (n = 6 per stage of estrous and sex) and pain behaviors were measured at 0, 10, 20 and 30 minutes post-injection. Thermal hyperalgesia was detected by measuring changes in paw withdrawal latencies to a noxious thermal stimulus using the Plantar Test (Ugo Basile). Mechanical allodynia was detected by measuring changes in force in grams to elicit paw withdrawal using the Dynamic Plantar Aesthesiometer (Ugo Basile). Here we report that female rats in proestrus and estrus exhibited significantly greater thermal hyperalgesia within 10 minutes of 5HT injection compared to males and diestrus females. Proestrus and estrus females also retained significant hyperalgesia at 20 minutes, while males and diestrus females returned to baseline. These data provide evidence of a modulatory role of steroid hormones on 5HT-evoked pain, which may underlie the greater prevalence of pain disorders in women. Our ongoing

studies are aimed at delineating the role of various 5HT receptors and the possible interaction with TRPV1 in female rats.

Title: Controlling transmission of sensory information by optical manipulation of the thalamo-cortical pathway in the anesthetized mouse

Authors: ***P. BORDEN**, A. D. ORTIZ, H. J. V. ZHENG, G. B. STANLEY;
Georgia Tech., Atlanta, GA

Abstract: The thalamus plays a vital role in processing and integrating both sensory afferent and motor efferent signals. Although previous work has shown that thalamic state has a dramatic effect on ongoing cortical state, it is not yet clear how this alters the transmission of sensory information to the cortex. The thalamic ventral posterior medial (VPm) region is a whisker driven excitatory region, which receives modulatory, polarizing inputs from many regions including cortex, brainstem, and other thalamic nuclei such as reticular thalamus, all of which may interact to set thalamic state and set the degree of synchronization and burst/tonic firing. Here, we directly determined how thalamic membrane potential alters downstream cortical processing of sensory signals, using a combination of electrophysiological recordings and optogenetic techniques in the anesthetized mouse lemniscal pathway. We performed simultaneous extracellular recording of thalamic (VPm) single units and wide-field voltage sensitive imaging of cortical spatiotemporal activity (S1 Barrel Field) while modulating thalamic membrane potential and stimulating the single whisker of the anesthetized mouse. We virally transfected young mice with optogenetic modulatory channels (ChR2, and eNph3.0) for direct manipulation of thalamic membrane potential. Our preliminary results suggest that the ongoing thalamic membrane potential dramatically alters the corresponding evoked cortical

spatialtemporal activity in a nonlinear fashion. In particular, by hyperpolarizing the thalamic membrane immediately prior to whisker stimulation, there is an observed increase in the corresponding cortical spatial response for all sensory stimuli. Additionally, hyperpolarization of the VPm thalamic membrane appears to shift the cortical velocity response curve by increasing the sensitivity to lower velocity stimuli. This effect, therefore is not simply adjusting the gain of the sensory information, but altering how sensory stimuli are encoded and transmitted to the cortex. This work is further evidence that the thalamus may not act as a passive relay, but instead as a dynamic filter, that controls how information is encoded and processed.

Title: Information coding through adaptive control of synchronized thalamic bursting

Authors: *C. WHITMIRE[1], C. WAIBLINGER[1], C. SCHWARZ[2], G. STANLEY[1];
[1]Wallace H Coulter Dept. of Biomedial Engin., Georgia Tech/Emory, Atlanta, GA; [2]Hertie Inst. for Clin. Brain Res., Univ. of Tübingen, Tübingen, Germany

Abstract: Beyond performing as a simple relay from the periphery to cortex, the thalamus acts as a “gate” for the peripheral signals, controlling what does and does not get transmitted to cortex. Furthermore, this gating is dynamic, and can be influenced through both bottom-up sensory influence and top-down mechanisms related to wakefulness and attention. In this work, we explored the bottom-up effect of stimulus adaptation on the encoding of sensory features in the whisker thalamocortical circuit of the fentanyl-cocktail anesthetized rat. Previous work has

demonstrated that adaptation can lead to enhanced discriminability paired with reduced detectability, but the underlying mechanism is only beginning to be studied. In the context of a sensory adaptation paradigm, we investigated the role of the level of adaptation, as quantified by the strength of the adapting input, on thalamic spiking, burst spiking, and synchronous firing. Increasing levels of adaptation reduced the amplitude of the evoked response and effectively shifted thalamic neurons from burst to tonic firing when conveying information related to an embedded sensory signal. Furthermore, increasing adaptation led to reduced levels of synchrony across pairs of simultaneously recorded neurons. These experimental results demonstrate that thalamic cells fire more burst spikes in response to "signals" presented in isolation than in noise and that this leads to a higher detectability, but a lower discriminability, as assessed using an ideal observer analysis of the thalamic unit spiking activity. Direct depolarization of the thalamic neurons using channelrhodopsin was also able to shift the encoding of sensory features from burst to tonic spikes. We developed an integrate and fire model neuron with an incorporated burst mechanism to investigate the role of depolarization on thalamic encoding. Consistent with the experimental findings, the model suggests that the sensory adaptation is depolarizing the membrane potential of the simulated cell and that this is sufficient to explain the shift in bursting. Taken together, these results suggest that the level of sensory adaptation may have a sustained depolarization effect that dynamically gates information flow through modulations to the sensory evoked response, the burst spiking activity, and the synchrony across neurons. Furthermore, these results could have broad implications for a more comprehensive coding strategy whereby ongoing sensory stimulation, as experienced constantly in natural sensing conditions, dynamically alters the state of the thalamus to fundamentally shape the functional encoding of the pathway.

Title: Thalamic control of sensory perception in the awake behaving rat

Authors: *C. WAIBLINGER[1,2,3], C. J. WHITMIRE[1], C. SCHWARZ[3,2], G. B. STANLEY[1]; [1]Wallace H Coulter Dept. of Biomed. Engin., Georgia Tech. and Emory, Atlanta, GA; [2]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Res., University of Tübingen, Germany; [3]Systems Neurophysiol., Werner Reichardt Ctr. for Integrative Neurosci., University of Tübingen, Germany

Abstract: The rodent ventro-posterior-medial nucleus (VPm) is the thalamic station of ascending whisker signals and has been viewed as the gateway for sensory information to enter the barrel cortex. Whether simple sensory detection or discrimination tasks can be processed subcortically is still hotly debated. Here, we set out to investigate how different sensory inputs are encoded by VPm neurons and whether thalamic processing can modulate sensory perception. Our previous work on the whisker thalamocortical circuit of the anesthetized rat suggests that sensory adaptation dynamically gates information flow through modulation of the sensory evoked response, elicited burst spiking activity and the synchrony across neurons. Using a similar signal-in-noise paradigm with precise whisker stimuli that mimic whisker vibrations upon texture contact, we trained head-fixed rats to discriminate fast kinematic features (tagged 'slip-like events') from background-noise at the level of their perceptual threshold (equal number of hit and miss trials) while simultaneously recording in the principal VPm barreloid. We found that isolated single units encoded slip-like events by fast transient responses, showing elicited bursts in a fraction of trials. Introducing background-noise reduced the sensory evoked response and burst activity similar to the findings in the anesthetized preparation. When investigating multi-unit population activity regarding the animal's behavioral response, we found that spiking activity differed with respect to hit versus miss trials in prolonged time periods. Spike counts were lower before and higher after presentation of the reward associated stimulus in hit compared to miss trials, suggesting an ongoing thalamic influence on the animal's response probability. Taken together, our results confirm the finding in the anesthetized animal that thalamic processing is significantly altered by adapting sensory signals and further elaborates the idea that sensory perception is partially determined by subcortical structures.

Title: Effects of spatial and cross-modal focusing of attention on somatosensory neuronal activity in primate thalamus

Authors: *E.-M. MEFTAH[1], A. CYBULSKA-KLOSOWICZ[2], E. C. CHAPMAN[1];
[1]Neurosciences, Univ. De Montreal, Montreal, QC, Canada; [2]Lab. of Neuroplasticity, Nencki Inst., Warsaw, Poland

Abstract: Focusing our attention enhances perception but knowledge of the underlying neuronal substrates is incomplete. We have shown that selective attention to tactile texture produces a generalized additive increase of texture-related activity in both primary (S1) and secondary (S2) somatosensory cortex and a focused multiplicative increase of texture-related activity in S2 (Meftah et al. 2001; Chapman and Meftah 2005). Using the same paradigm, we extended our recordings to an earlier level of processing, corresponding to the somatosensory thalamus (VPL, ventral posterior lateral nucleus) and showed that attention modulated neuronal responsiveness to textured stimuli, potentially contributing to the modulation seen in S1 and S2 (Cybulska-Klosowicz et al. 2010, SFN). We have now extended our previous investigation to include thalamic cells with a cutaneous receptive field (RF) that was either directly stimulated by the moving textured surfaces (on-focus, tips of digits 3/4) or not (off-focus, elsewhere). Our working hypothesis was that attention would enhance inputs critical for task performance and also suppress irrelevant cutaneous inputs (off-focus). Single unit recordings were made from VPL while a trained macaque performed a cross-modal attention task, attending and discriminating changes in tactile roughness or light intensity. Competing stimuli (tactile and visual) were presented in each trial. Attention was manipulated by an instruction cue prior to each trial. Recordings were made from 38 cells with a cutaneous RF, 21 on-focus and 17 off-focus RFs. The former showed an increase in discharge as textured surfaces were displaced under the fingertips, and were frequently texture-related (12/21). Our results confirmed that attentional modulation is frequently encountered for on-focus VPL cells (11/21), with discharge being enhanced with directed attention (10/11). The discharge of 14 off-focus cutaneous neurones was modulated during tactile stimulation, but most showed decreased discharge (8/14); none were texture-related. A small proportion of off-focus neurones were modulated by directed attention (5/17) but the sign of the effect was mixed (3 decrease, 2 increase). For both on- and off-focus cells, the attentional effects were concentrated in the texture change period. These results confirm that selective attention modulates neuronal responses to tactile stimuli at a very early stage of processing, VPL. In addition, a filtering process suppresses cutaneous information not

relevant for the task providing a spatial focus on the digit tips, the source of information critical for detecting the salient change in roughness.

Title: Vibrotactile perception is enhanced by anodal transcranial direct current stimulation, tDCS, of primary somatosensory cortex, S1

Authors: ***S. LABBÉ**, E.-M. MEFTAH, E. C. CHAPMAN;
Univ. De Montréal, Montreal, QC, Canada

Abstract: tDCS is a non-invasive technique whereby weak, direct current stimulation is applied to the cortex to enhance, anodal (a), or decrease, cathodal (c), cortical excitability. We previously showed that vibration detection thresholds are decreased during a-tDCS but not c-tDCS (Labbé et al. SFN 2014). Here, we examined the effects of tDCS (a-, c- and sham), applied to the right S1, on vibrotactile discrimination of the amplitude of pairs of 20 Hz vibrations applied to the distal pad of the left middle finger. Performance was measured in 5 blocks of trials: before (2), during (1) and after (2) tDCS (intensity, 1 mA; duration 20 min). All subjects (n=12) participated in 3 sessions (a-, c-, s-tDCS; order counterbalanced). Discrimination threshold was measured in a two-alternative forced choice paradigm. Pairs of stimuli were presented (duration, 0.8 s; interstimulus delay, 0.8 s). The amplitude of the standard stimulus was 50 μm; comparison stimuli of 50, 53, 56 and 59 μm were presented (order counterbalanced). Subjects identified the larger stimulus in each pair (first or second). The mean discrimination threshold at baseline (75% correct) was 7.5 μm (range, 3 - 13.5 μm). There was a significant difference in threshold across sessions during tDCS ($p = 0.027$). Post hoc tests showed that threshold was significantly lower

during both a-tDCS, 15%, and c-tDCS, 14%, vs sham. Overall, 9/12 subjects (responders) showed a decrease during and immediately after a-tDCS; their threshold returned to baseline 30 min later. Threshold varied significantly as a function of group (responder vs non responder) across the 5 blocks of the a-tDCS session, with group explaining 52% of the variance in threshold. Group was not a significant factor for either the c- or the s-tDCS sessions (effect sizes, 2 and 3%). Finally, the non responders had the lowest baseline thresholds of all subjects in the anodal session, 3.8 to 5.5 μm. The lack of effect with a-tDCS may represent a ceiling effect. The present results are mostly in accordance with our previous results for vibrotactile detection thresholds. Together, the results suggest that S1 a-tDCS enhances cortical excitability by shifting the underlying stimulus-response function to the left (decreased detection threshold) and increasing its slope (decreased discrimination threshold).

Title: Local and thalamic origins of ongoing and sensory evoked cortical synaptic correlations

Authors: ***B. MOHAR**[1,2], K. COHEN-KASHI MALINA[1], I. LAMPL[1];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Janelia Res. Campus, Ashburn, VA

Abstract: The contribution of local circuits versus remote inputs in the generation of synchronized activity in sensory cortices is poorly understood. In sensory cortices, ascending information from the thalamus targets cells in L4. However, the impact of these inputs is controversial. The majority of the synaptic contacts in L4 are between neighboring cortical cells. However, electrophysiological studies have suggested that thalamic inputs are powerful enough to evoke the observed subthreshold response of L4 cells, without requiring inputs from

neighboring cortical cells. How then such a low number of thalamic inputs can have such a profound impact on cortical response? A widely accepted mechanism that explains the robust activation of L4 cells is thalamic synchrony, implying that thalamic inputs of neighboring L4 cells are highly correlated. To address this question we used optogenetic silencing of cortical firing, by expressing ChR2 in inhibitory interneurons. This was done in order to isolate the thalamic inputs of simultaneously whole cell recorded nearby L4 neurons (<200 μm) in the mice barrel cortex. Surprisingly, we found that although on average 46% of the total sensory evoked excitatory current in these cells originates from thalamic cells, thalamic synaptic inputs to L4 cells are not correlated, neither in time nor in magnitude. During ongoing activity the correlation between pairs of cells dropped by an average of 72% upon silencing of cortical firing. Importantly, we found no relation between the trial to trial correlations of sensory evoked excitatory responses (during intact cortical activity) and those of the isolated thalamic inputs. Hence, synchronized activities in nearby L4 cells during spontaneous and sensory evoked activities do not emerge from thalamic inputs. Additionally, we found that the relative thalamic contribution, measured from the average response, was invariant to stimulation conditions, but could be substantially different in the simultaneously recorded cells. In summary, we suggest that nearby L4 cells receive their inputs from independent pools of thalamic neurons which are amplified in a distinct manner in each cell and thus, synchronized activity emerges due to distinct intracortical network properties.

Abstract: The vibrissa sensory system is a popular model of sensory processing. In the rodent trigeminal pathway, sensory inputs from the face are topographically mapped onto S1, and the orderly arrangement of whiskers on the snout is represented centrally by arrays of cellular aggregates referred to as barrels. By contrast, it is still now unclear how the central nervous system processes time in the early sensory processing. Temporal processing is required for simple sensory problems, such as interval, duration and motion discrimination. In this study, we examined how peripheral sensory input was encoded at cortical and subcortical levels of the vibrissa sensory system. Here, the juxtacellular labeling technique, which allows selective labeling and visualization of individual neurons in which electrophysiological data have been obtained, was applied to recordings. The vibrissa of rats was pushed mechanically by a piezo-driven vibrating insertion device, and neuronal responses to the whisker deflection were analyzed in waking head-restrained rats. As a result, this study revealed several new findings. (1) Subgroups of neurons in thalamic VPM nucleus showed onset and late (50ms-) responses to whisker deflection, and LTS bursts were hypothesized to be the origin of the late response. (2) The reticular nucleus (TRN) provides the only source of GABAergic projections to VPM, and whisker-responsive TRN neurons showed burst discharge in onset period, and the burst firing could induces to suppression prior to late response in VPM. (3) In contrast, less cortical neurons showed late response, and some corticothalamic projection neurons in the barrel column showed short latency sensory response as well as layer 4 neurons as dominant thalamic recipient. (4) By microinjection of GABA, we found effects of S1 inactivation to both onset and late responses of VPM and TRN neurons. In summary, the present experiments reveal that thalamic neurons have not simple relay function, and thalamic sustained spatiotemporal processing could be modulated by corticothalamic feedback during waking state. These observations suggest the thalamus gates peripheral sensory input based on the current cortical demand such as active sensation.

Title: Early experience is associated with individual differences in brain organization and thalamic connectivity in prairie voles (Microtus ochrogaster)

Authors: *A. M. SEELKE[1], A. PERKEYBILE[2], K. BALES[3], L. KRUBITZER[3];
[1]Dept. of Psychology, Univ. California, Davis, Davis, CA; [2]Psychology, Northeastern Univ., Boston, MA; [3]Psychology, Univ. of California, Davis, Davis, CA

Abstract: Early life sensory experiences have a profound effect on brain organization, connectivity and subsequent behavior. In most mammals, the earliest sensory inputs are delivered to the developing brain through tactile contact with the parents, especially the mother. Prairie voles (Microtus ochrogaster) are monogamous and biparental rodents. Similar to other rodents, the type and amount of parental behavior exists on a spectrum, ranging from low contact (LC) to high contact (HC). However, very little is known about how these early and pervasive differences in tactile stimulation and social experience influence cortical organization and connectivity. To address this question we used neuroanatomical tracing techniques to examine the cortical, callosal, and thalamocortical connections of the primary somatosensory area (S1) in the offspring of HC and LC voles. Injection sites within S1 were matched so that direct comparisons between these two groups could be made. We observed several important differences between these groups. The first was that HC offspring had a greater density of intrinsic connections within S1 compared to LC offspring. The HC offspring had a more restricted pattern of ipsilateral connections while LC offspring had dense connections with areas of parietal and frontal cortex that were more widespread. Additionally, LC offspring had a broader distribution of callosal connections than HC offspring and a significantly higher percentage of callosal labeled neurons. Finally, similar to the connection patterns seen in the cortex, HC voles had a more restricted pattern of connections with a small number of thalamic nuclei. The majority of labeled cells were found in the ventral posterior nucleus (VPM and VPL), and the remainder of labeled cells were found in the posterior nucleus (PO), the ventral lateral nucleus (VL), and the ventral medial nucleus (VM). In contrast,LC voles had a broader distribution of connections with a greater number of nuclei. Labeled cells were found in VP(M+L), PO, VL, and VM, as well as the central lateral nucleus (CL) and paracentral nucleus (PC). To date, this is the first study that examines individual differences in neuroanatomical

connections and suggests that they may be related to natural differences in parental rearing styles associated with tactile contact. Ultimately, the population variation generated by these individual differences may play a role in the process of natural selection.

Title: Effects of bicuculline and NMDA on the vibrotactile responses of cortical neurons in the rat SI cortex

Authors: *B. VARDAR, B. GÜÇLÜ;
Inst. of Biomed. Engin., Bogazici Univ., Istanbul, Turkey

Abstract: We previously found that bicuculline (GABA_A receptor antagonist) and NMDA had contradictory, i.e. increasing and decreasing, effects on the average spike rates of neurons from the hindpaw representation in the rat SI cortex. We studied this in more detail by classifying neurons based on location (layers III, IV, V) and spike shape (regular-spiking (RS), fast-spiking (FS), and intrinsically bursting (IB)). We recorded single-unit spike activity during and after drug microinjection from 30 tactile neurons in 9 anesthetized Wistar albino rats. A combination electrode (5 injection barrels + 1 carbon-fiber electrode for recording) was used for applying aCSF (sham condition), 200 μM bicuculline, and 10 μM NMDA by a pneumatic microinjection pump (5 pulses of ~8 nL volume). After mapping the receptive field of each neuron, vibrotactile stimuli (bursts of 5-, 40-, and 250-Hz sinusoidal displacements; duration: 0.5 s; amplitude range: 33-158 μm) were applied on the glabrous skin of the hindpaw. Intracortical drug injection preceded the tactile stimulus. Average firing rates were calculated for the baseline before the stimulus (Rb) and for the entire stimulus duration (0.5 s) (Rd). 3-way ANOVAs (factors: stimulus frequency, cortical layer, drug vs. sham) showed significant main effects of vibrotactile frequency on Rd (p's = 0.001 and 0.046 for bicuculline and NMDA respectively). However, due to the large variation of responses, significant drug effects were not found in ANOVA. Therefore, we analyzed Rd based on paired comparisons between the drug and sham conditions at each frequency. Bicuculline significantly increased Rd at 5 and 250 Hz (paired t-test; p's =

0.010), but not at 40 Hz. On the other hand, NMDA significantly increased Rd only at 40 Hz (paired t-test; p = 0.020). For both drugs, Rd-Rb was mostly not affected, which shows that background firing rate somewhat also increased with drug application. For both drugs and at all frequencies, Rd was significantly increased in RS neurons (n=14). However, Rd of presumably inhibitory FS neurons (n=11) was not significantly affected by drug application. These results suggest that vibrotactile responses of the SI cortical neurons are influenced by complex excitatory and inhibitory interactions which are difficult to predict just by considering the established roles of the applied drugs.

Title: Whisking-related changes in neuronal firing and membrane potential dynamics in the somatosensory thalamus of awake mice

Authors: ***N. L. URBAIN**[1,2], P. SALIN[3], L. GENTET[4], C. PETERSEN[2];
[1]CRNL INSERM U1028, CNRS UMR 5292, Lyon, France; [2]Lab. of Sensory Processing, EPFL, Lausanne, Switzerland; [3]Physiopathologie des réseaux neuronaux du cycle sommeil, [4]Integrated Physiol. of Brain Arousal systems, CRNL, INSERM U1028-CNRS UMR5292, Lyon, France

Abstract: In rodents, active somatosensory perception is particularly relevant through rhythmic and rapid sweeps of facial whiskers contacting objects in the surrounding environment. Faithful transmission of whisker-related sensory information from the periphery to the neocortex is thought to occur through the ventroposteromedial thalamic nucleus (VPM). On the other hand, neurons of the posterior group of the thalamus (Pom), the other major somatosensory thalamic nucleus, respond weakly to whisker stimuli. Our current knowledge of thalamic processing in the whisker sensorimotor system is largely based on recordings from anesthetised rats, but to uncover the functional relevance of these parallel sensory pathways, we carried out

electrophysiological recordings in awake animals during whisker-related behaviour. We therefore developed a technical approach to perform intra- and extracellular single-unit recordings in the mouse somatosensory thalamus coupled with local field potential recordings in primary somatosensory barrel cortex (S1-LFP) and video-tracking of whisker movements. Our results reveal strong correlations of both VPM and Pom neuronal activity with behavioural and cortical states. When mice enter quiet states, slow oscillations appear in S1-LFP and both VPM and Pom thalamic cells display abrupt reductions in spontaneous firing rates associated with membrane hyperpolarization. In contrast, while mice start whisking, thalamic cells shift to more depolarized potentials. During whisking, we find an increase in the rate of fast-rising EPSPs specifically in VPM neurons, contributing to drive increased spiking. We further find that a subset of VPM neurons code whisker position (phase) during the whisking cycle. In Pom cells, we do not observe an increase of fast-rising EPSPs related to free-whisking, but a significant increase in slow EPSPs (20-80% rise-time > 0.6 ms) during whisking compared with no-whisking waking state. Our data therefore demonstrate differential firing and subthreshold activity of VPM and Pom neurons during whisking behaviour.

Title: The modulation of oral sensory information in the trigeminal and thalamic nuclei during superior laryngeal nerve stimulation

Authors: ***S. SAKAI**, T. SUZUKI, K. TSUJI, J. MAGARA, T. TSUJIMURA, M. INOUE; Niigata Univ., Niigata City/Niigata, Japan

Abstract: Introduction: The aim of the present study was to investigate the possible neuronal mechanisms for the modulation of oral sensory transmission during swallowing evoked by electrical stimulation of superior laryngeal nerve (SLN) in anesthetized rabbits. Materials and Methods: Experiments were carried out on rabbits anesthetized with urethane. Single unit responses evoked by the electrical stimulation of the inferior alveolar nerve (IAN) were recorded in either the trigeminal or thalamic nucleus. To evoke the swallowing reflex, SLN was stimulated and current intensity for SLN stimulation was set between 1 and 4 times of the threshold for evoking the swallowing reflex in 10 seconds. Activation of single neurons in either investigated

area was compared between with and without SLN stimulation. Recording sites in central regions were histologically identified. Results & Conclusion: 1. Responses of most neurons recorded in both the trigeminal and thalamic nuclei were inhibited during 2 or 4 times SLN stimulation. 2. Recording sites of the neurons were identified in the main sensory trigeminal nucleus and subnucleus oralis of the spinal trigeminal tract in the trigeminal nuclei and nucleus ventralis posteromedialis in thalamus. 3. Current results suggest that the transmission of oral sensation including ascending pathway is modulated during SLN-evoked swallowing. References: •Takako Fukuhara et al., 2011. Title: Representation of object properties and hand kinematics in somatosensory (S1) and posterior parietal cortex (PPC)

Authors: *E. P. GARDNER[1], J. L. BAKER[2], J. RYOU[2], J. CHEN[1];
[1]Dept Physiology/Neuroscience, New York Univ. Sch. Med., New York, NY; [2]Brain and Mind Inst., Weill Cornell Med. Col., New York, NY

Abstract: To analyze the roles of PPC and S1 during skilled manual tasks, we trained monkeys to perform an instructed-delay bimanual prehension task, using visual cues to guide object selection. Five objects (2 spheres, 2 cylinders, 1 rectangular block) were arrayed symmetrically on a panel placed at shoulder height at the midline; icons on a computer screen represented their shape and/or location. In shape-cued trials, we displayed a single large red icon at the screen center whose shape matched that of the rewarded object. When the icon color changed from red to green, the animal had to reach, grasp, pull and hold a matching object. As there were two

spheres and cylinders, the animal could choose which hand to use; the rectangular block at the center was equally accessible to both hands. In shape+location-cued trials, five icons showed the shape and location of all 5 objects simultaneously. The rewarded object was colored red at trial start; its location on the right or left side of the screen indicated which hand to use. Kinematic contingencies were identical in both trial types. Motor planning of prehension thus required target selection and movement selection. To assess the role of task type during motor planning and performance, we recorded spike trains with microelectrode arrays implanted at bilaterally symmetric sites in the hand areas of PPC and SI. We propose that PPC activity reflects task goals to grasp and manipulate specific objects. SI responses are hypothesized to confirm or rebut the subject's expectation of object features, providing feedback for error correction. By interleaving blocks of shape-only and shape+location trials, we tested whether neuronal shape selectivity is enhanced when needed for correct performance, or whether parietal areas serve kinematic, not sensory cognitive function. Kinematic factors were reflected in both neural and behavioral activity. The majority of PPC cells responded to reach and grasp in both tasks and for all objects. Actions of the contralateral hand produced higher firing rates, but left and right hands evoked similar firing patterns in both hemispheres. In the shape task, the animal used the right hand to grasp the sphere and cylinder in >90% of trials, even though reward probability was equal for left and right objects. The rectangular block was grasped with the left hand, similar to the choice made in the location task. This suggests that the hand used reflected an individual preference for manipulating specific objects. Moreover, neural responses to each knob were similar in both tasks, suggesting that while the animal was cognizant of object form, neural activity in PPC was more tightly linked to hand actions than to object features.

Title: Selective activation of infragranular layers of vibrissal primary motor cortex inhibits vibrissal sensory pathway via corticofugal projections

Authors: *M. LOHSE, E. SADER, L. UPTON, E. MANN;
Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: Sensorimotor integration is an important feature for optimising discrimination of the tactile world. We investigated how activation of vibrissal primary motor cortex (vM1) influences vibrissal sensory processing. We stimulated vM1 in anaesthetised mice using intra-cortical microstimulation, as well as optical stimulation of channelrhodopsin-2 (ChR2) expressed selectively in either vM1 layer V or layer VI. Whisker-evoked responses were recorded using both whole-cell patch-clamp recordings in vibrissal somatosensory cortex (vS1) and multi-unit recordings in somatosensory thalamus and vS1. We find that activation of vM1 inhibits whisker-evoked responses in both vibrissal sensory thalamus and cortex, with this inhibition decaying over a period of ~150 ms. We also show that activation of either vM1 layer V or layer VI is sufficient to drive activity in sensory thalamus, and inhibit subsequent vibrissal responses. Moreover, the inhibition of vibrissal responses in thalamus does not require activity in vS1. This suggests that sensory inhibition is initiated via direct corticofugal projections from vM1, rather than cortico-cortical connections. We propose that the inhibition comes about through reciprocal connections between thalamic nuclei (somatosensory and motor) and the thalamic reticular nucleus. This new sensorimotor phenomenon presents an opportunity for the nervous system to integrate information about the timing of motor commands and subsequent sensory stimulation.

Title: Distinct mGlu2 and mGlu3 receptor functions in modulation of sensory responses and burst firing in the ventrobasal thalamus during vibrissa stimulation

Authors: ***T. E. SALT**[1], S. A. NEALE[2], C. S. COPELAND[1];
[1]UCL Inst. Ophthalmology, London, United Kingdom; [2]Neurexpert Ltd, London, United Kingdom

Abstract: Group II mGlu (mGlu2 and mGlu3) receptors modulate responses to vibrissa stimulation *in vivo* (Copeland et al 2012). Response patterns of thalamic neurones to sensory

stimulation, and in particular transitions from tonic to burst firing mode, are thought to be important in cognition and attention. We therefore investigated how activation or blockade of these mGlu receptors affects burst firing and tonic firing of ventrobasal thalamus (VB) neurones in response to vibrissae stimulation. Extracellular single neuron recordings were made *in vivo* with multibarrel electrodes in the VB of urethane-anaesthetized adult Wistar rats. Drugs were applied locally by iontophoresis. VB neurons were activated by vibrissa stimulation (10Hz, 1s duration trains), and evoked action potential spikes were isolated and timed. Responses to vibrissae stimulation consisted of spikes that were classified offline as occurring either in bursts or not in bursts (Copeland et al 2015). Application of the pan-Group II antagonist LY341495 caused a reduction in the number of action potentials evoked by sensory stimulation (to 81±5.0% of control; n=6) and at the same time decreased the proportion of burst firing (12±4.4% decrease). These effects were mimicked by the dual mGlu3 antagonist / mGlu2 agonist LY395756 (responses reduced to 59±4.8% of control, burst firing decrease 12±6.4%; n=6). By contrast, the pan-Group II mGlu agonist LY354740 increased sensory responses (177±24% of control; n=6) and increased the proportion of burst firing (16±3.8%). This action could be mimicked by co-application of LY395756 with the mGlu2 Positive Allosteric Modulator (PAM) LY487379: sensory responses increased to 154±7.2% and proportion of burst firing increased by 10±5.5% (n=6). These results provide the first direct demonstration of an mGlu3 receptor-mediated modulation of sensory responses that is activated during stimulation. Furthermore, this appears to operate in addition to, but greater than and opposing the effects mediated via mGlu2 receptors that we have described before (Copeland et al 2012). This shows that mGlu2 and mGlu3 receptors have distinct functions in sensory processing at the thalamic level and are placed to shift the balance between burst and non-burst (tonic) firing, underlining their importance in regulation of cognitive and attention processes. Title: Layer- and cell-type segregation of thalamocortical input from POm in somatosensory cortex

Authors: *N. AUDETTE[1], M. MATSUSHITA[2], A. L. BARTH[1];
[1]Dept. Biol. Sci. and Ctr. for Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA;
[2]Carneie Mellon Univ., Pittsburgh, PA

Abstract: Thalamocortical inputs to the barrel cortex arise from the ventral-posterior nucleus (VPM), with dense axonal arbors in layer 4 and layer 5B, and from the posterior medial nucleus (POm) which projects to layer 1 and layer 5A. Prior work has shown that neurons in layer 2 show broad, multiwhisker subthreshold receptive fields that might be inherited from POm, since these thalamic neurons are also broadly tuned. In order to understand how different thalamic streams can influence firing of neocortical neurons, we used POm-targeted, viral-mediated channelrhodopsin expression to map POm inputs across cortical layers and cell types. Excitatory neurons in every layer receive direct, glutamatergic POm input, but the amplitude of this input is stratified by laminar location. Monosynaptic POm input was strongest in L5 neurons and then in L2 neurons. Interestingly, neurons in L2 receive significantly stronger input than neurons in L3, revealing a functional distinction between L2 and L3 neurons. Current clamp recordings show that POm engages deep and superficial neurons in two distinct patterns. Pyramidal neurons in L5 receive strong excitation rapidly followed by polysynaptic inhibition. In L2, optical activation of POm axons almost never elicited recurrent inhibition. To determine whether POm-triggered inhibition in layer 5 arises from direct activation of inhibitory neurons or recurrent activity in the neocortical circuit, we employed transgenic mice with different fluorescently labelled interneuron populations in combination with POm-targeted channelrhodopsin injections. Our recordings indicate that POm-initiated inhibition is likely to come from parvalbumin-expressing but not somatostatin-expressing interneurons. This widespread pattern of direct excitation confirms that PoM inputs may be an important source of the broad receptive fields observed in non-granular layers of the cortex.

Title: Functional consequences of bilateral facial maps along the thalamocortical system

Authors: *V. TSYTSAREV[1], H. ARAKAWA[2], P. GASPAR[3], A. CHEDOTAL[3], R. S. ERZURUMLU[4];
[1]Anat. and Neurobio., Univ. of Maryland, Baltimore, MD; [2]Dept. of Res. Administration, Sch. of Med., Case Western Reserve Univ., Cleveland, OH; [3]Inserm-UMRS 839, Inst. du Fer a Moulin, Paris, France; [4]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Midline crossing defect of trigeminal principal sensory nucleus (PrV) axons leads to formation of bilateral whisker maps in the ventroposteromedial (VPM) nucleus of the thalamus and subsequently in the primary somatosensory or "barrel" cortex in mice. In the PrV, whisker-specific barrelette neurons are largely derived from rhombomere 3 (r3). Conditional mutation of the Robo3 receptor in r3-derived neurons results in midline crossing defects of the PrV trigeminothalamic axons. We used voltage-sensitive dye optical imaging methods (VSDi), and somatosensory behavioral tests in Krox20cre/Robo3lox/lox mice to delineate functional consequences of bifacial maps in the somatosensory thalamocortical system. We visualized neural activity in the barrel cortex of mice with bifacial representation of the whiskers in response to ipsi- and contralateral single whisker stimulation with VSDi using the voltage-sensitive dye RH-1691 and MiCAM-02 system. Change in fluorescence was calculated as ΔF/F (%) in the barrel field using the Brain Vision Analyzer. A glass pipette was aimed at the E2 whisker and air-puff stimulus of 25 ms duration was applied through a compressor coupled to the imaging system, so that the air could be puffed onto the whiskers and optical signals collected simultaneously. In control animals only contralateral whisker stimulation elicited VSDi signals in a given cortex, while ipsilateral stimulation didn't evoke any activity. In all examined mutant animals both ipsi- and contralateral whisker stimulation evoked VSD signals in the cortex. Unilateral transection of the infraorbital nerve further confirmed the presence of ipsi- and contralateral whisker responsiveness in the barrel cortex of mutant mice. We used a battery of sensorimotor tests to investigate the behavioral outcome of bifacial cortical maps. We tested for general whisker tactile sensation tests (horizontal approach, floating in water and sticky paper tests); whisker sensorimotor ability (gap crossing, bridge crossing); and tactile cognitive tests (shape-texture recognition); as well as detailed analysis of whisking patterns including whisking laterality and object localization. The mutant mice showed notable deficits in performance in all of the whisker-dependent sensory-motor tests. Particularly, the horizontal localization by whiskers was impaired. Thus bifacial maps along the thalamocortical system do not offer any functional advantages; instead they lead to impairments probably due to interference between the ipsi and contra whisker representations in the same thalamus or cortex. Title: Effect of long-range feedback connections from motor cortex and thalamus to somatosensory cortex

Authors: T. ZOLNIK[1], *R. N. SACHDEV[2], M. LARKUM[3];
[1]Neurocure Ctr. for Excellence, Humboldt Univ., Berlin, Germany; [2]Charite-Berlin, Berlin, Germany; [3]Neurocure Ctr. for Excellence, Humboldt University, Berlin, Berlin, Germany

Abstract: A signature of feedback and long-range connections between cortical areas is their projection to layer 1. The functional consequences of projections to this thin, cell sparse layer, filled primarily with the distal apical dendrites of pyramidal neurons and a small number of non-fast spiking interneurons are a mystery: Can these connections trigger a somatic response in layer 5? Are the connections to layer 1 uniform in their effect on postsynaptic targets? Here we compare the effects of two connections that target layer I -- motor cortex and POm (paralemniscal) thalamus -- in primary somatosensory cortex. We use an optogenetic approach to specifically activate POm or M1 axons in somatosensory cortex, while recording activity in L1 interneurons and L2/3 and L5 pyramidal neurons in brain slices. Though the POm and M1 axons have a differential distribution in layer 1 -- the M1 connections cover a larger portion of layer 1 -- both POm and M1 axons can activate all classes of neurons we studied here. But, POm axons activate the layer 1 network more strongly than M1 inputs do (POm, 18.5+ 4.4 mV; M1, 9.7+ 2.3 mV) and have a weaker effect on L2/3 pyramidal neurons than does the M1 projection (POm, 4.0+ 1.0 mV; M1, 7.5+ 2.7 mV). Surprisingly, L5 pyramidal neurons are activated to a similar extent by both inputs (POm, 9.8+ 1.9 mV; M1, 8.0+ 2.6 mV). A notable difference is that 20 Hz stimulus trains create different post-synaptic dynamics: the effect of M1 inputs decays more rapidly than the effect of POm inputs. Activation of these axons in layer 5 produces a faster, larger, and shorter latency EPSP response than does activation in L1. To examine the anatomical distribution of presynaptic neurons that target layer 1 and 5, we are using retrograde AAV6-fluorophor viral vectors. To examine the functional / differential consequences of activating M1 and POm inputs to S1, we are using the photo convertible calcium indicator CaMPARI (Fosque et al., 2015). The consequences of activating these inputs during a sensorimotor whisker dependent task are also under study.

Title: Therapeutic window for correcting dendritic spine dysgenesis in SCI induced neuropathic pain

Authors: *A. M. TAN, S. LIU, M. HILL, P. ZHAO, S. G. WAXMAN;
Neurol., Yale University/VA Connecticut Healthcare Syst., West Haven, CT

Abstract: The primary objective of our work is to reveal mechanisms that contribute to neuropathic pain after spinal cord injury (SCI). Dendritic spines are micron-sized postsynaptic structures that represent modifiable sites of synaptic contact and contribute to neuronal physiology. Importantly, dendritic spines provide crucial insights into how neural networks form and retain function. Because dendritic spines are located on dorsal horn neurons within the spinal cord nociceptive system, dendritic spine remodeling provides a unique perspective to understand and address sensory dysfunction after SCI. Over fifty percent of patients with SCI experience neuropathic pain that is refractory to current medical treatment. Our previous work has shown a structure-function relationship between abnormal spine morphologies and neuropathic pain by demonstrating that acute pharmacological inhibition of Rac1-regulated dendritic spine remodeling on nociceptive dorsal horn neurons significantly attenuates electrophysiological and behavioral symptoms of neuropathic pain. In the present study, to identify a therapeutic window for correcting dendritic spine dysgenesis in SCI-induced neuropathic pain, we addressed two questions: First, does anti-Rac1 drug treatment early after SCI (<24hrs) prevent the progression of abnormal dendritic spine plasticity and the development of SCI-induced neuropathic pain? Second, does cessation/withdrawal of anti-Rac1 drug treatment allow relapse of SCI-induced abnormal dendritic spine morphology and neuropathic pain? Our findings demonstrate that Rac1 inhibition early after SCI has little to no efficacy in preventing the development of SCI-induced neuropathic pain, and that abnormal dendritic spine and pain pathologies relapse following cessation of anti-Rac1 drug treatment. Overall, our findings suggest the need for a more durable therapeutic strategy. To this end, we are developing a gene therapy approach to target dendritic

spine remodeling associated with neuropathic pain and other neuronal-hyperexcitability diseases after SCI.

Title: Awake behaving electrophysiological correlates of weakness and spasticity after cervical hemi-contusion in the rat

Authors: ***P. D. GANZER**[1,2], E. MEYERS[1,2], R. L. RENNAKER, II[1,3,2], M. P. KILGARD[3,2]; [1]Bioengineering, Univ. of Texas At Dallas, Richardson, TX; [2]Texas Biomed. Device Ctr., [3]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Cervical spinal cord injury (cSCI) is a major cause of disability, in many cases leading to long lasting impairments in forelimb function and quality of life. cSCI can interrupt descending motor control, promote aberrant sprouting of spinal afferent fibers and modify spinal excitability, which may all contribute to forelimb weakness and spasticity. In this study, we model hemi-contusion cSCI in the rat and assess its effects on forelimb strength and muscular dynamics (using awake behaving biceps and triceps EMG recordings). Prior to injury, animals: 1) were trained to proficiency on the isometric pull task, which quantitatively measures multiple parameters of forelimb strength; and 2) were tested for baseline paw withdrawal to a thermal stimulus using the Hargreaves method. After cSCI, testing was performed each week for 4 weeks. In a subset of animals, we also recorded biceps and triceps EMG during these assessments. Our results show classic attributes of spasticity following cSCI: weakness, increases in motor variability and withdrawal hyper-reflexia. We then used factor analysis to investigate the pre-motor drives associated with EMG activity across assessments before and after cSCI. Our results highlight the electrophysiological dynamics associated with interrupted descending motor control, aberrant spinal sprouting and modified spinal excitability reported previously after SCI and other types of upper motor neuron insults.

Title: Decoupling of hand and arm movements after spinal cord injury

Authors: *F. J. CALABRO[1,2], M. A. PEREZ[2,3];
[2]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: We have previously shown that spinal cord injuries impair the ability to execute bilateral reach-to-grasp movements, resulting in pronounced movement time delays of the stronger arm. The extent to which this reflects a deficit in interlimb coordination and/or a compensatory strategy to synchronize movements with the more impaired arm remains unknown. To address this issue, we studied bilateral self-paced and ballistic reach-to-grasp movements of a small (1 cm) and large (7.5 cm) cylinder in 16 individuals with incomplete cervical SCI and 20 uninjured controls. We found that SCI subjects exhibited reduced trial-by-trial correlations (decoupling) in the magnitude and in the time to reach maximum hand aperture compared with controls, regardless of object size and movement speed tested. However, there were no differences in the correlation between the magnitude and the time to reach peak arm velocity between SCI subjects and controls. In addition, SCI subjects showed a decreased synchronization during hand maximum aperture (time at which each hand reached maximum aperture) and grasping (time at which each hand grasped the object with the index finger and thumb) compared with controls in all conditions tested, suggesting that it is less likely that bilateral movement time delays were related to a compensatory strategy to synchronize movements with the more impaired arm. Thus, our results demonstrate that following cervical

SCI decoupling of the arms occurs at distinct phases during the reach-to-grasp movement, being present during grasping but not during arm acceleration. We suggest that this may reflect impaired interlimb coordination during grasping, providing an important target for rehabilitative interventions.

Title: Altered suppression of corticospinal drive prior to an upcoming action after spinal cord injury

Authors: *P. FEDERICO[1,2], M. A. PEREZ[1,2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL;
[2]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The ability to stop voluntary movement at a desired time is impaired in a number of individuals with incomplete spinal cord injury (SCI). The extent to which the corticospinal system is involved in this impairment after SCI remains unknown. Here, we used a GO and NOGO paradigm to test transmission in cortical and subcortical pathways prior to the execution and suppression of an upcoming voluntary command in humans with chronic incomplete cervical SCI and uninjured controls. Using noninvasive cortical and cervicomedullary stimulation we tested motor evoked potentials (MEPs) and short-intracortical inhibition (SICI) in the first dorsal interosseuous muscle during 2-5% of maximal voluntary contraction 60.1±31.4 ms after an

imperative signal. Index finger reaction time was shorter in controls (263.5±33.5 ms) compared with SCI subjects (292.9± 34.1 ms) at matched levels of background electromyographic activity. We found in GO trials that the size of cortically evoked MEPs increased and SICI decreased compared to baseline in both groups of subjects. In NOGO trials, MEP size decreased in controls (by 37.1±16.6%) but remained similar to baseline in subjects with SCI (decrease by 11.9±28.2%). Cervicomedullary MEP size increased compared to baseline in control but not in SCI subjects in GO trials, while it remained similar to baseline in both groups in NONGO trials. These findings suggest an impaired ability to suppress corticospinal drive prior to an upcoming command to stop a movement after SCI, likely related to deficits at the cortical level. Thus, feedforward cortical mechanisms might play a role in movement deficits after human SCI.

Title: Strengthening corticospinal synaptic transmission in a lower-limb muscle

Authors: *M. URBIN[1,2,3], M. A. PEREZ[2,3];
[1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Repeated pairs of presynaptic and postsynaptic volleys arriving within a precise time window at the spinal cord increase the efficacy of corticospinal transmission in upper-limb

muscles (Taylor and Martin, 2009; Bunday and Perez, 2012). Here, we examined whether spike-timing-dependent plasticity can be induced in synapses targeting lower limb muscles. Transcranial magnetic stimulation over the leg motor cortex activated corticospinal neurons producing presynaptic action potentials, whereas electrical stimulation of the common peroneal nerve elicited antidromic action potentials to depolarize tibialis anterior (TA) motoneurones. Motor evoked potentials (MEPs) in the TA muscle were measured before and after 200 pairs of stimuli delivered at 0.1 Hz in control subjects. Latencies of the M-wave (4.9±0.1 ms), F-wave (35.2±3.1ms), and MEP (30.7±2.2 ms) in the TA muscle were determined for each subject to calculate peripheral [PCT=(F-wave latency - M-wave latency) * 0.5] and central conduction times [CCT=MEP latency - (PCT + M-wave latency)]. Conduction times (CCT=10.7±1.6 ms; PCT=15.2±1.4 ms) were used to time the arrival of presynaptic volleys ~2 ms prior to postsynaptic volleys. We found that the size of TA MEPs increased by ~70% above the MEP baseline immediately after paired stimulation and remained increased for up to 30 minutes after the last pair of stimuli. The increase in MEP size was observed for up to 50 minutes in a subset of subjects. These findings demonstrate that spike-timing-dependent like plasticity can be induced in corticospinal projections targeting lower-limb muscles, which might open new targets for enhancing voluntary motor output in individuals with motor disorders.

Title: Subcortical contribution to bimanual force coupling after spinal cord injury

Authors: J. LONG[1,2], T. TAZOE[1,2], *M. OUDEGA[1,2], M. A. PEREZ[1,2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL;

Abstract: Previous evidence showed that cortical mechanisms contribute to the coupling of bimanual isometric forces in intact humans. Here, we examined the contribution of subcortical pathways to bimanual force coupling by testing individuals with and without subcortical damage due to incomplete cervical spinal cord injury (SCI). Subjects were instructed to perform unilateral and bilateral ballistic symmetric and asymmetric increasing levels of isometric index finger abduction (5%, 10%, and 30% of maximal voluntary contraction) when visual feedback of left and right forces were displayed with a single 2D cursor (Single-task) or two independent cursors (Dual-task). Force and electromyographic (EMG) activity in the first dorsal interosseous muscle were measured in all conditions. We demonstrate in uninjured controls that force and mean rectified EMG activity produced by the left and right hand were positively correlated in the Dual-task (both hands produced a similar motor output regardless of the asymmetry between targets) but not the Single-task (each hand produced a different motor output following the asymmetry of targets), suggesting that in controls the ability to engage the hands was modified by changes in the task demands imposed by the visual feedback. In contrast, SCI subjects showed that force and mean rectified EMG activity produced by both hands was positively correlated in the Dual-task and Single-task, suggesting an impaired ability to exert different levels of asymmetric forces between hands. Our results together indicate that subcortical pathways contribute to the coupling of independent bimanual isometric forces in humans.

Title: Late TMS-induced I-waves detect loss of voluntary motor output after spinal cord injury

Authors: *J. CIRILLO[1,2,3], M. A. PEREZ[3,4];
[1]Dept. of Sport and Exercise Sci., [2]Ctr. for Brain Res., Univ. of Auckland, Auckland, New Zealand; [3]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Using transcranial magnetic stimulation (TMS) we showed that late TMS-induced indirect (I) waves are critical for recruitment of spinal motoneurones in humans with anatomically incomplete spinal cord injury (SCI; Cirillo et al., 2015). Here, we examined whether late TMS-induced I-waves are sensitive to detect changes in voluntary motor output after injury. A single-pulse TMS was used over the hand motor cortex to elicit motor evoked potential (MEPs) in an intrinsic finger muscle during small levels of isometric voluntary contraction in uninjured controls and in individuals with incomplete chronic cervical SCI. During testing, the TMS coil was oriented in the latero-medial (LM), posterior-anterior (PA), or anterior-posterior (AP) direction to preferentially activate corticospinal axons directly, and early or late I-waves, respectively. In controls, we found that MEP latency was delayed by 1.8±0.5 ms with PA and by 3.3±1.1 ms with AP compared with the LM. In SCI subjects, we found two groups of individuals; one with similar latency differences as controls (LM-PA=1.6±0.6 ms and LM-AP=3.5±1.1 ms) and another where latency difference was not different across conditions (LM-PA=1.5±0.9 ms and LM-AP=1.6±1.3 ms). SCI subjects whose delay for LM-AP coil orientation was not different with LM-PA exerted significantly less maximal force and electromyographic (EMG) activity than SCI subjects with similar latency differences as controls. Notably, a positive correlation was found between latency differences in the LM-AP direction and force and EMG outcomes in all SCI subjects. Our findings indicate that late TMS-induced I-waves are a sensitive measure to detect loss of voluntary motor output after human incomplete SCI.

Title: Control of diaphragm activity after SCI in the absence of supraspinal input: the contribution of interneurons

Authors: *J. M. CREGG, L. T. LANDMESSER, J. SILVER;
Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Respiratory drive is relayed to phrenic motor neurons via bulbospinal projections. Spinal cord injury at or above cervical level 4 disrupts these descending projections and causes permanent loss of diaphragm function. In this study we examined whether cervical spinal cord circuitry--circuitry that retains local connectivity after high cervical spinal cord injury--can be mobilized to control the diaphragm in the absence of descending input from bulbospinal premotor nuclei. Using an *in situ* model of cervical spinal cord injury we demonstrate that in the absence of supraspinal input, tonic inhibitory synaptic transmission suppresses phrenic motor output. Pharmacological blockade of GABAergic/glycinergic transmission relieves inhibitory synaptic input to phrenic motor neurons, and furthermore, uncovers an excitatory propriospinal circuit capable of driving synchronous right/left phrenic motor output. Under conditions of disinhibition, we find that we can precisely control phrenic motor output by optogenetic stimulation of excitatory interneurons at defined frequencies. These results identify a discrete microcircuit in the cervical spinal cord that can coordinate right/left phrenic motor output in the absence of descending command from bulbospinal premotor nuclei. We further show that this circuit can be mobilized to promote hemidiaphragm function after lateral C2 hemisection *in vivo*. Thus, taken together, we demonstrate that the rich functional diversity of cervical phrenic interneurons can be exploited to allow function of an otherwise paralyzed muscle required for sustaining life.

Title: Modulation of the proteoglycan receptor PTPσ induces neuronal protease release to overcome Chondroitin Sulfate Proteoglycan inhibition of axon regeneration

Authors: *A. TRAN[1], B. T. LANG[2], J. SILVER[1];
[1]Neurosciences, Case Western Reserve Univ., Cleveland, OH; [2]Athersys, Cleveland, OH

Abstract: Following spinal cord injury, newly reformed growth cones of regenerating axons are halted by the extracellular matrix (ECM) of the glial scar. One ECM component in particular, chondroitin sulfate proteoglycans (CSPGs), actively prevent regeneration and sprouting through increased expression in both the lesion scar and perineuronal nets surrounding deafferented neurons. Protein Tyrosine Phosphatase-Sigma (PTPσ) has been identified as a receptor for CSPGs that is sufficient to signal axonal growth inhibition. Further, manipulation of PTPσ with the novel Intracellular Sigma Peptide (ISP), unlocks axonal plasticity within CSPG rich regions through a currently unknown molecular mechanism. We previously demonstrated that ISP treatment enhances recovery of sensorimotor, locomotor, and urinary function following severe spinal cord injury via unprecedented serotonergic sprouting (Lang et al. 2015). We now report that modulation of PTPσ, both *in vivo* and *in vitro*, increases the release of protease(s) from neurons that digest inhibitory components of the ECM, such as aggrecan. Using gel zymography, western blots, and *in vitro* assays, we were able to demonstrate that ISP induced protease digestion of aggrecan. Thus, we hypothesize that one of the critical downstream events underlying the failure of axon regeneration is a lack of cell growth-permitting protease release within CSPG rich regions. Further understanding of the mechanisms underlying CSPG-PTPσ signaling will further elucidate how axon regeneration is impaired following spinal cord injury.

Title: Effect of spinal cord injury on the expression of c-Fos in the cerebellum of male rats

Authors: *C. A. PEREZ-ESTUDILLO[1,2], E. CHANG-MOYA[2], M. L. LOPEZ-MERAZ[2], C. MORGADO-VALLE[2], L. BELTRAN-PARRAZAL[2], A. J. MARTINEZ-CHACON[3], G. A. CORIA-AVILA[2], J. MANZO[2];
[1]Univ. Veracruzana, Xalapa, Mexico; [2]Ctr. de Investigaciones Cerebrales, U.V., Xalapa, Mexico; [3]Ctr. de Investigaciones Biomedicas, U.V., Xalapa, Mexico

Abstract: The cerebellum participates in the regulation of fine movements, sexual responses and motor learning, including balance. Therefore it is a structure that integrates information arriving from the forebrain, but also from the spinal cord. Any change in the physiology of those structures is likely to modify the neural activity within the cerebellum. Thus, in the present study we assessed the expression of c-Fos in the cerebellum of male rats after 6 or 14 h of a spinal cord injury. Adult Wistar males were used. In a first experimental design they were divided into three groups: 1) intact, 2) sham and 3) 6 h after spinal cord injury. In a second experiment they were divided into: 1) intact, 2) sham and 3) 24 h after spinal cord injury. The lesion was performed by using a drop-weight technique. Thus, a 10 g weight was dropped from a height of 15 cm through a guide tube. The expression of c-Fos was then assessed with immunocitochemistry. The number of positive cells to c-Fos on the cerebellar vermis was analyzed through a Generalized Linear Model. The results of the first experiment showed that 6 h after the lesion there was a significant increase ($p< 0.01$) on the c-Fos expression of the granule cell layer of lobules 1, 5, 7, 9 and 10, as well as on the Purkinje layer of lobules 1, 7 and 9. For the second experiment, we observed that 24 h after the lesion there was an increase of c-Fos on the granule cell layer of lobules 3, 4 and on the fastigial deep nucleus (in comparison with both intact and sham rats). These results suggest that there are specific responses in a timed manner within the cerebellum after loss of spinal input. Such responses may be associated with biochemical processes that occurred during the primary damage (after 6 h), and with the secondary damage (after 24 h). Additionally, these results show that the cerebellum activates “motor” and “non-motor” lobules after the occurrence of the spinal cord injury.

Title: The 5-HT1 receptors are involved in the increased ability of AADC cells to produce 5-HT following spinal cord injury

Authors: *L. REN[1], K. ZHANG[2], L. CHEN[2], H. HULTBORN[3];
[1]Lab. of Spinal Injury and Rehabil., Chengde Med. U, Hebei Province, China; [2]Lab. of Spinal Injury and Rehabil., Chengde Med. Univ., Chengde City, China; [3]Dept. of Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Spasticity is a common disorder following spinal cord injury (SCI). Several mechanisms may contribute to the development of spasticity, but one important mechanism seems to be the return of persistent inward current in motor neurons which is controlled by their monoaminergic innervation. Following a spinal cord transection the descending monoaminergic systems are removed. However, spinal motor neurons become supersensitive to monoamines (receptor up-regulation) and spinal aromatic L-amino acid decarboxylase (AADC) cells could change their phenotype to be able to produce serotonin(5-HT) from 5-hydroxytryptophan after SCI. One possible mechanism for the increased ability of AADC cells to produce 5-HT following SCI might be the release of their repression by the raphe-spinal serotonergic innervation. We had previously found that 5-HT1B receptors could suppress 5-HT expression in the AADC cells, when a 5-HT1B receptor agonist (CP94253) was subcutaneously (s.c.) injected daily (0.1 mg/kg) for 8 consecutive days to chronic spinal animals (spinalized at S2) (Wienecke J et al ,J Neurosci. 2014, 34:11984-2000). We now investigate whether the other 5-HT1 receptor subgroups may also exert an inhibition of the AADC-enzyme e.g., 5-HT1A, 5-HT1D and 5-HT1F. We also investigated whether higher doses of the 5-HT1B agonist (CP94253) would be more effective than in our previous experiments. To investigate these hypotheses, we adopted the chronic S2 spinal cord transection model. A total of 42 Wistar rats were used.6 normal and 6 spinalized rats were used for AADC, 5-HT, 5-HT1A, 5-HT1B, 5-HT1D and 5-HT1F immunostaining. 24 spinalized rats were divided into 4 groups (Group 1A/1B/1D/1F) and each group(6 rats) received daily s.c. injection for 8 days with their agonist (5-HT1A agonist, (R(+)-8-OH-DPAT,0.3 mg/kg;5-HT1B agonist, CP94253, 0.3 mg/kg;, 5-HT1Dagonist, PNU-142633, 0.3 mg/kg; 5-HT1F agonist, LY-344864, 1 mg/kg; 6 normal rats were injected saline as control). 5-HT1A, 5-HT1B, 5-HT1D - but not 5-HT1F - immunolabeling were all found in AADC cells in the spinal cord of normal rats. Only 5-HT1B was expressed in AADC cells after SCI, 5-HT1B agonist can inhibit 5-HT production, but 5-HT1A /5-HT1D /5-HT1F agonist and saline had no

impact. 5-HT1B agonist (0.3 mg/kg) can inhibited more than 80% of AADC cells to produce 5-HT.In summary, our results demonstrate that 5-HT1B receptor play an important role in the enhanced ability of AADC cells to produce 5-HT after SCI.

Title: Opening a window of delayed spinal plasticity following ischemic brain injury

Authors: *A. M. WIERSMA[1,2], I. R. WINSHIP[1];
[1]Neurochemical Res. Unit, Edmonton, AB, Canada; [2]Neurosci. and Mental Hlth. Institute, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Recent studies suggest that significant adaptive plasticity occurs in the spinal cord after stroke. Our recent work suggests that this delayed spinal plasticity has a finite temporal window that closes concurrent with a plateau in spontaneous recovery, suggesting that reopening this window may improve recovery. Here, we assessed if targeted pharmacotherapy administered to the spinal cord during the chronic phase of stroke could restart spinal plasticity and augment functional recovery. To augment spinal plasticity, adult male Sprague-Dawley rats received intraspinal injections of Chondroitinase ABC (ChABC) into the cervical spinal cord one month after a photothombotic stroke lesioning the forelimb sensorimotor cortex. Prior to stroke, rats were trained on the Montoya Staircase task or the single pellet reaching task, behavioural tests commonly used to assess skilled forelimb function after brain injury. Forelimb use preference was also determined using the cylinder task. Reaching performance was assessed at baseline and between 3 and 28 days post-stroke. Rats with persistent reaching deficits at 28 days were assigned to treatment groups that received 1 μL unilateral intraspinal injections at C5 and C6 of the cervical cord (i.e. into the spinal grey matter receiving corticospinal input from the stroke affected cortex) of ChABC (10 U/ml) or penicillinase (10 μg/ml, the control injection for ChABC). After injection, rats were divided into groups that received no rehabilitation or task-specific reaching rehabilitation of varying intensity. Reaching testing was repeated for 30 days after spinal injection. Our data show that ChABC injection improves skilled reaching after

delayed intraspinal administration, even without reaching rehabilitation. In addition, we found that ChABC can potentiate the therapeutic effect of task-specific (skilled reaching) rehabilitation initiated even one month after cortical stroke. Following final behavioural testing, anterograde neuronal tract tracers were injected near the sight of ischemic injury to assess changes in spinal cord connectivity from the spared cortex adjacent the infarct. We found that ChABC spinal injection significantly increased the number and distribution of ipsilesional corticospinal tract axons innervating stroke affected spinal grey matter. These experiments suggest that functional connectivity between the cervical spinal cord and sensory-motor cortex can be augmented long after cortical ischemic damage has occurred, and that reopening the window for spinal plasticity improves spontaneous and rehabilitation-induced recovery from cortical stroke.

TYSSELING[3]; [1]Physiol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [2]Physiology, Physical Med. and Rehabilitation, Physical Therapy and Human Movement Sci., [3]Physiology, Physical Therapy and Human Movement Sci., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Spinal cord injury (SCI) induces the imbalance of excitatory and inhibitory input to the spinal motoneurons. SCI enhances the excitatory input over the inhibitory one, thus leading to hyperreflexia and muscle spasms. This over-excitation could be attributed to the loss of tonic serotonin (5-hydroxytryptamine; 5-HT) inhibition of the excitatory deep dorsal horn (DDH) neurons. The SCI-induced disinhibition of the DDH neurons could increase their firing responses by showing bursting responses or increased tonic firing. Thus, the disinhibited DDH neurons potentially provide an exaggerated excitatory drive to the spinal motorneurons. Surprisingly, activation of 5-HT1B/1D receptors can reduce muscle spasms without affecting the intrinsic

properties of spinal motoneurons, shown by studies in chronic SCI rodents and humans. Moreover, activation of N-methyl-D-aspartate (NMDA) receptors can induce the potentiation of excitatory postsynaptic potentials. Thus, NMDA receptors could be also involved in exaggerating the excitatory drive to the spinal motoneurons after SCI. However, it remains unknown how the activation of 5-HT1B/1D and NMDA receptors would affect the responses of the DDH neurons after SCI. Therefore, we characterize the firing properties of the DDH neurons during the acute stage of complete SCI in bath applications of NMDA and the selective 5-HT1B/1D receptor agonist zolmitriptan. Adult mice (Mus musculus) received a complete spinal transection during the *in vitro* sacral cord preparation for the acute SCI model. Extracellular recordings of firing properties were made from the DDH neurons located in the spinal lamina III-V, which received synaptic activation via dorsal root stimulation at four stimulus intensities. We found three types of the DDH neuronal responses upon dorsal root stimulation: simple, bursting, and tonic responses. In response to increasing stimulus intensities in controls, the majority of the recorded DDH neurons showed the increasing number of their responsive spikes, faster first-spike latency, and larger field potentials. Compared with the controls, NMDA increased both the number of responsive spikes and tonic firing, whereas zolmitriptan decreased both of them and also delayed the first-spike latency. In case of the DDH neurons with bursting responses, they also showed an increase in their bursting duration in response to increasing stimulus intensities. Compared with the controls, NMDA increased the bursting duration, while zolmitriptan decreased it. Together, these results suggest the facilitative effect of NMDA and inhibitive effect of zolmitriptan on the firing properties of the DDH neurons after acute SCI.

Title: Changes of calbindin-D28k immunoreactive neurons in the thoracic spinal cord after space flight

Authors: ***P. M. MASLYUKOV**, V. PORSEVA, A. STRELKOV, V. SHILKIN;
Yaroslavl Med. Acad., Yaroslavl, Russian Federation

Abstract: Calcium-binding proteins are involved in numerous functions, including cell signaling, calcium uptake and transport, cell motility and intracellular calcium acceptance. Calbindin-D28k (CB) is a calcium-binding protein located in separate groups of neurons including spinal cord. In studies of the spinal cord under microgravity condition, the most attention was focused on lumbar motoneurons. There are no data about structure and functions of thoracic motoneurons and interneurons after space flight. The aim of the work was to analyze changes in the location and morphological characteristics of CB-immunoreactive neurons of the thoracic spinal cord of C57BL/6N male mice after completion of a 30-day space flight on board the BION-M1 biosatellite (Russia, 2013). CB-positive neurons were identified using immunohistochemistry with subsequent fluorescent microscopy. Space flight induced multidirectional changes of the number and morphological parameters of CB-positive neurons. The number of IR neurons increased in laminae I (from 10 to 17 neurons per section), II (from 42 to 67 cells per section) and IX (from 2 neurons per segment to 2 neurons per section), but CB disappeared in neurons of laminae VIII. Weightlessness did not affect the number of CB-immunoreactive neurons in lamina III-V and VII including preganglionic sympathetic neurons. The cross-sectional area of CB-immunoreactive neurons decreased in lamina II and VII (group of partition cells) and increased in laminae III-V and IX. After a space flight, few very large neurons with long dendrites appeared in lamina IV. The results obtained give evidence about substantial changes in calcium buffer system and imbalance of different groups of CB-immunoreactive neurons due to reduction of afferent information under microgravity.

Abstract: The olfactory ensheathing cells (OECS) have been of great interest since they are promotors of the regeneration of the central nervous system (CNS) due to their inherent capacity in the olfactory system to support the continuous regeneration of olfactory neurons. These cells secrete proteins that help the occurrence of neurogeneration processes. Previously the mechanisms of cellular action in a spinal cord injury has been studied, specifically de OECS in animal models regarding the favoring of the recovery of the locomotive function. Even do, in previous studies performed by us have demonstrated the effect of these factors *in vivo*; it was necessary to quantify them *in vitro* so as to understand on a cellular level the process of regeneration. It is this way, that this research had as a purpose to: Identify the presence and expression of stimulating factors such as: aFGF, NT-4/5 and inhibitors such as: NOGO-A and MAG of neuroregeneration in cellular cultures and conditioned media of the olfactory ensheathing cells (OECS) using nanosensor technology as the biosensors that allow to determine in the real time the concentration of the secretions of these factors with a minimum sample, without pretreatment, free of markers of revealing agents facilitating this way the effective evaluation of the presence and expression of promoting and inhibiting factors for the neuroregeneration of the OECS. Results obtained, in the cellular culture phase showed a purification of the measured cells by flow cytometry. Posteriorly it was established the detection and quantification methodology of the promoting and inhibiting proteins aFGF, NT-4/5 and inhibitors NOGO-A and MAG following the interaction kinetics using SPR (Surface Plasmon Resonance). Data obtained with the optical biosensor, show detection results for the promoting factors in concentrations in a nm scale significant for the different cellular densities and sampling time of the culture media of the olfactory ensheathing cells. Standard curves were drawn to calculate the concentrations of the proteins according to the ICH harmonization guides. Finally the methodology was validated using and immunoassay (ELISA).

Title: Loss of descending serotonergic fibers transforms how GABA regulates nociceptive systems within the spinal cord: Role of KCC2

Authors: *Y.-J. HUANG[1], K. H. LEE[2], J. W. GRAU[1];
[1]Neurosci., Texas A&M Univ., College Station, TX; [2]Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA

Abstract: GABA is the chief inhibitory neurotransmitter in the mammalian central nervous system. Given this, disrupting GABA transmission within the spinal cord with the GABA-A antagonist bicuculline should enhance neural excitability and promote the development of nociceptive sensitization. We have shown, however, that bicuculline paradoxically attenuates behavioral and cellular indices of central sensitization in spinally transected rats. Rats that have undergone a spinal transection at the second thoracic vertebrae (T2) exhibit enhanced mechanical

reactivity (EMR), and ERK activation within the dorsal horn, when a hind paw is treated with capsaicin. Intrathecal (i.t.) bicuculline blocks both of these effects. We proposed that spinal injury alters GABA signaling because it down-regulates KCC2, which would cause intracellular Cl- concentrations to rise and lead to GABA having an excitatory (depolarizing) effect. Supporting this, we have shown using western blotting that spinal injury reduces membrane bound KCC2 (relative to the cytoplasmic fraction) and that pharmacologically inhibiting KCC2 (via i.t. DIOA) emulates the effect of spinal injury in intact rats. Conversely, pharmacologically lowering intracellular Cl, via i.t. bumetanide (a NKCC1 inhibitor), in transected rats reverses the effect of bicuculline. We hypothesized that spinal injury alters GABA function because it disrupts descending serotonergic (5HT) pathways that regulate nociceptive transmission. If this is true, administration of a 5HT agonist should reinstate GABAergic inhibition after spinal injury and reverse the effect of bicuculline. Spinally transected rats were given a 5HT1A agonist (DPAT) prior to bicuculline and peripheral capsaicin. In the absence of DPAT, bicuculline attenuated nociceptive sensitization. In DPAT treated transected rats, bicuculline had the opposite effect.

Title: Intelligence and functional connectivity in people with Cerebral Palsy

Authors: *R. E. ALCAIDE[1], J. E. HUGGINS[2], S. WARSCHAUSKY[2];
[2]Physical Med. and Rehabil., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Cerebral palsy (CP) is a term that describes a spectrum of disorders of impaired motor and sensory function caused by a brain lesion occurring during early development. These lesions may also lead to intellectual disability and specific cognitive impairments. Previous studies have investigated functional connectivity in children with CP. Results have suggested that children

with CP recruit more cortical regions, have longer global network path lengths and have decreased functional connectivity in lesion areas. It is believed that, in part, these findings reflect neural compensation for underlying pathology. Increased recruitment and decreased functional connectivity are also associated with lower intelligence in typically developing individuals. This would suggest that children with CP should have lowered intelligence, however, only fifty percent of children with CP exhibit intellectual disability. Currently, it is unknown whether connectivity as reflected in brain recruitment, network path length and functional connectivity, is directly correlated with level of intellect in children with CP. Examining connectivity and cognition in children with CP is an important step in advancing our understanding of brain-behavior relations and brain reorganization following lesions to the developing brain. Using our P300 BCI-adapted Pearson Peabody Picture Vocabulary Test (PPVT-IV) on 10 typically developing children and 10 age-matched children with CP, we collected electroencephalography (EEG) data and PPVT-IV results. The PPVT-IV is a single word receptive vocabulary test that can be used as a proxy for verbal intelligence. Subjects are shown an image with four colored illustrations, and a target word is presented audibly. The subjects then select the image that best matches the audible prompt using our adapted BCI adapted PPVT-IV. The EEG data collected by the BCI were processed for network dynamics to determine recruitment, network path length and functional connectivity. PPVT-IV results were correlated between network path length, number of areas recruited and functional connectivity of each subject. Lastly, a multiple analysis of variance was used to measure differences between CP and typically developing children.

Title: The effect of movement speed of visuomotor task on the activity of spinal inhibitory circuits

Authors: ***S. KUBOTA**[1,2], M. HIRANO[1,2], Y. KOIZUME[1], S. TANABE[3], K. FUNASE[1]; [1]Dept. of Human Sciences, Grad. Sch. of Integrate Arts and Sci., Hiroshima Univ., Higashi-hiroshima, Japan; [2]Res. Fellow of the Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Fac. of Rehabilitation, Sch. of Hlth. Sci., Fujita Hlth. Univ., Toyoake, Japan

Abstract: Objective: Previous studies have shown that spinal reflex circuits are modulated by motor skill training. However, the effect of task movement speed on the spinal reflex circuits have not been clarified yet. The aim of this research is to investigate whether spinal reflex circuits are affected by task movement speed. Methods: Thirty-eight healthy subjects participated in this study. In experiment 1, eighteen subjects performed visuomotor task that involve alternating ankle movement either slow (9 subjects) or fast (9 subjects) movement speed, and 9 subjects performed non-visuomotor task (control task) in fast movement speed. The movement speed was defined the time of 1 cycle of ankle movement; slow movement speed was set to 2000 ms (0.5 Hz rhythm), and fast movement speed was set to 750 ms (1.5 Hz rhythm). The amount of reciprocal Ia inhibition and presynaptic inhibition (D1 inhibition) were recorded before, immediately after, 15 min after, and 30 min after of the training session. In experiment 2, using transcranial magnetic stimulation (TMS), the effect of corticospinal descending inputs on presynaptic inhibitory pathways were examined before and after performing either visuomotor task (8 subjects) or non-visuomotor (8 subjects) task at fast movement speed condition. Results The amount of reciprocal Ia inhibition is affected by the movement speed of visuomotor task; it is increased in a fast movement speed condition, but unchanged in a slow movement speed condition. The amount of D1 inhibition is increased after visuomotor task irrespective of movement speed. Non-visuomotor task (control task) is not induced any changes in the amount of the reciprocal Ia inhibition and the D1 inhibition. TMS conditioned effect of presynaptic inhibitory pathways is changed following visuomotor task. Conclusion Corticospinal descending inputs to spinal cord during controlled limb movement are responsible for the changes in presynaptic inhibition, and that task movement speed is critical factor for inducing activity changes in reciprocal Ia inhibition in addition to corticospinal descending inputs.

Title: Reduced post-activation depression of the soleus H-reflex and root evoked potential following transcranial magnetic stimulation

Authors: *J. ANDREWS[1], R. STEIN[2], F. ROY[2];
[1]Physiol., Univ. of Alberta, Spruce Grove, AB, Canada; [2]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Post-activation depression of the Hoffmann (H)-reflex is associated with a transient period of suppression following activation of the reflex pathway. In soleus, the depression lasts for 100-200 ms during voluntary contraction and up to 10 s at rest. A reflex root evoked potential (REP), elicited following a single pulse of transcutaneous spinal stimulation to the thoracolumbar spine, has been shown to exhibit similar suppression. The present study systematically characterized the effect of transcranial magnetic stimulation (TMS) on post-activation depression using double-pulse H-reflexes and REPs. A TMS pulse reduced the period of depression to 10-15 ms for both reflexes. TMS could even produce post-activation facilitation of the H-reflex, as the second reflex response was increased to 243 ± 51% of control values at the 75 ms interval. The time-course was qualitatively similar for the REP, yet the overall increase was less. While recovery of the H-reflex was slower in the relaxed muscle, the profile exhibited a distinct bimodal shape characterized by an early peak at the 25 ms interval, reaching 72 ± 23% of control values, followed by a trough at 50 ms, and then a gradual recovery at intervals > 50 ms. The rapid recovery of two successively depressed H-reflexes, ~25 ms part, was also possible with double-pulse TMS. The effect of the TMS-induced corticospinal excitation on post-activation depression may be explained by a combination of pre- and postsynaptic mechanisms, though further investigation is required to distinguish between them.

Title: Machine learning classification of a hemiplegic and healthy patellar tendon reflex pair through an iPod wireless gyroscope platform

Authors: *R. C. LEMOYNE[1,3], T. MASTROIANNI[2];
[1]Independent, Running Springs, CA; [2]Independent, Pittsburgh, PA; [3]Northern Arizona Univ., Flagstaff, AZ

Abstract: The attributes of the patellar tendon reflex establish fundamental insight for the conventional neurological examination. Portable media devices, such as the iPod, have been demonstrated regarding the quantification of the patellar tendon reflex response. In particular, the gyroscope sensor of the iPod provides convenient measurement of patellar tendon reflex response. A software application enables the iPod to function as a wireless gyroscope platform. A further evolution involves the incorporation of machine learning to classify a feature set of the gyroscope signal for the patellar tendon reflex response. Machine learning applications have considerable potential to advance the acuity of standard neurological examinations. A hemiplegic and healthy reflex pair is comprised of visibly disparate features regarding the patellar tendon reflex response of both legs. The iPod as a wireless gyroscope platform records and transmits the gyroscope signal of the patellar tendon reflex response as an email attachment for further post-processing through machine learning. The iPod wireless gyroscope platform with machine learning successfully classifies the disparity of a hemiplegic and healthy reflex pair.

Title: Patterns of postural recovery in response to reflexly induced perturbation

Authors: *B. TAHAYORI[1], M. RAZEGHI[3], D. M. KOCEJA[2];
[2]Kinesiology, [1]Indiana Univ., Bloomington, IN; [3]Physical Therapy, Shiraz Univ. of Med. Sci., Shiraz, Iran, Islamic Republic of

Abstract: Control of perturbation during quiet standing entails a sequence of reactions (1). To withstand an externally applied perturbation both the muscular and the nervous system must generate proper reactions (2). In this study, we simulated an external perturbation by unexpectedly stimulating the posterior tibial nerve to cause a sudden twitch in the soleus muscle. Such a stimulation was applied to the right, left or both legs while the subjects stood on a Kistler® forceplate. Recordings from the soleus and tibialis anterior muscles were made through Ag-AgCl surface EMG electrodes. In healthy subjects, it was observed that regardless of the type of stimulation (left, right or bilateral), there was a fast forward perturbation followed by a slow recovery (showed by the red line). When stimulating the right leg, there was a brief burst of Sol with a simultaneous but long lasting contraction of TA (fig 1A). This pattern was reversed when

stimulating the left leg (and recording from the right side - fig 1B). In bilateral stimulation, both muscles showed long lasting cocontraction (fig 1C). In line with our previous studies on stroke pathology (3) we are conducting this experiment on hemiplegic patients to investigate the pattern of recovery in response to this type of experimental perturbation. Title: Effects of postural orientation and weight bearing on soleus H-reflex in young and elderly subjects

Authors: *M. R. ENYART[1], A. PHIPPS[1], K. KITANO[2], D. KOCEJA[2];
[2]Kinesiology, [1]Indiana Univ., Bloomington, IN

Abstract: It is known that the soleus H-reflex is suppressed in young subjects in response to a postural orientation change from spine to upright, whereas soleus H-reflex is facilitated among the elderly during the same postural orientation change. This contrary property of the soleus H-reflex is considered to be a result of improper information processing of inputs from the vestibular system in conjunction with proprioceptive information. The purpose of the study was to investigate the effects of postural orientation change on the soleus H-reflex with change in muscle tone. Soleus H-reflexes were measured from nine participants (six young and three elderly). The two postural testing positions were supine (0°) and tilted (60°). Two conditions were investigated; weight-bearing (WB) and non-weight-bearing (NWB). In NWB, subjects were fixed on a tilt table with a harness. At 0°, H-reflexes were evoked during a static condition (subjects were stationary). At 60°, H-reflexes were tested while the tilt table was moving at 4.3°/sec. The intensity of electrical stimulation was set to evoke small M-waves approximately equal to 5% of Mmax. In order to isolate the effects of the vestibular system, visual information was occluded. Modulation ratios were calculated as percentages of control values (H-reflex amplitude at 0°). Young subjects demonstrated 92% and 320% increases (facilitation) in WB and NWB conditions, respectively, whereas elderly subjects demonstrated the opposite: 320% and 160% increases in WB and NWB. A significant interaction ($F(1,7) = 75.8$, $p<.05$) was found between age group (young vs. elderly) and weight condition (WB vs. NWB). Results demonstrated that at 60 degrees of tilt, the young subjects produced greater facilitation to the soleus motor pool in the non-weight-bearing condition, whereas the elderly group demonstrated greater facilitation when weight bearing. These results coincide with earlier studies and suggest differences in weighting of both vestibular and somatosensory inputs in young and elderly.

Title: Ipsilateral and contralateral reflex modulation during tied-belt and split-belt locomotion in spinal-transected cats

Authors: *M.-F. HURTEAU, Y. THIBAUDIER, C. DAMBREVILLE, V. KUCZYNSKI, A. FRIGON;
Physiol. and Biophysics, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: During locomotion, cutaneous reflexes are modulated with task and with the phase of the step cycle to respond to perturbations. Here, we investigate the modulation of cutaneous reflexes during tied-belt (equal left-right speeds) and split-belt (different left-right speeds) locomotion in chronic spinalized adult cats. Three cats with a spinal-transection at T12-T13 level were implanted with electrodes for electromyography and to stimulate the left superficial peroneal (SP) nerve. Reflexes were evoked during tied-belt locomotion at 0.4 m/s and at 0.6 m/s and during split-belt locomotion with the slow and fast hindlimbs stepping at 0.4 m/s and 0.6 m/s, respectively. Both the left and right sides were used as the slow and fast sides. Approximately 120 single pulse stimulations were applied to the left SP nerve at 1.2 times the motor threshold throughout the cycle. The left hindlimb cycle was divided in 10 equal sub-phases. Short latency excitatory (P1) and inhibitory (N1) responses, as well as long latency excitatory responses (P2) were evaluated in ipsilateral flexors and extensors. Crossed responses were also assessed in flexors and extensors. During tied-belt locomotion, P1 and P2 responses in ipsilateral flexors (sartorius, semitendinosus, tibialis anterior) peaked during flexion. In ipsilateral extensors (vastus lateralis, lateral and medial gastrocnemius), N1 responses were observed during extension followed by P2 responses in 2 cats while in the other cat, P1 responses were observed. In all cats, P1 responses were observed in extensors during flexion. In contralateral flexors and extensors, excitatory responses were present during the flexion phase of the stimulated limb. During split-belt locomotion, patterns of reflex modulation found during tied-belt locomotion were preserved, although reflex amplitudes were reduced. Ipsilateral P1 and P2 responses in extensors were reduced by 34 % and 31.5%, respectively, during split-belt locomotion when compared to responses obtained during tied-belt locomotion at the same speed. Ipsilateral P1 and P2 responses in flexors were reduced by 22% and 17%, respectively. Contralateral responses were reduced in flexors and extensors by 25% and 32%, respectively. Therefore, during split-belt locomotion, reflex mechanisms are maintained to facilitate flexion of the stimulated limb during the swing phase while crossed reflex responses co-activate flexors and extensors, presumably to help stabilize the support limb. The reduction in reflex amplitude during split-belt locomotion might be a mechanism to decrease sensory perturbations in a less stable condition.

Title: Rat hind limb nociceptive withdrawal response to heat and mechanical stimuli depends on initial paw posture but not stimulus location

Authors: ***G. VERDI**[1], T. L. BERRENA[2], K. M. SEAMON[2], C. A. CHRZAN[2], M. HARTMANN[2], B. C. GUMPERT[2], M. N. KABORE[2], K. MOORE[2], C. L. CLELAND[2]; [2]Biol., [1]James Madison Univ., Harrisonburg, VA

Abstract: Rats rapidly withdraw their hind limb in response to a noxious stimulus applied to the plantar surface of their paw, which is an example of the Nociceptive Withdrawal Response (NWR). Previous studies in spinalized or lightly anesthetized non-human mammals have shown that the spatial organization of the response depends on stimulus location. The goal of our studies was to determine if the location of heat and mechanical stimuli, or other factors such as initial posture, determines the direction of withdrawal in intact, unanesthetized rats. For testing the response to heat stimuli, rats were placed on a glass plate through which an infrared laser (980 nm) was directed to heat a small (1mm) localized portion of the plantar surface of the foot. Heat stimuli were delivered along three dimensions (rostral-caudal, lateral-medial, to each of the five toes). For testing the response to mechanical stimuli, rats were placed on a wire mesh and a stimulus (nylon monofilament or 30g needle) was applied to one of five locations along the rostral-caudal and lateral-medial dimensions on the plantar surface. The resulting withdrawal response was recorded with three conventional camcorders (60 fps), one on the left, one on the right, and the third underneath the rat. From the video beneath the rat, the initial location and angle of the stimulated paw was recorded. In response to both heat and mechanical stimuli, the rat withdrew and rapidly (~40ms) replaced its paw on the glass/mesh, at which point the final location and angle of the paw were recorded. Rats withdrew and then replaced their paw on the glass in all possible directions. To determine if the location of the stimulus influenced response direction and magnitude, the rat's paw was stimulated along each of the three dimensions. Unexpectedly, we found that the direction of response did not depend on stimulus location across

both heat and mechanical stimuli and all three dimensions of stimulus location. However, we noticed that the initial position of paw varied in both location and angle. Consequently, we explored if initial position and paw angle influenced final location and angle. Our results consistently revealed that the direction and magnitude of the response depended significantly and strongly on the initial location and angle of the foot. For example, if the paw was initially rostral, the movement tended to be caudal, and if the paw was initially medial, it would move lateral. These results demonstrate, in contrast to studies in spinalized or anesthetized non-human animals, that initial posture plays a greater role in the programming of the NWR than stimulus location.

Title: Dependence of the nociceptive withdrawal response of the tail on stimulus location and intensity

Authors: *Q. KANG, S. J. THAI, J. KIM, J. A. BRAUN, C. L. CLELAND;
James Madison Univ., Harrisonburg, VA

Abstract: The nociceptive withdrawal response (NWR) allows mammals to avoid harmful stimuli that could cause tissue damage. The NWR has been studied across diverse groups of animals revealing that stimulus location can influence the spatial organization of the NWR. However, previous studies in non-human animals have been conducted largely under either light anesthesia or following decerebration. The aim of this study is to determine in intact, unanesthetized rats how the nociceptive withdrawal response to localized heat stimuli depends on rostral-caudal stimulus location and stimulus intensity. Adult intact, unanaesthetized Sprague-Dawley rats were placed inside an acrylic tube with their tail protruding straight from the rear of the tube. Thirteen circular dots were marked dorsally along the length the tail with a black marker. Localized (1mm diameter) heat stimuli were delivered continuously until withdrawal

with a laser diode (980nm) to the lateral surface of the tail at the caudal 12 levels. The resulting NWR of the tail was recorded using high speed video (650 fps) positioned directly overhead. Latency was used a proxy for stimulus intensity and varied between 0.5 and 15 s. The 13 dots were tracked automatically in software to obtain the location of each of the dots in the rostral/caudal - lateral/medial plane over time. The resulting movement stayed largely within the horizontal plane. The movement of the tail was quantified in terms of tail base rotation and local bend along the length of the tail. Preliminary results revealed that rotation of the tail at its base and local bend at various levels along the tail were the primary features of the withdrawal response. The level of the local bend typical progressed caudal through the movement. The rotation of the base of tail depended non-linearly with stimulus level; magnitude increased as the stimulus moved caudal from the base but then decreased as the stimulus level approached the caudal end of tail and actually reversed in direction for stimuli delivered to the last two levels. These results suggest that movement associated with nociceptive withdrawal of the tail is both complex and depends on stimulus location.

Title: Postural modulation of the nociceptive withdrawal response of the tail in intact, unanaesthetized rats

Authors: *J. KIM, Q. KANG, C. L. CLELAND;
Biol., James Madison Univ., Harrisonburg, VA

Abstract: The nociceptive withdrawal response (NWR) allows mammals to avoid harmful stimuli that could cause tissue damage. The NWR has been studied across diverse groups of animals revealing that both stimulus location and initial posture can influence the spatial organization of the NWR. However, previous studies in non-human animals have been conducted under either light anesthesia or following decerebration. The aim of this study is to determine in intact, unanesthetized rats how the relationship between stimulus location and

pattern of movement depends on tail curvature and rotation. Adult intact, unanaesthetized Sprague-Dawley rats were placed inside an acrylic tube with their tail protruding straight from the rear of the tube. Thirteen circular dots were marked dorsally along the length the tail with a black marker. Heat stimuli were delivered with a laser diode (980nm) to the lateral surface of the tail at three rostral-caudal levels. The posture of the tail was changed in two ways. First the tail was curved circularly with five different diameters (0, 8, 16, 32, 64 cm). Second, the tail was kept straight but the base of the tail was rotated to four different angles (0, 30, 60, 90 degrees). The resulting NWR of the tail was recorded using high speed video (650 fps). The 13 dots were tracked automatically in software to obtain the location of each of the dots in the rostral/caudal - lateral/medial plane over time. The resulting movement stayed largely within the horizontal plane. The movement of the tail was quantified in terms of tail base rotation and local bend along the length of the tail. Preliminary results from rats with variously curved tails suggest that rotation associated with the NWR around the base of the tail did not vary with tail curvature. However, the local bend was absent for the largest tail curvatures when the stimulus was applied from outside of the curve of the tail. These observations are similar to our recent results in the NWR of foot in which the response depends strongly on the initial posture of the foot.

Title: Post-stroke disruption of bilateral lower limb neuromuscular control in response to a unilateral gait perturbation

Authors: *B. SHARAFI[1], Y. Y. DHAHER[2];
[1]Ctr. for Physical Ergonomics, Liberty Mutual Inst. For Safety, Hopkinton, MA; [2]Northwestern Univ., Chicago, IL

Abstract: The goal of this study was to characterize post-stroke changes in the bilateral sequence of lower limb responses following a destabilizing unilateral perturbation during gait.

Previous studies have shown delayed reflexes in the paretic leg following balance perturbations from standing position. Investigating lower limb responses to gait perturbations may reveal post-stroke impairments of intra and inter-limb reflexes that are relevant to real-life situations in which stability is challenged. 11 stroke survivors and 8 healthy subjects walked on a treadmill. We interrupted the foot in early swing phase. Kinematics and lower limb electromyography were recorded. The interruption of the foot induced ankle dorsiflexion, followed by hip extension and knee flexion in the perturbed swing leg. In healthy subjects (Figure 1 A), the induced dorsiflexion evoked a short latency activation in the swing leg soleus (38 ms). Medium and long latency responses (50-70 ms) emerged in the swing leg rectus femoris (facilitation) and hamstrings (inhibition). Activation onsets of stance leg hamstrings and hip adductor and abductors occurred with latencies of 60-80 ms. In stroke patients, regardless of which leg was perturbed, the bilateral control sequence was disrupted (Figure 1, B and C). In the stance leg, as in healthy subjects, the earliest responses occurred in the hamstrings and the hip adductor and abductors. However, latencies were significantly ($\alpha<0.05$) longer. In both paretic and nonparetic swing legs, the short latency soleus response was absent. Disruption of the control sequence was more prominent when the paretic leg was perturbed; onsets of quadriceps responses were significantly later in the paretic swing leg than in the nonparetic swing leg. Moreover, the stance leg quadriceps activations were delayed when the paretic leg was perturbed. It is possible that the quality of the afferent input from the paretic swing leg contributes to the disruption of the bilateral control sequence. However, the altered sequence in the nonparetic perturbed leg suggests bilateral mechanisms of impairment.

Title: Effects of wrist orientation and level of muscle activation on the magnitude of reciprocal inhibition and cutaneous reflexes in forearm muscles

Authors: *Y. SUN[1,2,3], E. ZEHR[1,2,3,4];
[1]Rehabil. Neurosci. Laboratory, Univ. Victoria, Victoria, BC, Canada; [2]Human Discovery Science, Intl. Collaboration on Repair Discoveries (ICORD), Vancouver, BC, Canada; [3]Ctr. for Biomed. Research, Univ. of Victoria, Victoria, BC, Canada; [4]Div. of Med. Sciences, Univ. of Victoria,, Victoria, BC, Canada

Abstract: Amplitude modulation of reciprocal inhibition (RI) and cutaneous reflexes have been studied in various motor tasks in the human. In the lower limb, a common method to evoke RI is stimulating the antagonist mixed nerve while measuring the evoked response in the target muscle. Cutaneous reflexes have also been extensively examined to test the modulation of spinal pathways in the legs. Previous studies suggest that spinally-mediated reflex amplitudes are significantly affected by posture and muscle activation level. However, less is known about modulation of RI and cutaneous reflex amplitudes in the arm. We explored modulation of these evoked responses in extensor carpi radialis (ECR) muscle with varied contraction intensities (10, 25, 35 and 50% of maximal voluntary contraction (MVC)) and with the hand horizontal or vertical. RI was evoked by a single pulse stimulation applied to the median nerve (MED) in the upper arm. Cutaneous reflex were evoked by trains of stimulation to superficial radialis (SR) nerve or MED at the wrist. The largest effect of muscle activation level was observed for RI and was less affected by wrist position. This contrasts with results published elsewhere on forearm H-reflex amplitudes which are strongly modulated by wrist position. The relationships for cutaneous reflexes may be weaker than those observed for RI, suggesting that early latency cutaneous reflex amplitudes in ECR can be less sensitive to muscle activation level and joint orientation. We conclude that the modulation of reciprocal inhibition and early latency cutaneous reflexes may have different dependencies on the level of muscle activation and joint orientation.

Abstract: Stimulation of cutaneous nerve branches innervating the foot induces functional corrective responses that are phase-dependently modulated throughout the gait cycle. Cutaneous stimulation of discrete regions of the foot sole have been shown to induce specifically tuned "sensory steering" during locomotion. We hypothesized that this topographical organization would also be found on the dorsal foot surface. Non-noxious electrical stimulation was delivered to five discrete locations (base of 1st and 4th metatarsal, midfoot medial and lateral skin surfaces and ankle crease) on the dorsal surface of the foot during treadmill walking. Activity of muscles (EMG) acting at the ankle, knee, hip and shoulder joints was recorded along with kinematics at these joints. All data were sorted based on stimulus occurrence in twelve step-cycle phases, before being averaged together within a phase for subsequent analysis. The results illustrate large, dynamic and statistically significant site-specific and phase-dependent changes in reflex amplitudes and kinematics. The predominant effects of the dorsal foot stimulation were expressed during the swing phase and functionally served to maintain stability of the swinging limb. In general, responses of lateral and medial stimulation differed and the effects were most prominent at the distal end of the foot (1st and 4th metatarsals). Given the unstable nature of the swing phase, responses to stimulation go beyond the muscles that control the ankle to include muscles at the hip and shoulder. These results increase our understanding of how afferent feedback from specific cutaneous locations of the dorsum of the foot influences the mechanisms involved in swing phase corrective responses. These data may provide potential rehabilitative application to enhance function following neurological damage.

Title: Can five weeks of arm cycling training improve walking and neurological integrity in chronic stroke?

Authors: *C. KAUPP[1,2,4], T. KLARNER[1,2,4], Y. SUN[1,2,4], N. ZAPOTOCZNY[1], H. CULLEN[1,2,4], T. S. BARSS[1,2,4], G. E. PEARCEY[1,2,4], E. P. ZEHR[1,2,4,3];

Abstract: Strong interactions between the upper and lower body are well established across species and recent work has highlighted the implications of these connections for rehabilitation in humans. During walking, interlimb spinal networks regulate gait in healthy individuals and remain at least partially intact after stroke. What remains to be investigated is whether training the arms after stroke can facilitate these networks and result in improved walking function. The purpose of this study was to evaluate the contributions of rhythmic upper limb training to improvements in strength, reflex modulation, and walking function post stroke. Chronic stroke participants (at least 6 months post infarct) were recruited to a 5 week long (30 min @ 60rpm x 3 / wk) arm cycling intervention with a within-subject multiple baseline control. Over the course of the training, heart rate and rate of perceived exertion (RPE) were recorded in order to evaluate physiological cost. Resistance of the Sci-Fit Pro 2 ergometer was gradually increased over the five weeks in order to maintain a stable RPE. Muscle activation during treadmill walking and rhythmic arm cycling was assessed in the more affected (MA) and less affected (LA) side via surface electromyography (EMG) in the following muscles; tibialis anterior (TA), soleus (SOL), anterior deltoid (AD), biceps brachii (BB), triceps brachii (TB) and flexor carpi radialis (FCR).

Maximal voluntary isometric contraction strength was evaluated bilaterally in the legs via plantarflexion and dorsiflexion and in the arms via grip strength. In order to evaluate changes in interlimb neural coupling, cutaneous reflexes were elicited via electrical stimulation (5x1.0ms trains @ 300Hz) of the superficial radial nerve during treadmill walking. The effects of cervical networks on lumbar spinal cord excitability were assessed with bilateral soleus stretch reflexes elicited at rest and during 1Hz arm cycling. Clinical status and walking ability were determined via the six minute walk, ten meter walk, and timed up and go tests. Preliminary results show a modulation of interlimb connectivity, changes in strength and muscle activation during maximum voluntary contraction, and improvements in clinical walking function. Taken together, these results emphasize the utility for incorporation of upper limb activity in the functional rehabilitation of walking after neurotrauma.

Title: Effects of tonic cutaneous input on sensory feedback transmission in the upper limb

Authors: ***T. S. BARSS**[1,2,3], G. E. P. PEARCEY[1,2,3], B. MUNRO[5], E. P. ZEHR[1,2,3,4];
[1]Univ. of Victoria, Rehab Neuro Lab., Victoria, BC, Canada; [2]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada; [3]Ctr. for Biomed. Res., [4]Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada; [5]Nike Exploration Team Sport Res. lab, Natural Motion Div., Beaverton, OR

Abstract: Cutaneous feedback from the skin provides accurate perceptual information about joint position and movement (Edin, 1992, 2004; Collins et al., 1996, 2000, 2005). Integrated with other sensory modalities, cutaneous feedback informs judgements of position and movement around joints throughout the body. Afferent information from the skin is “tuned” by the nervous system depending upon the time of activation in the locomotor cycle and the task being completed (Zehr & Kido, 2001; Zehr, Collins, Frigon & Hoogenboom, 2003). This information goes largely unnoticed in conscious movement due to its relatively fast acting effects on motor

output. However, a constant tactile input to the skin may alter excitability through changes in pre-synaptic inhibition of muscle afferent feedback. The purpose here was to explore how tonic sustained input to the skin modulates sensory feedback transmission in the upper limb. Neurologically intact participants performed: 1) tonic muscle contractions (10% EMGmax); 2) Arm cycling @ 1Hz (60 rpm). Each of these tasks was completed under two conditions including, CONTROL (no cutaneous input), and CONSTANT (constant cutaneous input applied across the elbow joint). Outcome measures included reflex (H and cutaneous) amplitudes and background muscle activity assessed via electromyography (EMG). All data were normalized to maximum evoked M-waves. M-H recruitment curves were constructed using bipolar surface electrodes placed over the median nerve just proximal to the medial epicondyle of the humorous with single 1.0-ms pulses occurring pseudo randomly every 2 - 4 seconds. Conditioned recruitment curves were also elicited through stimulation of the superficial radial (SR) or median (MED) nerves at the wrist (3xRT for 5x1 ms @ 300Hz) 37 ms prior to median nerve stimulation above the elbow. Cutaneous reflex pathways were also evaluated through stimulation of the either the SR or MED nerve at the wrist during a 10% contraction. Reflexes during cycling were evoked at 4 specific positions in the movement cycle. EMG was recorded in the flexor and extensor carpi radialis as well as biceps and triceps brachii muscles. Results indicate that providing a constant tactile input to the skin modulates the excitability of afferent connections independent of descending input. Changes in pre or post synaptic inhibition within a limb receiving constant cutaneous input may alter the functional “set-point” of ongoing motor output.

Title: Fatiguing contractions of paretic knee extensors do not exacerbate stretch reflex responses

Authors: *R. BERRIOS, M. KIRKING, H. KUHNEN, S. HUNTER, B. SCHMIT, A. HYNGSTROM;
Marquette Univ., Milwaukee, WI

Abstract: Objective: Post stroke, hyper excitable stretch reflex responses in the leg can interfere with movement for activities such as gait. Previous studies have examined the effects of brief bouts of exercise on stretch reflex responses, but the effect of fatiguing contractions on stretch reflex responses is unknown. Clinically, this is relevant as strengthening regimens require muscle overload (fatigue). The purpose of this experiment was to investigate the effects of sub-maximal fatiguing knee extensor contractions on the magnitude of the stretch reflex response in individuals with chronic stroke. We predicted that the magnitude of the paretic patellar tendon reflex response (elicited by tendon tapping) would decrease following fatiguing contractions, but not as much as in control subjects. **Methods**: 10 subjects with chronic stroke and 10 age-matched controls participated in the study. Each subject group contained 5 females and 5 males. Subjects were seated on a System 3 Dynamometer (Biodex Medical Systems, Shirely NY) with their hips and knees at 90 degrees of flexion. A Linmot linear motor (LinMot Inc, Delavan WI) was used to tap the patellar tendon. 3-5 knee extensor maximal voluntary contractions (MVCs) were performed. Next, 5 tendon taps (2 Hz) to the patellar tendon were performed. The fatigue protocol consisted of 5 isometric knee extensor contractions (20% of MVC, 5s) and 1 MVC. This set was repeated until task failure. Immediately following the fatigue protocol, a final set of tendon taps was performed. For each individual, the peak reflex response was calculated and normalized to their baseline MVC. The percent decline between baseline and post fatigue reflex response measurements was then calculated. In addition, the post fatigue reflex response was correlated with post fatigue MVC values for both groups. **Results:** Individuals with stroke had shorter task duration (26.1 min $\pm$ 12.6) as compared to controls (40.2 min $\pm$ 14.0, p=0.03). The percent decline in peak reflex response was larger in controls (50.3% $\pm$ 34.0) as compared to the stroke group (16.3% $\pm$ 21.7, p=0.02). There was a positive correlation between the magnitude of the post fatigue reflex response and MVC for the controls (r^2=0.41), but not the stroke group (r^2= 0.003). **Conclusion**: Despite decreased task endurance, fatiguing exercises do not worsen stretch reflex responses in the paretic leg. Clinicians can utilize the fact that fatiguing exercises (necessary for overloading muscle and strengthening) will not increase hyper-reflexive activity or interfere with movement immediately following the exercise.

Title: The effect of fatigue on interlimb communication

Authors: ***S. GERVASIO**, A. J. T. STEVENSON, N. MRACHACZ-KERSTING;
Aalborg Univ., Aalborg, Denmark

Abstract: Performing repeated motor tasks during a volleyball, basketball, or soccer game can lead to muscular fatigue, inducing a decrease in the capacity of a muscle to generate force, changes in motor coordination, and an alteration in motor performance. These changes have been attributed to an elevated risk of musculoskeletal injury. Little is known about if and how fatigue affects the coordination between the two legs during a long lasting game, and whether this could be one of the causes behind the increased occurrence of injuries towards the end of a game. The aim of the present study was to investigate the possible effect of muscular fatigue on interlimb communication. Eight amateur male soccer players took part to two recording sessions in which they either performed a 90-minute simulated soccer match (SAFT90) or rested (control session). Interlimb communication was investigated by quantifying short latency crossed responses (SLCR) observed in muscles of the contralateral (dominant) leg following nerve stimulation of the ipsilateral (non-dominant) leg. SLCR and maximal voluntary contraction (MVC) of the ankle plantarflexors in the dominant leg were measured before and after the SAFT90 and control session. MVC was quantified while the participants performed a plantarflexion on a force platform, with the ankle and knee joints fastened at 90^{o} . SLCR were elicited by electrical stimulation of the ipsilateral tibial nerve while the participants walked on a treadmill. The stimulation (intensity 85% Mmax) was delivered at 80% of the participant's walking cycle. SLCR in the contralateral gastrocnemius lateralis were quantified as the ratio between the root mean square (RMS) value of the averaged EMG in a time window between 65 and 95ms after the stimulation, and the RMS in the same time window of the control EMG (average of gait cycles with no stimulation). One participant did not show any decrease in MVC after the SAFT90 and was therefore excluded from further analysis. The MVC significantly decreased ($P < .05$) from 1633 ± 151 N to 1263 ± 292 N in the SAFT90 session, but not in the control session (1354 ± 391N before and 1352 ± 404 N after). No significant changes were observed in the SLCR amplitudes. However, a bigger decrease (18% decrease, from 206 ± 107 to 183 ± 85%) was observed after the SAFT90 compared to the control session (14% decrease, from 171 ± 55%

to 146 ± 34%). These preliminary results show that fatigue induces a reduction, although not significant, of the SLCR. Further testing is needed to confirm this hypothesis. Such information may be relevant for preventing musculoskeletal injuries caused by fatigue.

Title: The roles of contralateral conditioning and ipsilateral control stimulus intensities on soleus h-reflex modulation

Authors: A. M. PHIPPS[1], M. R. ENYART[2], K. KITANO[2], *D. M. KOCEJA[2];
[1]Kinesiology, [2]Indiana Univ., Bloomington, IN

Abstract: H-reflex has been extensively used to investigate spinal mechanisms. When used with conditioning techniques, it can prove greater insight into specific circuitries. One should pay attention to the stimulus intensities of both conditioning and test stimulations to provide reliable assessment of modulation. Precisely, the magnitude of modulation in the soleus H-reflex induced by conditioning stimulation depends on the size of the control H-reflex as well as conditioning stimulus intensity. Whereas many studies have investigated the role of unilateral reflex conditioning the role of contralateral conditioning can uncover information about more complex neural networks. However, the influence of both the control H-reflex and the intensity of the conditioning stimulation are still unclear. Therefore, the purpose of this study was to assess effects of (1) control H-reflex size and (2) intensity of conditioning stimulation applied to the contralateral common peroneal nerve on the soleus H-reflex. Six participants were tested in the prone position. Two amplitudes of control H-reflex on the ipsilateral side and three intensities of conditioning stimulation applied on the contralateral side were tested. The conditioning stimuli, a train of four for 20ms, to the contralateral common peroneal nerve preceded the ipsilateral soleus test stimulation by 25, 50, 75, 150, and 300ms. Soleus control H-reflex was set to 50% of H-max and 15% of M-max. Three intensities were used as a conditioning stimulation (1.2, 1.0, and 0.8 X tibialis anterior motor threshold). Subjects received six conditions (2 H-reflex sizes by three conditioning intensities). At 50ms the H-reflex was modulated by -2% (inhibition), +25% (facilitation), and +51% with 0.8, 1.0, and 1.2 X MT conditioning stimuli, respectively. An ANOVA with repeated measure showed a significant difference ($F(2, 10)= 4.44$), and post-hoc

test revealed facilitation by 1.2 X MT was significantly different from that by 0.8 X MT. No significant difference was found between the sizes of the control H-reflex. These results show a stepwise increase of the conditioned soleus H-reflex amplitude as the intensity of the contralateral conditioning stimulation is increased. This suggests that small diameter afferent fibers may play a greater role in modulating the soleus H-reflex induced by contralateral common peroneal nerve stimulation.

Sciences., Makkah, Saudi Arabia; [3]Texas electrophysiology Services, Houston, TX; [4]Kuwait University, Fac. of Allied Hlth. Sciences, Physical Therapy Department., Kuwait, Kuwait; [5]Umm Al Qura University, Fac. of Applied Med. Sciences, Makkah, KSA, Makkah, Saudi Arabia

Abstract: BACKGROUND: The etiology of Idiopathic Adolescent scoliosis (IAS) is mostly unknown. Neuromuscular alteration of the motor drive was proposed as a possible cause. H-reflex is an electrophysiological procedure to evaluate the spinal motor drive. Its amplitude is the best measure for muscular reflex excitability and nerve root function. Side-to-side H-amplitudes reflex asymmetry (RA) in IAS could indicate neuromuscular imbalance with a possible deficiency in neural drive. IAS may have respiratory dysfunctions. Reduced forced vital capacity (FVC), forced expiratory volume (FEV), and maximum voluntary ventilation (MVV) are reliable respiratory functions(RFs).PURPOSE: To measure the side-to- side H-reflex amplitude in patients with IAS to document RA and to compare these changes to the magnitude of the scoliotic curve (SC) as well as the associated RFs METHODS: Subjects (26 patients) with IAS (mean age = 15.2 ± 5.6, weight = 56.2 ± 23.5, height = 156.8 ± 11.2, Cobb angle = 15.5o ±3.9o) were examined in this study. Testing included H-reflex and RFs (FVC, FEV1, FEV1/FVC and MVV). The tibial nerve was electrically stimulated at the popliteal fossa while recording soleus

muscle H-reflex using surface electrodes. H-reflex was recorded bilaterally during lying (unloading) and standing (Loading). Recording parameters were 1-2 mV/div using 10 Hz-10Khz. filter. Five traces peak-to-peak amplitudes averaged and side-to-side (H/H) amplitude ratios were calculated. RFs were evaluated during standing while breathing normally for several cycles, followed by maximal inspiration, and a MVV. FVC, FEV1 and FEV1/FVC were evaluated. MVV was measured during a 10 seconds of fast breathing. Descriptive statistic was used to compare the results of the H-reflex and RFs. The degree of SC was measured using a scoliometer during Adam's stooping position. RESULTS: All patients showed RA with varying degrees. During lying, RA was 6-95% that increased during standing with increased SC. Smaller reflex asymmetry (6%-20%) was related with smaller amplitude on the concave side. Larger degree in RA (20-90%) showed the smaller amplitude on the convex side of SC. These results indicate alteration of the reflex activity and motor drive on bilateral vertebral column correlated with the aggravation of the SC. RFs showed mild restrictive pattern [FVC;75.09%, FEV1;70.6%, FEV1/FVC; 98.4 % of predicted values] reflecting impaired RFs. Reduced MVV (69.09% predictive values) reflects impaired respiratory muscles mechanical strength. CONCLUSIONS: Soleus H-RA in IAS indicates neuromuscular alteration of the motor drive as a possible etiology that was associated with alteration in RFs.

Title: Double-step torques reveal a fixed 50 ms delay in integrating multi-joint motion for corrective action

Authors: *I. KURTZER;
Biomed. Sci., New York Inst. of Technol. - Col. of Oste, Old Westbury, NY

Abstract: Sudden limb displacement evokes a complex pattern of compensatory muscle activity. The earliest burst is generated by spinal circuits (short-latency reflex = 20-45 ms) whereas subsequent bursts are generated by spinal and cortical circuits (long-latency reflex = 50-100 ms; voluntary reaction > 120 ms). Cortical processing allows muscles to respond to the motion of the whole arm rather than local stretch information. However, it is unknown whether cortical circuits play an integrative role throughout an evolving corrective action, or whether the integrative role is delegated from cortical to spinal circuits (i.e. propriospinal neurons). If cortical circuits retain the same role, then a double step torque will evoke an integrative response to each perturbation at the same ≈50 ms delay. Alternatively, an integrative response of ≈20 ms delay to the second perturbation would point to a spinal contribution. Twelve healthy subjects (mean age = 25.5 yro; 7M & 5F) participated in an experiment testing between these possibilities. Surface EMG was obtained from their shoulder extensor (posterior deltoid) while a programmable robot (KINARM, BKiN Technologies) applied mechanical loads in two different directions: a shoulder flexion torque to flex the shoulder and a shoulder-elbow flexion torque to flex the elbow. Perturbations were applied either as a step torque or double-step torque in the same direction (35 ms, 60 ms, and 110 ms offset). Note that the step torque and double-step torques had the same initial magnitude and were randomly intermingled so we could examine the evoked response to the unexpected second perturbation. The first perturbation in the series evoked a short-latency reflex based on local stretch (i.e. when shoulder displacement evoked shoulder muscle activity, $p < 0.001$) and a long-latency reflex that integrated multi-joint motion (i.e. when elbow displacement evoked shoulder muscle activity, $p < 0.001$). All double-steps of shoulder displacement evoked a short-latency response in the shoulder muscle aligned to the second perturbation onset ($p < 0.05$). Critically, all double-steps of elbow displacement only evoked a long-latency response in the shoulder muscle aligned to the second perturbation onset ($p < 0.001$). A running receiver-operating-curve found that shoulder muscle responses had a ≈25 ms delay to the second shoulder displacements and a ≈55 ms delay to the second elbow displacements. Accordingly, the nervous system utilizes cortical circuits to integrate multi-joint motion throughout a corrective action.

Title: Motor equivalence during whole body reaching in healthy young adults

Authors: *Y. TOMITA[1,2], A. G. FELDMAN[3,2], M. F. LEVIN[1,2];
[1]McGill Univ., Montreal, QC, Canada; [2]Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal (CRIR), Montreal, QC, Canada; [3]Univ. of Montreal, Montreal, QC, Canada

Abstract: The large number of kinematic degrees of freedom (DFs) of the body allows tasks to be accomplished using different combinations of DFs (motor equivalence). Despite this redundancy, certain movement features remain invariant. For example, hand trajectory and endpoint precision remained invariant when trunk movement was unexpectedly blocked during reaching from a sitting position. We hypothesized that hand trajectory and endpoint precision may remain invariant regardless of unexpected postural perturbations during whole body reaching from standing, which involves a larger number of DFs. Five healthy young subjects moved the hand to a remembered target located beyond the arm length with their eyes closed during standing (Free-Hip trials; FH). In randomly chosen trials, hip flexion was unexpectedly prevented by an electromagnetic device, forcing the subject to take a step while reaching (Blocked-Hip trials; BH). Reaching movements were also recorded when subjects intentionally made a step (Intentional-Step trials; IS). Upper/lower limb and trunk kinematics and ground reaction forces were recorded. Endpoint trajectory, joint kinematics and shifts in the postural center of pressure were analysed. Reaching trajectories and endpoint precision were invariant between FH and BH trials, while those of IS trials in some subjects differed. Invariance in the endpoint trajectory between FH and BH trials was maintained by changes in elbow/shoulder interjoint coordination patterns which occurred after the time of endpoint peak velocity. Stepping reactions resulting from the perturbation were also initiated after the time of the endpoint peak velocity in BH trials. Thus, unexpected recruitment of additional DFs that challenges postural stability during reaching from a standing position did not affect hand trajectories and endpoint precision. Movement adaptation occurred after the endpoint peak velocity to maintain invariance in endpoint trajectories, confirming our hypothesis that the nervous system can take advantage of the redundancy in the number of DFs to stabilize task performance, resulting in motor equivalence.

Title: Control of posture and movement with respect to gravity by setting the referent orientation of the body

Authors: *A. MULLICK[1,3], S.-C. HSU[3,2], S. K. SUBRAMANIAN[3,4], N. TURPIN[3,4], A. G. FELDMAN[3,4], M. F. LEVIN[1,3];

Abstract: It has been suggested that multiple muscles of the body are controlled as a coherent unit based on the difference between the referent body configuration specified by the brain and the actual, body configuration. The referent configuration is the configuration at which muscles begin to be activated. We suggest that there are referent body configurations that are used to orient actual body postures (straight or leaned) during standing and most body movements in humans and animals relative to gravity. In other words, we suggest that neural control levels can specify a referent body orientation (R) at which multiple muscles of the body reach their activity minimum. Under the influence of gravity, the body is deflected from the referent direction to a direction Q, at which the emerging muscle activity results in forces that balance gravitational forces and body stability is maintained. This hypothesis predicts that during back-and-forth movements, R and Q may momentarily coincide, bringing the activity of multiple muscles of the body to a minimum. We tested this prediction by analyzing the activity of multiple body muscles during rhythmical changes in the body orientation during standing. To manipulate R and create situations in which minima occur, participants were required to stand on 3 surface orientations, ascending, horizontal, and descending, and perform whole body sways and mini squats. EMG minima were identified from EMG signals recorded in 11 muscles across the body and the body postures at which EMG minima occurred were determined. Global minima were identified in all conditions, both in swaying and squatting movements. The EMG minima occurred in 20%-82% of movement cycles. The postures at which global EMG minima occurred were different in different conditions. Preliminary results thus confirm the hypothesis. This study contributes to the understanding of how posture and movement are controlled in the gravitational field. It also extends the previous suggestion that multiple muscles of the body are controlled as a coherent unit depending on the difference between the actual and referent configurations of the body.

Title: Threshold position resetting suppresses both stretch reflexes and background muscle activity in arm muscles in response to prolonged muscle lengthening

Authors: N. A. TURPIN[1,3], R. RAHAL[2,3], S. K. SUBRAMANIAN[1,3], M. F. LEVIN[4,3], *A. G. FELDMAN[1,3];
[1]Neurosci., [2]Biomed. Engin., Univ. Montreal, Montreal, QC, Canada; [3]Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal (CRIR), Montreal, QC, Canada; [4]Sch. of Physical and Occup. Therapy, McGill, Montreal, QC, Canada

Abstract: Since the work of Sherrington (1906), it has been recognized that, together with other proprioceptive reflexes, the stretch reflex (SR), i.e. position- and velocity-dependent resistance to muscle lengthening, plays a fundamental role in the control and stability of posture and movement. The spatial threshold of the SR, i.e. the muscle length or respective joint angle at which the SR begins to act, is broadly regulated by spinal and supra-spinal systems in a task-specific way. We tested the hypothesis that the SR threshold can be reset to suppress both SR reactions and background muscle activity in response to high amplitude lengthening, thus preventing overstretching active sarcomeres. The forearm and hand of subjects (n=12) were placed on a horizontal manipulandum. Elbow flexor or extensor muscles were pre-activated by compensating an external load (1-3 Nm) applied to the manipulandum by a torque motor. The muscles were stretched by rotating the manipulandum by 60° at different velocities (8-120°/s) randomly selected for each trial. EMG signals (biceps brachii, brachioradialis, triceps brachii lateralis and medialis), displacement and velocity were recorded. In training trials and subsequent experimental trials, subjects were instructed to abstain from intentionally modifying their responses to perturbations. Trials in which subjects changed EMG levels prior to stretch onset were excluded. SR responses to muscle stretch (lengthening), if present, were minimal and

occurred at latencies of 25-35 ms and after about 70 ms the EMG activity was suppressed for about 80 ms. After that, the stretched muscles were reactivated during the ongoing muscle lengthening. Results are consistent with the notion of resetting of spatial thresholds for muscle activation, rather than with suppression (gating) of the SR in time. In general, threshold resetting is used not only to prevent muscle overstretching but also in the control of intentional movement. By resetting thresholds, the nervous system converts posture-stabilizing to movement-producing mechanisms, thus solving the classical posture-movement problem. The possible relationship between the notion of SR threshold resetting and the clasp-knife phenomenon in some neurological conditions is discussed.

Title: The long-latency stretch response accounts for kinematic redundancy of the arm

Authors: ***J. WEILER**, P. GRIBBLE, A. PRUSZYNSKI;
The Brain and Mind Inst., The Univ. of Western Ontario, London, ON, Canada

Abstract: Many studies have shown that muscle activity in the long-latency epoch (i.e., 50-100 ms after mechanical perturbation onset) displays goal-dependent modulation that shares many of the sophisticated characteristics of voluntary motor control. These observations are inline with the idea that voluntary motor actions are accomplished by the intelligent manipulation of sensory feedback. One notable capacity of voluntary motor control is its ability to take advantage of kinematic redundancy. For example, patterns of joint variance during pistol shooting appear structured to keep the shot on target. We hypothesize that the intelligent manipulation of sensory feedback also accounts for kinematic redundancy that is afforded to voluntary motor actions. We tested this hypothesis by randomly applying a flexion or extension step-torque to participants' (n=17) elbow or wrist (i.e., perturbation), which displaced the hand either into or away from a

target. Participants were required to quickly move their hand into the target following perturbation onset. Notably, the positioning of the targets were such that a perturbation applied to the elbow that displaced the hand away from the target could be counteracted by a volitional movement of the wrist, and vice versa. We found that participants responded to applied elbow or wrist perturbations that moved the hand away from the target with concurrent elbow and wrist movement. In addition, muscles that were stretched because they articulated the mechanically perturbed joint showed increased activity within the long-latency epoch when the hand was displaced away from the target compared to into the target. Critically, musculature that did not articulate the perturbed joint also displayed increased activity within the long-latency epoch when that muscle acted to move the joint in a manner that assisted transporting the hand into the target. This latter finding demonstrates that kinematic redundancy is incorporated into the intelligent manipulation of sensory feedback used to execute goal-directed actions. We are now testing whether muscle activity within the long-latency epoch accounts for kinematic redundancy when the wrist, elbow and shoulder are concurrently perturbed for reaching movements in the horizontal plane.

Title: Heightened attention to proprioceptive feedback is not sufficient for long-latency reflex modulation during arm posture

Authors: *E. H. E. WALKER[1,4], R. RUIZ-TORRES[2], E. J. PERREAULT[1,4,3], L. E. MILLER[1,3,2];
[1]Biomed. Engin., Northwestern Univ., Evanston, IL; [2]Physiol., [3]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [4]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: When the arm maintains a posture against destabilizing forces, such as when holding a dumbbell overhead against gravity, the relevant muscles demonstrate an increased sensitivity of long-latency reflexes (Krutky et al. 2010). Although the involvement of motor cortex is known to be crucial for this reflex modulation (Shemmell et al. 2009), the factors that drive cortical regulation of the reflex remain unknown. Instabilities likely induce heightened arousal or attention, and studies suggest that attention can increase ascending sensory drive (Staines et al. 2000) and that mental arousal may enhance stretch reflexes (Rossi-Durand 2002; McIntyre et al. 2004). However, it is unclear whether interaction with the unstable environment is required, or if heightened attention alone is sufficient to modulate reflexes. Our main objective was to test the hypothesis that reflex sensitivity is increased due to heightened attention alone; particularly attention to proprioceptive feedback. We tested reflexes during maintenance of elbow posture while subjects attended to proprioceptive or visual stimuli; a control condition with no attention requirement was also tested. A two-alternative force choice (2AFC) task with adaptive stimulus intensities ensured continuing attention. Meanwhile, occasional ramp-and-hold perturbations were used to elicit stretch reflexes. In a subset of subjects, H-reflexes and somatosensory evoked potentials were also assessed as further probes of reflex pathway sensitivity. Our results showed that attention alone is not sufficient for reflex modulation. Although subjects demonstrated appropriate attention (proprioceptive, visual, or none) through their 2AFC responses, there were no detectable differences in reflex sensitivity for either short-latency ($p \geq 0.11$), early long-latency ($p \geq 0.64$), or late long-latency ($p \geq 0.20$) reflex periods in any monitored muscles. H-reflexes and SEPs also remained statistically equivalent in all attention conditions ($p=0.32$; $p=0.85$). This suggests that reflex modulation during a postural arm task requires more than simply heightened attention. Our paradigm effectively decoupled the attention and the postural task, such that attention was not required for purposes of stabilization, but merely for a discriminatory response. We conclude that engagement in the motor task is crucial for the type of reflex modulation that has been observed during destabilized arm posture.

Title: Muscle innervation patterns for human wrist control as biofeedback signals for robotic rehabilitation

Authors: *A. CUPPONE[1], M. SEMPRINI[1], V. SQUERI[1], J. KONCZAK[2];
[1]Inst. Italiano Di Tecnologia, Genova, Italy; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Robotic rehabilitation techniques typically provide extrinsic feedback to a human patient with the goal to improve motor outcomes and to aid recovery. However, feedback can be bi-directional, that is, the rehabilitation device may receive feedback about the motor performance or related physiological signals of the human user. We here focus on the usefulness of normal and abnormal muscle activation patterns as potential sources of biofeedback for controlling and optimizing force output of a robot. Before using user-generated electromyographic signals (EMG) as biofeedback, it is imperative to consider that a) the muscular redundancy found in many human limb systems and b) force generation of human muscles is not linear. Thus, it becomes important to understand how synergistic muscular control influences joint force and joint kinematics. It is the purpose of this study to characterize the electromyographic activation patterns of the major human muscles involved in controlling the hand/wrist system. By means of a robotic exoskeleton, the electromyographic activity underlying the three degrees of freedom (DoF) of hand motion was separately evaluated: wrist flexion-extension, wrist adduction-abduction and forearm pronation-supination. For each DoF four different task conditions were employed: free movements, passive movements with open eyes, passive movements with closed eyes and resistive movements. We recorded surface EMG activity of 7 muscles of the arm and forearm of healthy adult subjects. We created a lookup table by linking kinematics parameters (such as movement duration, linearity and peak velocity) with the root mean square value of the EMG signals calculated for different episodes during movement execution. This lookup table allows for identifying prototypical wrist movement patterns across the three DoF and will subsequently be integrated with the software controlling the robotic exoskeleton during experiments with motor impaired patients in order to provide them with haptic force feedback delivered when needed and with the proper amount of assistance.

Title: A geometric model of defensive peripersonal space

Authors: ***R. J. BUFACCHI**[1], M. LIANG[3], L. D. GRIFFIN[2], G. D. IANNETTI[1];
[1]Neuroscience, Physiol. and Pharmacol., [2]Computer Sci., UCL, London, United Kingdom; [3]Sch. of Med. Imaging, Tianjin Med. Univ., Tianjin, China

Abstract: The defensive peripersonal space (DPPS) is a protective area surrounding the body. Within this space, potentially harmful stimuli elicit stronger defensive reactions. However, the spatial features of the DPPS are poorly defined, and limited to descriptive estimates of its extent along a single dimension. Here we postulated a family of geometric models of the DPPS, to address two important issues related to its spatial features: What is its fine-grained topography? How does the nervous system represent the body area to be defended? These models are based on a set of assumptions about how the nervous system represents threatening stimuli, and their formalization supports the concept that when a threatening stimulus is closer to an individual, its potential for harm is increased, resulting in a stronger defensive reaction. As a measure of the DPPS, we used the strength of the defensive blink reflex elicited by electrical stimulation of the hand (hand-blink reflex, HBR), which is reliably modulated by the position of the stimulated hand in egocentric coordinates. The best fitting model indicated that (1) the nervous system's representation of the body area defended by the HBR can be approximated by a half-ellipsoid centred on the face, and (2) the DPPS extending from this area has the shape of a bubble elongated along the vertical axis. This modelling approach can be generalised to describe the spatial modulation of any defensive response.

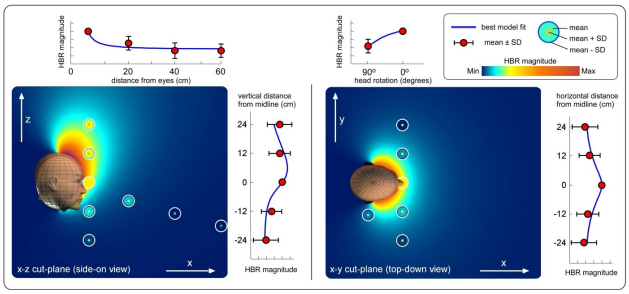

Figure 1. Effect of hand position on HBR magnitude, and geometrical modelling of DPPS. Combined description of the experimental data with the best fitting geometrical model. The measured HBR data (mean±SD) are represented as concentric circles located where the measurements were taken. The background colour represents the HBR magnitude predicted by the best-fitting geometric model. The line graphs at the side of each colour plot show HBR

magnitudes (mean±SD) along each axis, together with the best fitting geometric model (blue line).

Title: Influence of task complexity on brainstem contributions to motor execution after stroke

Authors: H. LEE[1,2,4], C. HONEYCUTT[5], *R. L. HECKMAN[6,2], E. J. PERREAULT[1,2,3]; [1]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [2]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL; [3]Dept. of Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [4]Sch. for Engin. of Matter, Transport, and Energy, [5]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [6]Sensory Motor Performance Program, Chicago, IL

Abstract: The startReact response, an involuntary release of a planned ballistic motor action triggered by a startling acoustic stimulus, has been used as a non-invasive means to probe brainstem function and its contributions to motor planning and execution. We recently demonstrated that stroke survivors have intact startReact responses, paving the way to study their capacity to plan and execute ballistic movements [1]. Tasks studied to date, however, have been quite simple, involving single degree of movements in gravity-compensated environments. Stroke survivors have difficulty compensating for gravity and coordinating the actions of multiple joints. These more demanding tasks involve a spread of motor cortical activity well beyond that observed in unimpaired subjects [2]. Given the important role of the motor cortical areas in regulating brainstem activity, it is unclear if the startReact response would be present in stroke survivors performing the more demanding tasks that are integral to many activities of daily living. Our objective was to quantify how task complexity alters the startReact response following stroke. Our hypothesis was that challenging tasks that engage large areas of the motor cortex would alter the ability to activate brainstem pathways for rapid motor execution. We

exploited the well-documented abnormal motor synergies coupling shoulder antigravity muscles and elbow flexor muscles following stroke. Data were collected from 11 stroke survivors and 8 age-matched controls. Ballistic elbow extension movements were performed with and without a requirement of activating the shoulder abductors. The task involving abduction was challenging for stroke subjects who typically couple shoulder abduction with elbow flexion. Our primary finding was that the probability of eliciting a startReact response was lower for stroke subjects performing the reaching task during volitional shoulder abduction (0.73 (0.23): Mean (SD)) than when performing the same task without the need for simultaneous shoulder activity (0.43 (0.33)). The difference between tasks was significant for the stroke subjects ($\Delta = 0.30$; p=0.0003). In contrast, no significant difference was observed for the control group ($\Delta = 0.01$; p=0.53). These results indicate that cortical lesions due to stroke can significantly influence the ability to regulate brainstem pathways in a task dependent manner. Title: Effect of sodium channel blockers on the initiation of swallows in anesthetized guinea pigs

Authors: *K. TSUJI[1], T. TSUJIMURA[1], M. INOUE[1], B. J. CANNING[2];
[1]Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata City, Japan; [2]Johns Hopkins Asthma and Allergy Ctr., Baltimore, MD

Abstract: Purpose: Swallowing is probably initiated by the activation of the afferent nerves that are similar to those that regulate coughing. Local anesthetics have been reported to have antitussive effects and this is due to blocking the sodium channels in sensory nerves. However, the effects of these anesthetics on initiation of swallow remains unclear. The aim of this study is to clarify the effect of sodium channel blockers on initiation of swallowing. Method(s): Ninety-

three urethane-anesthetized male guinea pigs (1.5 g/kg, i.p.) were used. Swallows were evoked by esophageal water perfusion (280 μl/min) and confirmed by electromyographic bursts from the suprahyoid muscles and increases in esophageal pressure. Drugs were added to the perfusate water. The number of swallows was measured during 30 minute water perfusion among the conditions. Effects of intraluminal drug administration on esophageal muscle contraction evoked by vagus nerve stimulation were then evaluated. Finally, changes of afferent nerve activities during esophageal distention with or w/o intraluminal drugs administration were examined *in vitro*. Result(s): Swallows were constantly evoked by esophageal water perfusion. The number of swallows w/o drugs administration was 116.6 ± 15.1. Sodium channel blockers inhibited swallowing initiation evoked by esophageal distention, in that the number of swallows was 66.1 ± 16.5 (1 mM Lidocaine), 48.3 ± 9.5 (0.1 mM Mexiletine), and 47.6 ± 11.2 (1 mM Ambroxol). Intraluminal sodium channel blockers did not inhibit esophageal muscle contraction and afferent nerve activities. Conclusion: Sodium channel blockers may inhibit swallows via not mechanosensitive afferent fibers in the myenteric plexus of esophagus, but mucosal afferent sensory nerves.

Title: ER-mitochondria communication breakdown in ALS

Authors: ***H. KAWAMATA**[1], C. KONRAD[2], A. ARREGUIN[2], G. MANFREDI[2];
[1]BMRI, Weill Med. Col. of Cornell Univ., New York, NY; [2]BMRI Weill Med. Col. of Cornell Univ., New York, NY

Abstract: The endoplasmic reticulum (ER) and mitochondria are major regulators of calcium homeostasis. Numerous lines of evidence suggest that dysfunction of both mitochondria and ER participates in the pathogenesis of neurodegenerative conditions, including amyotrophic lateral sclerosis (ALS). Since these organelles are physically and functionally intertwined, it is logical

to investigate ER-mitochondria interactions to understand their roles in ALS pathogenesis. In many cell types, including astrocytes, the ER is a reservoir for intracellular calcium. Calcium released from the ER regulates a multiplicity of calcium-dependent systems. Mitochondria take up calcium, in a membrane potential dependent manner. Calcium entry in mitochondria boosts oxidative phosphorylation, as the dehydrogenases of the Krebs cycle are stimulated. Overall, the rebalancing of cytosolic calcium after ER release is an energy consuming process, since the calcium pumps that extrude calcium or refill the ER require ATP and mitochondria expend membrane potential to take up calcium. We had shown that astrocytes from SOD1 mutant mice have exaggerated ER calcium stores, which cause abnormal intracellular calcium signaling (Kawamata et al. J. Neurosci., 2014). We had also shown that skin fibroblasts from ALS patients have increased mitochondrial membrane potential and mitochondrial mass (Kirk et al. Ann. Neurol., 2014). Here, we investigated the mechanistic relationship between ER calcium handling and mitochondrial function. In mutant SOD1 astrocytes, we found an increase of mitochondrial membrane potential, similar to that found in fibroblasts from sporadic and familial ALS patients. In fibroblasts from sporadic and different forms of familial ALS, we found ER calcium dynamics abnormalities similar to those found in mutant SOD1 astrocytes. Importantly, there was a significant correlation between calcium alterations and bioenergetics, including membrane potential, oxygen consumption and glycolysis, suggesting that ER calcium alterations and energy metabolism are mechanistically related. Surprisingly, in ALS cells, ATP content was not increased, despite the higher energy metabolism, suggesting greater ATP consumption. Based on these findings, we propose a common pathway of dysregulation in sporadic and familial ALS, which involves abnormal ER calcium handling that triggers increased energy metabolism, but also higher energy expenditure. This mechanism could cause the bioenergetic machinery to work at its higher functional limits, thereby lowering the threshold for life threatening bioenergetic crises in high-energy demanding cells, such as neurons and astrocytes.

Title: Motor Physiology in C9orf72 amyotrophic lateral sclerosis-frontotemporal dementia

Authors: *M. FLOETER[1], T. J. LEHKY[2], L. BRAUN[2], D. BAGEAC[2], B. TRAYNOR[3], O. SCHANZ[2];
[2]NINDS, [3]NIA, [1]NIH, Bethesda, MD

Abstract: BACKGROUND: Persons with a repeat expansion mutation in the gene C9ORF72 may have clinical features of frontotemporal dementia (FTD), amyotrophic lateral sclerosis (ALS), or a combination of ALS and FTD. Non-invasive physiological measures of upper (corticospinal) and lower motor neuron function have been used to monitor disease progression in clinical trials and in animal models of ALS. It is uncertain whether such motor physiology measures reflect disease progression across the spectrum of C9orf72 clinical phenotypes. OBJECTIVE: To determine whether non-invasive physiological measures of upper or lower motor neuron dysfunction correlate with clinical findings in persons with a repeat expansion in the C9orf72 gene. DESIGN/METHODS: Clinical and physiological measures were made from 21 patients and asymptomatic carriers with a confirmed mutation at baseline, with follow-up visits at 6- and 18-months in a subset. Clinical signs and symptoms of motor and cognitive testing were carried out at each visit. Clinical measures included the Dementia rating scale, ALS functional rating scale, finger and foot tapping rate, 9-hole peg test times, and timed gait. Physiological measures included transcranial magnetic stimulation (TMS) measures of cortical thresholds, silent periods, and central motor conduction times; electrical impedance myography (EIM) of 8 muscles of the arm and leg on one side; and the compound muscle action potential (CMAP) and motor unit index (MUNIX) from the thenar muscles bilaterally. RESULTS: Compared to healthy controls, the cortical threshold was reduced in the C9+ group, particularly in patients with an ALS phenotype. Lower cortical thresholds were associated with shorter cortical silent periods and relatively preserved finger tapping speed. In patients returning at 6-months, cortical thresholds were stable. EIM, MUNIX, and CMAP declined, consistent with findings of amyotrophy. CONCLUSION: These findings point to motor cortical hyperexcitability in C9orf72 patients. Because it is more prominent in those patients with signs of ALS who still have good dexterity, it is likely to be an early event in the disease process.

Title: Elevated CDK5 activity leads to dysregulated axonal transport in neurons

Authors: *E. KLINMAN[1], E. L. F. HOLZBAUR[2];
[1]Univ. of Pennsylvania Sch. of Med., Philadelphia, PA; [2]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Axonal transport is essential for neuron function and survival, and defects in transport are associated with neurodegenerative disease including Amyotrophic Lateral Sclerosis (ALS). Increased activity of cyclin dependent kinase 5 (CDK5) and its stress-induced activator p25 is observed in human patients with ALS and in mouse models of the disease. CDK5 modulates both anterograde (kinesin) and retrograde (dynein) motor proteins, but the mechanisms of regulation remain unknown. Here, we show that expression of p25 significantly increases the number of nonprocessive events across a wide range of organelles including autophagosomes, lysosomes, mitochondria, and TrkB signaling endosomes. Similar defects are observed in $SOD1^{G93A}$ neuron, wherein reducing CDK5 activity partially rescues transport. We demonstrate that the effects of aberrant CDK5 activation depend on the Lis1/Ndel1 complex, which directly regulates dynein activity. Tight binding of Ndel1 to Lis1 requires CDK5 phosphorylation of Ndel1. Mutating the phosphorylation sites in Ndel1 prevented CDK5-mediated transport disruption. Moreover, *in vitro* imaging reveals that activated CDK5 increases dynein binding to microtubules. Together, these studies identify CDK5 as a Lis1/Ndel1-dependent regulator of cargo transport in stressed cells, and suggest that dysregulated CDK5 contributes to transport disruption in disease.

Title: A novel link between C9ORF72 expansion and phosphorylated TDP-43 aggregation

Authors: *T. NONAKA, G. SUZUKI, F. KAMETANI, M. HASEGAWA;
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: An expanded hexanucleotide repeat in C9ORF72 gene is the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). Unconventional non-ATG translation of the expanded hexanucleotide repeat produces dipeptide repeat proteins (DPRs), which form insoluble, ubiquitinated, p62-positive aggregates that are most abundant in the cerebral cortex and cerebellum. Besides accumulation of DPR proteins, the second pathological hallmark in brains of patients with C9ORF72 mutation is the accumulation of phosphorylated TDP-43. Although the presence of DPR and TDP-43 co-accumulation in the same neurons was found to be a rare event, recent studies suggest that DPR pathology precedes TDP-43 accumulation and might trigger TDP-43 aggregate formation in a subset of neurons. To explore the link between C9ORF72 expansion and TDP-43 aggregation, we investigated whether DPR aggregation induces intracellular TDP-43 alterations using cultured cells. Synthetic cDNAs encoding 100 repeat of DPR (GFP-tagged poly-GA, -GP, -GR, -PA or -PR) without a hexanucleotide repeat sequence were prepared and transfected into SH-SY5Y cells to examine the effects of these proteins on these cells. We found that poly-GA protein was most aggregation-prone of these DPRs, and that poly-GA protein aggregates were immunoreactive with ubiquitin and p62. Surprisingly, these inclusions were co-localized with cytoplasmic aggregates composed of endogenous phosphorylated TDP-43. We also observed a few phosphorylated TDP-43 aggregates in cells expressing poly-PA or -PR. Immunoblot analyses of sarkosyl-insoluble fraction prepared from cells expressing poly-GA revealed that endogenous TDP-43 was aggregated with abnormal post-translational modifications such as phosphorylation at Ser409/410 and fragmentation. On the other hand, tau or alpha-synuclein was not accumulated in the presence of poly-GA inclusions, suggesting that poly-GA specifically induces TDP-43 aggregation. These results suggest that DPR aggregation leads to TDP-43 alterations, providing new insights into the relationship between C9ORF72 mutation and aberrant TDP-43 aggregation.

Title: Involvement of muscle-specific mirna-206 in the spinal muscular atrophy pathogenesis

Authors: *M. M. BOIDO[1], V. VALSECCHI[1], E. DE AMICIS[1], A. PIRAS[2], A. VERCELLI[1]; [1]Univ. of Turin, Orbassano (TO), Italy; [2]Karolinska Institutet, Stockholm, Sweden

Abstract: Spinal muscular atrophy (SMA) is a fatal paediatric genetic disease, characterized by motor neuron (MN) death, leading to progressive muscle weakness, respiratory failure, and, in the most severe cases, to death. SMA is due to the deletion or mutation of the telomeric survival MN gene (SMN1), on chromosome 5. Its homologous, SMN2 gene, only produces a limited amount of functional protein which can modulate SMA severity. Specific or general changes in the activity of ribonucleoprotein containing micro RNAs (miRNAs) play a role in the development of SMA. Additionally miRNA-206 has been shown to slow amyotrophic lateral sclerosis progression by promoting a compensatory regeneration of neuromuscular synapses. Therefore, we correlated the morphology and the architecture of the neuromuscular junctions (NMJs) of the quadriceps, a muscle which is affected early in SMA, with the expression levels of miRNA-206 in a murine model of intermediate SMA (SMA II). Our results showed a decrease in the percentage of type II fibers, an increase in atrophic muscle fibers and a remarkable accumulation of neurofilament (NF) in the pre-synaptic terminal of the NMJs in the quadriceps of SMA II mice. Furthermore, molecular analysis highlighted a direct link between miRNA-206 - HDAC4 - FGFBP1, and in particular, a strong up-regulation of this pathway in the late phase of the disease. We propose that miRNA-206 is activated as survival endogenous mechanism, although not sufficient to rescue the integrity of motor neurons. We speculate that early modulation of miRNA-206 expression might delay SMA neurodegenerative pathway and that miRNA-206 could be an innovative, still relatively unexplored, therapeutic target for SMA. Title: TDP-43 influences synaptic function through translational regulation of synaptic mRNA targets

Authors: *A. COYNE, J. JOHANNESMEYER, D. ZARNESCU;
Univ. of Arizona, Tucson, AZ

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disease affecting upper and lower motor neurons. TDP-43, an RNA binding protein linked to the majority of ALS cases, is involved in several aspects of RNA metabolism. Using a *Drosophila* model of ALS based on TDP-43 we have previously identified a role for TDP-43 in the translation regulation of specific mRNA targets. Here we use a combination of genetic, molecular, imaging, and electrophysiology approaches to show that TDP-43 regulates the translation of *hsc70* mRNA in a variant dependent manner. Hsc70 is a molecular chaperone that functions at multiple steps in the synaptic vesicle cycle. Overexpression of Hsc70 in the context of TDP-43 mitigates multiple aspects of TDP-43 toxicity including locomotor dysfunction and reduced lifespan. Notably, this rescue is dependent on the chaperone activity of Hsc70 as evidenced by genetic interactions with an Hsc70 ATPase mutant that no longer rescues TDP-43 dependent phenotypes. In addition, Hsc70 overexpression restores synaptic vesicle cycling, specifically in the context of disease associated mutant TDP-43. FM1-43 dye uptake experiments reveal defects in endocytosis and a reduction in the size of the readily releasable and recycling vesicle pools in both TDP-43 variants. However, upon overexpression of Hsc70, endocytosis is restored specifically only in the disease associated mutant. Furthermore, overexpression of Hsc70 reduces the amount of insoluble TDP-43 in a variant dependent manner. Our results provide evidence for TDP-43 regulating synaptic function and the synaptic vesicle cycle through the translational regulation of its synaptic mRNA targets. Ultimately, this dysregulation of translation may lead to depletion of key synaptic proteins at the neuromuscular junction and synaptic failure preceding neurodegeneration. Additionally, our results provide evidence for

differential regulation of mRNA targets by disease associated mutant TDP-43 and dysregulation of synaptic function through altered ribostasis, a key event in the progression of ALS.

Abstract: Corticospinal motor neurons (CSMN) degenerate in various motor neuron disorders such as amyotrophic lateral sclerosis (ALS), primary lateral sclerosis, and hereditary spastic paraplegia. CSMN are long-distance projection neurons located in the layer V of the motor cortex that collect, integrate and transmit cerebral cortex' inputs toward spinal cord targets. Therefore, their proper modulation is essential for the initiation and modulation of voluntary movement. CSMN receive both excitatory and inhibitory inputs from many different neuron types in the cerebral cortex, and the fine balance between these excitatory and inhibitory inputs both from local circuitries and long-distance projection neurons modulate CSMN activity. We previously revealed a selective pattern of apical dendrite degeneration with spine loss especially in layer II/III of the $hSOD1^{G93A}$ ALS mouse motor cortex. This could account for early cellular CSMN vulnerability due their inability to process cerebral input. We developed an anatomical and electrophysiology approach to investigate mechanisms that could potentially be involved in CSMN vulnerability and progressive degeneration. Using electrophysiological recordings, coupled with retrograde labeling and analysis of distinct neurons types in different layers of the

motor cortex, we begin to reveal the details of early connectivity defects in ALS. Our ongoing studies suggest that CSMN degeneration could be due to a complex imbalance between excitation and inhibition signals, in addition to their intrinsic vulnerability.

Title: Aberrant nuclear pore pathology in c9orf72 als-ftd and neurodegeneration

Authors: *J. C. GRIMA[1], M. J. ELRICK[1], K. RUSSELL[1], L. PETRUCELLI[2], R. H. BROWN[3], L. W. OSTROW[1], C. J. DONNELLY[1], R. SATTLER[1], J. D. ROTHSTEIN[1];
[1]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Mayo Clin., Jacksonville, FL; [3]Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Familial and sporadic Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Dementia (FTD) share a common genetic mutation in chromosome 9. An expanded hexanucleotide (GGGGCC) repeat within a non-coding region of the C9orf72 gene is the most common genetic cause of familial and sporadic ALS and FTD. It is also the most common cause of Huntington disease phenocopies. The repeat expansion leads to the loss of one alternatively spliced C9orf72 transcript, pathological inclusions of TDP-43 protein, the formation of nuclear

RNA foci and accumulation of cytoplasmic dipeptide repeats. However, the underlying mechanisms by which this bi-directionally transcribed expanded repeat causes these diseases have not been fully elucidated. Nonetheless, it is becoming increasingly evident that Nuclear Pore Complex (NPC) dysfunction may be a key pathogenic contributor. NPCs are the largest protein assemblies in eukaryotic cells. They span the nuclear envelope, consist of multiple copies of 30 different proteins called nucleoporins, and serve as the only transport conduit between the nucleus and cytoplasm. These molecular machines not only regulate the flow of molecules into and out of the nucleus but also have transport-independent functions such as regulating genome organization and gene expression. Work from our lab and others indicate that nucleocytoplasmic transport dysfunction may be a fundamental pathway for C9orf72 ALS-FTD pathogenesis. Proteins in this pathway are potent genetic modifiers of GGGGCC repeat expansion-mediated cytotoxicity in a *drosophila* model and in iPS neurons derived form C9orf72 patients. Our ongoing studies suggest that products of the C9orf72 repeat expansion are likely to disrupt nucleocytoplasmic transport at the NPC. To this end, we assessed the integrity of nucleoporins, the basic building blocks of NPCs, in C9orf72 human tissue, ips neurons, and various transgenic animal models. Our preliminary data using a large cohort of human autopsy brain and spinal cord as well as transgenic mouse tissues and human C9orf72 iPS cell lines indicate that select nucleoporins are severely affected in the disease with aggregation at the nuclear membrane and altered nuclear to cytoplasmic distribution. This study suggests NPC pathology and function are a fundamental defect in the pathway of C9orf72 ALS-FTD.

Center, Amsterdam, the Netherlands., Amterdam, Netherlands

Abstract: Amyotrophic lateral sclerosis (ALS) is a rapidly progressive and ultimately fatal neurodegenerative disease, caused by the loss of motor neurons in the brain and spinal cord. Although 10% of ALS cases are familial (FALS), the majority are sporadic (SALS) and probably associated to a multifactorial etiology. Currently there is no cure or prevention for ALS. A prerequisite to formulating therapeutic strategies is gaining understanding of its etio-pathogenic mechanisms. In this study we analyzed whole-genome expression profiles of 41 motor cortex samples of control (10) and sporadic ALS (31) patients. Unsupervised hierarchical clustering was able to separate control from SALS patients. In addition, SALS patients were subdivided in two different groups that were associated to different deregulated pathways and genes, some of which were previously associated to familiar ALS. These experiments are the first to highlight the genomic heterogeneity of sporadic ALS and reveal new clues to its pathogenesis and potential therapeutic targets.

Title: TDP-43 accumulation causes aberrant motor neuron excitability

Authors: *Y. LIU[1], H. DONG[1,2], R. D. DAYTON[3], R. L. KLEIN[3], M. P. MATTSON[1]; [1]Lab. of Neurosci., Natl. Inst. on Aging, Baltimore, MD; [2]Dept. of Neurol., the Second Hosp. of Hebei Med. Univ., Shijiazhuang, Hebei, China; [3]Dept. of Pharmacology, Toxicology and Neurosci., Louisiana State Univ., Shreveport, LA

Abstract: TDP-43 (transactive response DNA-binding protein-43) accumulates in abnormally high amounts in motor neurons of patients with sporadic amyotrophic lateral sclerosis (ALS). Overexpression of TDP-43 result in TDP-43 accumulation and degeneration of motor neurons in animal models. To elucidate alterations in neuronal excitability that may occur in response to TDP-43 proteopathy prior to motor neuron degeneration, we performed whole-cell patch clamp recordings from motor neurons in spinal cord slices from mice overexpressing either wild type human TDP-43 (hTDP-43) or GFP. Expression in motor neurons was achieved using AAV-9 vectors that were injected intracerebroventricularly into neonatal mice (see Wang DB et al. Mol Ther 2010; 18:2064-2074). Recordings were made from spinal cord motor neurons of 7-10 day old pups, and tests of motor function were performed in 19-21 day old mice. Motor neurons of hTDP-43 mice exhibited hyperexcitability with a 37% greater frequency of spontaneous action potentials (AP), a lower threshold for AP induction and smaller AP amplitude compared to control mice. Motor neurons of hTDP-43 mice also showed more spikes during current step stimuli. Whereas control mice gained weight progressively, hTDP-43 mice lost weight beginning at day 14. By the time they were 19-21 days old hTDP-43 mice exhibited a greatly reduced grip strength and severe motor dysfunction on the rotarod. Our findings show that elevation of hTDP-43 levels results in hyperexcitability of motor neurons that occurs prior to motor deficits and neuronal death. We are currently developing interventions to counteract the adverse effects of hTDP43 on motor neuron excitability and degeneration.

Title: The role of mitophagy and parkin in SOD1-ALS

Authors: G. M. PALOMO[1], A. ARREGUIN[1], J. MAGRANE[1], *G. MANFREDI[2];
[1]Feil Family Brain and Mind Res. Institute, Weill Med. Col. of Cornell Univ., New York, NY;
[2]Weill Med. Col. Cornell Univ., New York, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease caused by the degeneration of upper and lower motor neurons. Familial forms represent 10% of all cases, 20% of which are linked to mutations in the Cu-Zn superoxide dismutase 1 (SOD1) gene. Different mechanisms have been proposed to explain the deleterious effects of mutant SOD1, including accumulation of misfolded protein on the mitochondrial outer membrane and in the intermembrane space and mitochondrial structural and functional damage, suggesting that mitochondrial dysfunction plays a role in disease pathogenesis. Damaged mitochondria need to be either repaired or eliminated by quality control mechanisms to maintain a sufficient pool of functional mitochondria in neurons. Selective mitochondrial autophagy (mitophagy) is essential to this process. Here, we investigated mitophagy in G93A mutant SOD1. We used spinal cords of G93A-SOD1 transgenic mice and motor neuron-like NSC34 cells, stably transfected with either mitochondria-targeted SOD1 or untargeted SOD1. We studied the involvement of several key players of autophagy, mitophagy, and mitochondrial dynamics. In G93A spinal cords, Parkin, an E3 ubiquitin ligase involved in initiation of mitophagy, was decreased at all disease stages tested (pre-symptomatic, disease onset and end stage). However, Parkin mRNA levels were not affected, suggesting that the decline of the protein was due to increased turnover. Similarly, Drp-1, a protein necessary for mitochondrial fission, was reduced in G93A mutant spinal cords, at disease onset and end stage. Furthermore, we detected increases in ubiquitination of mitochondrial proteins by western blot, using both lysine 63 and lysine 48 ubiquitin antibodies, and in the association of p62, an adaptor with the autophagosomes, with mitochondrial fractions. NSC34 cells expressing mutant or wild type SOD1 were induced to differentiate and transfected with YFP-Parkin (NSC34 do not express detectable endogenous Parkin), prior to exposure to stress by removal of antioxidants from the culture media. Parkin expression was protective, suggesting that facilitating mitophagy through Parkin overexpression may contribute to neuroprotection in SOD1 mutant cells. Together, these results suggest a mechanism by which excessive requirements for the removal of dysfunctional and damaged mitochondria in mutant SOD1 neurons lead to exhaustion of essential components of mitophagy, such as Parkin and Drp-1 and to the accumulation of ubiquitin-tagged mitochondria. Inability to maintain an adequate mitochondria quality control could contribute to the motor neuron demise in ALS.

Abstract: Corticospinal motor neurons (CSMN) are unique in their ability to collect, integrate, translate and transmit cerebral cortex's input towards spinal cord targets. Their degeneration is the key in numerous neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS). Mutations in the Alsin 2 (ALS2) gene are reported to be responsible for juvenile primary lateral sclerosis, infantile onset ascending hereditary spastic paraplegia, and are the most common cause for autosomal recessive juvenile ALS. In addition, upper motor neuron signs and bulbar symptoms are often prevalent in patients with juvenile ALS. However, cellular and molecular aspects of CSMN degeneration has not been studied in detail due to lack of selective markers to visualize these neuron populations *in vivo*. By crossing UCHL1-eGFP with AlsinKO, we generated AlsinKO-UeGFP mice, a CSMN reporter line to investigate upper motor neuron defects in the absence of Alsin. This novel reporter line helped us visualize and study CSMN at different stages of disease progression. Different from the hSOD1G93A mice or the TDP-43 mouse models, the numbers of CSMN do not show dramatic reduction in the absence of Alsin. However, detailed cellular analysis using immunocytochemistry coupled with electronmicroscopy (EM) revealed very precise aspects of cellular defects that are restricted to CSMN. We find that even though CSMN do not undergo massive cell loss, the neurons are not healthy. The apical dendrites of CSMN become vacuolated, and this cellular defect is observed only in CSMN in the motor cortex. In addition, there are defects in the mitochondria, and there are signs of defective autophagy, with enlarged lysosomes that contain defective mitochondria,

in addition to other proteins. The integrity of the cell membrane is impaired and becomes leaky especially towards end-stage. These findings suggest that Alsin is an important protein for proper CSMN function, and in its absence CSMN display precise neuronal defects, but such defects do not initiate their clearance. Therefore, even though the neurons are still present at layer V of the motor cortex, they are unhealthy and potentially nonfunctional.

Title: Expression of Stasimon rescues select defects in the sensory-motor circuit of SMA mice

Authors: *C. M. SIMON, F. LOTTI, E. BIANCHETTI, S. TISDALE, G. Z. MENTIS, L. PELLIZZONI;
Col. of Physicians and Surgeons, Motor Neuron Ctr., New York, NY

Abstract: Ubiquitous SMN deficiency causes the neurodegenerative disease SMA. While SMN activity in the assembly of spliceosomal snRNPs is well established, splicing targets of SMN deficiency that contribute to motor system pathology in mouse models of SMA are unknown. We previously identified Stasimon as an evolutionarily conserved, SMN-regulated U12 intron-containing gene that contributes to motor circuit deficits induced by SMN depletion in *Drosophila* and zebrafish models. Here, we investigated the role of Stasimon dysfunction in an SMA mouse model. We found that SMN deficiency disrupts U12 splicing and reduces expression of Stasimon mRNA in motor circuit neurons of SMA mice. To study the effects of increased Stasimon expression on the disease phenotype of SMA-Δ7 mice, we employed ICV injection of scAAV9 vectors at P1, which results in efficient transduction of motor neurons and

sensory neurons. scAAV9-GFP and scAAV9-SMN were used as negative and positive controls, respectively. Stasimon restoration neither enhanced SMN expression nor corrected snRNA levels and downstream RNA processing events disrupted by SMN deficiency in SMA mice, consistent with Stasimon being a downstream mRNA target of SMN function in splicing. Importantly, Stasimon expression improved motor behavior of SMA mice assessed by righting time. Remarkably, while Stasimon did not improve neuromuscular junction denervation of affected muscle, it rescued the loss of proprioceptive synapses on both soma and dendrites of motor neurons. Moreover, functional assays revealed robust, Stasimon-dependent functional improvement of central sensory-motor neurotransmission, which is severely disrupted in SMA mice. Correction of these morphological and functional abnormalities of the motor circuit was associated with reduced loss of SMA motor neurons. Our work reveals the direct contribution of Stasimon dysfunction to select deficits in the sensory-motor circuit of SMA mice, establishing Stasimon as the first RNA splicing target of SMN deficiency with a demonstrated role in SMA pathology of an animal model that resembles the human disease. Our findings that Stasimon restoration improves some but not all of the disease-related deficits in SMA mice also support the view that SMA pathology results from a complex set of defects involving SMN-dependent mis-splicing of multiple genes and possibly disruption of other RNA pathways. Lastly, our results identify Stasimon as a gene with a key role in development and disease of the mammalian motor system.

Title: Activation of the sigma-1 receptor (Sig-1R) by ligands or ER stress results in increased receptor mobility, subcellular redistribution and the modulation of the Unfolded Protein Response

Authors: ***A. Y. WONG**[1], P. CHUDALAYANDI[1], E. HRISTOVA[1], N. AHLSKOG[1], J. K. NGSEE[2,1], R. BERGERON[1,2];

Abstract: Background: Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disease characterized by the selective degeneration of upper and lower motor neurons (MNs). While an array of triggers exists for ALS, they all converge on one of two main pathological mechanisms, RNA metabolism or proteostasis. One form of familial ALS (ALS 16) arises from a point mutation (E102Q) in the ligand-binding domain of an ER chaperone protein, the sigma-1 receptor (Sig-1R). As the Sig-1R is a protein chaperone, it is thought to modulate proteostasis during endoplasmic reticulum (ER) stress by modulating the Unfolded Protein Response (UPR), which is upregulated in ALS and could contribute to MN degeneration. **Results:** Induction of ER stress, by either DTT or Tunicamycin, resulted in an increased mobility of wild-type (WT) Sig-1R, and aggregation into immobile puncta. Co-localization analysis suggests that these puncta are ER quality control compartments. In contrast, the E102Q mutant has a significantly higher mobility and tendency to cluster in the absence of ER stress. Activation of wild-type Sig-1R by the agonist SKF-10,047 attenuated the expression of apoptotic markers and promoted recovery from DTT-induced ER stress in NSC-34 cells and MEFs derived from WT mice. This was not observed in NSC-34 overexpressing E102Q or MEFs from Sig-1R$^{-/-}$ knockout mice. **Conclusion:** Aggregation of the E102Q mutant leads to dysregulation of adaptive mechanisms of the UPR during ER stress and subsequent MN death in ALS.

Title: Expression of human FUS induces an early loss of CCAP neurons resulting in wing expansion and cuticle tanning defects in *Drosophila*

Authors: J. A. STEYAERT[1], N. WILMANS[1], W. SCHEVENEELS[1], P. VAN DAMME[2], W. L. ROBBERECHT[2], P. CALLAERTS[3], E. BOGAERT[1], *L. M. VAN DEN BOSCH[1]; [1]Lab. of Neurobiology, Vesalius Res. Center, VIB, Leuven, Belgium, Leuven, Belgium; [2]Univ.

Hosp. Leuven, Dept. of Neurol., Leuven, Belgium; [3]Lab. of Behavioral and Developmental Genetics, VIB, KU Leuven, Leuven, Belgium

Abstract: Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD) belong to a group of complex neurodegenerative disorders. A subgroup within this disease spectrum, the FUSopathy, is characterized by FUS inclusions in neurons and glial cells. The observation that mutations in FUS cause ALS emphasizes the involvement of FUS in the disease pathogenesis. In order to examine the pathogenic role of FUS, we generated four different transgenic fly lines, allowing expression of wild type human FUS (WT hFUS) and three disease-associated mutant human FUS proteins (R521G hFUS, R521H hFUS and P525L hFUS). Selective expression of hFUS transgenes in the motor neurons via the UAS-GAL4 expression system resulted in a partial developmental lethality as pharate adults were not able to hatch. Furthermore, adult escapers show a wing inflation phenotype and a defect in cuticle tanning. These defects are posteclosion events regulated by the secretion of the neurohormone 'Bursicon' by a subset of 15 'crustacean cardioactive peptide' (CCAP) expressing neurons located in the ventral nerve cord. Restricting hFUS expression to these neurons recapitulated partially the phenotype: the posteclosion defects were still present, but the pupal lethality was absent. Toxicity, induced by mutant hFUS expression in the CCAP neurons, causes an accelerated cell death. Furthermore, this cell death is most pronounced in the CCAP neurons that secrete Bursicon, although selective hFUS expression in these neurons is not toxic. We hypothesize that overall toxicity in all CCAP neurons is needed to affect Bursicon secretion. To prove this, Bursicon and CCAP levels will be analysed in the hemolymph. In conclusion, our findings indicate that mutant human FUS expression in CCAP neurons is the underlying cause of the immature fly phenotype which is caused by neuronal death of a subset of neurons.

Title: Cellular localization of ALS-linked FUS regulates neurite fragmentation under oxidative stress

Authors: M.-H. JUN, H.-H. RYU, W.-K. JEONG, Y.-K. LEE, *J.-A. LEE;
Hannam Univ., Dajeon, Korea, Republic of

Abstract: Mutations in fused in sarcoma (FUS), a DNA/RNA binding protein, are associated with familial amyotrophic lateral sclerosis (fALS) and some forms of frontotemporal lobar dementia (FTLD). However, little is known about how specific ALS-causing mutations induce neurodegeneration associated with FUS positive inclusion and stress granules. In this study, we identified protein arginine methyltransferase 1 (PRMT1) as an associating protein with ALS-linked FUS (R521C). Association between R521C and PRMT1 was RNA dependent, but methylation independent. Loss of PRMT1 cause accumulation of FUS-positive stress granules and neurite fragmentation under oxidative stress while overexpression of PRMT1 reduce cytosolic localization of FUS into stress granule and neurite fragmentation in FUS(R521C) expressing neurons. Taken together, these data suggest that PRMT1 could regulate FUS-associated SGs and neurite fragmentation under oxidative stress. Overall, this study provide a novel pathogenic mechanism of the FUS mutation associated with oxidative stress in ALS and therapeutic insight regarding FUS pathology

Title: The respiratory motor system in amyotrophic lateral sclerosis - dendritic growth and regression is coupled with motor neuron loss and impaired respiratory function

Authors: *M. C. BELLINGHAM[1], M. J. FOGARTY[2], E. W. H. MU[2], J. R. DRIEBERG-THOMPSON[2], N. A. LAVIDIS[2], P. G. NOAKES[2,3];
[2]Sch. of Biomed. Sci., [3]Queensland Brain Inst., [1]Univ. of Queensland, Brisbane, Australia

Abstract: The progressive loss of respiratory motoneurons (MN) in brainstem and spinal cord is a critical factor in respiratory impairment and death in amyotrophic lateral sclerosis (ALS). However, while evidence suggests that MN intrinsic excitability and excitatory synaptic inputs onto MNs are increased prior to MN death, the timing and nature of changes in the respiratory motor system remains unclear. In pre-symptomatic (postnatal [P] day 25-35), disease onset (P60-70), mid-disease (P100-120) and end-stage (>P140) $hSOD1^{G93A}$ (SOD1) and wild type (WT) control mice, we examined single respiratory MN morphology, using Golgi-Cox impregnation for brainstem hypoglossal (XII) MNs or retrograde labelling with Alexa555-cholera toxin B for spinal cord phrenic MNs (n=10 animals per age/genotype). MN arbors were traced in Neurolucida and were analysed by two-way ANOVA with Bonferroni post-tests, with significance at $p<0.05$. Unbiased stereological counts of XII and phrenic MNs counts were done (n=>4 animals per age/genotype). Unrestrained whole body plethysmography (Buxco) measured respiration volumes and frequency from P125 onwards (n=8 per genotype). Progressive increases in dendritic arbors (branch elongation and more branching) of XII (49%) and phrenic MNs (63%) were seen at pre-symptomatic ages in SOD1 mice compared to WT mice. Pre-symptomatic XII MNs had a 51% increase in dendritic spine density/100 μm dendrite length. XII MNs showed a 51% decrease in dendrite arbors at disease onset age, while phrenic MN dendrite arbours had regressed and were not significantly different to WT phrenic MN arbors. Both XII (-74%) and phrenic (-20%) MNs showed reduction in dendritic arbors at mid-disease ages. XII MN numbers decreased from P35 onward, while phrenic MN numbers did not decrease until mid-disease age. Respiratory volumes but not frequency were significantly decreased in SOD1 mice from P125. Our results suggest that significant morphological changes, illustrated by excessive arborisation and spine increases, occur prior to loss of key respiratory MNs, while respiratory MN loss is associated with dendrite regression and impaired respiratory function. Interestingly, respiratory MNs seem to be degenerating at a slower rate or later age, compared to lumbar MNs. Pre-symptomatic structural changes seen in respiratory MNs may represent an adaptive response, which reduces or delays respiratory dysfunction. Our findings correlate with symptom progression seen in many ALS patients, where declines in respiratory motor function are typically seen later in disease progression.

Title: Active zone degeneration causes neuromuscular junction denervation in ALS model rodents

Authors: *H. NISHIMUNE[1], S. TUNGTUR[1], J. A. STANFORD[2], T. TANAKA[1], L. L. NADEAU[1];
[1]Anat. & Cell Biol., [2]Mol. & Integrative Physiol., Univ. of Kansas Sch. of Med., Kansas City, KS

Abstract: Amyotrophic lateral sclerosis (ALS) model rodents exhibit denervation of neuromuscular junctions (NMJs) prior to motor neuron degeneration, suggesting that ALS is a dying-back neuropathy. However, etiology of NMJ denervation and ALS remains unknown. To investigate the cause of NMJ denervation in ALS, we focused on NMJ active zones, which are essential presynaptic structure for synaptic transmission. Active zone loss impairs synaptic transmission efficiency. We have analyzed the numbers of active zones and active zones aligned with junctional folds in innervated NMJs of $SOD1^{G93A}$ male mice using electron microscopy, and compared them to age- and sex-matched wild-type mice. Active zone number decreased in the presymptomatic stage before significant denervation was detected in diaphragms. However, NMJ size and total number of synaptic vesicle in nerve terminals did not change between $SOD1^{G93A}$ and wild-type mice. Degenerated mitochondria were detected in presynaptic terminals, but active zone defect did not correlate with the detection of degenerated mitochondria. These results suggest that the active zone loss is a very early defect of ALS NMJs, which is not a secondary defect to degeneration of presynaptic terminals or mitochondria degeneration. The causality of active zone loss in NMJ denervation was tested using a mouse model of active zone loss. Previously, we identified a molecular mechanism for active zone organization, which is accomplished by a synapse organizer laminin β2 binding extracellularly to its specific receptor P/Q-type voltage dependent calcium channels and anchoring active zone proteins to presynaptic membrane including Bassoon. Acute inhibition of the interaction between the ligand laminin β2 and its receptor calcium channels causes a decrease of active zone number in NMJs of wild type mice. In the current study, the laminin β2 - calcium channel interaction was chronically inhibited, which caused significant denervation of NMJs in wild-type mice. These data suggest that a decrease of active zone number causes NMJ denervation in ALS. Interestingly, the NMJ denervation can be ameliorated by exercise indicating a potential intervention to ameliorate the early stage ALS symptom. In summary, active zone degeneration plays a key role in NMJ denervation in ALS model rodents.

Title: Immortalized human neuronal progenitor cells (ReNcell CX) are an ideal model to investigate the inhibition of adult neurogenesis in the SVZ mediated by TGF-β

Authors: *S. KUESPERT[1], E. ZITZELSPERGER[1], S. PETERS[1], S. KLATT[2], T.-H. BRUUN[1], L. AIGNER[3], U. BOGDAHN[1];
[1]Dept. of Neurol., [2]Dept. of Hematology, Univ. Hosp. Regensburg, Regensburg, Germany; [3]Inst. Regenerative Med., Paracelsus Med. Univ., Salzburg, Austria

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative lethal disorder with no effective treatment so far. The current molecular genetic campaign is increasingly elucidating the molecular pathogenesis of this fatal disease; from previous studies it is known that Transforming Growth Factor-β (TGF-β) is found in high concentrations in Cerebrospinal Fluid (CSF) (Morganti-Kossmann et al., 1999) of ALS patients. These high levels of circulating TGF-β are known to promote stem cell quiescence and therefore lead to inhibition of adult neurogenesis within the sub ventricular zone (SVZ) of the brain (Kandasamy et al., 2014). Thus, regeneration of degenerating neurons seems to be prevented by an enhanced TGF-β signaling. In this study we wanted to figure out if selective inhibition of TGF-β signaling mediated by antisense-oligonucleotide against TGF-βRII might allow regeneration of adult neurogenesis. First we investigated if an immortalized human neuronal progenitor cell line isolated from the cortical region of human fetal brain (ReNcell CX; Millipore) is a proper model to analyze the TGF-β-mediated effects. Therefore, we examined the ability of ReNcell CX to respond to TGF-β by analyzing the respective molecules up- and downstream (TGF-β1, 2 and 3, pSmad2/3, CTGF, PAI-1) of the canonical TGF-β pathway by quantitative RT-PCR, immunoblotting and immunocytochemistry. Next, stem cell quiescence induced by TGF-β1 is shown on ReNcell CX cells by treatment of the cells with 10 or 50 ng/ml TGF-β1 for 7 d. Afterwards, ReNcell CX cells were treated with different concentrations (2.5 and 10 µM) of a TGF-βRII - antisense-oligonucleotide by gymnotic delivery for different time points. Probes were subsequently

examined with regard to downregulation of TGF-βRI and II and its effect on Smad2/3-cascade, MAP/Erk- and Akt-pathway by quantitative RT-PCR, immunoblotting and immunocytochemistry. Results indicate that ReNcell CX cells represent an adequate model to investigate regeneration of adult neurogenesis by selective antisense oligonucleotide-mediated blocking of TGF-β signaling due to TGF-β response, cell cycle arrest following TGF-β-exposure. Further, the ReNcell CX cell line demonstrated a proper downregulation of TGF-βRII and showed thereby an inhibition of TGF-β signaling due to gymnotic transfer of a selective antisense-oligonucleotide against TGF-βRII.

Title: Reciprocal binding between SMN and the COPI coatomer subunit alpha-COP is required for neuronal morphology in cell and animal models of spinal muscular atrophy

Authors: ***S. K. CUSTER**[1], H. LI[1], L. T. HAO[2], C. E. BEATTIE[2], E. J. ANDROPHY[1]; [1]Dermatol., Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Spinal muscular atrophy (SMA) is a hereditary neuromuscular disorder caused by loss of the SMN1 gene and the resultant decrease in its protein product, Survival Motor Neuron (SMN). The functions of the SMN protein in developing and mature neurons remain a mystery. We are using cell and animal model systems to understand the importance of the SMN interaction with the alpha-COP subunit of the COPI vesicle. Although mainly involved in Golgi-ER retrograde trafficking, the α-COP coat protein is observed in cultured neurons in the Golgi, growth cone, and neurite, and we have reported that SMN moves with α-COP in these neuronal processes. To characterize the biological role of the association between SMN and α-COP, we

mutated a dilysine motif in SMN exon 2b, which we previously identified as the minimal α-COP binding domain in SMN, and found these do not bind to α-COP and are unable to restore neurite outgrowth in our NSC-34 cells model of SMA. We have now been able to demonstrate the functional significance of the interaction of SMN with α-COP *in vivo* using murine and zebrafish models of SMA. Surprisingly, transient expression of α-COP in SMN-depleted NSC-34 cultures restores neurite outgrowth without increasing SMN protein levels. We have also queried the functions of alpha-COP in developing neuronal cells. α-COP knockdown completely abolished the ability of NSC-34 cells to form neurites, which was restored by transient expression of human α-COP. Depletion of α-COP in primary cortical neurons showed a similar effect on both Map2 positive dendrites and tau positive axons. We have isolated a point mutant of α-COP which is unable to bind SMN, but retains the ability to form COPI coatomer as evidenced by immunoprecipitation of the epsilon, beta and gamma COP subunits. This mutant α-COP is unable to restore neurite outgrowth in α-COP depleted NSC-34 cells despite the fact that it rescue normal Golgi-ER retrograde traffic. This mutant was unable to restore neurite outgrowth in SMN-depleted NSC-34 cultures, demonstrating that there is reciprocal functional importance for the SMN/ α-COP interaction in the growth and maintenance of neuronal processes in normal conditions and SMA model cells. Finally, RNA from the dilysine SMN mutants, wildtype and mutant α-COP were injected into SMN depleted zebrafish embryos. Wildtype SMN fully restored motor neuron pathfinding, while the dilysine mutants did not. Similar to what we've seen in our NSC-34 cell model of SMA, wildtype α-COP significantly restored motor neuron morphology while the mutant which is unable to bind SMN did not. These data demonstrated that this interaction is crucial for proper growth of motor neurons in a vertebrate animal model of SMA

Title: Poly(A)-binding protein nuclear 1 suppresses TDP-43 toxicity and aggregation in ALS disease models

Authors: *C.-C. CHOU[1,2], O. M. ALEXEEVA[1], Y. ZHANG[1,5], F. LIU[1,6], B. MO[1], K. R. WILLIAMS[1], D. C. ZARNESCU[7], N. T. SEYFRIED[3,4,2], G. J. BASSELL[1,2,4], W. ROSSOLL[1,2]; [1]Dept. of Cell Biol., [2]Ctr. for Neurodegenerative Dis., [3]Dept. of Biochem., [4]Dept. of Neurol., Emory Univ., Atlanta, GA; [5]Dept. of Neurol., Xiangya Hospital, Central South Univ., Changsha, Hunan, China; [6]Dept. of Ophthalmology, the Second Hosp. of Jilin Univ., Changchun, China; [7]Dept. of Mol. and Cell. Biol., Univ. of Arizona, Tucson, AZ

Abstract: Among the growing number of known amyotrophic lateral sclerosis (ALS) disease proteins, TAR DNA binding protein 43 (TDP-43) has emerged as a key player. Nearly all sporadic and familial ALS cases are characterized by cytoplasmic aggregations of hyper-phosphorylated, ubiquitinated, and cleaved TDP-43 fragments and the loss of nuclear TDP-43. TDP-43 pathology is also common in frontotemporal dementia (FTD-TDP), as well as other TDP-43 proteinopathies. In rare cases, mutant TDP-43 can trigger the ALS disease process, establishing a clear causal role for TDP-43 in neurodegeneration. TDP-43 inclusion pathology may reflect an exaggeration of normal accumulation of TDP-43 into cytoplasmic RNA granules under stress conditions. The toxic aggregation in the cytoplasm as well as the loss of endogenous TDP-43 from the nucleus may contribute to the disease progression by impairing normal RNA and protein homeostasis. Therefore, both the removal of pathological protein and the rescue of TDP-43 mislocalization may be critical for halting or reversing TDP-43 proteinopathies. In this study, we investigated the effect of pathogenic TDP-43 and regulators of TDP-43 toxicity in *in vivo* and *in vitro* models. From a yeast-two-hybrid screen and co-immunoprecipitation experiments, we identified poly(A)-binding protein nuclear 1 (PABPN1) as a novel TDP-43 interaction partner that acts a potent suppressor of TDP-43 toxicity in yeast, *Drosophila*, and cultured primary neurons. PABPN1 expression reduced TDP-43 aggregation and also restored the nuclear localization of endogenous TDP-43, while promoting the turnover of disease-associated mutant TDP-43 protein and its C-terminal fragment. Quantitative proteomics suggested that PABPN1 rescued the perturbation of protein homeostasis in TDP-43 pathology. In addition, PABPN1 expression rescued the dysregulation of SG dynamics observed in our cellular models of TDP-43 proteinopathy. Knock-down of PABPN1 on the other hand enhanced TDP-43 aggregation and mislocalization and reduced cell viability. Taken together, these findings demonstrate a role for PABPN1 in rescuing several cytopathological features of TDP-43 proteinopathy by selectively increasing the turnover of pathogenic proteins.

Title: Iron accumulation promotes TACE-mediated TNF-α secretion and neurodegeneration in a mouse model of ALS

Authors: *J.-K. LEE[1], J.-H. SHIN[2], B. GWAG[3], E.-J. CHOI[1];
[1]Korea Univ., Seoul, Korea, Republic of; [2]Sch. of Med., Ajou Univ., Suwon, Korea, Republic of; [3]GNT Pharma, Suwon, Korea, Republic of

Abstract: Oxidative stress contributes to degeneration of motor neurons in patients with amyotrophic lateral sclerosis (ALS) as well as transgenic mice overexpressing ALS-associated human superoxide dismutase 1 (SOD1) mutants. However, the molecular mechanism by which the ALS-linked SOD1 mutants including SOD1(G93A) induce oxidative stress remains unclear. Here, we show that iron was accumulated in ventral motor neurons from SOD1(G93A)-transgenic mice even at 4 weeks of age, subsequently inducing oxidative stress. Iron chelation with deferoxamine mesylate delayed disease onset and extended lifespan of SOD1(G93A) mice. Furthermore, SOD1(G93A)-induced iron accumulation mediated the increase in the enzymatic activity of TNF-α converting enzyme (TACE), leading to secretion of TNF-α at least in part through iron-dependent oxidative stress. Our findings suggest iron as a key determinant of early motor neuron degeneration as well as proinflammatory responses at symptomatic stage in SOD1(G93A) mice.

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease that is characterized by progressive loss of motor neurons. The underlying pathogenic mechanisms of ALS are multifactorial and, at present, not fully determined, therefore the treatment options for ALS patients are very limited. Neuronal loss in ALS is accompanied by a neuroinflammatory reaction including proliferation of CNS resident microglia, increased cytokine levels in the blood and CNS and recruitment of peripheral immune cells to the CNS. While the infiltration of lymphocytes to the CNS of ALS patients has been described before, we show for the first time that peripheral monocytes also invade the CNS of ALS patients. Moreover, we found a significant redistribution of monocytic subpopulations in the peripheral blood of ALS patients, and pre-symptomatic carriers of ALS mutations. Peripheral human monocytes are dividable into two subpopulations, the pro-inflammatory CD14++ monocytes and the regenerative CD16++ monocyte subtype. We show, that the pro-inflammatory CD14++ monocyte subpopulation is significantly overrepresented in the blood of ALS patients and pre-symptomatic carriers of ALS mutations compared to healthy, age-matched controls, shifting the monocytic composition towards the pro-inflammatory side. Functional characterization of the CD14++ monocyte subpopulation revealed impaired phagocytosis and vesicle trafficking in CD14++ monocytes from sALS patients, as well as altered adhesive properties and migration potential. Concordantly, we found CD14++ monocytes of sALS patients to exhibit a distinct gene expression signature, not only separating sALS monocytes from monocytes of healthy donors, but also substantiating the functional differences described above. Further, we found that immunomodulatory treatment of ALS patient derived CD14++ monocytes *in vitro* reverses the shift of monocyte subpopulations observed in ALS patients and delays the disease onset in an ALS mouse model *in vivo*. Taken together, our findings indicate the involvement of especially the CD14++ monocyte subpopulation in ALS and we present a possible strategy of pharmacological intervention.

Title: Cell-to-cell transmission of TDP-43 across axon terminals

Authors: *M. FEILER[1], B. STROBEL[3], A. FREISCHMIDT[2], A. HELFERICH[2], B. BREWER[4], D. LI[4], D. THAL[2], A. C. LUDOLPH[2], K. M. DANZER[2], J. H. WEISHAUPT[2]; [1]Experimenal Neurol., [2]Ulm Univ., Ulm, Germany; [3]Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany; [4]Vanderbilt Univ., Nashville, TN

Abstract: Causative mutations in TDP-43-encoding gene TARDBP were identified in fALS and sALS patients. Furthermore, TDP-43 is an aggregation-prone prion-like domain-containing protein and component of pathological intracellular aggregates. TDP-43 oligomers have been postulated to be released and subsequently nucleate TDP-43 oligomerization in recipient cells, which might be the molecular correlate of the systematic symptom spreading observed during ALS progression. We developed a novel protein complementation assay allowing quantification of TDP-43 oligomers in living cells. This assay is based on the principle of using non-bioluminescent Gaussia princeps luciferase fragments fused to TDP-43. Aggregation of the TDP-43 molecules leads to reassembly of the two luciferase fragments - complementation - and therefore luciferase activity. Initial assay validation studies not only demonstrated that luciferase signal is a specific result of TDP-43 oligomerization and not promoted by potential self-complementation of the luciferase fragments, but also prove that cellular stress-induced TDP-43 aggregation can, as expected, be detected by the assay. Therefore, we used the assay to investigate TDP-43 oligomerization and axonal transport. Our results show that mutated TDP-43 has a higher tendency to aggregate as compared to the wild type protein. Moreover, we demonstrate the presence of TDP-43 oligomers in microvesicles/exosomes and show that microvesicular TDP-43 is preferentially taken up by recipient cells, where it exerts higher toxicity than free TDP-43.Using nanotechnology-derived microfluidic devices that fluidically isolate neuronal cell bodies from axon terminals in culture, we show both, anterograde and retrograde trans-synaptic transmission of TDP-43. Finally, we demonstrate TDP-43 oligomer seeding by TDP-43 derived from both, cultured cells and ALS patient-derived CNS tissue extracts. Thus, using an innovative detection technique, we provide evidence for preferentially microvesicular and bidirectional synaptic intercellular transmission and seeding ability of TDP-43 oligomers.

Title: Transplantation of human neural progenitor cells expressing GDNF into the motor cortex as a therapeutic strategy for treating amyotrophic lateral sclerosis

Authors: *G. M. THOMSEN, G. G. GOWING, J.-P. VIT, O. SHELEST, D. RUSHTON, P. SUEZAKI, C. N. SVENDSEN;
Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: There is a lack of understanding in regards to the role that upper motor neurons play in amyotrophic lateral sclerosis (ALS) disease pathology. Our work builds on the hypothesis that upper motor neurons are a crucial component of ALS that should be therapeutically targeted. We have previously shown that the motor cortex is important in initiating disease onset in the SOD1G93A (SOD1) rat model of ALS by knocking down mutant SOD1 in the motor cortex alone. The mechanisms underlying this phenomenon however, remain unknown. It has been shown that glial cell line-derived neurotrophic factor (GDNF) can protect motor neuron function and survival in models of ALS. Here, human neural progenitor cells expressing GDNF (hNPC-GDNF) injected bilaterally and directly into the motor cortex of SOD1 rats survived and released GDNF, which was then taken up by surrounding neurons including corticospinal motor neurons. Critically, these targeted injections of hNPC-GDNF into only the motor cortex could significantly delay disease onset and extend survival. This current treatment strategy, unlike our previous study, does not involve altering mutant SOD1 expression, and is thereby more relevant to sporadic ALS cases. The novel approach of therapeutically targeting cortical motor neurons has great potential for a successful ALS treatment. Targeting the brain is much less invasive than targeting other affected central nervous system regions such as the spinal cord, making it ideal for fast translation to the clinic.

Title: The neurotoxin psychosine disorganizes plasma membrane lipids in the Krabbe disease

Authors: *L. D'AURIA[1], M. MARSHALL[1], E. LI[1], C. REITER[1], G. LI[2], R. VAN BREEMEN[2], M. ESCOLAR[3], E. BONGARZONE[1];
[1]Anat. and Cell Biol., [2]Medicinal Chem. and Pharmacognosy, UIC, Chicago, IL; [3]Children's Hosp., Univ. of Pittsburgs, Pittsburgs, PA

Abstract: Krabbe disease is a lysosomal storage disease with severe demyelination and neuronal dysfunctions. The disease is caused by a deficiency of galactosylceramidase and the toxic accumulation of the membrane-bound neurotoxin, psychosine, which activates intracellular pathogenic pathways by unknown mechanism(s). Because of its association with membranes, psychosine might initiate its toxicity by affecting the overall membrane and/or its sub-structures, the lipid domains. Indeed we have discovered that psychosine can accumulate in lipid rafts from Twitcher mice, a natural murine model for the disease. The goal of this study was to test the hypothesis that psychosine interferes with membrane fluidity and/or disrupts the architecture of specific plasma membrane lipid domains and can relay the toxicity into intracellular pathogenic pathway. For this, we first used plasma membranes from erythrocytes, a well-established featureless membrane model to study changes in membrane architecture and dynamics. Our work used, among others, cutting-edge techniques of high-resolution confocal microscopy, membrane fluidity measurement by LAURDAN-based dual-photon microscopy, fluorescence

recovery after photobleaching and fluorescence resonance energy transfer. Psychosine perturbs architecture of endogenous lipids. Concomitantly, the neurotoxic lipid induces focal changes of the overall rigidity of cell membranes as revealed by LAURDAN polarization. Psychosine also affects lipid dynamics since it specifically modulates the mobility of lipids. Equivalent experiments using oligodendrocytes (the main cell synthesizing psychosine in the brain) showed membrane reorganization upon exposure to psychosine which confirms its role in membrane perturbation. Altogether, these results are, for the first time, direct and quantitative evidence that psychosine's toxicity is initiated by perturbation of plasma membrane lipid domains. This work is relevant to understanding how psychosine causes toxicity in general and promotes myelin instability leading to demyelination in particular. These results may provide breakthroughs leading to alternative/complementary strategies to develop new therapies to cure the Krabbe disease. The fundamental discovery on how the neurotoxic psychosine affects the membrane can also provide mechanistic understanding of other sphingolipid storage diseases and demyelinating conditions such as Multiple Sclerosis.

Title: SMN functions as a chaperone for neuronal mRNP complex assembly

Authors: *P. G. DONLIN-ASP, C. FALLINI, J. P. ROUANET, S. P. H. HUANG, K. R. WILLIAMS, G. J. BASSELL, W. ROSSOLL;
Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Spinal muscular atrophy (SMA) is a neuromuscular disease characterized by a specific degeneration of motor neurons. SMA is caused by mutations leading to reduced levels of survival of motor neuron (SMN) protein, which is ubiquitously expressed with a well

characterized essential role in the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs). While general defects in splicing have been observed in SMA models, they are not unique to motor neurons. We have discovered specific defects in the axonal localization of mRNAs (β-actin, Gap43) and mRNA-binding proteins (HuD, IMP1) in axons and growth cones of SMN-deficient motor neurons. We also observed that overexpression of both HuD and IMP1 can restore axon outgrowth and GAP43 protein levels in growth cones of SMA motor neurons. Our findings led to the hypothesis that SMN plays a critical role in the assembly and/or trafficking of messenger ribonucleoproteins (mRNPs) in neuronal processes. To test our hypothesis, we have established a trimolecular fluorescence complementation (TriFC) assay in motor neuron cultures as a sensor for mRNA and protein association. Our findings reveal a deficiency in the assembly of IMP1 protein/β-actin mRNA containing complexes in SMA motor neurons. These results are further supported by immunopreciptation experiments from SMA tissue extracts, which show a substantial reduction in the levels of mRNAs associated with IMP1. In addition, size fractionation of neuronal RNA granules using density gradient centrifugation demonstrate a shift of mRNPs toward lighter fractions upon SMN depletion. We further show that SMN-deficiency results in defects in axonal local translation, likely as a consequence of impaired mRNP transport complex assembly. Local translation of β-actin and GAP43 are known to play an important role in axon outgrowth and branching. Taken together our findings reveal a novel function for SMN in the assembly of axonally transported mRNP complexes, and uncover effects on axonal mRNA localization and translation that may contribute to SMA pathology.

Title: Vulnerable motor units become hypoexcitable before denervation in mouse models of ALS

Authors: L. MARTINEZ-SILVA, D. ZYTNICKI, *M. MANUEL;
UMR 8119, CNRS / Univ. Paris Descartes, Paris, France

Abstract: One of the proposed mechanism to explain the death of motoneurons (MNs) in ALS is an excitotoxic process, i.e. an excess electrical activity leading to an overload of intracellular calcium triggering cell death. We have recently shown (Delestrée et al., J Physiol 2014) that spinal MNs of adult mice are not intrinsically hyperexcitable in SOD1-G93A mice. Instead, we found that a subpopulation of MNs lost their ability to fire repetitively in response to a stationary input. Furthermore, we have developed an *in vivo* adult mouse preparation allowing simultaneously recording intracellularly spinal MNs and recording the force developed by their motor unit (MU). Using this preparation we were able to identify the physiological type of recorded motor units. We were able to demonstrate that FF and FR MUs (that are vulnerable in ALS), but not the S type MUs (that are resistant in ALS), become progressively hypoexcitable before they lose their connections to their muscle fibers (Manuel et al., SfN 2014). To determine whether this phenotype is specific to SOD1-G93A mice or is a hallmark of the physiopathology of ALS, we performed experiments using a different mouse model, the FUS-P525L mouse (Sharma et al., submitted). The FUS gene has a very different cellular function than SOD1, and this model can thereby reveal alterations that are shared between different types of ALS. In this model, denervation occurs early (P30) in Tibialis Anterior (TA) and later (P180) in the Soleus (Sol) muscle, but it remains to be determined if this difference in the timing of denervation is due to muscle fiber composition or muscle function. We recorded motor units from ankle extensor muscles (including Sol), and ankle flexor muscles (including TA) at two time points (P30 and P180). Similarly to our previous report in SOD1 mice, preliminary experiments reveal that the excitability of motoneurons from ankle flexors at P180 is not different between mutant and control mice. For example, input conductance is 0.36 ± 0.12 uS (N=10) in mutants vs. controls (0.32 ± 0.12 uS; N=7), and rheobase is 8 ± 7 nA (N=7) vs. 6 ± 4 nA (N=5). However, a larger proportion of motoneurons are incapable of firing repetitively in response to stationary inputs in mutants (4/12) compared to controls (1/6). Remarkably, this deficit in excitability tends to affect larger FF and FR MUs. The excitability of S-type motoneurons remain to be studied, as muscles from ankle flexor muscles are mostly devoid of slow-contracting muscle fibers.

Title: Neurodegeneration-linked nuclear loss of RNA/DNA binding protein TDP-43 impairs DNA double-strand break repair in neuronal genomes

Authors: *E. N. GUERRERO[1,2,3], J. MITRA[2], P. HEGDE[2], H. WANG[2], J. RAO[1], M. HEGDE[2];
[1]INDICASAT-AIP, Panama, Panama; [2]Radiation Oncology, Houston Methodist Res. Inst., Houston, TX; [3]Biotech., Acharaya Nagarjuna Univ., Guntur, India

Abstract: TAR DNA-binding protein 43 (TDP-43),is an RNA/DNA-binding protein involved primarily in RNA processing, but its cytoplasmic aggregates have been found to be a pathological hallmark in motor neurons affected with Amyotrophic Lateral Sclerosis (ALS). In normal neurons, TDP-43 shuttles between nucleus and cytoplasm due to its function in RNA processing; but TDP-43 also binds to DNA, although its DNA-binding functions have not been explored. A significant accumulation of genomic damage is observed in TDP-43-linked diseases and previous studies identified a DNA repair protein "Ku" in a TDP-43 immunocomplex from human cells. In this study we investigated the possibility of TDP-43's involvement in DNA damage repair; a previously unexplored area. We used *in situ* Proximity Ligation Assay (PLA) to examine in cell interaction of TDP-43 with double strand breaks repair (DSBR) proteins in human neural stem cell (hNSC) line differentiated into spinal motor neurons. The PLA showed a strong interaction between TDP-43 with DSBR proteins Ku70, DNA-PKcs, XRCC4 and DNA ligase IV. The TDP-43's association with DSBR proteins was significantly enhanced in cells exposed to DSB-inducing ionizing radiation (IR). The in cell association was confirmed by immuno-precipitation (IP) analysis with endogenous TDP-43 and FLAG-TDP-43 ectopically expressing cells, including enhancement of interaction after IR. Neutral and Alkaline comet assay analysis in TDP-43 depleted cells showed a persistent accumulation of DSBs in the absence of any genotoxic agent which is highly significant. Loss of TDP-43 affected recruitment of 53BP1 and XRCC4/DNA LigaseIV complex (two key components of non-homologous end joining mediated DSB repair pathway) at DSB sites. Together these data strongly suggest a role of TDP-43 in efficient DSB repair in neuronal genomes and its pathological linkage to neurodegeneration.

Title: Subclinical abnormal sensory-motor integrations at spinal level in ALS patients

Authors: *V. MARCHAND-PAUVERT;
U1146, Inserm, Paris, France

Abstract: Using electrophysiology and spinal diffusion tensor imaging, we recently confirmed early sensory defects in patients with amyotrophic lateral sclerosis (ALS) who did not exhibit any sensory impairment when assessed using routinely used clinical scales(1). We have stimulated the median and ulnar nerves at writ level to investigate the sensory evoked potentials (SEPs) produced by afferent inputs from the hand area. In parallel, we have tested the sensory-motor integrations at motoneuron level. For this, we combined transcranial magnetic stimulation (TMS) over the primary motor cortex, with median and ulnar nerve stimulations. All the patients exhibited hand motor weakness but no proximal motor defects, especially in triceps brachii. We first investigated the recruitment curve of motor evoked potentials (MEP) in triceps brachii to investigate the corticospinal excitability. Then, TMS (at about I50) was combined to median or ulnar nerve whose intensity was adjusted at 6 x the perceptual threshold in order to activate group Ia afferent fibers from intrinsic hand muscles which are known to have monosynaptic projections onto triceps motoneurons(2). We compared the size of the MEP produced by isolated TMS and by combined stimulation. Except an increase in MEP threshold in ALS patients (n=21), the MEP recruitment curves were similar to those in gender and age matched controls (n=21). Despite a similar mean size of MEP produced by isolated TMS between groups, the MEPs produced on combined stimuli were significantly larger in ALS compared to controls. In the same group of participants, the peripheral SEPs were smaller in ALS(1). Therefore, despite less sensory afferent inputs at spinal level and similar corticospinal excitation, we observed an enhanced excitation at motoneuron level in ALS. Given the absence of evidences for excitability changes at motoneuron level, the results suggest specific changes at the level of the synapses between group Ia afferents and motoneurons leading to hyperexcitability. One possible mechanism would be a change in the control of primary afferent depolarization interneurons mediating presynaptic inhibition of group Ia afferents to compensate the sensory de-afferentation. This enhanced synaptic activity may contribute to the motoneuron excito-toxicity, which is among the causes of motor neuron death in ALS. Given the diffuse monosynaptic

excitations from Ia inputs to human upper limb motoneurons(3), especially from distal muscles to more proximal muscles, such a mechanism would participate in the propagation of motor neuron disease. Title: Non-invasive muscle impedance measurements correlate to muscle force in ALS mice

Authors: *J. LI, B. SANCHEZ, A. PACHECK, S. RUTKOVE;
Neurol., Harvard Med. School, Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Objective: Evaluate the relationship between force generating capability and muscle impedance in ALS mice. Methods: Twenty eight ALS (B6SJL-Tg(SOD1-G93A)1Gur/J) mice, between 13 and 18 weeks of age, obtained from Jackson Laboratories were examined. *In vivo* muscle electrical impedance myography (EIM), *in situ* isometric force, and the compound motor action potential (CMAP) were measured from a unilateral gastrocnemius. . Body weight, paw grip strength, and muscle weight were also measured. Results: Higher resistance, lower phase but not much differences of reactance were found in mice with more advanced ALS. For instance, at 50 kHz, 18-week old animals had on average a 33% higher resistance than 13-week old animals (375 ± 17.2 Ω vs. 283 ± 6.68 Ω respectively, $p < 0.01$); and on average a 23% smaller phase than 13-week old animals (13.7 ± 0.82 ° vs. 17.8 ± 1.33 ° respectively, p 0.05). Additionally, a modeled multifrequency impedance parameter, the center frequency, was also evaluated. It was markedly higher (93% on average) in the 18-week (53.5 ± 5.43 kHz) versus 13-week (103 ± 16.9 kHz) old mice ($p = 0.05$). Similarly, the 18-week old mice showed weaker grip strength than 13-week old mice. For the front paw, there was a significant difference (63% on average, 0.03 ± 0.01 kg vs. 0.08 ± 0.01 kg respectively, p 0.05). Force generating capability was evaluated by both maximum force and maximum velocity under tetanic stimulation. Maximum force was 17% lower on average for 18-week (934 ± 116 mN) than for the 13-week old mice (1119 ± 168 mN); Maximum velocity was 14% lower on average for 18-week (33.6 ± 1.21 mm/s) than 13-week old

mice (39.1 ± 2.33 mm/s). Nevertheless, none of their differences were statistically significant. There were strong correlations among EIM parameters, front paw grip strength, and force. For example, phase correlates to front paw grip strength with r as 0.74 ($p < 0.001$); to maximum force with r as 0.48 ($p < 0.02$). Conclusions: Impedance measures are sensitive to the progressive deterioration in strength in ALS mice, with major alterations in the 50 kHz phase and the resistance parameters, and very large increase in the center frequency parameter in the oldest mice. These alterations correspond closely with the observed alterations in force production. The results support that non-invasive impedance measurements could serve as a useful easily obtained surrogate measure of weakness in ALS.

Title: Early and late somatosensory evoked potential impairment in amyotrophic lateral sclerosis

Authors: *S. SANGARI[1], V. MARCHAND-PAUVERT[2];
[1]UMPC/INSERM/CNRS, Paris, France; [2]U1146, INSERM, Paris, France

Abstract: Amyotrophic lateral sclerosis (ALS) is an adulthood neurodegenerative disease characterized by the loss of cortical and spinal motor neurons, leading progressively to muscle weakness, paralysis and death. Often considered as a purely motor disease, evidences of sensory pathway involvement are emerging. Study of Somatosensory Evoked Potential (SEP) allows subclinical assessment of proprioceptive pathways at peripheral (Erb point) and cortical (parietal cortex) level. Several SEP studies have been carried out on ALS patients: evidences have been brought for amplitude reduction with central but no delayed peripheral latency, and SEP from lower limbs are more altered than those from upper limbs while no patients exhibited clinical sensory troubles. To our knowledge, SEP studies focused early SEP (N9 and 20) but none on late SEP (latency > 35 ms). It is admitted that early SEP are generated from thalamo-cortical

projections onto primary somatosensory area (S1) and its relationships with the motor and pre-motor areas. The late SEP are generated from secondary somatosensory area (S2). In our previous study (Iglesias & Sangari et al. 2015), we have shown that the amplitudes of N9 and N20 produced by median and ulnar nerve stimulation at wrist level and the central conduction velocity were reduced in ALS patients compared to gender and age matched controls. Moreover, we observed a reduction in the following early (P25-N35) and late SEP recorded over the contra- and the ipsi-parietal cortex. This raises the questions whether i) the reduction of early and late SEP in ALS patients would be correlated to N9 reduction (and thus due to less sensory inputs), or would include excitability changes of pons-thalamus relay and/or cortico-sub-cortical interaction, and ii) the reduction of SEP recorded ipsi-laterally would be just far-field potentials from contralateral cortex or due to transcallosal or ipsi-parietal cortex impairment. We performed electroencephalographic recording on 15 healthy participants at the Erb point, bilateral parietal and occipital cortices. We electrically stimulated median and ulnar nerve at wrist level at 1.5, 3, 6 and 9 time the perceptual threshold (PT). Preliminary results showed independent relation between stimulation intensity and potentials: N9 increased linearly with stimulus intensity, early SEP reached a plateau at 6xPT, and late SEP reached quickly a saturation plateau at 3xPT and then decreased. Ipsilateral potentials recorded seem to be far-field potentials from de contra-parietal side. Thus, it seems that ALS patients exhibit relay and cortico-sub-cortical impairment of the contra-somatosensory area, early in the disease.

Title: Role of ADARB2 in GLUA2 editing deficiency in C9ORF72 amyotrophic lateral sclerosis and frontotemporal dementia

Authors: *E. F. MENDEZ[1], E. L. DALEY[2], X. TANG[2], S. VIDENSKY[2], R. SATTLER[2]; [2]Neurol., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: A mutation consisting of a GGGGCC (G4C2) hexanucleotide repeat expansion (HRE) sequence in the chromosome 9 open reading frame 72 (C9orf72) gene has been identified as the most common cause of both familial and sporadic amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). This mutation, when transcribed, causes RNA to form toxic foci that sequester RNA binding proteins, including a member of the RNA-specific adenosine deaminase (ADAR) family, ADARB2. Using patient-derived iPS neurons and postmortem patient tissue, we show that the (G4C2) mutation causes RNA editing deficits of the GluA2 α-amino-3-hydroxyl-5-methyl-4-isoxazole propionate AMPA receptor subunit and we implicate that a combination of ADARB2 sequestration and reduced ADARB1 transcript levels are involved in this phenomenon. This misediting is suggested to lead to increased susceptibility to glutamate-induced excitotoxicity observed in C9orf72 mutant iPS neurons - a hallmark mechanism known to contribute to motor neuron loss. In addition, lack of editing of GluA2 is likely to contribute to cognitive impairment and synaptic dysfunction as observed in both C9orf72 ALS and FTD patients.

Title: PGC-1alpha signalling system in mouse models of FUS- and SOD1-related amyotrophic lateral sclerosis

Authors: H. BAYER[1], K. LANG[1], J. HANSELMANN[1], I. MERDIAN[1], L. DUPUIS[2], *P. WEYDT[1], A. WITTING[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is characterized by hypermetabolism. Genetic variants of a brain-specific promoter of the metabolic transcriptional coactivator peroxisome proliferator-activated receptor (PPAR) gamma coactivator 1-α (PGC-1α) modify age of onset in human ALS1 suggesting that changed function or activity of PGC-1α contributes to the metabolic changes in ALS. We investigated the PGC-1α expression and function in different tissues and cells of two ALS mouse models, SOD1(G93A) mice and a knock-in Fus mouse model deleted of the nuclear localization signal (FusΔNLS). We showed that the canonical and brain-specific PGC-1α isoforms are reduced in spinal cord and brain stem of diseased mice from the SOD1 mouse model, whereas PGC-1α remains unchanged in unaffected brain regions and in non-diseased FusΔNLS/+ mice. In contrast, in peripheral tissues like brown adipose tissue and muscle PGC-1α was upregulated in SOD1 mice during disease progression. In primary neurons and glia cells of both mouse models the basal expression of PGC-1α was unchanged in comparison to corresponding controls. In contrast, in primary brown adipocytes of FusΔNLS/ΔNLS mice basal levels of Pgc-1α and Ucp-1 were increased. To investigate the effect of ALS-associated mutations we stimulated the PGC-1α signaling pathway by lactate in neurons and norepinephrine in adipocytes. The lactate-induced PGC-1α expression and signaling was not influenced by the tested ALS-associated mutations. In contrast, in primary brown adipocytes of FusΔNLS/ΔNLS mice stimulation with norephinephrine resulted in a stronger increase of Pgc-1α and Ucp-1 levels. So far, our results suggest that PGC-1α expression is changed in the CNS and peripheral tissues in diseased animals. In contrast to SOD1 mutations, ALS-associated Fus mutations increase the PGC-1α signaling in adipocytes which would contribute to the hypermetabolism of ALS.

Title: Leveraging informatics to assess the SOD1 G93A amyotrophic lateral sclerosis mouse model

Authors: *R. KIM, C. IRVIN, J. KNIPE, C. S. MITCHELL;
Georgia Inst. of Technol., Atlanta, GA

Abstract: The superoxide dismutase-1 glycine 93 to alanine (SOD1 G93A) transgenic mouse model has been a mainstay in the field of Amyotrophic Lateral Sclerosis (ALS) for over two decades with hundreds of published studies depicting relationships and observations thought to contribute to the disease etiology. It has been our ongoing goal to leverage this extensive research utilizing informatics-based approaches. To this end, we continue to build a comprehensive database that includes figure captions and quantitative data recaptured from over 2,000 published articles. A searchable SOD1 G93A figure caption database is freely available on our website, www.pathology-dynamics.org. Using our comprehensive database, we present an informatics-based systematic review of the field's primary experimental research to determine the distribution of article belonging to the following ontological categories: axonal transport, apoptosis, cellular chemistry, excitability, energetics, oxidative stress, inflammation, proteomics and protein aggregation, and systemic contributors and effects. Additionally, we present example informatics-based meta-analyses of published temporal experimental data examining mitochondrial function, calcium, and oxidative regulation. Finally, we present preliminary results of a multi-treatment meta-analysis to predict which ontological category(s) of treatments appear the most promising for future preclinical study.

Title: Analysis of SOD1 transmission to motor neurons in a SOD1G85R mouse amyotrophic lateral sclerosis (ALS) model

Authors: *E. V. THOMAS[1], W. A. FENTON[2], M. NAGY[1], D. LI[1], J. M. MCGRATH[3], A. L. HORWICH[4];
[2]Genet., [3]Comparative Medicine/Genetics, [1]Yale Univ., New Haven, CT; [4]Genet., Yale University/Howard Hughes Med. Inst., New Haven, CT

Abstract: Transmission of aggregation-prone proteins, such as tau, alpha-synuclein, amyloid beta, and mutant SOD1, from one neuron to another has been hypothesized to contribute to neurodegeneration in patients and mouse models. In fact, anatomical progression of disease symptoms in amyotrophic lateral sclerosis (ALS) patients suggests spread of pathology in the spinal cord. Mutations in superoxide dismutase 1 (SOD1) cause approximately 20% of familial ALS cases. SOD1 mutations cause protein aggregation in motor neurons in the spinal cord; therefore, motor neuron demise in ALS patients is thought to be due to a toxic gain-of-function as a result of SOD1 misfolding. SOD1 aggregates can be taken up by dividing cells in culture, and injection of spinal cord lysate from diseased SOD1G93A transgenic mice can accelerate ALS pathogenesis in a low-copy SOD1G85R-YFP transgenic mouse strain. These data ask whether mutant SOD1 can be taken up by motor neurons in the spinal cord *in vivo*, thereby causing disease spread. We have modeled SOD1-linked ALS using transgenic mice expressing G85R SOD1-YFP. G85R SOD1-YFP mice develop large, cytosolic, YFP-fluorescent aggregates in motor neurons and paralyze by six months of age, while wt SOD1-YFP mice do not develop aggregation or motor neuron disease symptoms. In order to visualize SOD1 propagation in motor neurons and assess its contribution to ALS pathogenesis, we generated a second transgenic mouse strain expressing G85R SOD1-CFP. Chimeric mice were then formed from embryos of the two G85R SOD1-FP strains resulting in spinal cord neurons expressing one or the other fluorescently labeled mutant SOD1. Transfer of mutant SOD1 between neurons will result in cells co-labeled by both the endogenously expressed mutant SOD1 and SOD1 derived from cells expressing the other fluorescently-tagged mutant. Our studies indicate that while no mutant SOD1 is transferred at early time points (1 month), small amounts of SOD1 can be transmitted preferentially to motor neurons at later time points (3 months) in symptomatic, SOD1 chimeric mice. Of note, other neuronal sub-types do not exhibit CFP/YFP co-labeling at three months. These results are a proof-of-principle that a predominantly cytosolic protein can exit cells and be taken up by motor neurons *in vivo*, a necessary step if misfolded SOD1 is to template aggregation in recipient cells. However, the exact contribution of SOD1 intercellular propagation to disease is unclear. These data support the need for further studies to address the mechanism and pathogenicity of SOD1 protein transfer, as interruption of this process may comprise a therapeutic avenue in ALS patients.

Title: Effects of caspase-3 cleavage-resistant Eaat2 on the Sod1-G93A mouse model of amyotrophic lateral sclerosis

Authors: *L. T. ROSENBLUM[1], P. PASINELLI[2], D. TROTTI[2];
[1]Dept. of Neurosci., Philadelphia, PA; [2]Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a rapidly progressive and fatal neurodegenerative disease that primarily affects the corticospinal tract. In ALS, astrocytes cause toxicity to upper and lower motor neurons in a process known as non-cell autonomous toxicity. It has previously been shown that in spinal cord astrocytes of the SOD1-G93A ALS mouse model, activated caspase-3 cleaves the glutamate transporter, EAAT2, leading to the accumulation of a sumoylated C-terminal fragment (CTE-SUMO1) as disease progresses. Furthermore, expression of an artificial CTE-SUMO1 construct by astrocytes, mimicking the *in vivo* astrocytic accumulation, causes the secretion of one or more factors that are toxic to motor neurons in *in vitro* experiments. We sought to determine the significance of this pathway *in vivo* by genetically blocking the caspase-3 cleavage of EAAT2 in a novel mouse model. We report here the generation of a knock-in mouse model with a point mutation on the astrocytic glutamate transporter, EAAT2, which prevents cleavage by activated caspase-3 (EAAT2-D504N). EAAT2-mutant mice were crossed with the SOD1-G93A mouse model of ALS to generate SOD1-G93A mice homozygous for either EAAT2-WT or EAAT2-D505N. Non-SOD1-G93A mice homozygous for EAAT2-WT or EAAT2-D505N were also generated and used as healthy controls. Mice were followed past post-natal day 160, the normal end-stage for SOD1-G93A mice, and assessed for disease progression by pathology and behavioral assessments.

Title: Astrocyte Cx43 contributes to motor neuron toxicity in ALS

Authors: *A. A. ALMAD[1], A. DORESWAMY[2], S. K. GROSS[2], N. HAUGHEY[3], N. J. MARAGAKIS[2];
[2]Neurol., [3]Neuropathology, [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease resulting in progressive degeneration of motor neurons (MN) in the brain and spinal cord leading to weakness and death. Astrocytes play a critical role ALS influencing course of disease and contributing to MN death. Studies from *in vitro* and *in vivo* models demonstrate astrocytes are altered in ALS and in turn affect MN survival. Here we investigate a potential mechanism through which astrocytes lead to MN toxicity. Astrocytes are interconnected through connexins (Cx) and Cx43 is a major astrocyte connexin conducting crucial homeostatic functions in the CNS. Under pathological conditions, connexins are altered and their functions are compromised as observed in spinal cord injury, Alzheimer's disease, Parkinson's, ischemia, and others. We hypothesized that abnormal Cx expression serves as a potential mechanism for astrocyte-mediated toxicity in ALS. We examined if Cx43 is altered during course of the disease using $SOD1^{G93A}$ mouse model of ALS and observed Cx43 protein increased at disease onset and remained significantly elevated in the spinal cord of endstage mice. Notably, this increase in Cx43was observed not only in ALS mouse model but also in motor cortex and spinal cord of ALS post-mortem patients compared to age-matched controls. To investigate if these changes in Cx are specific to astrocytes, we isolated astrocytes from $SOD1^{G93A}$ and $SOD1^{WT}$ mice and characterized their Cx43 expression and function. We found even in the absence of neurons, Cx43 expression was elevated in $SOD1^{G93A}$ astrocytes compared to control. This increase in Cx43 protein expression translated to alteration in functional properties of mutant astrocytes as we conducted Cx specific assays and found that mutant astrocytes exhibited enhanced dye spreading, hemichannel mediated uptake and intracellular calcium levels compared to control astrocytes. Finally, to understand the impact of increased expression of Cx43 on survival of MNs, we conducted co-culture experiments between astrocytes and HB9-GFP positive MNs. We tested if blocking Cx43 protects MNs from the toxic effects of $SOD1^{G93A}$ astrocytes and monitored their survival in the presence or absence of Cx43 mimetic peptide. We noted significantly better survival of MNs on top of $SOD1^{G93A}$ astrocytes treated with Cx43 peptide blocker versus without the peptide. These results demonstrate aberrant Cx properties of ALS astrocytes and indicate blocking Cx43 confers neuroprotection to MNs. These novel findings have widespread implications for other neurodegenerative diseases as well and provides a therapeutic strategy targeting glial cells to protect the vulnerable MNs.

Abstract: Amyotrophic Lateral Sclerosis (ALS) also known as Lou Gehrig´s disease, represents a progressive and fatal neurodegenerative disorder affecting motor neurons with a typical median disease course of 2 to 5 years and a lifetime risk of 1:400 (Ingre et al. 2015). Despite the expanding research interest, the heterogenous etiology of ALS in combination with the lack of validated biomarkers and active therapeutic agents obstruct effective treatment of this orphan disease. In the last decades a growing number of studies including cell culture experiments, animal models, but also human studies indicate immune and inflammatory abnormalities to contribute to the pathogenesis of ALS (McCombe et al. 2011). It has been demonstrated that during disease progression a protective Type 2 (pre-symptomatic or stable disease) traverses into a neurotoxic Type 1 immune response (progressive disease) (Murdock et al. 2015). Here we first reveal the activation state of the TGF-β pathway incl. most important downstream molecules within spinal cord (SC) and motor cortex (MC) tissue homogenates (kindly provided by Prof. Thal, MND network Germany) of ALS and control patients via Western Blot analysis and *in situ* hybridisation. Next, we investigated the neurogenesis in SC and MC tissue of ALS and controls by measuring the expression profiles of early neuronal differentiation and proliferation markers. Subsequently, we examined the SC and MC tissue for a correlation of tissue-infiltrating immune cells and local neuronal, glial, and microglial components. Finally, we determined the hematological alterations of plasma samples obtained from ALS patients and healthy controls regarding their levels of leukocytes, chemokines, pro- and anti-inflammatory cytokines, and

vascular as well as angiogenic factors using electrochemoluminescence and FACS analysis. We were able to demonstrate enhanced circulating levels of pro-inflammatory cytokines (IFNγ, TNFα, IP-10) within the serum of ALS patients compared to healthy controls. Further, a trend towards reduced expression of Tie-2 and VEGF-C indicated diminished angiogenesis in ALS patients. Finally, there was a positive correlation between the circulating levels of monocytes and the ALS-FRS-R and an inverse correlation of mobilized eosonophils and the ALS-FRS-R with the latter being confirmed by enhanced levels of plasma eotaxin of ALS patients compared to healthy controls. Taken together, the results of the current study might shed some light on biomarker discovery and provide possible purchases for a successful treatment development in ALS.

Title: Antisense oligonucleotide treatment protects against neuromuscular denervation in the SOD1-G93A mouse model of ALS as evaluated by a pre-symptomatic electrophysiological measure

Authors: *B. J. FARLEY[1], N. T. COMFORT[1], J. L. GOODMAN[1], A. M. KUSZPIT[1], T. COLE[2], H. KORDASIEWICZ[2], E. SWAYZE[2], A. MCCAMPBELL[1], M. WITTMANN[1]; [1]Biogen, Cambridge, MA; [2]Isis Pharmaceuticals, Carlsbad, CA

Abstract: ALS is a neurodegenerative disease characterized by progressive motor neuron loss and eventual death. Mice overexpressing a mutant form of human SOD1, a gene linked to approximately 20% of familial ALS cases, represent a widely used ALS model. These mice recapitulate many of the histological and behavioral characteristics of the human disease. We evaluated whether an antisense oligonucleotide (ASO) directed against the mutant SOD1 expressed in SOD1-G93A mice (B6.Cg.-Tg(SOD1*G93A)1Gur/J) could rescue deficits present in an electrophysiological measure, compound muscle action potential (CMAP), of neuromuscular denervation. We first characterized the timecourse of CMAP deficits in SOD1-G93A mice. CMAP recordings were performed under anesthesia every two weeks from week 5 to week 13, with CMAP amplitudes being measured from the tibialis anterior muscle in response

to sciatic nerve stimulation. Deficits in CMAP amplitude were present in untreated SOD1-G93A mice relative to WT mice (two-way ANOVA, $p<0.0001$) beginning at week 7 and persisted thereafter. Thus, the electrophysiological deficits are present at least 10 weeks before symptom onset is known to occur, confirming CMAP in tibialis as an early and sensitive pre-symptomatic measure for evaluating disease course in this model. In a second experiment, mice were treated with an ASO targeted against mutant SOD1 (SOD1-ASO) at week 5.5. We found that intra-cerebroventricular injections of SOD1-ASO protected against the CMAP decline observed in sham-treated SOD1-G93A mice (two-way ANOVA, $p<0.0001$), with CMAP values being higher in treated than sham-treated mice beginning at week 7 and the effect persisting through week 13, the last time point measured. At this last time point, CMAP values were indistinguishable between WT and ASO-treated SOD1-G93A mice (WT: 74 ± 4 mV; SOD1 ASO-treated SOD1-G93A: 70 ± 2 mV; sham-treated SOD1-G93A: 31 ± 3 mV). These results demonstrate that a SOD1-ASO injected at an early time point protects against neuromuscular denervation in this model and that this treatment effect can be measured pre-symptomatically using electrophysiology.

Title: Inhibition of p38 MAPK alpha rescues retrograde axonal transport defects in ALS

Authors: ***K. L. GIBBS**[1], B. KALMAR[1], M. AHMED[2], E. BROWNE[2], C. DAVIES[2], L. GREENSMITH[1], G. SCHIAVO[1];
[1]Sobell Dept. of Motor Neurosci. and Movement Disorders, Inst. of Neurol., London, United

Kingdom; [2]GlaxoSmithKline Res. and Develop. China Singapore Res. Ctr., The Helios, Singapore

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease caused by the degeneration of both upper and lower motor neurons. Defects in retrograde axonal transport have been found pre-symptomatically in the $SOD1^{G93A}$ mouse model of ALS. However, the exact role that these defects play in ALS disease pathogenesis is not yet fully understood and still remains a subject of much controversy in the field. In order to address this, we screened a library of small molecule inhibitors in search of pharmacological enhancers of retrograde axonal transport in motor neurons. Several inhibitors of p38 MAPK were identified in our screen and were subsequently shown to correct deficits in the retrograde axonal transport of signalling endosomes *in vitro* in primary $SOD1^{G93A}$ motor neurons. Knockdown of p38 MAPK isoforms using lentiviral vectors revealed that p38 MAPK alpha was responsible for the transport deficits observed in $SOD1^{G93A}$ motor neurons. Using *in vivo* imaging of the sciatic nerve in live anaesthetised mice, we found that a specific inhibitor of p38 MAPK alpha and beta could rescue axonal transport impairments in early symptomatic $SOD1^{G93A}$ mice. Our findings demonstrate for the first time the pathogenic effect of p38 MAPK alpha over-activation on retrograde axonal transport. Since axonal transport deficits have been implicated in the pathogenesis of ALS, the ability to pharmacologically reverse these defects may represent a novel therapeutic strategy for ALS.

Title: S6K-mediated cellular change in a mouse model of ALS

Authors: *S.-W. KUO[1], C. J. HECKMAN[1,2];
[1]Dept of Physiol., Northwestern Univ., Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: In ALS, spinal motoneurons with various sizes show distinctive degenerating rates in which large motoneurons are particularly vulnerable. ALS spinal motoneuron size is increased since neonatal stage accompanied with abnormal electrical properties. Motoneuron size enlargement may be the subsequence of initial responses to morbific prodromal factors such as altered expression level of proteins related to survival and translation. We hypothesize that the early-stage abnormal soma size and electrical properties might link to the selective susceptibility of motoneurons in ALS. S6K is selected for motoneuron size manipulation due to its regulatory roles in protein translation, cell growth and synapse development. Our results showed that neonatal motoneuron size was abnormally enlarged, and that S6K inhibitor could maintain the size of lumbar spinal motoneurons in early-stage G93A mice. Post-symptomatic S6K inhibitor administration onto adult mice revealed distinctive responses upon different doses. Lower dose mildly prolonged the lifespan, while the higher does significantly accelerated the disease progression and shorten lifespan. The early-stage abnormality can be amended by S6K-suppression implies the involvement of S6K pathway in ALS pathogenesis. The distinctive dose-dependent responses at late-stage suggested the importance of S6K management in ALS.

Title: Exocytosis regulates the trafficking of GABA and glycine heterotransporters in spinal cord glutamatergic synapses: a mechanism for the excessive heterotransporter-induced glutamate release in amyotrophic lateral sclerosis

Authors: *C. USAI[1], M. MILANESE[2], T. BONIFACINO[2], E. FEDELE[2], C. REBOSIO[2], L. CATTANEO[2], F. BENFENATI[3], G. BONANNO[2];
[1]Natl. Rese Council, Genova, Italy; [2]Dept. of Pharmacy, Pharmacol. and Toxicol. Unit - Ctr. of Excellence for Biomed. Res., Univ. of Genoa, Genova, Italy; [3]Dept. of Neurosci. and Brain Technol. and Dept. of Exptl. Med., Italian Inst. of Technol. and Univ. of Genoa, Genova, Italy

Abstract: Protein trafficking is a crucial process in CNS plasticity. Several evidences show that functional membrane proteins can be rapidly trafficked from the cytosol to the plasma membrane

and vice-versa, exploiting endo/exocytotic events (Buckley et al., J Physiol. 2000, 525:11-19,). In particular it has been proposed that transporters for a given neurotransmitter are rapidly trafficked to and from the plasma membrane in relation to the exocytotic release of the neurotransmitter it self and that this type of trafficking is important in regulating neuronal signaling (Geerlings et al., J BiolChem., 2001, 276:17584-90; Deken et al., J Neurosci. 2003, 23:1563-68). The impact of synaptic vesicle endo-exocytosis on the trafficking of nerve terminal heterotransporters was studied by monitoring membrane expression and function of the GABA transporter-1 (GAT-1) and of type-1/2 glycine (Gly) transporters (GlyT-1/2) at spinal cord glutamatergic synapses. Experiments were performed by inducing exocytosis in wild-type (WT) mice, in amphiphyisin-I knockout (Amph-I KO) mice, which show impaired endocytosis, or in SOD1G93A mice as a model of human amyotrophic lateral sclerosis that shows a constitutively excessive Glu exocytosis (Milanese et al., J Neurochem. 2011, 116:1028-42). Exposure of spinal cord synaptosomes from WT mice to a 35 mM KCl pulse increased the expression of GAT-1 and GlyT-1/2 at glutamatergic synaptosomal membranes and enhanced the GABA and glycine-induced glutamate (Glu) release. Preventing depolarization-induced exocytosis normalized the excessive GAT-1 and GlyT-1/2 heterotransporter-induced Glu release in WT mice. Impaired endocytosis in Amph-I KO mice increased GAT-1membrane expression, the GABA uptake and the GAT-1 heterotransporter-evoked release of Glu in spinal cord synaptosomes. The constitutively excessive Glu exocytosis in SOD1G93A mice resulted in augmented GAT-1 and GlyT-1/2 expression at glutamatergic synaptosomal membranes paralleled by an increased of GABA and glycine-induced Glu release. Thus, endo-exocytosis regulates the trafficking of GAT-1 and GlyT-1/2 heterotransporters sited at spinal cord glutamatergic nerve terminals. As a consequence, it can be hypothesized that the excessive GAT-1 and GlyT-1/2 heterotransporter-mediated Glu release (Raiteri et al., 2005, Neurotoxicol. 26:883-92; Milanese et al., 2010, J Neurochem. 113:489-501), in the spinal cord of SOD1G93A mice, is due to the heterotransporter over-expression at the nerve terminal membrane, promoted by the excessive Glu exocytosis.

Title: A temporal assessment of excitability in the SOD1 G93A Amyotrophic Lateral Sclerosis mouse model

Authors: *I. VERNON, Y. SHI, M. JENSEN, Z. SEILING, C. S. MITCHELL;
Georgia Inst. of Technol., Atlanta, GA

Abstract: Excitotoxicity occurs when an abnormal amount of glutamate is present in the synaptic cleft of the pre-and post- synaptic neuron, which activates both AMPA and NMDA ionotropic receptors, causing the postsynaptic neuron to die of toxic overstimulation. Abnormal amounts of glutamate could be due to the presynaptic neuron over-releasing the neurotransmitter or due to the inability of the glutamate transporters, commonly referred to as EAAT-2 and GLT-1, to fully reuptake glutamate. Excitotoxicity has been suggested as one possible contributor to the multifactorial Amyotrophic Lateral Sclerosis (ALS) pathophysiology. In fact, the sole FDA-approved treatment, Riluzole, is thought to work by decreasing excitotoxicity. Early electrophysiological studies of transgenic mouse models suggested that embryonic ALS mouse motoneurons are hyperexcitable, but more recent studies of adult motoneurons have suggested that ALS-affected motoneurons may be hypoexcitable. We hypothesize that these findings could be explained by temporal changes in excitability that are a function disease progression. We perform a meta-analysis of quantifiable excitability measures in the SOD1 G93A (superoxide dismutase-1 glycine 93 to alanine) transgenic ALS mouse model and compare the results to age-matched wild type mice. Included measures comprise assessments of glutamate concentration, glutamate transports (GLT-1 and EAAT2), receptor activation (NMDA, AMPA, GABA), calcium concentration, acetylcholine concentration, and compound muscle action potential (CMAP) amplitude. Our results reveal that many of the assessed measures fluctuate over the course of disease progression, likely in an attempt to maintain homeostasis. Specifically, there is a distinct change that occurs prior to disease onset, which results in an apparent shift from hyperexcitability to hypoexcitability.

Title: Hyperexcitability in synaptic activity as a component of excitotoxicity in adult mouse model of amyotrophic lateral sclerosis

Authors: *C. HECKMAN[1], M. JIANG[2];
[1]Dept. of Physiol., [2]Northwestern Univ., Chicago, IL

Abstract: Hyperexcitability likely contributes to the degeneration of spinal motoneurons (MNs) in amyotrophic lateral sclerosis (ALS). Studies thus far indicate that there is no hyperexcitability in the intrinsic electrical properties of MNs in the adult mutant SOD1 mouse model of ALS (high copy number, mSOD1G93A). In this study, we obtained two types of measurements, reflexes to assess net system behavior and intracellular recordings in motoneurons to assess single cell behaviors. All studies were carried out in an adult *in vitro* preparation of the sacral spinal cord of mSOD1G93A mice and their wild type controls (age range: 50 - 90 days). At the system level, we found that the maximum compound action potentials (coAPs) evoked in ventral roots by short train stimulation of corresponding dorsal roots were similar between the mSOD1 G93A mice and their nontransgenic (NG) littermates. There was however substantial depression of coAPs during the course of the train stimulation and this depression was significantly reduced in the mSOD1G93A mice, suggesting presence of a net increase in potency of sensory input to MNs. At the single cell level, intracellular recordings revealed no changes in the amplitudes of excitatory postsynaptic potentials (EPSPs) in the mSOD1G93A MNs. In contrast, short lasting poly-EPSPs coupled to both oscillations and depolarizations (PEODs) in membrane potential were significantly more common and could be produced with significantly lower stimulation intensity in mSOD1G93A MNs. These PEODs depended on spinal network and activation of NMDA receptors and were associated with increased levels of spontaneous activity. No significant changes were found in intrinsic properties of these mSOD1G93A MNs. Taken together, these findings revealed hyperexcitability in synaptic mechanisms in MNs of mSOD1G93A mice, which could contribute to the excitoxicity in ALS.

Title: Split-belt treadmill adaptation in trans-tibial amputees

Authors: *B. P. SELGRADE, M. E. TONEY, Y.-H. CHANG;
Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: A common paradigm used to study locomotor adaptation is split-belt treadmill walking, in which the subject adapts to walking with each leg moving at a different speed. Recent work indicates that this adaptation is driven by optimizing metabolic power (Finley et al, 2013). The changes in walking mechanics that drive these metabolic changes, however, are not fully understood. Previously, we showed that, as subjects begin walking in the split-belt condition, the single support (SS) work by the leg on the fast belt increases immediately. As subjects adapt to split-belt walking, reductions in total mechanical work on the center of mass per stride mirror the changes in metabolic power. Notably, there is a decrease in positive work by the SS leg and a corresponding increase in positive work done during the step-to-step transition (STS). This shift in mechanical power generation from SS to the trailing leg in STS agrees with the general principles of dynamic walking. However, it is unknown how the loss of the ankle joint, the primary power producer, would impact this split-belt locomotor adaptation. Therefore, we examine changes in mechanical work done by trans-tibial amputees during split-belt adaptation. We hypothesized that, for both amputees and controls, total stride work and positive work during SS would decrease as subjects adapted to split-belt treadmill walking, while positive work during STS would increase. Eight trans-tibial amputees and 8 matched control subjects participated in this study. Subjects walked with the prosthesis (non-dominant leg for controls) on a belt moving at 150% of preferred walking speed (PWS) and the intact leg on a belt moving at 75% PWS. We calculated mechanical power and work done by each leg on the center of mass. For control subjects, the hypotheses were supported. Total stride work decreased between early and late adaptation, as did positive work done during SS, particularly for the leg on the fast belt. Positive work done during STS increased over this time. For amputees, the hypotheses were partially supported. Total stride work decreased from early to late adaptation, but positive work during STS did not increase over this time. Thus, amputees only slightly reduced SS work between early and late adaptation. For controls, the fast trailing leg provided most of the positive work during STS. In contrast, amputees were limited in the push-off work from their prosthetic leg on the fast belt. Rather than relying on ankle work during STS, amputees rely on the less economical strategy of hip work during SS, which could represent a generalized strategy that amputees use in novel walking conditions.

Title: Effects of decreased contralateral afferent feedback on ipsilateral motor output during pedaling

Authors: *Y.-H. CHANG, T. L. NORMAN;
Sch. of Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: The neuromuscular control of locomotion is modulated by peripheral sensory feedback. It is not understood exactly how sensory feedback modulates locomotion, or to what functional effect. In human pedaling studies, Ting and colleagues (1998, 2000) showed that an increase in contralateral extension force elicits a decrease in ipsilateral flexor motor output during the pedaling upstroke, suggesting contralateral extensor muscle afferents (e.g., force-dependent Ib afferents from golgi tendon organs) inhibit the ipsilateral flexor muscles. A similar response was shown in a reduced rat preparation during swing phase of walking (Hayes et. al, 2012; Hochman et. al, 2013). We hypothesized that ipsilateral flexor motor output would increase when contralateral plantarflexor afferent feedback was decreased. To test this hypothesis we employed the use of a custom cycle ergometer with mechanically decoupled cranks and instrumented pedals. We collected preliminary data on six subjects participating in the IRB-approved protocol (males, 5; females 1). On day one, subjects underwent training on the decoupled cycle ergometer. On day two, subjects completed 45-second pedaling trials where the left (recipient) leg always pedaled. A baseline trial of bilateral pedaling was collected and used to compare to decreased afferent feedback conditions. We decreased contralateral plantarflexor afferent feedback by imposing ischemic deafferentation to the right (donor) leg. A cadence of 60 rpm was maintained for all conditions. We collected kinematics (120Hz, Vicon), kinetics (300Hz, Kister), and electromyographic data (1080Hz, Noraxon) from tibialis anterior, soleus, medial gastrocnemius, biceps femoris long head, rectus femoris, and gluteus maximus muscles. Mean muscle activations of four functional pedal cycle quadrants were analyzed: Q1. anterior transition; Q2. Extension; Q3. posterior transition; Q4. flexion. After 20 minutes of right (donor) leg ischemic deafferentation, the left (recipient) rectus femoris and tibialis anterior activations were not significantly different from baseline during Q4. flexion (96±13% baseline activation, $p=0.960$ and 83±31% baseline activation, $p=0.244$, respectively). In the subsequent pedaling phase, Q1. anterior transition, the left (recipient) left rectus femoris activation was significantly

lower than baseline (58±21% baseline activation, p=0.005) and tibialis anterior activation trended toward a significant decrease from baseline (67±39% baseline activation, p=0.092). Our preliminary findings do not support our hypothesis and require further investigation.

Title: Interlimb reflexes following ipsilateral knee joint rotations are suppressed in an unstable walking environment

Authors: *A. J. STEVENSON[1], S. S. GEERTSEN[2,3], T. SINKJÆR[1,4], J. B. NIELSEN[2,3], N. MRACHACZ-KERSTING[1];
[1]Ctr. for Sensory-Motor Interaction, Aalborg Univ., Aalborg, Denmark; [2]Dept. of Nutrition, Exercise and Sports, Univ. of Copenhagen, Copenhagen, Denmark; [3]Dept. of Neurosci. and Pharmacology, Univ. of Copenhagen, Copenhagen, Denmark; [4]The Danish Natl. Res. Fndn., Copenhagen, Denmark

Abstract: Interlimb reflexes play an important role in human walking, such as when dynamic stability is threatened by external perturbations or changes in the walking surface. For example, we have previously shown that interlimb reflexes in the contralateral biceps femoris (cBF) following ipsilateral knee (iKnee) extension rotations during walking contribute to slowing the forward progression of the body in order to maintain dynamic stability following the perturbation (Stevenson et al., 2015). However, little is known about how such interlimb reflexes are modulated in an unstable walking environment. Based on experiments investigating intra- and interlimb cutaneous reflexes and soleus H-reflexes (Llewellyn et al., 1990; Haridas et al., 2005; 2006; Krauss and Misiaszek, 2007), we hypothesized that the amplitude of interlimb reflexes following iKnee perturbations is altered when walking in an unstable environment. To test this, interlimb reflexes were elicited in participants (n = 6) by either iKnee extension rotations during the late stance phase (50%) of the gait cycle or iKnee flexion rotations during the mid-swing

phase (80%). The iKnee perturbations were applied while the participants walked normally on a treadmill (stable condition), or while random increases or decreases in velocity were applied to the treadmill (unstable condition). The abrupt treadmill velocity changes were applied every 3-8 steps, included three different velocity changes between ±1.12 m/s, and lasted for 1.5 seconds. They were strong enough to cause instability, but not enough to result in a fall. In the unstable condition, the iKnee perturbations were applied in steps without treadmill velocity changes. During normal walking, iKnee extension perturbations elicited facilitatory interlimb reflexes in the cBF and contralateral soleus (cSOL) muscles with onset latencies of 81 and 92 ms, respectively, while iKnee flexion perturbations elicited reflexes in the cBF (facilitatory) and cSOL (inhibitory) with onset latencies of 66 and 85 ms, respectively. The cBF reflex amplitudes were significantly suppressed (P's < .05) in the unstable walking condition following both types of iKnee perturbations, while the cSOL reflexes remained unchanged. Consistent with previous studies, these preliminary results suggest that challenging dynamic stability during walking leads to specific changes in reflex amplitudes that are not related to a generalized change in reflex excitability. Descending cortical influences likely contribute to the specific modulations based on the environmental demands.

Title: Postural responses to various frequencies of vibration of the triceps surae and forefoot sole during quiet standing

Authors: *M. NAKA[1], K. FUJIWARA[2], N. KIYOTA[3];
[1]Morinomiya Univ. of Med. Sci., Osaka-Shi, Japan; [2]Fac. of Sports and Hlth., Kanazawa Gakuin Univ., Kanazawa, Japan; [3]Fac. of Hlth. Sciences, Dept. of Rehabil., Japan Hlth. Care Col., Sapporo, Japan

Abstract: Sensory information from lower-leg muscles and soles of the feet is important for the perception of standing position. When a subject is standing with eyes closed, vibration of the triceps surae or forefoot soles at 20-150 Hz induces backward-lean of the body for most subjects. The postural response to vibration is thought to occur as a compensatory response to the

illusionary perception created via the sensory reference system. In quiet standing, the center of pressure sways within ± 1 cm at very low frequencies, mainly ≤ 2 Hz. It may be assumed that the resulting low-frequency oscillations in sensory information from the lower-leg muscles and foot soles are involved in the organization of the sensory reference frame in quiet standing. However, vibration frequencies lower than 20 Hz have not been previously investigated. In present study, we investigated the postural responses induced by vibration of the triceps surae and/or forefoot sole at various frequencies (1-60 Hz) to determine the role of somatosensory input to the sensory reference system in quiet standing. Thirteen participants participated in the full experiment. The experiment consisted of two sessions: 1) single vibration and 2) simultaneous vibration. Vibration at high and low frequencies induced backward- and forward-lean responses, respectively. The lowest vibration frequencies (defined as B-LF) inducing backward-lean responses were 15-55 Hz for the triceps surae and 16-60 Hz for the forefoot sole. The highest frequencies (F-HF) inducing forward-lean responses were 3-18 Hz for the triceps surae and 1-20 Hz for the forefoot sole. When vibration was simultaneously applied to the triceps surae and forefoot sole at F-HF, no response was induced in 70% of trials. A forward-lean response was induced in the remaining 30% of trials. Simultaneous vibration of the triceps surae and forefoot sole at B-LF induced backward-lean responses in all trials. All postural responses occurred 0.5-4.3 s after vibration onset. Postural responses to high-frequency vibration conceivably occur as a compensatory movement to the illusionary perception that standing position is deviating forward from quiet standing, which must be a reference position. Postural responses to low-frequency vibration possibly occur to equalize the positional information that received from the triceps surae and the forefoot sole. Both postural responses are likely to involve the sensory reference system, which is located in the supraspinal nervous system.

Title: Flexor and extensor muscle recruitment during repetitive leg movements in chick embryos

Authors: ***S. SUN**, N. S. BRADLEY;
Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Prior to hatching, chick embryos spontaneously produce repetitive limb movements (RLMs). RLMs are a developmental precursor to walking after hatching. They exhibit features of walking, including alternating leg flexor and extensor muscle bursts at step cycle frequencies. Frequently, however, flexor activity is rhythmic for many cycles, whereas extensor activity often drops out for one or more cycles. We hypothesize that during RLMs the spinal pattern generator for stepping more readily recruits leg flexor muscles than extensors. The purpose of this study is to determine if flexor and extensor muscle recruitment differs during RLMs. We recorded electromyography (EMG) and kinematics during spontaneously produced leg movements at embryonic day 20. Leg EMG was recorded either ipsilaterally (hip and ankle flexor and extensor muscles) or bilaterally (ankle flexor and extensor muscles). RLM EMGs were identified by 3 criteria: 4 or more consecutive rhythmic bursts in at least 1 muscle; burst cycle frequencies at 1-10 Hz; and accompanied by leg movements. To test for differences in flexor and extensor recruitment, RLM burst counts, burst durations and burst amplitudes for antagonist muscle pairs of the hip or ankle were compared within embryo (N=21, Wilcoxon signed rank test). Burst amplitudes were normalized to the maximum value within muscle to estimate the recruitment differences between antagonist muscle pairs. Results indicated that flexor bursts outnumbered extensor bursts in 35 of 37 antagonist muscle pairs, and the difference was significant ($p < 0.001$). Flexor bursting in the absence of extensor bursting commonly occurred, whereas extensor bursting in the absence of flexor bursting was rare. Burst duration and normalized burst amplitude were similar for antagonistic muscle pairs. However, flexor peak burst amplitude was lowest if the extensor was not recruited during an RLM, and greatest if the extensor participated in all cycles of an RLM ($p < 0.006$). Our results provide evidence that flexor muscle recruitment and extensor recruitment differ during RLMs. Results suggest that flexor muscles are preferentially recruited at lower levels of neural drive, and extensors are recruited as drive increases, consistent with our hypothesis. Our findings also suggest that the spinal pattern generator readily recruits flexor motor pools independent of extensor pools, but rarely recruits extensor pools independently. However, when both antagonist motor pools are recruited, similar burst durations and amplitudes are produced. These findings lead us to conclude that recruitment threshold and burst generation are separately controlled during RLMs in chick embryos.

Title: Early activation of ankle muscles following light touch displacement at the fingertip during treadmill walking

Authors: T. SHIVA[1], J. FORERO[1], *J. E. MISIASZEK[2];
[1]Fac. of Rehabil. Med., Univ. of Alberta, Edmonton, AB, Canada; [2]Univ. Alberta, Edmonton, AB, Canada

Abstract: Recently, we demonstrated that unexpected displacement of a touch reference during eyes-closed standing can produce rapid activation of leg muscles consistent with an automatic postural response, despite the absence of a mechanical disturbance to balance. However, these responses were relatively small, not expressed in all participants and not expressed in subsequent trials. We speculated that the touch-evoked reaction would be more pronounced when the touch cue had a greater functional relevance. Light touch at the fingertip has been shown to allow individuals to walk on a treadmill in the absence of vision. Light touch also affects the amplitude of corrective reactions to unexpected balance disturbances during treadmill walking. Therefore, we hypothesized that unexpected displacement of a touch reference during eyes-closed treadmill walking would result in pronounced corrective reactions, comparable to reactions produced following mechanical balance disturbances during walking. To test this hypothesis, participants walked on a motorized treadmill with their vision occluded and lightly touching a rod with their right index finger. The rod was positioned in front of the participants at shoulder width such that their upper arm was vertical and their forearm was horizontal with a neutral wrist. After several minutes of walking with eyes-closed and touching the stable rod, a rapid displacement (1.25 cm, 12.5 cm/s peak velocity, 187.5 cm/s/s peak acceleration) of the rod was applied at right heel-strike. The direction of the initial displacement (forwards/backwards) was randomized across participants. Nine additional displacements in the same direction were then applied at heel-strike at unexpected intervals. Electromyographic recordings from 4 leg and 4 arm muscles were sampled along with joint kinematic data from the elbow, knee and ankle. Rapid displacement of the touch reference resulted in short-latency (<100 ms) responses in the muscles of the leg. Evoked responses were particularly pronounced in tibialis anterior following forward displacement of the touch reference. Response amplitudes were largest for the initial, unexpected displacement. Responses continued to be evoked throughout the experiment in most participants. Responses in the arm muscles were rarely observed. Following the experiment some participants reported that they believed changes to the speed of the treadmill were introduced, rather than a displacement of the touch reference. These results indicate that cutaneous input from a single fingertip can initiate a profound and robust adaptation to ongoing walking, consistent with a balance corrective response.

Title: Modulation of afferent feedback from paw pad afferents affects interlimb coordination and adaptation to split-belt treadmill locomotion in the cat

Authors: H. PARK, R. MEHTA, S. P. DEWEERTH, *B. I. PRILUTSKY;
Georgia Inst. Technol., Atlanta, GA

Abstract: Split-belt treadmill locomotion has been used to study the organization of interlimb coordination in cats (Forssberg et al. 1980) and locomotor adaptation in humans (Dietz et al. 1994). These studies have revealed some neural constraints on left-right and fore-hind limb coordination and brain structures contributing to locomotor adaptation. Motion-dependent sensory feedback is important for interlimb coordination and locomotor adaptation. For instance, differences in visual information between overground and treadmill locomotion appear to influence interlimb coordination in cats (Blaszczyk, Loeb, 1993) and the amount of adaptation in humans (Torres-Oviedo, Bastian, 2010). Here we investigated the role of cutaneous feedback from cat paws on interlimb coordination and split-belt treadmill adaptation in adult cats. Four adult cats were implanted with stimulating nerve cuff electrodes on distal tibial and sural nerves innervating skin on plantar surface of paw and foot. A recording cuff electrode was implanted on sciatic nerve. Thresholds for activation of cutaneous sensory fibers to single pulse and train of pulses of electrical stimulation were established in each animal by recording the responses in the sciatic nerve. Several locomotor conditions were investigated including: (1) tied-belt walking with the same speed of left and right belts (LBS=RBS=0.4 m/s), (2) tied-belt walking at 0.4 m/s with the right forepaw and hindpaw anesthetized by lidocaine injections, (3) tied-belt walking at 0.4 m/s with low-intensity train stimulations of distal tibial or/and sural nerves (</= 1.2T, duration </= 250 ms) triggered by right hindpaw contact with the ground, (4) split-belt walking (LBS=0.4 m/s, RBS=0.6 m/s and RBS=0.8 m/s), (5) split-belt walking with the right forepaw and hindpaw anesthetized, and (6) split-belt walking with the right forepaw and hindpaw anesthetized and with stimulations of sensory nerves during stance. Symmetry between right and left step/stride length and relative phase between fore- and hindlimbs were affected by

manipulation of cutaneous feedback from paw pad afferents. For example, paw pad anesthesia increased step length symmetry between the left and right sides but increased ground reaction forces on the affected side. The combination of anesthesia and sensory nerve stimulation reduced pacing and variability of the stride length symmetry index during split-belt walking. We concluded that interlimb coordination and adaptation to split-belt walking depends on sensory feedback from paw pad cutaneous afferents.

Title: Gait characteristics of children walking barefoot and with socks

Authors: *C. W. CHAU, L. ALBERT, A. AUFIERO, L. MOCK, K. WARD;
Nazareth Col., Rochester, NY

Abstract: The aim of this study is to compare the characteristics of spatiotemporal gait parameters in typically developing 4 and 5 year old (yo) children while walking barefoot and with socks, at a self-selected regular and fast walking speed. Twenty children (10 male and 10 female) participated in this study. All subjects walked on the GAITRite® (CIR System Inc. NJ), a portable carpeted walkway (3X14ft) embedded with electronic pressure sensors that record footprints. Each subject completed four trials of the four walking conditions (barefoot and with socks at regular speed and fast speed) in a randomized order. Spatiotemporal gait parameters were recorded and analyzed with the GAITRite® system which included velocity, cadence, step and stride length, cycle time, stance and swing phase duration, single and double support percentages. Paired t-tests were used to compare gait parameters while walking barefoot and with socks, for both regular and fast walking speeds. The preliminary results showed that spatiotemporal gait parameters were comparable between walking barefoot and with socks at a regular walking speed, but different when walking at a fast speed. During fast walking with socks as compared to barefoot, there was 1) a statistically significant increase in cadence (+10.9 steps/min,) and decrease in cycle time (-30ms); 2) a slight, but statistically insignificant, increase in velocity (+6.0 cm/sec), swing (+0.5%), and single support (+0.6%); and 3) a decrease in stride length (-2.1 cm), stance (-0.4%), and double support (-0.6%). The foot length and width are comparable between walking barefoot and with socks. Similar but slightly greater differences in

cycle time (-3.2 ms), step length (-0.5 cm), stride length (-0.6 cm), and cadence (+3.1 steps/min) was observed in 5-yo children as compared to 4-yo children during fast walking with socks. These findings suggest that children walking at a fast speed with socks displayed a more unstable gait than when walking barefoot. It is possible that socks may alter cutaneous input and also increase slippage especially during fast walking. During regular walking speed, similarities in spatiotemporal gait parameters between walking barefoot and with socks was consistent with literature suggesting that cutaneous input exerts minimal effect on undemanding locomotion. Greater changes in 5-yo as compared to 4-yo children suggest that developmental maturation may play a role in the ability to adapt the locomotor pattern to different conditions.

Title: Development of a reliable proprioception measure during gait using a robotised ankle-foot orthosis and its relationship with static and dynamic balance

Authors: *J. BOUFFARD[1,2], A. FOURNIER-BELLEY[2,1], D. MORIN[1], C. MERCIER[1,2], J.-S. ROY[1,2], L. J. BOUYER[1,2];
[2]Ctr. for interdisciplinary research in rehabilitation and social integration, [1]Univ. Laval, Quebec, QC, Canada

Abstract: Background: Proprioception is a crucial property of the sensorimotor system providing feedback for motor control and learning. Most proprioception measures currently used

evaluate the ability of individuals to detect movement, position or force imposed to their limb in an otherwise static state. However, proprioceptive capacities in dynamic tasks such as gait are much more complex than what is evaluated by such tests as the sensory signals coding for movement, position and force interact together and with the expected feedback related to the ongoing movement. **Objective:** To develop and validate an innovative evaluation of proprioceptive capacities during gait using a robotised ankle-foot orthosis. **Method:** Twenty-five healthy individuals were tested twice in a 3 to 7 days interval. On each lab session, participants walked on a treadmill using a robotised ankle-foot orthosis during two ~6 minutes periods. During those walking periods, force perturbations of varying amplitudes resisting participants' ankle dorsiflexion during swing were applied every 3 to 7 strides. Participants were asked to press on a handheld switch whenever they detected a perturbation. They also performed the Star Excursion Balance Test (SEBT) and the Balance Error Scoring System (BESS) as ankle proprioception is considered to influence balance. **Data analysis:** The peak ankle error caused by the perturbations, i.e. the maximal difference between ankle movements of a perturbed stride and of the unperturbed strides, was calculated for each perturbed stride. A sigmoid curve presenting the detection probability in relation to the peak ankle error caused by the perturbations was then computed for each lab session. The peak ankle error with a detection probability of 50% was considered as the detection threshold. The intraclass correlation coefficient (ICC) and minimal detectable change (MDC_{95}) were calculated to determine test-retest reliability of detection threshold. Pearson correlation coefficients between detection threshold and balance scores were calculated. **Results:** The mean detection threshold of the participants was 5.04° (range 1.04°-9.14°). The detection threshold has a good reliability with an ICC of 0.79 and a MDC_{95} of 2.39. The detection threshold correlates moderately with the SEBT (dynamic balance, r=0.61) but not with the BESS (static balance, ns). **Conclusion:** The newly developed measure provides a reliable method to assess proprioception. The correlation with a dynamic balance score supports its validity. This innovative measure will offer important opportunities in gait rehabilitation and in basic motor control research.

Abstract: Treadmill training of spinalized animals promotes recovery of locomotor function and typically focuses on walking on horizontal surfaces, a model that fails to include the difficulties faced by patients with spinal cord injury (SCI) operating in a community environment. The purpose of this study was to investigate the contribution of various sensory modalities of the ankle extensor muscles and paw cutaneous feedback in the adaptations to walking on graded surfaces in spinal cats. Eight cats were utilized in these experiments. Four cats (group 1) underwent lateral gastrocnemius/soleus (LGS) self-reinnervation in the right hindlimb 3 months prior to spinalization while the remaining four (group 2) did not undergo any surgery prior to spinalization. After collection of pre-transection kinematics data, all cats underwent complete spinal cord transection. After transection, cats were trained to step on a treadmill at a speed of 0.4m/s until their locomotor performance plateaued, which took from 4 to 12 weeks. Once stepping proficiency was attained, kinematic recordings were taken for all cats stepping on a treadmill at 0.4m/s on flat, incline, and decline surfaces (10° and 25°). Group 2 cats then underwent right hindlimb deafferentation at the L7-S1 levels. Daily training continued post-deafferentation and kinematics were recorded for these cats 1, 8, and 12 weeks post-deafferentation. Animals that underwent LGS self-reinnervation before spinal transection recovered plantar weight-bearing stepping on the treadmill for flat, ±10°, and ±25° sloped surfaces. These animals showed limited differences in the kinematics of the two hindlimbs, suggesting that ankle Ia afferent feedback of these major ankle extensors, which is permanently lost after self-reinnervation (Cope et al 1994), has minimal effects on locomotor recovery in spinal animals. In animals that underwent an L7-S1 deafferentation, affecting both length and force feedbacks of the triceps surae muscles as well as the footpad cutaneous feedback, a persistent deficit in ankle plantar-flexion prevented recovery of stepping on flat or graded surfaces. These results are consistent with modeling studies (Markin et al, 2015) showing that muscle and cutaneous load-sensitive afferents play a greater role in the production of extensor torque at the ankle during stance than length- and velocity-sensitive afferents.

Title: The effects of plantar vibration stimulation on lower limb muscle activity during stepping

Authors: S. MITCHELL-EWART, M. CANNING, *S. D. PERRY;
Kinesiology & Physical Educ., Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: The somatosensory system has been shown to play a significant role in balance control in conjunction with vision and the vestibular system. Evidence has shown that manipulation of the mechanoreceptors, on the plantar surface of the foot, has a direct effect on balance control. By manipulating these receptors with vibration, researchers are capable of stimulating the mechanoreceptors within the foot to better understand the role that vibration plays in the potential enhancement of balance control via measurement of its effect on muscle activity within the lower limb. A total of eight healthy young participants were recruited for this study. The participants were asked to complete a voluntary stepping task while undergoing three different vibration conditions. The stepping task involved a three-step forward gait movement that terminated with the feet side-by-side. The participants performed this task with no vibration, subthreshold (90% of perceptual threshold, white noise) vibration (delivered throughout the trial), and suprathreshold (3x perceptual threshold, 60 Hz) vibration on the plantar surface of the feet (triggered by stepping onto the first force plate (~10N force level)). The vibration was placed under the first metatarsal and the heel of the right foot. The subsequent muscle activity during these tasks was recorded and analyzed to determine changes in onset, magnitude and reflex activity of muscle activity, occurring just prior to the second step of the gait termination task, within the three experimental conditions. The results of this study indicated that there was a significant decrease in the magnitude of the medial gastrocnemius activity for both the subthreshold and suprathreshold vibration conditions ($p<0.05$). Furthermore, it was observed that the medial gastrocnemius also demonstrated an earlier onset timing of activity for both vibratory conditions in comparison to the no vibration condition ($p>0.05$). Reflex analysis indicated that the introduction of vibration demonstrated facilitation of gastrocnemius muscle activity within short (150ms) and long (>250ms) latency time frames. Therefore, this study demonstrates that the use of vibration stimulation is modulating muscle activity (magnitude, timing, and reflexes) within the lower limb. However, the direct connection between vibration and lower limb muscle

activity hasn't been fully investigated. Thus further research needs to be completed in order to identify the specific relationship between muscle activity and vibration in balance control.

Title: The influence of vision and foam pad on the coherence analysis between the center of pressure and light touch tangencial force during quiet stance

Authors: C. R. SILVA[1], F. H. MAGALHÃES[2], *A. F. KOHN[3];
[1]Neurosci. Program, [2]Sch. of Arts, Sci. and Humanities, Univ. of Sao Paulo, São Paulo, Brazil;
[3]Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Removing visual information in a healthy adult population typically leads to an increase in mean sway amplitude. If this change is coupled with an unstable surface, the postural sway can be even greater. The tactile information from a fingertip lightly and voluntarily touching a fixed surface (active touch) has been suggested to be able to reduce postural sway. So, the aim of the present investigation was to evaluate whether the absence of vision and the unstable support surface (Airex balance pad - FP) change the relationship between the center of pressure (COPAP) and fingertip forces (Fx) during quiet standing. Sixteen healthy subjects were requested to keep a quiet stance during upright stance in four conditions: 1) V = vision - no FP; 2) VFP = vision with FP; 3) D = no vision - no FP and 4) DFP = no vision with FP. In all conditions the subjects performed the tests touching a mini force platform with the tip of the index finger (vertical force < 1 N). The four experimental conditions were presented in a randomized order. The subject performed 4 trials, each lasting 90 s, for each of the two experimental conditions. A resting period of ~120 s between trials was allowed to avoid fatigue (subject sat in a comfortable armchair placed next to the force plate). The COPAP was measured using a force platform. The coherence analysis was performed between Fx and COPAP signals for all conditions (FxCOP). There was no significant coherence in the V and D condition. Subjects standing on the FP showed a significant anti-phase coherence for a frequency range from approximately 0.05 to 0.3 Hz and 0.01 to 0.6 Hz for VFP and DFP, respectively. These

results suggest that vision does not provide influences on FxCOP in conditions without FP (V versus D). However, in FP conditions (VFP versus DFP) the absence of vision shows an anti-phase pattern in a greater range of frequency. The influence of the FP (V versus VFD and D versus VDF) in the analysis shows a change in the interactions between the COPAP and the Fx, with significant coherence at low frequencies (no presented in FP-free condition). When standing on foam, the information from the mechanoreceptors of the feet is believed to become less reliable, changing the discharge patterns from the receptors, which increases postural sway and changes the standing strategy. The results suggest possible changes in biomechanic factors (stiffness, viscoelasticity, muscle activity pattern) involved in the control of during quiet stance. Thus, further analyses of other variables such as muscle EMGs and other body angles are under way to provide a more global understanding of the possible mechanisms behind postural control of humans standing on unstable surfaces.

Title: Cortical recovery rate of proprioceptive responses to passive finger movements

Authors: E. SMEDS, *R. K. HARI, H. PIITULAINEN, M. BOURGUIGNON, V. JOUSMÄKI; Dept. of Neurosci. and Biomed. Engin., Aalto Univ., Espoo, Finland

Abstract: Objective: An increase in stimulus repetition rate typically results in attenuation of cortical evoked responses; the longer the latency of the response, the stronger the effect. Previous

research has shown that this pattern applies over a wide range of sensory modalities. Proprioceptive responses, however, require further characterization that would benefit both basic and clinical research. Therefore, we here studied the stimulus-rate dependence of cortical responses to passive finger movements. **Methods:** We measured magnetoencephalographic (MEG) signals from 15 healthy adults during passive intermittent extension and flexion movements of the right index finger (306-channel whole-scalp device by Elekta Oy; passband 0.1-330 Hz; sample frequency 1000 Hz). The motion occurred mainly at the metacarpophalangeal joint, which moved between a neutral and a slightly over-extended position. We here present data only for the extension movements. A specially designed pneumatic movement stimulator (http://dx.doi.org/10.1016/j.neuroimage.2015.03.006; Piitulainen et al., Neuroimage 2015) elicited passive movements at interstimulus intervals (ISIs; times between consecutive extensions) of 0.5, 1, 2, 4, 8, and 16 s. The ISI remained unchanged in each measurement condition, and the order of conditions was randomized for each subject. The movements were monitored with an accelerometer attached to the fingernail. MEG signals were averaged time-locked to the movement onsets and low-pass filtered at 40 Hz. The peak amplitudes of the averaged responses were determined from the gradiometer vector sum at the site of the maximum response (fixed site for all ISIs of a single subject). An exponential model of the form $A(ISI) = A_{plateau}(1 - e^{-ISI/\tau})$ was fitted to the response amplitude (A), where A_{plateau} is the saturation amplitude, and τ is the recovery constant of the response. **Results:** The main response to extension movements peaked at ~80 ms, with sources in the contralateral primary somatosensory cortex. Responses were absent or weak at the shortest (0.5-s) ISI, and increased in amplitude as the ISI was extended, reaching a plateau at the 8-s ISI. The exponential model yielded a recovery constant τ = 1.2 s. This dependence implies that, for passive finger extension movements, a ~1.5-s ISI would maximize the signal-to-noise ratio of the cortical response in a fixed measurement time. **Conclusions:** Our findings can be exploited to develop efficient proprioceptive stimulation protocols. Cortical responses to accurately timed passive movements provide a novel quantitative tool for assessment of human proprioception, which currently lies beyond the reach of clinical tests.

Informatics, Univ. of Geneva, Geneva, Switzerland; [5]Neural Engin. Area, The BioRobotics Inst., Scuola Superiore Sant'Anna, Pisa, Italy

Abstract: Execution of complex movements, such as reaching and grasping, requires the integration of multisensory inputs by the human brain. Tactile and proprioceptive information are combined across brain areas and coordinated with eye, limb, and hand movements. This complex integration process requires the exchange of information between independent functional brain regions. Therefore, whole-brain functional data are necessary to visualize these processes and the underlying multi-functional organization of brain activity. Analysis of electroencephalographic (EEG) microstates could be used to identify the recurrent organization of the whole-brain activity that might play a role in the sensory-motor integration processes of the human cortex. Several studies have shown that brain activity during resting-state is organized in meta-stable states characterized by periods of coherent synchronized activation of neural networks, i.e., EEG microstates, that can be detected from EEG recording as polarity-independent topographic maps with a typical duration of 80-150 ms. These topographic maps could characterize different global brain states. In our preliminary work, we showed, in a small group of subjects, that analysis of EEG microstates reveals a recurrent organization of brain networks during movement execution. We here extended our previous investigation to pure reaching and reaching and grasping movements, separating movement phase and holding phase, in eight healthy subjects. We found that the EEG microstate repertoire for execution of voluntary movements was richer than for resting state, although the four prototypical microstates of resting state were still present in both settings, but with a reduced duration during movement execution. In particular, we found two new topographies common in different motor tasks, and one task-specific EEG microstate, which disappeared during the holding phase. The EEG microstates related to movement execution were event-related and the movement network activity was located in pre-motor and posterior parietal cortex. Intracranial sources were estimated using eLORETA on an average brain model. Interestingly, during the movement planning phase, we observed a significantly increased occurrence of the EEG microstate that has been previously linked to the executive-control network. In conclusion, our results provide evidence of movement-specific EEG microstates that capture whole-brain states and that are located in the fronto-parietal network typically involved in voluntary movements. This analysis helps

understanding how sensory-motor-control strategies are implemented in the central nervous system.

Title: Pain-related suppression of beta oscillations facilitate movement initiation

Authors: ***S. COOMBES**, E. OFORI, J. CHUNG, G. MISRA;
Univ. of Florida, Gainesville, FL

Abstract: How pain affects movement is a subject of extensive research. Several electroencephalography (EEG) studies on the effect of pain on movement have made the onset of pain and onset of movement either concurrent or dependent. The goal in the current study was to determine the neural correlates of how ongoing pain influences the initiation and execution of movement. EEG studies of pain have demonstrated a pain-induced reduction in power in the alpha and beta bands. EEG motor studies have also demonstrated a movement-induced reduction in power in the same frequency bands, which suggests that pain may prime the motor system and facilitate movement. To test this hypothesis, healthy subjects performed a visually guided ballistic elbow flexion task during a 4 second long thermal pain stimulus while we recorded EMG signals from the arm and high density EEG signals from the scalp. We implemented a novel whole brain analysis based on independent component analysis, source localization, and measure projection analysis. We found that ongoing pain shortens reaction time significantly but does not affect movement velocity, acceleration and accuracy. The shortening was due to a reduction in pre-motor time and not due to a reduction in motor time. Spectral power in the beta band was source-localized to the contralateral sensorimotor cortex and was reduced significantly in the presence of pain. Further, beta power correlated positively with reaction time and pre-motor time but not with motor time. Hence, the mechanism of pain-induced shortening of reaction time cannot be peripheral but must be central in origin. Our findings demonstrate that a pain-related suppression of beta oscillations facilitates movement initiation.

Title: Effect of competition and prior probability of optional actions on beta-band EEG during preparation of movement

Authors: *Y. MATSUMOTO, A. FUJIKAWA, R. TAMAMURA, Y. KAKIMOTO, O. ARAKI;
Dept. of Applied Physics, Tokyo Univ. of Sci., Tokyo, Japan

Abstract: In recent years, relations between neural oscillations and brain functions such as action and perceptions have been studied. It is known that the power of beta-band oscillatory decreases during the preparation and execution of movement. In the previous study (Tzagarakis et al., 2010), it is suggested that the more the number of possible actions is, the less the decrease of beta-band power from the baseline is. This modulation of beta-band decrease is thought to be due to the uncertainty of a target action. Here we questioned whether the uncertainty depends on the competition between plural optional targets or prior probability of each option. In both cases of alternative actions with equal or unequal prior probability and one target action with different probabilities, if only competition is dominant, the beta-band power decrease will remain constant, and if only prior probability is dominant, the beta-band power decrease will change depending on the probability. Thus, the purpose of our study is to verify these hypotheses, whether beta-band power decrease depends on the competition or the prior probability. We recorded electroencephalography (EEG) of 12 subjects during a reaching task, where the subject reaches for a target indicated by the color 1000 ms after candidates for target (red or green) are presented for 200 ms. We used five patterns of pre-cued possible target(s): one possible target with the probability of becoming a target 100%, 80% or 20%, and two possible targets with the prior probabilities 80%-20% or 50%-50%. We observed the effect of competition by comparing the data between one-target and two-targets, and the effect of prior probability by comparing those in different probabilities. The higher the prior probability is, the shorter the response time is when there is one target and there are two targets, which shows preparation for movement. When there are two possible targets (competitive condition), the decrease of beta-band power became smaller around the primary motor and premotor cortex during 400 ms before Go signal. On the other hand, in response to one possible target, the decrease of beta-band power remains constant in spite of prior probability. Consequently, these results show that the decrease of beta-

band power changes only under the competitive condition. Accordingly, the results suggest that the decrease of beta-band power is closely concerned with which way to go rather than whether to go or not during action preparation.

Title: Increased amplitude and earlier onset of EEG readiness potentials preceding voluntary actions associated with sensory consequences

Authors: *D. REZNIK, S. SIMON, R. MUKAMEL;
Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: Self-generated, voluntary actions, are preceded by a slow negativity in the scalp EEG signal recorded from frontal regions (termed ‘readiness potential’; RP). This signal is mainly regarded as preparatory motor activity associated with the forthcoming motor act. However, it is not clear whether this neural signature is associated with preparatory motor activity or rather expectation of its associated sensory consequences. Here we recorded electroencephalography (EEG) data from 13 healthy subjects while they performed self-paced button-presses with their right index finger. In one condition (active) these button-presses triggered a sound while in a different condition (silent) they did not. Additionally, subjects passively listened to sounds delivered in expected timings (passive condition). Behaviorally, inter-press-intervals were

similar across the active and silent conditions. The EEG signal amplitude (locked to time of button press) was significantly more negative (500 ms prior to button press) in the active compared with silent condition. Importantly, no signal negativity was observed prior to sound delivery in the passive condition, and the increased negativity in the active condition was significant even after taking into account the activity preceding passive listening to the same sounds (passive condition). Furthermore, while the EEG signal negativity started 370 ms prior to silent button presses, in the active condition it started already 1430 ms prior to button presses. Thus differences in signal amplitude and temporal onset between active and passive conditions cannot be attributed to mere auditory expectation. Our results suggest that the motor activity preceding voluntary actions, encodes the expected auditory consequences and can modulate subsequent sensory-evoked activity in auditory cortex.

Title: Dependence of lateralized readiness potential on the prior probability of target-movement in a Go/Nogo task

Authors: A. FUJIKAWA, Y. MATSUMOTO, R. TAMAMURA, Y. KAKIMOTO, *O. ARAKI;
Tokyo Univ. of Sci., Tokyo, Japan

Abstract: Lateralized readiness potential (LRP), which is the potential difference between the left and right hemispheres in the motor related areas immediately before movement, is concerned with movement preparation and execution. Furthermore, LRP is considered to be affected by the prior information about the expected movement. However, it is unclear how the prior probability (PP) of cued information affects LRP in a reaching task, where the visual cue indicates left or right hand under the condition that the indicated hand should be moved finally. In a previous study, Miller (1998) reported contralateral LRP to a hand movement with 75% probability when left or right hand movement is cued with 75-25% PP. On the other hand, Scheibe et al. (2009) attempted three conditions of 100-0%, 75-25%, and 50-50% PPs and reported that LRP were not observed except 100-0%. These studies reported conflicting results as follows: LRP occurs when the PP is 100% only or when the PP is quite high. The issue that the LRP to 75-25% condition is

uncertain will be due to possible cancellation of readiness potentials in both hemispheres. Thus, lateralizing readiness potential to a hemisphere by indicating left or right hand and PP of the target action at the same time, we aim to reveal whether LRP occurs or not when the PP is not 100% and further the quantitative relationship between PP and LRP. We recorded electroencephalography of 13 subjects during a reaching task, where a spatial cue with an instruction which hand to use was presented at first and the subject was required to move the hand to the target or not, following the next Go or Nogo cue. Subjects were allowed to prepare for the action based on PP because the thickness of lines in the spatial cue implies go probability, i.e. one of 100%, 80%, and 20%. The result showed LRP occurrence when the PP is 80%. To reveal the effect of PP, we compared LRPs in different PP conditions for 100ms just before the Go/Nogo cue was presented. When PP was 100% and 80%, LRP were significantly observed, but were not when PP was 20%. In addition, the LRP amplitude with 100% PP is larger than that with 80%, and the LRP with 80% PP is larger than 20%. The average response times for 100% and 80% PPs are 482 ms and 521 ms, respectively. Both are shorter than 603 ms in the control condition ($p < 0.001$), that confirms the preparation for actions in these conditions. The results suggest the dependence of LRP on PP such that the higher the PP is, the larger the LRP amplitude is. It is also suggested that the possibility of a partial preparing state for movement in the motor related cortical areas, which was observed as the smaller LRP.

Title: Differential effects of continuous theta burst stimulation (cTBS) over left premotor cortex (PMC) and right prefrontal cortex (PFC) on modulating upper limb somatosensory input

Authors: ***M. J. BROWN**, W. R. STAINES;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Somatosensory evoked potentials (SEPs) recorded from cortical surface electroencephalography (EEG) after median nerve (MN) stimulation measure mixed afferent

somatosensory input. SEPs recorded maximally over frontal electrodes, such as frontal N30 and N60 peaks, represent somatosensory processing in non-primary motor areas compared to parietal SEPs (i.e. P50) that represent relay into somatosensory cortices. Several neural areas including the premotor cortex (PMC) and prefrontal cortex (PFC) have been associated with the preparation and planning of upper limb movements. However, it is currently unclear how PMC and PFC contribute to the selection of somatosensory input to inform upcoming movement. In the current study, two experiments examined SEP modulations after continuous theta burst stimulation (cTBS) to produce transient disruptions of left PMC (Experiment 1) and right PFC (Experiment 2). In both Experiment 1 (n=15) and Experiment 2 (n=16) pre-post experimental designs had participants receiving vibrotactile (VibT) stimuli to either their left index (D2) or pinky finger while also receiving MN stimulation time-locked relative to VibT onset during pre-stimulus (250 ms before VibT), early response selection (250 ms after VibT), late preparatory (750 ms after VibT) and execution (1250 ms after VibT) phases. SEPs were compared between passive stimulation in the No Task condition to Attend and Move condition, where participants attended to VibT stimuli to D2 and executed a pre-matched finger sequence with the right (contralateral) hand to specific VibT targets. The key findings of Experiment 1 revealed significant decreases in N30 and N60 peak amplitudes after cTBS to PMC. In contrast, the results of Experiment 2, also found significant decreased N60 peak amplitudes as well as trends for increased N30 and P50 peak amplitudes. A direct comparison of Experiment 1 and Experiment 2 confirmed differential modulation of N30 peak amplitudes after PMC (gated) compared to PFC (enhanced) cTBS. Collectively, these results support that both the left PMC and right PFC have modulatory roles on early somatosensory input into non-primary motor areas represented by frontal N30 and N60 SEPs. These results confirm that PMC and PFC are both part of a network that regulates somatosensory input for upper limb motor control.

Title: The influence of movement observation on movement execution: an EEG study on automatic imitation

Authors: *L. ZAPPAROLI[1,2,3], J. KILNER[2];
[1]Univ. of Milano-Bicocca, Milano, Italy; [2]Sobell Dept. of Motor Neurosci. and Movement Disorders, Inst. of Neurol., London, United Kingdom; [3]IRCSS Galeazzi, Milan, Italy

Abstract: Automatic imitation is a robust stimulus-response compatibility effect in which the characteristics of movement stimuli (non relevant for the task) facilitate compatible actions and interfere with the incompatible ones. Previous studies have explained the effect the observed movement has on the timing of the executed action in terms of incompatible motor programs underlying the different observed and the executed actions. Despite many behavioural studies that have replicated this automatic imitation effect, very little is known about the neurophysiological mechansims that underlie it. The aim of this study was to explore the neurophysiological underpinnings of this effect using EEG, with particular attention to the role of beta oscillations. In particular, our goal was to test whether the automatic imitation is related to the compatible pre-activation of the motor system during action observation. We tested the hypothesis that modulations in beta power in the motor system driven by the observed action prior to the imperative cue could account for variance in the reaction time to the imperative cue. To this end, we recorded The EEG from 18 young right-handed healthy participants using a 128 electrode active EEG system whilst the participants performed an automatic imitation task. In the task subjects observed short movies of moving hands (non-relevant stimulus), followed by an imperative cue that guided their responses. Participants were instructed to response as quickly and as accurately as possible to the imperative cue. For the behavioural data (reaction times) analysis we performed repeated-measures ANOVA. In agreement with previous studies we found significantly shorter reaction times for trials in which the motor response was compatible with the observed movement. For the EEG data, after a preprocessing phase, we performed a time-frequency analysis and averaged over the beta frequency range (15-30 Hz); we then analysed the EEG data with a general linear model approach with the reaction times as covariate of interest. We found significant changes of beta oscillations prior to the imperative cue during action observation over the cortical areas of the motor system. Furthermore, these changes were significantly correlated with the subsequent reaction time to the imperative cue. Our results demonstrate an important role of the beta oscillations in the prediction of how action observation influences the execution of a successive movement. These findings could have an important role for further research on neurological diseases that are characterized by deficit of inhibition of automatic movements (e.g. Tourette Syndrome).

Abstract: The vast majority of motor actions, i.e. their preparation and execution, is the result of a complex interplay of various brain regions. Novel methods in computational neuroscience allow us to assess interregional interactions from time series acquired with *in vivo* techniques like electro-encephalography (EEG). These methods have helped provide first insights as to how brain areas assemble into functional networks depending on the motor task. However, our knowledge on the neural signals that encode individual movements and how they are changed during stroke is relatively poor. EEG data (64 channel system) were recorded continuously from 17 right-handed healthy participants (27±4 years, 10 female) during a simple motor task. The participants had to execute left or right index finger tapping movements that were triggered either by a visual cue or by voluntary choice. We used phase-difference analysis of the Hilbert phases of the Laplacian referenced EEG data to identify the coupled brain regions during the motor task. We analyzed the connectivity for electrodes lying above the premotor areas (PM: FC3, FC4), the supplementary motor areas (SMA: Cz, FCz) and the primary motor cortex (M1: C3, C4). Our analysis revealed an underlying coupling structure during the preparatory phase of the movement in the delta-theta-frequency band (2-7 Hz) that is common to all conditions irrespective of the hand performing and the cue triggering the movement. We hypothesize that this underlying network of synchronous activity makes the motor system more excitable so that transient cue signals are able to induce different kinds of movements during movement preparation.

Title: Network effects on individual movement representations: Evidence from an EEG study

Authors: *B. WANG[1], S. VISWANATHAN[2,1], R. ABDOLLAHI[1], N. ROSJAT[3,1], S. POPOVYCH[3,1], S. DAUN-GRUHN[3,1], C. GREFKES[2,1], G. FINK[2,1];

Abstract: The specialized circuits of the motor system can be flexibly recruited by very different cognitive networks. For example, the motor-system can be recruited differently to execute movements in response to an external stimulus, or, to an intention without a stimulus. Even though the executed movement itself may be identical, it is unclear whether and how the recruiting cognitive networks can affect the neural representations of the movement. We hypothesized that such different recruiting networks may affect the movement representations and different motor tasks will share common neural representation of the motor output if the executed movements are identical. We collected 64-channel EEG data from 21 young healthy participants while they made index-finger movements with either their right or left hands in two different contexts. In the Cued-condition, participants responded to an arrow cue that pointed either to the right or to the left by pressing a button with the corresponding hand. In the Self-paced condition, participants produced freely chosen right or left hand button-presses at regular intervals without an external cue. Accelerometers measured the finger accelerations to estimate the movement performance: processing time (PT) from the stimulus to the movement onset, and movement time (MT) from movement onset to button press. We found the P300 amplitude in parietal (Pz) correlates with the stimulus-related PT, while there was no relationship with the MTs. Interestingly, we show that individual mean MT were highly correlated between visually cued and self-paced condition despite of the differences of recruiting network. And, we found the increased lateralized readiness potential (LRP) in motor cortex is associated with the faster MT for both conditions even though the pattern of brain activity are different between two conditions. In addition, we show the synchronous LRP of parietal cortex involved in self-paced movement, while the synchronous LRP of prefrontal cortex in visually-cued movement, which further suggested the different recruiting network of different motor tasks in term of LRP. Together, our findings provided the electrophysiological evidence to reveal the common underlying mechanism that is independent of tasks and the recruiting network to control the motor output for two actions under the control of different neural network.

Title: Phase-locking in the delta-theta band is an EEG marker of movement execution

Authors: ***S. GRUHN**[1], S. POPOVYCH[2], N. ROSJAT[2], B. WANG[3], L. LIU[2], C. GREFKES[2], G. R. FINK[4];

Abstract: Motor actions are the result of a complex interplay of various brain regions. Since the same brain regions can assemble into different functional networks depending on the action, identifying the neural signals that encode an action's component (such as selection, preparation and execution) remains a challenging task. In the study reported here, we sought to identify neural markers of a movement's execution that are invariant under differences in the functional networks in which movement is initiated. EEG data (64 channel system) were recorded continuously from 17 right-handed healthy participants (27±4 years, 10 female) as they performed a simple motor task. The task required participants to execute a left or right index finger tapping triggered by (i) a visual cue, or (ii) by an uncued voluntary choice. Despite the substantial differences in how the movements emerged in these two conditions, we hypothesized that the common movements executed in both conditions could be associated with common EEG markers. We used time-frequency and phase-locking analysis of the Laplacian referenced EEG data centered on movement onset. We analyzed the EEG signals recorded from the electrodes which were located above different regions of the motor cortex (C2 and C4 over rM1, C1 and C3 over lM1, FC3 over lPM, FC4 over rPM, FCz and Cz over SMA) and used the electrode Oz (above the visual cortex) to record and check the visual activity in the cued movement condition. Data analysis revealed that both the voluntary and the visually triggered movement condition exhibited the same significant phase-locking effect in the delta-theta frequency band (2-7 Hz) of the EEG signals at the electrodes above the contralateral motor regions, irrespective of whether

the left or the right index finger performed the movement. Our results suggest that phase-locking in the delta-theta frequency band is an electrophysiological marker of the execution of movement no matter how it is initiated.

Title: Delay differential analysis: a framework for multimodal non-linear classification of Parkinson's disease

Authors: *M. E. HERNANDEZ[1], J. WEYHENMEYER[2], C. LAINSCSEK[3], T. SEJNOWSKI[3], H. POIZNER[4];
[1]Kinesiology and Community Hlth., UIUC, Urbana, IL; [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]The Salk Inst. for Biol. Studies, La Jolla, CA; [4]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstract: Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder in the world, yet has no standard diagnostic test. PD is known to lead to marked alterations in cortico-thalamo-basal ganglia activity and subsequent movements, which may provide a biomarker for PD diagnosis. DDA is a time domain analysis framework based on embedding theory in non-linear dynamics. An embedding reveals the nonlinear invariant properties of an unknown dynamical system (here the brain) from a single time series (EEG or behavioral signals). The DDA embedding serves as a low-dimensional nonlinear functional basis onto which the data are mapped. The combination of behavioral and neurological observations gives rise to a multimodal analysis framework that will improve the understanding and classification of

neurological disease. We demonstrate how 750 ms of multimodal data can be used to improve DDA classification performance of PD after an unexpected perturbation of a virtual target during reach to grasp movements. We found that the anteroposterior hand position and hand aperture, in particular, provide improved classification performance in comparison to clean EEG data, as evaluated by the area under the ROC curve (AROC), (AROC increases from 0.71 to 0.81 with the addition of behavioral data). Thus, multimodal DDA may provide a tool for aiding the clinician in the diagnosis of PD and allow for earlier intervention with disease modifying therapeutics.

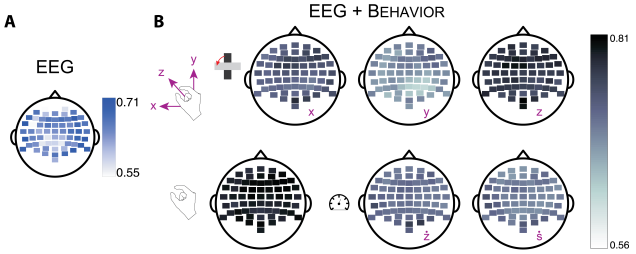

Figure 1. PD off-medication versus Controls classification performance of DDA of A) EEG data and EEG and behavioral data during reaching to grasp movements during virtual target perturbations, as evaluated by the area under the ROC curve (AROC).

Title: The neurophysiological correlate of perceptual sensory attenuation measured using a force-matching paradigm

Authors: *C. E. PALMER[1], M. DAVARE[1,2], J. M. KILNER[1];
[1]Inst. of Neurology, Univ. Col. London, London, United Kingdom; [2]Movement Control & Neuroplasticity Res. Group, Biomed. Sci. Group, Dept of Kinesiology, KU Leuven, Leuven, Belgium

Abstract: During movement incoming sensory information is filtered via central mechanisms: sensory gating. This gating has been described at two levels. At a neurophysiological level cortical electroencephalogram (EEG) recordings have highlighted a suppression of somatosensory evoked potentials (SEPs), produced in response to electrical stimulation of the median nerve, prior to and during movement onset. At a perceptual level, sensations which are self-generated are perceived as less intense than those which are externally generated, which explains why we are unable to tickle ourselves. A force matching paradigm in which participants must match a target force either by pushing on themselves or via an external mechanism is classically used to quantify this phenomenon. Participants consistently overestimate matched forces during the self-matching condition. It has previously been assumed that the sensory gating of SEPs during movement underlies this perceptual sensory attenuation, however specific predictions regarding this have not been addressed. The aim of this study is to identify the neurophysiological correlates of the percept of sensory attenuation. In this experiment 12 participants carried out a traditional force matching task whilst brain activity was recorded using EEG. Participants received median nerve stimulation 1) during phasic muscle contraction whilst finding the perceptually equal force (on select trials); 2) during isometric contraction when holding the matched force. Both right and left median nerves were stimulated in separate sessions. A control condition was included in which participants received a series of median nerve stimuli at rest (baseline) and whilst producing a self-paced movement of the index finger of the stimulated hand. Consistent with previous findings: we found that participants significantly overestimated the perceived force during the self-generated condition compared to the externally-generated condition. Interestingly, we found as expected a significant attenuation of the SEP secondary complex in the control movement condition compared to baseline, but no significant difference in SEP component amplitudes in the self-generated vs the externally-generated condition. This data suggests neurophysiological gating of SEPs in response to movement may occur via a different mechanism to the perceptual sensory attenuation observed in response to self-generated vs externally-generated movements. Further EEG analyses in the time-x-frequency domain will aim to uncover the neurophysiological correlate underlying this perceptual sensory attenuation.

Title: Shared patterns of activation during tool-use and tool-making in the human brain: an ALE meta-analysis

Authors: *L. D. REYES, S. BIANCHI, C. C. SHERWOOD;
Ctr. For The Advanced Study of Human Paleobiology, The George Washington Univ., Washington, DC

Abstract: The manufacture and use of complex tools is one of the most distinctive human behaviors. Humans have a left lateralized tool-use circuit involving areas in the inferior frontal gyrus (Broca's area), dorsal and ventral premotor cortex (PMD, PMV; area 6), superior and inferior parietal lobes (SPL, IPL), and temporal lobe. Neuroimaging studies of human stone tool-making have found activation patterns resembling that of tool-use. We thus performed a quantitative activation likelihood estimation (ALE) meta-analysis (GingerAle 2.3) on results from published whole-brain studies to identify clusters activated across tool-use and stone tool-making. A total of 387 foci were selected from 32 published tool-use studies consisting of tool-use planning, imagery, pantomime, and execution. Tool-making foci (78) were selected from four tool-making experiments, consisting of novice, trained, and experienced tool-makers. We performed a cluster level analysis on each group (cluster level inference: $p \leq 0.05$, permutation threshold = 1000, cluster-forming threshold: uncorr. $p \leq 0.001$) and a contrast analysis identified shared and unique activity between groups (uncorr. $p \leq 0.001$, p value permutations = 10000, min. cluster volume = 250 mm^3). The meta-analysis confirmed a left lateralized tool-use circuit that overlapped with tool-making (ALE value = 0.01), with shared activation in the left PMD (MNI: -23, -7, 61; -28, -6, 58), Broca's area (-53, 5, 30), somatosensory cortex (-46, -32, 45), and intraparietal sulcus (-39, -40, 44). Tool-making showed activity not observed in tool-use studies (ALE value = 3.15-3.89), including bilateral activation in posterior SPL (-28, -64, 56; 25, -55, 58) and visual cortex (-15, -71, 7; -18, -86, 31; 19, -91, 23; 16, -78, 11; 28, -79, 6), and left activation in PMD (-21, 6, 55) and anterior IPL (-46, -37, 41). Significant tool-making clusters in the visual cortex were observed in novice tool-makers, while PMD, posterior SPL, and anterior IPL activity was not associated with tool-making experience. Tool-making shares much of its neural circuitry with tool-use but activates additional areas that may support increased visual demands during stone tool manipulation. Although tool-based processing likely drives much of

the shared activity, processing of sequenced information may also contribute to shared circuitry. Broca's area and IPL in particular are also involved in sequential aspects of speech and language such as word generation and syntax. Investigating shared circuitry between language and tool processing may reveal how more efficient sequential processing might have evolved to support these distinctive human characteristics.

Title: Brain reorganization following upper limb motor rehabilitation in patients with multiple sclerosis

Authors: *L. BONZANO[1], A. TACCHINO[2], G. BRICHETTO[2], L. ROCCATAGLIATA[1], A. DESSYPRIS[1], P. FERACO[1], L. LOPES DE CARVALHO[2], M. BATTAGLIA[2], G. MANCARDI[1], M. BOVE[1];
[1]Univ. Genoa, Genoa, Italy; [2]Multiple Sclerosis Italian Fndn., Genoa, Italy

Abstract: Upper limb impairments can alter the ability to perform daily living activities in patients with Multiple Sclerosis (PwMS). Motor rehabilitation has the target to maintain the residual capacities to the highest possible level, but consistent data on its efficacy are lacking. Individual patients' outcomes are variable, due to variations in brain functional properties and to the adopted rehabilitation protocol. Brain adaptation occurs following damage in PwMS, and an efficient motor rehabilitation might influence this process. We investigated the effects of upper limb rehabilitation on motor function and related brain activity patterns in PwMS. Thirty PwMS in a stable phase of the disease were randomized to receive an active (AMT group, n=15) or passive motor rehabilitation treatment (PMT group, n=15). Both groups underwent twenty 1-hour treatment sessions, three times a week: the AMT group performed voluntary task-oriented exercises, whereas the PMT group was treated with passive mobilization of the different segments of both limbs. Before and after treatment, upper limb motor performance was evaluated by standard evaluation protocols and an engineered glove to quantify finger motor performance accuracy. In the same sessions, brain activity was investigated by fMRI at 1.5 T

during sequences of finger opposition movements with the right hand following a metronome at 2 Hz; thus, all patients were asked to perform exactly the same task in all sessions, allowing the comparison of brain activations between groups and sessions (performance during fMRI was recorded by an MR-compatible glove). Laterality Index (LI) was calculated in the frontal lobe (Brodmann Area - BA 4 and 6), parietal lobe (BA 2/3 and 40) and cerebellum. Motor performance improved in all PwMS as effect of treatment. At baseline, in both groups task-related activations were found bilaterally in the sensorimotor areas, and cerebellum. After treatment, activity was reduced in the right sensorimotor and supplementary motor areas ("compensatory" areas) in the AMT but not in the PMT group. Particularly, in the AMT group activations were strongly left lateralized in the cerebrum and right lateralized in the cerebellum; in the PMT group the right BA 6 and left cerebellum were also activated. Accordingly, LI indicated increased laterality in all brain regions in the AMT group, but only in the parietal lobe in the PMT group. The active motor treatment was able to reduce brain resource demand, altered by the disease, and should be preferred to passive mobilization: motor planning and execution in voluntary movements integrate proprioceptive information and can be important stimuli for neuroplasticity.

Title: Age-specific cortical control during quadriceps activation: a fNIRS investigation

Authors: ***E. MORA**[1], R. MEHTA[1], S. MAPAR[2];
[1]Texas A&M Univ. - TAMHSC Sch. of Publ. Hea, College Station, TX; [2]Independent, College Station, TX

Abstract: Existing neuroimaging capabilities have limited hemodynamic brain activation investigations of neuromuscular activation to smaller upper extremity or lower extremity (ankle dorsiflexion) muscles. Quadriceps strength is an important predictor of falls in the elderly and

quadriceps precision force control is an essential function for precision gait and balance. The use of functional near infrared spectroscopy (fNIRS) enables cortical measurements during activation of larger muscles and during dynamic tasks. The goal of this study was to examine age-related changes in brain activation patterns during maximum voluntary contraction (MVC) and precision force control (FC) of the quadriceps using fNIRS. Fourteen younger (6 M, 8 F; 23.2 (4.1) years) and eight older (4 M, 4 F; 72.6 (5.7) years) adults performed two different static knee extension tasks (MVC and FC). In the MVC task, participants were instructed to push as hard as they can for a total of 3 trials with 20 seconds rest. During the FC task, participants controlled knee extension force at the target level (30% of MVC) for 10 seconds with 20 seconds rest for a total of 6 trials. fNIRS data was recorded at 50Hz from Fp1 and Fp2 regions in the prefrontal cortex (PFC) and bilaterally from the supplementary motor areas (Motor A) and the primary motor cortex (Motor B). A 2 (age) x 2 (task) x 6 (brain regions) mixed-effects model was employed to investigate the main and interaction effects of these factors on the 10-second average oxygenated hemodynamic (HbO) response levels. Both PFC regions exhibited higher HbO levels than the left Motor regions ($F(5,17)=5.8$, $P<0.0001$), and younger adults exhibited greater cortical activation than older adults ($F(1,20)=4.8$, $P=0.03$). Brain region had significant interactions with age ($F(5,17)=3.8$,$P=0.002$) and task ($F(5,17)=2.5$, $P=0.03$). A significant task, brain region, and age interaction was found ($F(5,17)=2.9$, $P=0.01$); younger adults exhibited higher HbO levels during the MVC task than the FC task in the right PFC region, however, no such differences were found in the older adults. These results indicate that increased right PFC activation during MVC of the quadriceps in younger adults plays a major role in MVC activation that is not observed in older individuals or during FC tasks. These findings may account for why older adults may have more difficulty recovering from falls. Future work includes detailed investigation of the relationship between brain hemodynamics and biomechanical outcomes of quadriceps activation.

Title: Reliability of functional near-infrared spectroscopy during expert juggling

Authors: *R. WOLLNY[1], C. ANDRÄ[2], M. CLAUß[2], J. MEHNERT[3], D. CARIUS[1];
[1]Martin Luther Univ. Halle-Wittenberg, Halle (saale), Germany; [2]Univ. of Leipzig, Leipzig, Germany; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: This functional near-infrared spectroscopy (fNIRS) study focuses on the reliability of the cortical hemodynamic responses during juggling balls by experts. Comparing EEG and fNIRS, the latter is less sensitive for movement artifact induced noise and potentially a suitable technique for measuring cortical hemodynamic changes during the execution of spacious motoric movement (Rooks et al., 2010). During the execution of small movements like finger tapping cortical hemodynamic changes over central motor areas showed a good reliability (Plichta et al., 2007). However, spacious motoric movements with higher intensities cause higher hemodynamic responses (Harada et al., 2009). To our knowledge nothing is known about the reliability of these responses during the execution of spacious motoric movements like juggling. We recorded hemodynamic responses from 15 juggling experts (26.3 ± 5.2 years), able to juggle at least five balls for a duration of 20 seconds, in premotor, primary motor, primary somatosensory areas and the area MT/V5 on both hemispheres (Piper et al., 2014) using a recently developed portable 16-channel fNIRS device (NIRSport 88, NIRX GmbH, Berlin). Attenuation changes of both wavelengths (850 nm and 760 nm) were transformed to concentration changes of oxygenated and deoxygenated hemoglobin (oxyHb and deoxyHb, respectively) using the modified Beer-Lambert approach (Kocsis et al., 2006). Each juggler performed eight repetitive blocks of 2-ball (left and right hand), 3-ball, and 5-ball juggling, respectively, for 20 seconds in a randomized order. The experiment included a longer break of 20 minutes where optodes were not removed. Test-retest was performed by intra-session reproducibility of measurements, which were assessed channel-wise by intra-class correlation coefficients (ICC(3,1)) according to the procedure proposed by Hopkins (2000). Channel-wise contrasts of test with retest (t-test for change in the mean) for hemodynamic responses (grand-averages) during juggling tasks only differed for oxy-Hb during 2-ball juggling left and right hand as well as 5-ball juggling. Hemodynamic responses were lower in the second session as compared to the first. Both variables, concentration changes of oxyHb (3-ball juggling: ICC(3,1) = .69 - .93, 2-ball juggling right hand: ICC(3,1) = .63 - .89, 2-ball juggling left hand: ICC(3,1) = .72 - .86, 5-ball juggling: ICC(3,1) = .82 - .94) and deoxyHb (3-ball juggling: ICC(3,1) = .86 - .97, 2-ball juggling right hand: ICC(3,1) = .81 - .95, 2-ball juggling left hand: ICC(3,1) = .78 - .97, 5-ball juggling: ICC(3,1) = .81 - .96) showed fair to good test-retest reliability. This is the case for all measured channels.

Title: Distributed representation of movement hierarchy in human neocortex

Authors: *A. YOKOI[1,2], U. HERTZ[1], E. BAMBER[3], J. DIEDRICHSEN[1];
[1]Inst. of Cognitive Neurosci., London, United Kingdom; [2]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The idea of motor chunking (Lashley, 1951) is that the brain breaks down longer sequences of movements into smaller sub-sequences, which enables superior memory and motor performance. While there have been a number of behavioural studies supporting the concept (Rosenbaum et al., 1983; Sakai et al., 2003), it is still unknown how motor chunks are hierarchically represented across cortical motor regions. To address this issue, we analysed the functional magnetic resonance imaging (fMRI) data from 12 human participants, which performed 8 different trained sequences in the scanner. We externally imposed a chunk structure through the way the sequences were memorized: On the first day of training, participants were taught 8 individual chunks of 2 or 3 presses. On the four subsequent days of training, they then learned to produce 8 sequences, each of which were composed of 4 of those chunks (11 presses total). Basic movement parameters were matched for all sequences. During scanning, participants repeated the same sequence twice within 8 seconds. The order of the 8 sequences was randomized and each sequence type was repeated three times in each of the 9 runs. Using representational similarity analysis (Kriegeskorte et al., 2008), we then tested whether the similarity structure of brain activity pattern follows the structures predicted by various representational models of sequence representation. A post-scanning behavioural test indicated that the imposed chunk structure in the early training significantly influenced the performance. The inter-press-intervals within a chunk were significantly faster than other intervals ($p<0.001$), both when chunks occurred within trained sequences or in the context of novel sequences. Representational fMRI analysis revealed that there was a regional-specific mixture of representations. Whereas the representation in contralateral M1 was mostly dictated by single finger presses, contralateral premotor and bilateral parietal areas showed clear evidence of representations for chunks and whole sequence in a spatially segregated manner. Furthermore, a non-hierarchical representation of transitions of finger presses was found in the ipsilateral dorsal

premotor cortex and the SMA. In summary, our results suggest that premotor areas represent learned sequences both in a hierarchical and non-hierarchical fashion.

Abstract: Our interactions with objects are strongly influenced by their physical properties. However, not only object's features can drive an action. Also our hand configuration, in terms of shape and orientation, can be easily modified to flexibly interact with them. The neural correlates subtending our capacity of reaching and grasping objects, i.e. prehension, have been classically localized within a fronto-parietal cerebral network. This system includes a dorsomedial pathway, considered to process reaching information, and a dorsolateral pathway, considered to process grasping information. However, recent studies have challenged this classical subdivision by showing coding for grasp-related information, such as grip type and hand orientation, within both pathways. Consequently, it is yet unclear if there is an exchange of information between these two pathways or if they independently code similar action properties. Here we adopted dynamic causal modelling (DCM) analysis on fMRI data to investigate the connectivity between and within the two pathways. Participants were requested to perform non-visually-guided grasping actions directed on an object. The actions were executed with their right hand while lying in the MR scanner. We used a 2x2 factorial design, including grip type (precision grip vs. whole hand prehension) and hand orientation (0° vs. 90°) as factors. We showed a modulatory effect of the considered experimental factors, grip type and hand orientation, on the connectivity profiles within the prehension network. DCM analysis provided evidence for an exchange of information between the two pathways, suggesting that the two dorsal streams are not functionally independent. Our study offers new insights into the connectivity dynamics occurring

within the prehension network, supporting the idea of inter-regional interactions based on specific properties of the performed action.

Title: Visual gain induced changes in visuomotor system activity in chronic stroke

Authors: ***D. B. ARCHER**, G. MISRA, C. PATTEN, S. MARBLE, S. COOMBES;
Univ. of Florida, Gainesville, FL

Abstract: The visuomotor network has been extensively studied in healthy individuals. Recent motor neuroimaging studies have associated region specific changes in the visuomotor network with changes in the properties of visual feedback such as visual gain. Increasing visual gain (i.e. magnifying error) during a visuomotor task reduces force error in chronic stroke individuals, but corresponding changes in functional activity in and beyond the visuomotor network have not been studied in this cohort. Previous visuomotor fMRI studies show that stroke individuals engage the visuomotor network more bilaterally, and that contralesional activity increases with task difficulty. Here, we used functional MRI to examine the functional brain activity that is associated with visual gain related improvements in force performance in chronic stroke individuals as compared to healthy age-matched controls. Chronic stroke and control individuals performed three visuomotor tasks during fMRI with their impaired/non-dominant hand. Visual gain was parametrically increased between tasks. The stroke group had greater error as compared to the control group at all gain levels, but both groups showed a progressive decrease in force error with an increase in visual gain. Increasing visual gain led to increased activity in key visuomotor regions such as the extrastriate visual cortex, premotor cortex, and inferior parietal lobule in stroke and control groups. Our observations also revealed increased activity in the contralesional premotor and primary motor cortex in the stroke group. Together, our findings show that visual-gain related improvements in force performance in chronic stroke are associated with a progressive increase in functional activity in the visuomotor network. We also found evidence of increased activity in ipsilateral motor areas in the stoke group across all levels of

visual gain. We conclude that changes in visual gain during a visuomotor task in chronic stroke lead to increased activity in regions within and beyond the visuomotor network.

Title: Precise hemodynamic control of primary motor cortical activity using an adaptive feedback paradigm

Authors: *E. OBLAK[1], M. U. JAKOB[2], J. S. SULZER[1];
[1]The Univ. of Texas at Austin, Austin, TX; [2]ETH Zurich, Zurich, Switzerland

Abstract: Real-time fMRI (rtfMRI) gives us a whole-brain neural signal that can be used as an indication of an individual's current brain state. An exciting prospect of measuring neural states in real-time is to be able to guide individuals toward specific neural states, for example to enhance task performance or to facilitate neurorehabilitation. The most common approach thus far has been to use the brain state signal as feedback to the participant. More recent iterations have developed adaptive paradigms capable of triggering or changing a stimulus based on a real-time brain state, without the participant's knowledge of their own brain activity. Such paradigms may be advantageous as they can overcome confounding issues with the varying cognitive abilities of different individuals. Our approach expands these processes via an adaptive control system. This system calculates the difference between the current real-time brain state and the desired brain state, and then uses an a priori model to change the ongoing task to achieve a brain state that is closer to the desired one. Here, we apply this concept by developing a system to guide an isometric motor task in two stages: in the first fMRI session, we characterize the neural circuit involved in the task to develop the initial parameters for an adaptive controller; and in a second fMRI session, we apply an adaptive controller to fine-tune the model during task execution. Specifically, in the first session, we parameterize the BOLD activity in the hand area of the primary motor cortex (M1) of one subject based on force applied and the complexity of an isometric precision grip task; and in the second stage, we successfully apply this adaptive

controller to another subject in a subsequent fMRI session to achieve M1 BOLD percent signal changes (PSC) of 0.33, 0.66, and 1.00. Our preliminary results show that it is possible to use an rtfMRI signal to adaptively adjust a motor task to achieve a specific neural state. This work represents the first model-based hemodynamic control system with error-based reference tracking. Future iterations will extend this adaptive control technique to differential region of interest control as well as control of multi-voxel fMRI patterns within motor cortical structures.

Title: Neural correlates of nonlinear integration of visual and proprioceptive feedback during wrist stabilization

Authors: *A. J. SUMINSKI[1], R. A. SCHEIDT[2];
[1]Electrical Engin. and Computer Sci., Milwaukee Sch. of Engin., Milwaukee, WI; [2]Biomed. Engin., Marquette, University, WI

Abstract: Limb stabilization is a fundamental motor behavior requiring closed loop feedback control. The availability of multiple feedback sources (e.g. vision and proprioception) raises the question of how sensory information is combined to drive feedback compensation for kinematic performance errors caused by perturbations encountered during stabilization. Here we investigated how the neural mechanisms involved in feedback control of limb position were modulated in response to manipulation of the fidelity between visual and proprioceptive information. Twelve healthy subjects steadied their wrists while resting supine in a 1.5T MRI scanner. They stabilized against either predictable, constant extensor torque perturbations (CT) or unpredictable, pseudo-random extensor torques (RT) having the same average extensor torque as the CT perturbation. Direct view of the arm was precluded, although a cursor representing wrist angular deviations from a target was visible via prism glasses. One of 3 types of visual

feedback was available: true vision (TV), pseudo-random vision (RV) and no vision (NV). Scanning runs were made up of 30 s of stabilization in each of the 6 conditions, with 30 s of rest preceding and following each stabilization period. Behaviorally, performance errors accumulated more quickly during trials where the fidelity of visual feedback decreased. Analysis of functional images was conducted in 2 stages. First, a blocked design multilinear regression analysis revealed expected task-related activations in a cerebello-thalamo-coritcal circuit previously linked with feedback stabilization. Importantly, we found that BOLD activity within this network varied based on the fidelity of visual feedback. A second regression analysis, performed on residuals from the blocked analysis, evaluated correlation between BOLD signal fluctuations and kinematic performance errors during RTRV stabilization. Importantly, BOLD signals in areas supporting feedback stabilization only exhibited correlation with hand errors, not cursor errors. In comparing BOLD signal correlations with hand errors during the NV and TV conditions, we found that addition of veridical visual feedback caused marked changes in the overall network activity (a drop-out of prefrontal activation as well as dramatic increases in parietal and cerebellar areas engaged in feedback control). These results favor a nonlinear, competitive integration strategy when V and P are in conflict. This nonlinearity is further reflected in the observation that relative to the NV condition, addition of veridical visual information modifies the network structure mediating sensory feedback control.

Title: Comparison of decoders in multi-voxel pattern analysis for identifying task-specific resting-state brain activity in primary motor cortex

Authors: *T. KUSANO[1], H. KURASHIGE[3], I. NAMBU[2], Y. MORIGUCHI[4], T. HANAKAWA[5], Y. WADA[2], R. OSU[6];

[1]Dept. of Electrical Engin., [2]Nagaoka Univ. of Technol., Nagaoka, Japan; [3]Univ. of Tokyo, Kashiwa, Japan; [4]Gunma Univ., Maebashi, Japan; [5]Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [6]Advanced Telecommunications Res. Inst. Intl., Soraku, Japan

Abstract: The human brain activity at rest by functional magnetic resonance imaging is called resting-state fMRI (rs-fMRI), which has been shown its physiological significance for memory, maintenance of brain function, and creative thinking, and it is used for a biomarker for brain disease or classifying internal states. To classify brain states or identify fine brain activity patterns specific to a task (event), multi-voxel pattern analysis (MVPA) has become popular in fMRI analysis. However, MVPA applied to rs-fMRI has not been examined well. The purpose of this study is to investigate applicability of MVPA for rs-fMRI to identify fine brain activity patterns in the human motor cortex. In many cases, MVPA is usually applied to whole brain which includes large areas. Support vector machine (SVM) is commonly used as a decoder (classifier) because it generally shows high classification accuracy. However, we do not yet know that SVM is the best decoder for rs-fMRI. In this study, we compared two decoders: SVM and regularized logistic regression (RLR). We designed a decoder to detect voxel-level neural representations corresponding to task-specific activation in primary motor cortex (M1). Thus, each decoder was trained using the data in which the subject performed wrist/finger flexion movement. Next, we applied the decoder to rs-fMRI and defined obtained result as wrist versus finger index (WFI): how much rs-fMRI pattern is similar to each task-induced pattern. Finally, to confirm that resting-state brain activity reflects task-induced brain activity pattern, we compared WFI using weight parameter of designed decoder and that using random shuffled weight parameters by evaluating standard deviation (SD) of WFI distribution. Results showed that the average accuracy of each decoder was over 80% and RLR obtained higher accuracy than SVM. More than half of subjects showed significantly larger SD than that using random WFI histogram in each decoder, and the number of subjects showing significantly larger SD was larger in RLR. These results suggest that the resting-state brain activity includes multi-voxel patterns similar to the neural representation for the tasks and RLR is more adequate than SVM in MVPA for rs-fMRI.

Title: Getting a handle on Virtual Tools: An examination of the neuronal activity associated with virtual tool use

Authors: *A. RENO, K. FERCHO, R. FINN, T. BOSCH, L. A. BAUGH;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Research has demonstrated that tool use is primarily supported by left hemisphere brain networks responsible for tool identification and tool action knowledge. With the advent of computers, virtual tools have become increasingly important in our day-to-day lives. Virtual tools can be thought of as those tools that have a separation between the tool's effector and the tool user. A common example is a computer mouse in which the onscreen movement of the cursor is not necessarily mapped in a one-to-one fashion with hand movements and lacks much of the somatosensory feedback that is common among real tool use. Recent behavioral work has provided evidence that these virtual tools may be represented in a similar manner to real tools by the brain. Using a virtual tool manipulated to hit targets appearing at various eccentricities during a functional magnetic resonance imaging (fMRI) task, this study assessed whether virtual tools activate the same neuronal networks elicited by real tool use. Participants performed in a single fMRI experiment consisting of two experimental conditions, each with a reversal and non-reversal block of trials. In the first condition (Vision), a visual schemata illustrating the relationship between hand and cursor position was provided. During the reversal trials, this information consisted of a stick pivoting around a center point connecting hand position and cursor position; therefore, leftward hand movements were required to hit targets appearing on the right. During the non-reversal trials, the relationship between hand and cursor was represented by a stick connecting hand position and cursor that translated with hand movement. The second experimental condition (No Vision) was similar to the first, but the stick was not made visible to participants. Subject's hand movements were sampled throughout the experiment while functional neuroimaging was performed. Behavioral results matched previously reported reaction time effects, with vision of the tool in the reversal condition decreasing movement initiation times when compared to conditions in which vision of the tool was not provided. Vision of the tool elicited activity within the left hemisphere ventro-dorsal and dorso-dorsal visual streams, regions previously identified as being critical in tool use. Activity within the posterior middle temporal gyrus, superior supramarginal gyrus, anterior intraparietal cortex, dorsal premotor cortex, and supplemental motor area all showed condition dependent activity. The present study demonstrates that the brain capitalizes on a similar network of regions to support the use of virtual tools as those utilized during real-world tool use.

Title: Cortical activity during expert juggling

Authors: *D. CARIUS[1], C. ANDRÄ[2], M. CLAUß[2], J. MEHNERT[3], M. BUNK[4], R. WOLLNY[1];
[1]Martin Luther Univ. Halle-Wittenberg, Leipzig, Germany; [2]Univ. of Leipzig, Leipzig, Germany; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany; [4]Inst. of Applied Athletics Training, Leipzig, Germany

Abstract: This functional near-infrared spectroscopy (fNIRS) study focuses on cortical hemodynamic changes during juggling balls by experts. Although current findings suggest structural changes by long lasting training (Gerber et al., 2014; Scholz et al., 2009), little is known about the functional changes during the execution of spacious motoric movements and their dependence on the expertise of the juggler. We recorded hemodynamic responses from 15 juggling experts (26.3 ± 5.2 years), able to juggle at least five balls for a duration of 20 seconds, in premotor, primary motor, primary somatosensory areas and the area MT/V5 on both hemispheres (Hashimoto et al., 2006; Mehnert et al., 2013, Piper et al., 2014) using a recently developed portable fNIRS device (NIRSport 88, NIRX GmbH, Berlin, Germany) with 8 light source and 8 detectors, which form 16 actual measurement channels. Attenuation changes of both wavelengths (850 nm and 760 nm) were transformed to concentration changes of oxygenated and deoxygenated hemoglobin (oxyHb and deoxyHb, respectively) using the modified Beer-Lambert approach (Kocsis et al., 2006). Each juggler performed eight repetitive blocks of 2-ball (left and right hand), 3-ball, and 5-ball juggling for 20 seconds in a randomized order. The 5-ball juggling expertise of the jugglers was quantitatively rated using a semi-automated cinematographic analysis (kinematic parameters: tosses per second, velocity of the toss, angle of the toss, both, for left and right hand). Due to our results, brain activity in the somato-motoric brain regions rises according to the subjectively rated level of difficulty across conditions (3-ball juggling < 2-ball juggling [in one hand] < 5-ball juggling). As hypothesized 5-ball juggling, by far, recruited most neuronal activity as compared to the other conditions in most of the channels. Furthermore, the level of expertise, acquired by cinematographic video analysis, is related to the functional changes of 5-ball juggling in the right primary motor area (R-M1) such that a higher level of expertise corresponds with less cortical activity (Spearmann's rank correlation; oxy-Hb: R-M1 $\rho = .694$, $p = .012$; deoxy-Hb: R-M1 $\rho = .718$, $p = .009$). The current study reports, according to our knowledge, for the first time transient cortical activity during the

execution of a spacious and complex motoric task: ball juggling and thereby provides the basis to research the interplay between functional and structural changes in the human brain induced by learning. Subjectively rated difficulty levels of the different conditions are associated with the amount of activity in the somato-motoric system.

Title: Brain connectivity associated with muscle synergies in humans

Authors: M. RANA[1], M. S. YANI[1], S. ASAVASOPON[2], B. E. FISHER[1], *J. J. KUTCH[1]; [1]USC, Los Angeles, CA; [2]Loma Linda Univ., Loma Linda, CA

Abstract: The human brain is believed to simplify the control of the large number of muscles in the body by controlling muscles in groups, termed muscle synergies. Muscle synergies are considered to be structured in spinal cord as modules of motor action, whose combination allows for a variety of movements and postures. However, the neural connectivity allowing the human brain to access and coordinate muscle synergies remains unknown. Here, we use a surprising pair of synergists in humans, the flexor hallucis longus (FHL, a toe flexor) and the anal sphincter, as a model well-suited to elucidate the neural connectivity underlying muscle synergy control. First, using electromyographic recordings, we demonstrate that voluntary FHL contraction is associated with synergistic anal sphincter contraction, but voluntary anal sphincter contraction occurs without FHL contraction. Second, using functional magnetic resonance imaging (fMRI), we show that two important medial wall motor cortical regions emerge related to these tasks - one located more posteriorly that preferentially activates during voluntary FHL contraction and one located more anteriorly that activates during voluntary FHL contraction and voluntary anal sphincter contraction. Third, using transcranial magnetic stimulation, we demonstrate that the

anterior region is more likely to generate anal sphincter contraction than FHL contraction. Finally, in a repository fMRI dataset of 48 men (www.nitrc.org), we estimated the functional connectivity of the anterior region and posterior region. We found that the anterior region has preferential connectivity to regions involved in the brain-bladder control network, including insula and dorsal anterior cingulate cortex. Whereas, the posterior region has preferentially connectivity to the regions involved in navigation networks, including primary somatosensory cortex, frontal cortex, parietal cortex, posterior cingulate and occipital cortex. We conclude that specific motor cortical regions in humans provide access to different muscle synergies, allowing distinct brain networks to coordinate the muscle synergy activation necessary for functional tasks. Thus, the interaction of brain networks encoding task demands with muscle synergy input nodes in the motor cortex may form the basis for the flexible combination of muscle synergies

Title: Sensorimotor plasticity following speech motor adaptation

Authors: ***M. DARAINY**[1], S. VAHDAT[2], D. J. OSTRY[1];
[1]McGill Univ., Montreal, QC, Canada; [2]Univ. of montreal, Montreal, QC, Canada

Abstract: In recent publications there is increasing evidence showing that there are changes to sensory systems following motor learning and there are likewise changes to the motor system after perceptual training. It is fair to say, we may not have pure motor or somatosensory learning but rather sensorimotor learning. Here we have investigated the neural bases of speech motor adaptation. Subjects tested for two experimental sessions over two days. We used custom build dental appliances to connect subject's lower jaw to the robotic manipulandum and to stabilize the head. On the first day of experiment subjects were asked to repeat words shown on a computer monitor while the robot recorded their jaw movement without force application. Every 1.5 s a word chosen randomly from four words ("head", "said", "ted", "bed") came up on the screen and the subject was required to repeat it aloud as soon as possible. Afterward, subjects underwent

fMRI scans of the brain at rest. Then they returned to the lab to complete a perceptual discrimination task. In the perceptual discrimination task, two words “hid” and “head” or “head” and “had” were highlighted on the screen and then subjects heard a word, which was taken from a continuum that spanned the perceptual distinction between the highlighted words. They were required to classify the auditory stimulus as one of the words. On the second day of the study the order of procedures was exactly the same with one exception. Specifically, as the subject produced repetitions of the words, the robotic manipulandum applied forces in protrusion direction that increased in magnitude with vertical jaw displacement. Our behavioral data show that subject compensated for the action of robotic device. Moreover we observed consistent changes to perceptual boundary. We calculated behavioral indices of motor and perceptual change associated with learning and used them as predictor in the fMRI analysis. We found persistent changes in resting-state functional connectivity between auditory areas and both motor and somatosensory areas of the brain. The functional connectivity change in some of these connections correlated more with the motor learning while others correlated more with the perceptual change. Specifically, a network involving primary and secondary somatosensory cortex, primary motor cortex, cerebellar cortex and primary auditory cortex show changes in connectivity linked to motor indices of learning, while a network comprised of ventral premotor cortex, secondary somatosensory cortex, supplementary motor area, primary auditory cortex and inferior parietal lobule correlated more with the perceptual changes that occur in conjunction with learning.

Title: Learning the exotic: Effects of direct experience with unfamiliar tools on motor resonance during tool use action observation

Authors: ***T. J. BOSCH**, K. FERCHO, A. RENO, L. A. BAUGH;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: When examining non-human primate tool use, research has shown that once trained to use a tool, populations of neurons within premotor cortex (F5/PM) and the inferior parietal lobule (PFG/ IPL) exhibit similar responses when both executing a tool use movement and

observing the same tool use, a process termed motor resonance. Tool use in humans elicits a similar resonance response within PM, IPL, and primary motor cortex (M1). An important question is whether gaining experience with a tool is necessary for motor resonance, as is observed in non-human primate research. In humans, differences have been noted between individuals with extensive experience with a tool and those with minimal experience, leading to the equating of motor resonance with action understanding. Whether differences in motor resonance result directly from experience or if those differences are present prior to obtaining experience is unknown. To directly assess this question, participants were trained to skillfully use chopsticks, a tool which many lack experience using. It was predicted that motor resonance activity would increase as experience with the tool was acquired. Participants underwent a baseline functional magnetic resonance imaging (fMRI) session in which a video of skilled chopstick use was presented. Following, four weeks of training was performed utilizing chopsticks to accomplish a skilled motor task. During training, participants picked up a marble from the bottom of a cylinder and dropped it into the top of the cylinder, repeating this action as quickly as possible. Behavioral measurements of task performance were recorded and eye movements were tracked to verify skill acquisition. Following training, a second fMRI scan was performed using an identical paradigm as the baseline scan and the neural activity obtained pre- and post-training was compared. Both behavioral and eye-tracking data confirmed all participants significantly improved in the use of chopsticks over the training period. When comparing baseline fMRI activity to post-training activity, significant differences within regions previously identified as exhibiting motor resonance (M1 and PM) were observed. This data confirm the hypothesis that motor resonance, as it is related to tool use, is dependent on extensive experience similar to non-human primates. These findings suggest that although humans are unique in their extensive repertoire of tool use capabilities, there is little evidence for a biological system supporting this ability, but rather that the motor resonance observed when using a variety of tools is likely the result of humanity's comprehensive experience with a variety of tools.

Title: Virtually perfect recall: An examination of the memory systems involved in the recall of complex virtual tool use

Authors: *K. A. FERCHO, A. RENO, T. BOSCH, L. A. BAUGH;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Tool use relies on three visual streams (the ventral visual stream, ventro-dorsal visual stream, and dorso-dorsal visual stream), as well as the frontal lobe to understand, plan, and execute tool movement. An essential component of tool use is the ability to recall tool mechanics to guide the interaction between the body and the tool. Using a virtual tool manipulated to hit targets appearing at various eccentricities during a functional magnetic resonance imaging (fMRI) task, this study explored the neural activity underlying the recall of virtual tool dynamics. Two groups of subjects participated in a single fMRI experiment consisting of two experimental conditions, each with a reversal and non-reversal block of trials. In the first condition (Vision), a visual schemata illustrating the relationship between hand and cursor position was provided. During the reversal trials, this information consisted of a stick pivoting around a center point connecting hand position and cursor position; therefore, leftward hand movements were required to hit targets appearing on the right. During the non-reversal trials, the relationship between hand and cursor was represented by a stick connecting hand position and cursor that translated with hand movement. The second experimental condition (No Vision) was identical to the first, but the stick was not made visible to participants. The first group of subjects completed the Vision condition last (Group 1); the second group of subjects performed the Vision condition first (Group 2). To monitor behavioral performance, subjects' hand movements were sampled throughout each trial. By comparing the activity elicited in the reversal conditions of Group 1 and Group 2, an examination of the neural correlates associated with recalling virtual tool dynamics was possible. When participants were using the virtual tool in the reversal condition, areas of neuronal activity consistent with tool specific declarative and working memory were observed when contrasting Group 1 and Group 2. Activity included areas of the ventral visual stream, the intraparietal sulcus, and the superior parietal lobule. During the non-reversal conditions, no evidence of memory recall was found. Behavioral data supported the neuroimaging results with recall related activity related to increased performance. The data suggests that the simpler non-reversal condition of virtual tool use did not require the same memory systems and assumed recall of tool dynamics as was utilized for the reversal condition. This study offers an examination of the brain regions involved in the recall of information required to utilize a complicated virtual tool.

Title: Persistent left hemisphere asymmetries in the structure of lower sensory and motor pathways in chronic right hand amputees

Authors: *H. PENG, C. M. CIRSTEA, S. H. FREY;
Psychological Sci., Univ. of Missouri-Columbia, Columbia, MO

Abstract: Background: Work in animal models indicates that deafferenting injuries precipitate experience-dependent structural changes at various levels of the central nervous system including major efferent (corticospinal, CST) and afferent (medial lemniscus, ML) tracts. We employ diffusion tensor imaging (DTI) and probabilistic tractography to identify changes in the CST and ML pathways in upper extremity amputees. Specifically, we ask whether the left hemisphere asymmetry exhibited by right-handers in tract structural organization is diminished following loss of the dominant right hand. **Methods:** DTI was collected in 19 (42% female, 48.2±13.1yrs) chronic (15.2±13.9yrs) traumatic right-hand amputees and 32 age-, sex-matched (38% female, 41.8±13.2yrs) healthy controls. All participants were right-hand dominant. We delineated the CST in each hemisphere by selecting a seed in cerebral peduncle with internal capsule waypoint and cortical terminus in Brodmann area 4 (based on the Jeulich Atlas). For the ML, the seed was placed in the brainstem with a waypoint in the thalamus and terminus in the Brodmann areas 1, 2, and 3. Fractional anisotropy (FA), mean diffusivity (MD), and tract volume were quantified separately for the 4 pathways' lower segments (between seeds and waypoints). DTI measures are reflective of myelin sheath integrity, axon diameter, axon density, and fiber organization. Inter-hemispheric asymmetries were quantified with a laterality index: LI=(Left−Right)*100/(Left+Right). **Results:** Controls displayed higher FA and lower MD for the left CST compared to the right CST ($p<0.001$ for both FA and MD), lower FA and lower MD for the left ML ($p<0.001$), but no differences in tracts volume ($p>0.05$). Amputees also showed no asymmetries in tracts volume ($p>0.05$). Despite chronic right hand absence, the amputees (like controls) showed higher FA and lower MD for the left CST ($p<0.001$) and lower FA ($p=0.03$) and lower MD ($p=0.005$) for the left ML. Ipsilateral ML FA correlated with time post-amputation ($r=0.52$, $p=0.02$). Based on LI, left hemisphere CST asymmetry was significantly larger in amputees than controls ($p=0.03$). **Discussion:** Our results highlight similar left hemisphere CST and ML asymmetry in both controls and amputees. In amputees, the motor reorganization at the brainstem and internal capsule levels may account for larger left hemisphere CST asymmetry. The absence of changes in tracts volume is consistent with the

preservation of both inputs and outputs. Positive relationship between ipsilateral ML FA and chronicity may indicate increased use of the intact hand (as shown in previous motor practice studies, Sampaio-Baptista et al., 2013).

Title: Hydrogen sulfide plays a propyretic role during endotoxic shock

Authors: *R. RESTREPO FERNÁNDEZ[1], R. SORIANO[1], H. D.C. FRANCESCATO[2], J. SABINO[2], T. MACHADO COIMBRA[2], L. BRANCO[2];
[1]Physiol., Univ. De São Paulo, Ribeirao Preto, Brazil; [2]Physiol., Univ. De São Paulo, Ribeirão Preto, Brazil

Abstract: Thermoregulatory modulators are known to increase (propyretic) or decrease (antipyretic) the febrile response to lipopolysaccharide (LPS). Endogenous hydrogen sulfide (H2S) is produced in the preoptic area (POA) mainly by the enzyme cystathionine β-synthase (CBS). At low doses of LPS POA H2S levels are reduced and this molecule is a powerful antipyretic acting through suppression of prostaglandin E2 synthesis. Conversely nothing is known about the effects of doses of LPS high enough to cause endotoxic shock and both hypothermia and fever. Therefore, the aim of this study was to test the hypothesis that POA H2S production is increased during hypothermia and decreased during fever in response to high doses of LPS, and that these alterations correlate with the observed changes in body temperature (Tb). Adult male Wistar rats were anesthetized and submitted to median laparotomy so as to insert a temperature datalogger capsule (SubCue, Calgary, AB, Canada) into the peritoneal cavity to record deep Tb. After 7 days rats received intraperitoneal injection (ip) of saline (1 ml/kg, n=9) or (LPS 2.5 mg/kg, n=18). Tb was recorded (5-min intervals), starting 1 h before treatments and ambient temperature was set at 25°C. Rats were decapitated 85 minutes (hypothermia; n=9) and 180 minutes (fever; n=9) after ip injection and bilateral samples of the POA were excised with a punch needle for measurements of H2S levels. LPS caused typical hypothermia and fever. Levels of POA H2S in euthermic rats (ip saline) were 0.9575 ± 0.1925 μg/mg protein/h. H2S

levels were significantly decreased during hypothermia (0.6756 ± 0.2342 μg/mg protein/h, n=9; P< 0.0134) when compared to fever (1.105 ± 0.2986). We also investigated the putative effect of increased central bioavailability of H2S on Tb. After median laparotomy anesthetized rats were implanted with a guide cannula in the third ventricle for intracerebroventricular (icv) microinjection. Ip injection of saline (n=21) or LPS (n=22) was followed by icv administration of a donor of H2S (sodium sulfide, Na2S; 4 nmol/1 μl, n=13) or saline (1 μl, n=9). Tb was recorded. Na2S did not affect Tb control during euthermia (ip saline). Endotoxic rats and icv microinjected with Na2S had a significant increased Tb during hypothermia phase (289.6 ± 11.31 °C × min; P< 0.0104.) when compared to saline icv (242.1 ± 12.37 °C × min). We conclude that the gaseous messenger H2S modulates hypothermia and fever during endotoxic shock induced by high doses of LPS, acting as a propyretic molecule.

Title: NGF-induced PC12 cell differentiation and survival is inhibited by vasoinhibins

Authors: *Z. MELO, B. MORENO-CARRANZA, R. M. AROÑA, C. CLAPP, G. MARTINEZ DE LA ESCALERA;
Inst. de Neurobiologia, Univ. Nacional Autonoma de Mexico, Queretaro, Mexico

Abstract: Nerve growth factor (NGF) induces growth, differentiation and survival of peripheral neurons during embryonic development. Vasoinhibins (Vi) are a family of peptides derived from prolactin (PRL) that inhibit vasodilation and angiogenesis, functionally antagonizing the effects of various growth factors, including vascular endothelial growth factor (VEGF). In contrast to the abundant knowledge on the actions of Vi on endothelial cells, the information about the role played by Vi on the nervous system is limited. Vi have been detected in the SNC and are known to stimulate the release of vasopressin and to participate in the acute response to stress, increasing depression and anxiety-related behaviors. The aim of the present study was to evaluate the putative antagonistic action of Vi on the neurotrophic effect of NGF by measuring

survival and cell differentiation of PC12 pheochromocytoma cells. Our results show that the NGF-dependent neurite outgrowth is inhibited in the presence of human recombinant Vi. Vi (10 nM) reduced both the length and the density of NGF-induced neurites. PC12 cells infected with lentivirus carring a Vi gene were also resistant to the action of NGF (2 nM). Vi also reduced the metabolic activity, as determined by MTT assays, and increased apoptosis, as determined by DNA fragmentation measured by ELISA and TUNEL tests, in NGF-treated PC12 cells and NGF-treated Vi-expressing PC12 cells. These findings suggest that Vi perform a functionally antagonistic action over the effects triggered by NGF on periferal neurons, resulting in the abrogation of cell processes such as neurite outgrowth and survival.

Title: Artificial rearing condition affects the prolactin and growth hormone secretion in a primary culture of rat anterior pituitary cells

Authors: *C. G. TORIZ[1], C. SOLANO AGAMA[2], E. L. AGUIRRE-BENITEZ[3], A. MARTÍNEZ[5], I. JIMÉNEZ ESTRADA[2], J. HERNÁNDEZ FALCÓN[4], A. I. MELO SALAZAR[5], M. GONZÁLEZ DEL PLIEGO[3], M. E. MENDOZA GARRIDO[2]; [1]CINVESTAV-IPN, Mexico City, Mexico; [2]Dept. of Physiol. Biophysics and Neurosciences, CINVESTAV, México city, Mexico; [3]Dept. of Embryology, Fac. of Med., [4]Dept. of Physiol., Fac. of Med., UNAM, México city, Mexico; [5]CIRA, CINVESTAV-lab Tlaxcala, Tlaxcala, Mexico

Abstract: It is known (in rodents) that the communication between the hypothalamus and the pituitary is settling during the first two weeks of life, and any experimental manipulation or insult could affect the pituitary functionality. For example, Dwarf mice lacking somatotrophs

(growth hormones-secreting cell; GH) and lactotrophs (prolactin-secreting cells; PRL) exhibit a decrease in the number of tuberoinfundibular dopaminergic (TIDA) neurons, and low plasma levels of PRL. Exogenous administrations of PRL or GH prevent these effects. Furthermore, it is know that early in life there is an increment of PRL-cells and that bioactive compounds present in maternal milk during early lactation modified the number of these cells. It is believed that lactothophs originate from the somatotrophs through an intermediate phenotype cells known as somatolactotrophs (release GH and PRL). In pups that were separated from their mother and reared artificially (AR) we founded an increase in the serum levels of GH secretion at day 7 and a decrease of PRL secretion at 14 postnatal days (pnd). Also, we found an increase in the content of pituitary dopamine, without differences in the number of TH-positive hypothalamic neurons with regard to maternal rearing (MR) pups. Due to the above and because of lactotrophs secrete high levels of PRL in the absence of any hormone; we evaluated by a primary culture of rat anterior pituitary cells, whether there were differences in basal secretion. We found that there is an increase in the basal GH secretion at day 7 and a decrease in basal PRL secretion at day 14 in AR pups. These results are consistent with the previously observed at serum level. We also determined, by immunocytochemistry, the proportion of lactotrophs and somatotrophs cells in MR and AR pups of 7, 14 and 21 pnd. We did not find differences in the proportion of classic lactotrophs or somatotropes in all ages. We found a decrease in the proportion of somatolactotrophs cells (PRL/GH) at pnd 14, and an increase in the proportion of PRL-positive cells (PRL plus GH/PRL cells) at pnd 21. These results support the idea of importance of maternal milk in the process of maturation of the hypothalamic-pituitary axis.

Title: The spatial relationships between endocrine cells in the anterior pituitary gland and blood vessels

Authors: M. YOSHITOMI[1], K. OHTA[2], A. TOGO[2], K.-I. NAKAMURA[2], *M. MORIOKA[1]; [1]Kurume Med. Sch., Kurume/ Fukuoka, Japan; [2]Div. of Microscopic and Developmental Anat, Kurume Univ. Sch. of Med., Kurume, Japan

Abstract: The relationships between the endocrine cells and the endothelial cells in anterior pituitary gland are important for hormone releasing. Endocrine cells and endothelial cells in the anterior pituitary gland frequently make contact between them. Such close relationship between them in the anterior pituitary gland is generally considered to facilitate its efficient secretory functions. However, numerical and spatial relationships between them are still unclear. To understand the whole relationship between them, we obtained the compleat three-dimensional cellural structures of anterior pituitary tissue with electron microscopic resolution by scanning electron microscope (SEM) based 3D reconstruction method using focused ion-beam SEM machinary (FIB-SEM) and we first demonstrated that about 70% of endocrice cell have contact sites to the endothelial cells but almost 30% of endocrine cells are existed in the tissue completely isolated from the perivascular space. Our 3D analysis visualize the detail localization of secretory granules (SG) in endocrine cells. The reconstruction data showed that an accumulation of SG in the region near by the contact site to the blood vessel. However, the SG in the cell which isolated from the perivascular region seems to be distributed uniformly in the cytoplasm. There is a significant difference between the cells which have contact to the vessel or not when we compared the vector quantity from center of gravities of whole cell to the SG region. These data suggested that the cellular interaction between the endcrine cell and encdothrerial cell promote the uneven distribution of the SGs within the cytoplasm and there is a possibility of the novel interaction between them.

Title: Neuroendocrine characterization of cell lines derived from adult female mouse hypothalamus

Authors: S. F. BAMJI[1], B. N. RADDE[2], P. MULUHNGWI[2], C. M. KLINGE[2], *C. CORBITT[3]; [1]Biol., [2]Dept. of Biochem. & Mol. Genet., [3]Univ. Louisville, Louisville, KY

Abstract: Immortalized neural cell lines derived from adult female mouse hypothalamus have recently become commercially available (Cedarlane Labs), but their phenotypes are only partially characterized. Five of these hypothalamic cell lines (mHypoA-50, 51, 55, 59 & 63) appear to have an arcuate nucleus phenotype based on initial transcript screening done by others, *e.g*., all express estrogen receptors (*Esr1* and *Esr2*) and some also express kisspeptin, leptin receptor, and/or neuropeptide Y. Our goal is to develop a model to determine the effects of glyceollin (Gly) in the hypothalamus. Gly is a soy product known to have both estrogen receptor (ER) -mediated (mainly anti-estrogenic) and non-ER mediated effects both *in vivo* and *in vitro* (primarily studied in cancer cells). We reported that i.p. administration of Gly affects expression of over 250 gene targets in female mouse brain. Several Gly targets (*Esr1*, *Esr2, Gper1, Nr4a1, Gh*, *Prl* and *Kiss1*) are made in arcuate nucleus. Using real-time qPCR, we report the first 4 targets are expressed by all 5 mHypoA cell lines in both basal and estrogen-stimulated conditions. We detected *Gh* in all cell lines, *Prl* in mHypoA-50, 51 & 59 and *Kiss1* in mHypoA-55, 59 & 63, although transcript levels were low compared to *Esr1, Esr2, Gper1*, and *Nr4a1*. Based on consistency of target detection and estrogen responsiveness, we conclude that mHypoA-55 & 63 cell lines are suitable for studying effects of Gly on both ER- and non ER-mediated pathways in hypothalamus.

Title: Perinatal ethanol exposure alters the hypothalamus-pituitary-thyroid axis

Authors: *A. J. HOLDERMAN[1], R. LAWRENCE[2]; [1]Viterbo Univ., Amherst, WI; [2]Biol., Viterbo Univ., La Crosse, WI

Abstract: Developmental ethanol exposure is the leading cause of preventable developmental disabilities and produces dysfunction similar to hypothyroidism. Alcohol exposure has been linked to alterations in thyroid function, however, the specific location of the hypothyroid-pituitary-thyroid (HPT) axis and epigenetic mechanism has not been identified. We hypothesized the perinatal ethanol exposure would cause a change in the competency of the HPT axis. To determine this, we measured circulating TSH of the blood and TSH-β gene expression in the thyrotrophs of the anterior pituitary. A three trimester ethanol exposure model was used to best approximate human exposures. Pregnant Long Evans rats were divided into three groups: ethanol treated, intubated (stressed) control, and no treatment control. Once the pups matured, the blood, pituitary glands, and thyroid glands were collected. Using an Elisa assay kit, circulating levels of TSH were significantly elevated in the ethanol treatment group compared with the intubated control suggesting perinatal ethanol exposure mimics congenital hypothyroidism disorder potentially due to epigenetic alterations in TSHβ gene.

Title: Neurokinin 3 receptor associates with transcription factor c-Fos and nuclear proteins in paraventricular neurons of the hypothalamus following osmotic challenge in rats

Authors: *A. THAKAR[1], T. R. MORDHORST[2], F. W. FLYNN[2];
[1]Neurosci. Program, [2]Univ. of Wyoming, Laramie, WY

Abstract: Neurokinin 3 receptor (NK3R) is a G protein-coupled receptor that is widely expressed in brain and colocalizes with vasopressinergic neurons in the paraventricular (PVN) and supraoptic nuclei of the hypothalamus. We demonstrated that in response to hyperosmolarity, membrane-bound NK3R are activated, internalized to the cytoplasm, and translocated to the nucleoplasm of PVN neurons. Using co-immunoprecipitation (Co-IP) we showed that in nucleus, NK3R forms a complex with P300/CBP-associated factor (PCAF) and

acetyl-H3K9, and modifies chromatin structure and gene transcription. We next sought to determine if proteins with DNA binding motif, i.e. transcription factors, combined with NK3R in this complex. Male Charles River Laboratory rats were maintained on water or 2% NaCl, and chow (n=5/group) for 3 days. The rats were euthanized, the brain sectioned using a vibratome, and the PVN was isolated via micro punch (0.94 mm dia). PVN punches from rats in the same treatment group were combined, homogenized, and the nucleoplasm isolated. PCAF was conjugated to magnetic beads and used to pull down nuclear protein complexes. After elution, samples were probed for NK3R and then the following nuclear proteins: PCAF, c-Fos, GCN5, and acetyl-H3K9. Co-IP results showed that PCAF pulled down NK3R, c-Fos, β-actin, and acetyl-H3K9 in PVN samples from rats maintained on 2% NaCl, but not in control rat samples. The membrane was also probed for secretory carrier membrane protein 5 (SCAMP5) and, as expected, this protein was not present in the pulled down samples. We identify that the transcription factor c-Fos is pulled down by PCAF along with NK3R in nuclear samples from rats maintained on 2% NaCl. These data indicate that in response to an osmotic challenge (2% NaCl) NK3R are activated and translocated to the nucleus where NK3R forms a complex with PCAF to acetylate histones. Acetylation of histones relaxes chromatin structure and would allow for the recruitment of transcription factor c-Fos to specific promoter sites. Hyperosmolarity increases vasopressin and c-fos gene expression (Kawasaki et al., 2009). Interestingly, AP1 site is present on vasopressin promoter and c-Fos mediated increase in vasopressin gene promoter activity has been shown (Yoshida et al., 2008). Overall, our results suggests that within the complex, the role of NK3R may be to further target the binding of transcription factor c-Fos at AP1 site on VP promoter via selective histone acetylation by PCAF.

Title: Neuromorphological reconstruction using Brainbow reveals novel target regions innervated by magnocellular hypothalamic neurons in zebrafish larvae

Authors: *U. HERGET[1], A. GUTIERREZ-TRIANA[2], S. RYU[1];
[1]Max Planck Inst. For Med. Res., Heidelberg, Germany; [2]Ctr. for Organismal Studies, Heidelberg, Germany

Abstract: In vertebrates, a specialized group of hypothalamic neurons innervates the neurohypophysis, releasing arginine vasopressin (Avp) or oxytocin (Oxt) into the bloodstream. These neurons are called magnocellular due to their soma size, and are located mainly in the paraventricular (PVN) and supraoptic (SON) nuclei in rodents. Many studies in rodents have described important features of magnocellular neurons, yet their projections aside from pituitary innervation remained elusive. Recent advances have demonstrated the presence of central amygdala innervation by Oxt-producing cells in rats, but a comprehensive projectome analysis of magnocellular neurons is currently lacking since magnocellular neurons are difficult to access due to their deep location in the mammalian brain. Zebrafish larvae offer the possibility to investigate the entire brain in intact and living animals without the need for surgery or sectioning and therefore provide an opportunity to analyze structural and functional features of readily accessible hypothalamic neurons. In this work, we analyzed the 3D morphology of cells producing Avp or Oxt using genetic tools to specifically express Brainbow in the PVN-homologous region in larval zebrafish, the neurosecretory preoptic area (NPO). Brainbow was targeted to NPO cells using both an Oxt promoter and a conserved regulatory element of the transcription factor Orthopedia. Using inducible Cre recombination, the Brainbow cassette consisting of transgenes coding for different fluorescent proteins (XFPs) covering multiple colors is randomly recombined to express a different XFP in neighboring cells, thereby allowing the spectral separation of intermingled fibers. This approach shows the different long-range projections, which are difficult to analyze in rodent brains due to the need for histological sectioning. 3D reconstruction in Amira using a skeletonization plugin revealed the morphology of individual cells and their innervated target regions. Preliminary results show that Oxt-positive projections can reach into the tectum, the hypothalamus, and the telencephalon. Some broadly innervating Oxt-positive cells feature projections that cross the midline to the contralateral side. Our results suggest novel target regions innervated by these cells in several parts of the brain, providing insights into the potential structural basis of the many functions suggested for Oxt neurons. The detailed neuromorphological and hodological characterization of magnocellular cells established in this work provides the basis for the first comprehensive projectome analysis of Avp or Oxt-producing neurons in vertebrates.

Title: Hypertonicity-sensitive theta oscillations in hypothalamic paraventricular nucleus and intracerebral projecting axon-collaterals of individual vasopressinergic magnocellular neurons using *in vivo* extracellular recording and juxtacellular labeling and neuroanatomy methods

Authors: *V. S. HERNANDEZ, M. M. MARQUEZ, E. VAZQUEZ-JUAREZ, L. ZHANG; Dept. of Physiology, Fac. of Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: Conventional neuroanatomical, immunohistochemical and *in vitro* recording and labeling methods may fail to detect long range intracerebral-projecting axons of vasopressinergic (AVP) magnocellular neurosecretory neurons (MNNs) of the hypothalamic paraventricular nucleus (PVN). Here, by using *in vivo* extracellular recording and juxtacellular labeling, we show that MNNs possessed multi-axon-like processes and axonal collaterals branching very near to the somata, projecting intracerebrally to areas including the medial preoptical area, suprachiasmatic nucleus, lateral habenula, medial and central amygdala and to the conducting systems such as stria medullaris, the fornix and the internal capsule. Axon-collaterals were detected to express vesicular glutamate transporter 2. Under basal condition, local field potential (LFP) recorded inside PVN showed spontaneous theta rhythms (4-6Hz). Hypertonicity induced increase in power and frequency. Furthermore, *in vivo* activation of AVP-MNNs by hypertonic saline administration produced significant reduction of freezing behavior and an increase in active escaping, measured as climbing, rearing and displacement, during live cat exposure. Modified Fos expression patterns during fear processing in hypothalamus, amygdala, thalamus and LHb were also observed. Our data demonstrate that AVP-MNNs possessed multiple axon-like processes and the long-range intracerebral projection is a more common feature of the MNNs, than an “occasional” phenomenon as previously thought. These magnocellular AVP-glutamatergic non-canonical pathways found here may constitute a part of the central motivational circuit activated under multifaceted stress coping. The origin, physiological significance of the theta rhythms recorded inside the PVN and its modification by hypertonicity remain to be determined.

Title: Perinuclear organization of neurokinin B terminals at NK3 receptor expressing neurons in the paraventricular nucleus

Authors: T. R. MORDHORST, R. GRENVIK, A. THAKAR, *F. W. FLYNN;
Neurosci Prgm, Univ. Wyoming, Laramie, WY

Abstract: The tachykinin neurokinin 3 receptor (NK3R) is expressed by the majority of vasopressin magnocellular neurons in the paraventricular nucleus of the hypothalamus (PVN). Injections of NK3R antagonists prevent the release of vasopressin and c-Fos expression in response to hypotension and hyperosmolarity. Neurokinin B (NKB) is the endogenous tachykinin with the highest affinity for NK3R while substance P (SP) has a much lower affinity. Previous reports indicate that NKB terminals and fibers are found in the PVN, but their detailed relationship to NK3R-expressing neurons, most likely vasopressinergic, was not described. We used double label immunohistochemistry to identify the innervation of NK3R by NKB and SP. Images of NK3R expressing neurons in the posterior magnocellular PVN were captured using confocal laser scanning microscopy. A region of interest (ROI) was drawn around the cluster of NK3R magnocellular neurons and the area of NKB fluorescence was measured in the ROI and an equal area in the perinuclear area that was devoid of NK3R soma. There was limited NKB immunoreactivity in the NK3R ROI. NKB immunofluorescence in the perinuclear area surrounding the ROI was approximately 4x greater than that measured in the ROI containing NK3R expressing neurons. NKB immunofluorescence was 10x greater in the dorsal ROI and dorsal perinuclear area than in the corresponding ventral regions. Within the NK3R expressing ROI, very few NKB terminals contacted NK3R soma or dendrites. In contrast, SP immunoreactive terminals distributed throughout the area of NK3R expressing neurons. This anatomical arrangement suggests that SP may activate NK3R. To test this hypothesis, CHO cells

were transfected with a NK3R plasmid and calcium imaging was used to test the effects of SP, NKB, and senktide, a NK3R agonist. NKB and senktide (1 nM) elicited a large calcium response, but SP had no effect. In addition, we tested the morphological effects of application of SP, NKB, and senktide on transfected and nontransfected CHO cells. NKB and senkitde (0.01, 0.1, 1.0 nM) caused a morphological rearrangement of transfected CHO but not in non transfected cells; SP had no effect. These results indicate that while SP, rather than NKB, terminals are proximal to NK3R, SP does not appear to activate NK3R. Oldfield and Silverman (Brain Res Bull, 1985, 14, 143-57) previously reported that limbic system structures project to the PVN in a perinuclear fashion and the dense NKB terminals surrounding NK3R expressing neurons may arise from these structures. Furthermore, the anatomical relationship of NKB and NK3R suggests a local volume transmission mode of NKB action at NK3R expressing vasopressin neurons in the PVN.

Title: A novel DiI staining methodology to examine effects of estradiol on dendritic spine morphology in the arcuate nucleus of the female rat

Authors: *L. M. RUDOLPH, P. E. MICEVYCH;
Dept. of Neurobio., Univ. of California Los Angeles, Los Angeles, CA

Abstract: In female rats, estradiol promotes morphological changes in the arcuate nucleus of the hypothalamus (ARH) critical for lordosis behavior. Specifically, dendritic spine formation in ARH neurons is required for estradiol-induced sexual receptivity. This estradiol induction of lordosis behavior is mediated by two changes in dendritic spine morphology. First, estradiol benzoate (EB) rapidly induces the formation of immature, filapodial spines within ~4 h, a process initiated by membrane signaling. Secondly, there is a shift from immature filapodial to mature mushroom spines 30-48 h after EB treatment. The increase in the proportion of mushroom spines coincides with the period of maximal lordosis behavior, suggesting that it is

not the initial formation of spines, but the maturation of dendritic spines that is responsible for the exhibition of sexual receptivity. While it is clear that mature spines in the ARH are necessary for lordosis, the pre-and post-synaptic roles in synapse formation, maturation, and stabilization are unclear. Furthermore, current methods used to examine dendritic morphology of arcuate neurons have multiple limitations: Golgi histology uses toxic chemicals and stains a random assortment of cells, crystal implantation of the lipophilic tracer 1,1'-dioctadecyl-3,3,3',3'-tetramethylindocarbocyanine perchlorate (DiI) involves an extensive incubation period (e.g., months) for dye transport, and DiI labeling using gene guns (diolistics) is costly. To examine the morphology of dendritic spines in the ARH and circumvent these issues, we developed a novel technique of fluorescently labeling neurons using, DiI. DiI crystals were dissolved in ethanol and further diluted in phosphate-buffered saline (PBS). Perfused and fixed brains were blocked and sectioned at 200 μm on a vibratome and incubated in the DiI solution for 1 h, rinsed, and incubated overnight in PBS at 37°C. Sections were mounted and coverslipped with glycerol, sealed, and stored in the dark at 4°C until analysis with confocal microscopy. This technique allows for assessment of spine structures without additional equipment or prolonged incubation times, and can potentially be combined with immunocytochemistry to assess changes in spinogenesis and spine morphology in the ARH to understand the molecular mechanisms of estradiol-induced, spine-dependent expression of female sexual receptivity.

Title: The effect of diet-induced obesity on estradiol-induced hormonal surges in female rats

Authors: *S. BLYTHE[1], A. E. GONZALEZ-IGLESIAS[2], R. BERTRAM[3], G. WHITWORTH[1], N. TOPORIKOVA[1];
[1]Biol., Washington & Lee Univ., Lexington, VA; [2]Neurosci., [3]Mathematics, Florida State Univ., Tallahassee, FL

Abstract: Over the past 20 years, obesity has become a major global health crisis, as it is associated with a number of medical problems including reduced fertility. Indeed, obesity in

women can lead to irregularities in the menstrual cycle, polycystic ovarian syndrome, and reduced conception rates. Therefore, we have characterized the effect of diet-induced obesity on the amplitude and timing of estradiol-induced hormonal surges. Juvenile female rats consumed a control diet or a high sugar, high fat (HSHF) diet from weaning. After 10 weeks on their respective diets, ovaries were removed from all of the animals (OVX) and then half were implanted with slow-release estradiol pellets (OVXE). At termination, HSHF rats weighed significant more than the control diets animals, and OVXE rats weighed more than OVX rats. HSHF animals also exhibited greater levels of abdominal fat and insulin resistance as compared to control rats. Finally, trunk blood samples were collected at 11 am, 2 pm, 5pm, 8 pm and 11 pm. Blood prolactin was measured with radioimmunoassay. In all OVXE rats the daily prolactin surge was induced; however, the amplitude of the surge was significantly lower in animals on HSHF diet. Aberrant prolactin signaling has been linked with reproductive difficulties and may represent a novel target for therapeutic intervention in obesity-related infertility.

Title: Ovarian steroids regulate gene expression in the dorsal raphe of old female macaques

Authors: S. G. KOHAMA, *C. L. BETHEA, A. P. REDDY, H. F. URBANSKI;
Oregon Natl. Primate Res. Ctr., Beaverton, OR

Abstract: With extended lifespans in modern humans, menopause has become a significant risk factor for depression, anxiety, loss of cognitive functions, weight gain, metabolic disease, osteoporosis, cardiovascular disease and neurodegenerative disease. Clinical studies have found beneficial neural effects of ovarian steroid replacement (HRT) during the menopausal transition and data are emerging which suggest that these benefits can be sustained long-term. To further understand molecular underpinnings of the clinical studies, we used qRT-PCR to examine gene expression in the serotonergic dorsal raphe related to depression, cellular resilience and neurodegenerative disease. Old rhesus macaques (>21 yrs) maintained on a low fat and low sugar diet were ovariectomized (Ovx, surgically menopausal). Immediately after Ovx, groups of animals (n=5) were administered placebo, estradiol (E) or E + progesterone (E+P), which was continued for ~4 years. Significant beneficial changes were observed in 36 out of 48 genes examined. Increased expression was observed in mRNAs that encode proteins supporting serotonin neurotransmission (FEV.TPH2.CRFR2.UCN1), synapse assembly (NLGN3.NTRK.SNAP5.NCAM), glutamate neurotransmission (NMDA2a.AMPA2.GRM1), DNA repair (NBS1.NTHL.LIG4.RAD23.APEX1.DISS1), chaperones (HSP90B1.HSP60.HSP27), ubiquinases (UBE1.UBE2D3.UBE3A) and transport motors (KIF5.DCTN4.DYNCL1). Decreased expression of two mRNAs encoding proteins involved in neuropathology was also observed (APP.PSEN1). The data show that HRT maintains beneficial effects on gene expression in the serotonin system of old macaques after long-term treatment. Alternatively, the loss of ovarian steroids leads to decreased transcription at the gene level that may in turn lead to many of the observable neural deficits in serotonin target systems.

Title: The hormone prolactin is a novel survival factor for the retinal pigment epithelium through anti-oxidant actions

Authors: S. THEBAULT, *A. MARTINEZ-TORRES, R. MELÉNDEZ GARCÍA, D. ARREDONDO ZAMARRIPA, N. ADÁN, E. ARNOLD, G. BAEZA CRUZ, J. R. RIESGO-ESCOVAR, B. ORDAZ, F. PEÑA-ORTEGA, C. CLAPP;
INB-UNAM, Queretaro, Mexico

Abstract: Retinal pigment epithelial (RPE) cells form a polarized monolayer that is adjacent to the photoreceptors and indispensable for vision. Degeneration of RPE cells results in retinal disorders such as age-related macular degeneration. Because a major feature of this disease is the increased formation of reactive oxygen species (ROS), the identification of endogenous factors able to protect RPE cells from oxidative stress is important. Cell transplant strategies have potential therapeutic value for such disorders but an inadequate supply of donor cells limits their therapeutic success; therefore, identifying factors that help RPE cells to proliferate could provide a renewable source of cells for transplantation. Since we detected the hormone prolactin (PRL) and its receptor in RPE cells and previous studies reported PRL to be a survival factor, we postulated that RPE cells are a target for the PRL trophic effect. Using a cell line derived from human RPE (ARPE-19), we showed that conditioned medium from ARPE-19 monolayers contains PRL and that a specific anti-PRL antibody or a competitive PRL receptor antagonist reduces ARPE-19 cell viability. Also, we found that PRL prevented both the reduction in viability and proliferation and the increase in apoptosis of ARPE-19 cells induced by the oxidant hydrogen peroxide. ARPE-19 cells were also protected from hydrogen peroxide when PRL was applied after the oxidant. We further observed that PRL up-regulated the mRNA levels of the anti-oxidant glutathione S-transferase and reduced intracellular ROS levels in the presence of the oxidant. Because we detected the Transient Receptor Potential Melastatin 2 (TRPM2) channels in ARPE-19 cells and Ca2+ influx through TRPM2 in response to ROS promotes cell death, we examined the role of TRPM2 in the protective effect of PRL. TRPM2 inhibition by 3-aminobenzamide or TRPM2 silencing siRNA protected ARPE-19 cells from hydrogen peroxide-induced apoptosis. PRL also prevented the hydrogen peroxide-induced intracellular Ca2+ increase. Notably, RPE cells from mice lacking the PRL receptor showed reduced levels of glutathione S-transferase and higher levels of ROS and apoptosis than RPE cells from wild-type animals. This latter effect was exacerbated in aging animals. Taken together, these results indicate that PRL is a novel endogenous survival factor for the RPE that is able to protect it from oxidative damage.

Title: Amylin induces neurogenesis-like processes in the AP of adult rats

Authors: *C. LIBERINI[1], C. NEUNER BOYLE[2], T. A. LUTZ[3];
[1]Univ. of Zurich, Zürich, Switzerland; [2]vetsuisse faculty, Institue of Vet. Physiol., University of Zurich, Switzerland; [3]vetsuisse faculty, institue of Vet. Physiol., university of Zurich, Switzerland

Abstract: The area postrema (AP) is a sensory circumventricular organ characterized by extensive fenestrated vasculature and neurons which are capable of detecting circulating signals of osmotic, cardiovascular, immune and metabolic status. The peptide-hormone amylin is co-secreted with insulin by pancreatic β-cells in response to nutrient stimuli. Next to its role in the inhibition of glucagon secretion and in delaying gastric empting, amylin acts as a satiation signal by activating specific amylin-sensitive neurons in the AP. Moreover, amylin has been shown to promote the formation of neuronal projections originating from the AP. Thanks to the development of next-generation sequencing (NGS) technologies, systematic transcriptome analysis is now a highly sensitive approach to investigate changes in genetic expression. Here, RNA-sequencing was used to assess the influence of amylin on gene expression in the rat AP. Animals were treated with vehicle (0.1 mL/injection volume, i.p.), amylin (20 μg/kg, i.p.) and the amylin antagonist AC187 (500 μg/kg, i.p), and rat APs were collected under different feeding situations (e.g., fasting and re-fed). Our findings revealed that amylin affects several biological pathways, the most representative being neurogenesis, nervous system development, neuron generation and differentiation, synaptic transmission and cell-cell signaling. Several target genes identified by the NGS analysis were independently validated using RT-qPCR. NeuroD1 (Neuronal Differentiation 1) was strongly up-regulated (15 fold change) in the AP of adult rats after amylin treatment and this response was successfully blocked by the administration of AC187. Gabrb3 Gamma-Aminobutyric Acid (GABA) A Receptor, Beta 3), Gabra2 (GABA-A Receptor, Apha 2) and Gabrd GABA-A Receptor, delta) were also up-regulated in the same conditions; on the other hand, WNT4 (Wingless-Type MMTV Integration Site Family, Member) was consistently down-regulated by amylin treatment in food-deprived rats. Overall, because those genes were differentially expressed in the AP of adult rats, this suggests that amylin might mediate neurogenesis-like processes during adulthood in the AP.

Title: Characterization of the HAP1-immunoreactive cells in the subiculum and retrohippocampal formation in rat

Authors: *G. WROBLEWSKI, M. N. ISLAM, R. FUJINAGA, M. R. JAHAN, C. MATSUO, J. NEMOTO, K. TANAKA, K. ISHII, A. YANAI, K. SHINODA;
Yamaguchi Univ. Sch. of Med., Ube, Japan

Abstract: Huntingtin-associated protein 1 (HAP1) is a neural huntingtin interactor with putative protective functions against some neurodegenerative diseases. HAP1-immunoreactive (ir) neurons are abundant in the hypothalamus and some limbic regions and have also been characterized in the hippocampus as “sporadically lurking HAP1-ir (SLH)” cells, which express estrogen receptor (ER) α and are likely involved in memory function. In the present study, using paraformaldehyde-fixed frozen sections of adult male Wistar rat brains (9W), HAP1 expression was analyzed immunohistochemically in two additional memory-associated regions: (1) the subiculum and (2) the retrohippocampal formation, including the subiculum-associated complex (SAC) (post-, pre- and parasubiculum), and medial/lateral entorhinal, perirhinal and retrosplenial cortices. HAP1-ir cells were present in all regions and confirmed as neurons through double immunostaining with NeuN. Most intriguing, however, were two distinct HAP1-ir cell-dense zones. The first was a thin, continuous line of intensely-stained neurons in layer V of SAC just inferior to the lamina dissecans, most containing HAP1-ir stigmoid bodies (STB) in the cytoplasm. While no such layer was present in the bordering subiculum, entorhinal and retrosplenial cortices, the cells spanned the entire SAC and were thus dubbed the “SAC HAP1-ir layer (SACHL).” The second was a band of densely-packed, light-to-moderately-stained neurons without clear STBs, which coincided with layers II/III of the retrosplenial granular cortex (RSG) and was termed the “HAP1-ir retrosplenial granular band (HRGB).” Both structures were immunonegative for calbindin (CB), parvalbumin (PV), Wfs1 and ERα, with only minor exception. Solitary, intensely HAP1-ir neurons were also scattered through nearly every layer of the subiculum and retrohippocampal and neighboring cortices, but in general, none of the cells immunostained for CB, PV, or Wfs1. Most of the sporadic ERα-ir neurons, however, coexpressed HAP1 - particularly in superficial layers - resembling SLH cells in the hippocampus. The current study clearly showed that HAP1 is a distinct marker for both the SAC

and RSG, where the SACHL and HRGB, respectively, were first identified. The former could be the site of grid, border and head direction cells linked to proper orientation and cognition, while the latter might be associated with the precuneus in human, recently recognized as a compromised area in Alzheimer's disease. Thus, due to putative HAP1 protection, the HAP1-ir neurons detected in these memory-associated brain regions should be more stable against apoptosis in neurodegenerative disease.

Title: Interaction between serum and brain insulin like growth factor-1 participates in recovery after brain injury

Authors: *A. SANTI[1,2], L. GENIS[1,2], A. TRUEBA-SAINZ[1,2], R. HERRO[1,2], T. NISHIJIMA[1,2,3], J. PIRIZ[1,2,4], I. TORRES-ALEMAN[1,2];

Abstract: Brain insulin-like growth factor I (IGF-I) input arises from local sources (paracrine) and also from the periphery (endocrine), as this growth factor is taken up from the blood-stream. Because the functional significance of this dual origin of IGF-I neuroprotection is poorly understood, we examined the role of paracrine and endocrine IGF-I in the response to brain injury. We found that brain damage abrogated an inhibitory action that serum IGF-I exerted on the expression of brain IGF-I. Indeed, brain injury elicited increased IGF-I synthesis in the affected area. Furthermore, systemic administration of IGF-I to increase low serum IGF-I levels seen only in severely injured mice, lead to restored brain function. Collectively, these data indicate that brain injury reorganizes regulatory interactions between brain and circulating IGF-I to increase its trophic input in the affected region. These observations also support the use of serum IGF-I levels as a biomarker of brain injury severity.

Title: Membrane associated androgen receptor associated with G-proteins

Authors: ***J. G. CONTRERAS**[1], B. SNYDER[2], S. HOLMES[2], R. L. CUNNINGHAM[2]; [1]UNTHSC, Fort Worth, TX; [2]UNTHSC, Ft. Worth, TX

Abstract: Men have a two-fold risk for Parkinson's disease (PD) than women. PD is typified by the loss of dopamine neurons in the substantia nigra. Our previous studies show that testosterone, the major male sex hormone, can increase oxidative stress, calcium influx, and cell death in dopamine neurons. Furthermore, these studies showed that the membrane impermeable testosterone (T-BSA) also caused oxidative stress and cell death in dopamine neurons. Therefore, we hypothesize that a membrane bound receptor coupled to a G-protein receptor binds testosterone and mediates testosterone's negative effects on dopamine neurons. To test our hypothesis we used co-immunoprecipitation of membrane fractions from a dopaminergic cell line, N27 cells, and substantia nigral tissue from male rats to determine if the androgen receptor is associated with g-proteins., such as Gαq or Gαo subunits. Our results show that the androgen receptor is associated with both Gαq or Gαo subunits in the membrane fraction of N27 dopaminergic cells and in substantia nigral tissue. Thus, our data indicates that testosterone may induce a cell signaling cascade originating from a Gαq subunit, leading to increased oxidative stress, calcium influx, and cell death in dopamine neurons

Title: Maternal high fat diet consumption during pregnancy and lactation affects cholinergic anti-inflammatory pathway in offspring mice

Authors: T. BALIANI, S. F. LEMES, T. FANTE, A. REGINATO, C. M. SILVA, M. MILANSKI, A. S. TORSONI, *M. A. TORSONI;
Faculdade De Ciências Aplicadas/Unicamp, Limeira, Brazil

Abstract: Introduction: The acetylcholine binds to α7nAChR and reduce cytokines production through cholinergic anti-inflammatory pathway (CAP). The human obesity has been associated to increased inflammatory cytokines level and reduced nicotinic acetylcholine receptor (α7nAChR) expression in white adipose tissue (WAT). Maternal obesity predisposes offspring to obesity in the adulthood. We aimed to evaluate cholinergic anti-inflammatory pathway in mice of obese dams. Methods: Liver and WAT fragments were extracted from male offspring mice (Swiss) (28 days old-d28) of dams fed either control diet (SC-O) or high fat diet (HFD-O) during pregnancy and lactation. Leptin and cytokines levels, expression and phosphorylation of α7nAChR, JAK2/STAT3, and M1/M2 polarization of peritoneal macrophages (PM) were evaluated using ELISA, western blot, immunofluoresce and qRT-PCR, western blot, and immunofluorescence. Results: HFD-O mice presented higher body weight, WAT mass, blood leptin and TNFα level, and p-JNK1 in liver and WAT than SC-O mice. In addition HFD-O showed reduced expression of M2 markers (Chill3, IL-10, and ARG-1) compared to SC-O mice. α7nAChR expression, p-JAK2 and p-STAT3 were reduced in liver and WAT of HFD-O compared to SC-O mice. In SC-O mice α7nAChR protein was observed in both, macrophages (F4/80) and cells that did not express F4/80 protein, likely adipocytes and hepatocytes. However, the α7nAChR expression was not detected adipocytes of HFD-O mice. HFD-O mice showed reduced activation of CAP after challenger with either LPS (IP) or nicotine (ICV) compared to SC-O. Conclusion: HFD-O mice presented early inflammatory pathway activation and obesity, and reduced sensitivity of cholinergic anti-inflammatory pathway compared to SC-O mice.

Impair in cholinergic anti-inflammatory pathway can predispose to exacerbated inflammation and metabolic disorders in response to invaders and TLR4 activation

Title: *In vivo* electrophysiological evidence demonstrating the anti-opioid effect of the neuropeptide FF system

Authors: *J. KIM, C. H. BROWN, G. M. ANDERSON;
Univ. of Otago, Dunedin, New Zealand

Abstract: Agonists of the neuropeptide FF receptors (NPFFR1 and NPFFR2) have been generically termed “anti-opioids” for their putative ability to block opioid function. However *in vivo* evidence for this has been limited to nociceptive tests, which are confounded by the pronociceptive effects of the NPFFR ligands. To elucidate the functions of the NPFFRs, we first identified and characterised a true, potent, and selective antagonist, called GJ14. Next, we used the vasopressin neurons of the supraoptic nucleus as a model to examine the anti-opioid function of the NPFFR ligand, RFamide related peptide-3 (RFRP-3). In extracellular single-unit recordings from urethane-anaethetised rats, the spontaneous firing rate of vasopressin neurons was significantly reduced by morphine (i.v. 30 ug/kg). This inhibition was virtually abolished by pretreatment with RFRP-3 (i.c.v. 12 nmol) and morphine sensitivity was recovered 10 min after RFRP-3 treatment. Control rats receiving 3 consecutive morphine treatments alone did not show any change in morphine sensitivity. RFRP-3 alone had no effect on vasopressin neuron firing rate. A challenging notion is that chronic opioid treatment triggers the upregulation of these anti-opioid systems, which in turn attenuates the effect of morphine, thereby producing tolerance. To test this hypothesis, rats were given a continuous dose of morphine (10 mg/kg/day) via osmotic mini pumps for 6 days. Vasopressin neuron reponses to morphine (i.v. 30 ug/kg) were virtually absent in morphine-infused rats, confirming morphine tolerance. Pretreatment with GJ14 (i.c.v. 50 nmol) increased the sensitivity to morphine in vasopressin neurons of tolerant rats. In

summary, this is the first evidence demonstrating an anti-opioid function *in vivo* using electrophysiology. Furthermore using our novel antagonist, we report convincing evidence that the NPFFRs are an important part of a genuine anti-opioid system that regulates opioid sensitivity.

Title: Genetic variations in the glucocorticoid and mineralcorticoid receptor genes are associated with disrupted hypothalamic functional connectivity and elevated nocturnal cortisol secretion in depression

Authors: *K. D. SUDHEIMER, J. KELLER, R. O'HARA, G. MURPHY, A. F. SCHATZBERG;
Psychiatry, Stanford Univ., Palo Alto, CA

Abstract: Our group has recently demonstrated that patients with typical depression (NPMD) and patients with psychotic major depression (PMD) have reduced resting state hypothalamic functional connectivity (FC) with the subgenual cortex. Looser cortisol regulation, driven by genetic predispositions built into the structure of the cortisol receptors themselves, may play a key role in driving these reductions in FC. Here we demonstrate that a significant amount of the variance in hypothalamic connectivity to the subgenual cortex can be explained using measures of genetic variance in the two main cortisol receptors and measures of cortisol secretion during the evening hours Down-regulation of cortisol receptors is thought to play a key role in causing HPA axis dysregulation and producing the emotional/neurophysiological changes that accompany major depression. Genetic variability in cortisol receptors could increase/decrease susceptibility to these changes by altering the structure/sensitivity of the receptors. We have presented evidence that resting-state functional connectivity (FC) between the hypothalamus and the subgenual cortex (SGC) is disrupted in patients that have major depression with psychotic features and that these disruptions are associated with symptom severity. We hypothesized that genetic variability across the glucocorticoid receptor (GR) and mineralcorticoid receptor (MR)

would be associated decreases in hypothalamic FC to the SGC and elevated cortisol during the circadian nadir. 74 patients in 3 groups (healthy, major depression, psychotic major depression) had genetics data for 9 GR single nucleotide polymorphisms (SNP), and 14 MR SNPs. Backwards step-wise linear regressions were conducted to determine associations between genetic variance in GR or MR and hypothalamic FC to the SGC. The final GR regression model explained 36.2% of the variance in hypothalamic FC to the SGC $F(6,65)=7.72, p<0.001$. Higher cortisol, age, and 2 GR SNPs (rs41423247, rs2918419) were associated with more disrupted connectivity. A single GR SNP (rs12655166) was associated with less disrupted connectivity. The MR regression model explained 21.2% of the variance in connectivity $F(3,69)=7.46, p<0.001$. In this model, age and the MR SNP (rs5522) were associated with disrupted connectivity. These results indicate that genetic variability in the GR and MR genes could be affecting the neurophysiological networks associated with the symptoms and severity of depression.

Title: Glucocorticoid receptors in the arcuate nucleus mediate a fast feedback of corticosterone secretion

Authors: *L. A. LEON, D. HERRERA MORO CHAO, M. C. BASUALDO SIGALES, R. M. BUIJS;
Univ. Nacional Autonoma De Mexico, Distrito Federal, Mexico

Abstract: Precise control of the level of glucocorticoids in the circulation is necessary to regulate several physiological processes as the metabolism of glucose and lipids and the response to stress. Although the endocrine portion of the Paraventricular nucleus of the hypothalamus (PVN) has been proposed as one of the major centers involved in glucocorticoid regulation, there is ample evidence of a key role of the autonomic portion of the PVN in the control of the release of corticosterone (Cort) from the adrenal gland. We demonstrate here that the autonomic neurons of the PVN lack Cort receptors (GR) therefore we hypothesized the PVN may require an additional system to sense hormonal changes in the bloodstream. The arcuate nucleus of the hypothalamus (ARC), is a circumventricular organ that possesses GR type I and II and projects monosynaptically to the PVN. We investigated whether the ARC is able to detect and produce fast changes of Cort in the circulation in order to elucidate a neural pathway involved in the control of the adrenal production of Cort. We retrodialyzed pharmacological agonists or antagonists for GR type I and II bilaterally into the ARC and took blood samples to measure Cort and ACTH. We found that the GR antagonist produced a fast and sustained increase in Cort levels which was not accompanied by changes in total ACTH in the morning. On the other hand, when dialyzed in the afternoon, when the circadian peak is produced, we found a clear effect of the GR agonist on the levels of Cort. In addition, we retrodialyzed GR antagonist unilaterally to characterize the activation of the PVN after the infusion and examined the expression of per1 and CYP11A1 in the adrenal. The result was a clear unilateral activation of the PVN and an increased expression of the analyzed genes in one adrenal gland. Taken together, our findings demonstrate the importance of the arcuate nucleus to maintain accurate Cort levels, and suggest an autonomic neural pathway responsible for controlling the production of GC in the adrenal gland. Title: PARP-1 regulates neuroinflammatory phospholipase A2 (PLA2) and HMBG1 in alcohol-binged rat adult brain slice cultures

Authors: *M. A. COLLINS[1], N. TAJUDDIN[1], E. J. NEAFSEY[1], H.-Y. KIM[2];
[1]Mol. Pharmacol., Loyola Univ. Chicago, Maywood, IL; [2]Lab. of Mol. Signaling, NIAAA, Bethesda, MD

Abstract: Chronic/subchronic alcohol (ethanol) binges cause brain neurodegeneration via neuroinflammatory/neuroimmune mechanisms that likely require protein activators (cytokines; Crews et al. 2013) and lipid mediators (PLA2, arachidonic acid (ARA) and possibly downstream eicosanoids; Collins et al. 2014). Focusing on the lipid mediator processes, we have found elevated levels of Ca+2-dependent PLA2 (cPLA2 IVA), phosphorylated (activated) p-cPLA2, secretory PLA2 (sPLA2 IIA), aquaporin-4 (AQP4), and poly [ADP-ribose] polymerase-1 (PARP-1) that correlate with neurodegeneration in binge alcohol-treated rat organotypic hippocampal-entorhinal cortical slice cultures of adult brain age (~60 d; Tajuddin et al. 2014). Excessive ARA release by PLA2 could cause neurotoxic oxidative stress. Also, nuclear PARP-1 has DNA repair functions, but its overactivation can trigger a regulated necrotic neuronal death route (parthanatos). In that respect, we have reported that a potent PARP-1 inhibitor (PJ-34) affords neuroprotection in the alcohol-binged slice cultures. Here we examined whether PARP-1 might modulate levels of the above PLA2's and AQP4 (which is known to be linked to neuroinflammatory edema). The results with binge alcohol indicate that PARP-1 does not fuel elevations in AQP4; however, the nuclear enzyme is evidently upstream of cPLA2 and sPLA2, since PJ-34 completely suppresses both to about control levels. This may be the first evidence in brain for PLA2 levels being coupled to enhanced PARP-1. Furthermore, relevant to cytokine involvement, the PARP-1 inhibition significantly antagonized alcohol-induced increases in high mobility box group 1 (HMBG1) protein, an endogenous toll-like receptor-4 agonist associated with secretion of proinflammatory IL-1β. Thus, interconnected pro-oxidative necrotic cascades of neuroinflammatory phospholipid-derived and protein mediators induced by neurotoxic binge alcohol exposure could be dependent, at least in part, on a "master" regulator, PARP-1. Crews et al. (2013) Biol. Psychiat. 73:602-612; Collins et al. (2014) Mol. Neurobiol. 50:239-245; Tajuddin et al. (2014) PLoS ONE 9(7):e101223.

Title: Prenatal LPS exposure preferentially increases kynurenine pathway metabolism in the fetal brain

Authors: *F. M. NOTARANGELO, K. S. WONS, R. SCHWARCZ;
Maryland Psychiatric Res. Center, Dept of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Maternal infection during pregnancy increases the risk for the offspring to develop a broad spectrum of psychiatric disorders, including schizophrenia (Brown and Patterson, 2011). Prenatal exposure of mice to lipopolysaccharide (LPS) leads to brain and behavioral abnormalities in the offspring, but the underlying mechanisms are still unknown. The kynurenine pathway (KP) of tryptophan degradation is strongly regulated by the immune system (Saito et al., 1992) and may constitute a molecular link between immune activation and psychiatric diseases. Notably, the KP contains several neuroactive metabolites, including kynurenic acid (KYNA), an antagonist of the α7 nicotinic acetylcholine receptor and the N-methyl-D-aspartate (NMDA) receptor, and, in a competing branch of the pathway, the free radical generator 3-hydroxykynurenine (3-HK) and quinolinic acid (QUIN), an agonist of the NMDA receptor. In the present study, we evaluated the effect of an intraperitoneal injection of a low dose of LPS (100 μg/kg) on gestational day 15 on KP metabolism in CD1 mice. To this end, kynurenine, KYNA and 3-HK levels were determined in maternal plasma and brain, as well as in placenta and fetal brain, 4 and 24 h after the immune challenge. No differences in maternal body weight or number of embryos were observed between controls and LPS-treated mice. Moreover, KP metabolite levels were slightly elevated in placenta 4 and 24 h after LPS injection, but the increases did not reach statistical significance. In contrast, kynurenine levels were significantly increased in the fetal brain 4 h after exposure to LPS ($p<0.01$, $n=3$), compared to the control group, and were still elevated after 24 h ($p<0.05$, $n=4$). A similar trend was observed for KYNA and 3-HK levels, with significant increases seen 4 h after the LPS injection ($p<0.01$, $n=3$). Interestingly, this increase in KP metabolism was not observed in the maternal brain at this low dose of LPS, indicating a higher susceptibility of the developing brain to infection. These results suggest that even relatively modest prenatal immune activation, by increasing KP metabolism specifically in the fetal brain, may have detrimental long-term consequences during postnatal development. In particular, the observed elevation in KYNA levels in the fetal brain may increase the risk of developing psychiatric disorders later in life (Pocivavsek et al., 2014).

Title: Pleiotrophin differentially modulates microglial response and astrocytosis in LPS- and amphetamine-induced neuroinflammation

Authors: *G. HERRADON[1], C. PEREZ-GARCÍA[1], E. GRAMAGE[1], R. FERNÁNDEZ-CALLE[1], M. FERRER-ALCÓN[2], M. URIBARRI[2], M. VICENTE-RODRÍGUEZ[1]; [1]Pharmacol. Lab, CEU San Pablo Univ., MADRID, Spain; [2]BRAINco Biopharma, Derio (Bilbao), Spain

Abstract: Pleiotrophin (PTN) is a cytokine that is upregulated in CNS pathologies characterized by chronic neuroinflammation and has been shown to exert a pivotal role in some of these disorders including Parkinson's disease and drug addiction. Amphetamine-induced striatal astrocytosis is increased in PTN genetically deficient (PTN-/-) mice. In contrast, PTN is known to induce inflammatory mediators and its expression levels are significantly reduced by administration of anti-inflammatory drugs. Therefore, it is important to clarify the modulatory role of PTN in neuroinflammation. For this purpose, we have now comparatively studied the astrocytic and microglial responses to lipopolysaccharide (LPS) and amphetamine treatments in PTN-/- mice and transgenic mice overexpressing PTN in the brain cortex (PTN-Tg). In immunohistochemistry studies, we found that a single, very low, dose of LPS (0.5 mg/kg) induced a significant increase in the number of glial fibrillary acidic protein (GFAP)-positive cells only in the prefrontal cortex (PFC) of wild type (WT) mice compared to saline-treated animals. Amphetamine treatment (10 mg/kg, 4 times, every 2 h) did not alter the astrocytic response in the PFC of WT and PTN-Tg mice but it was found significantly down-regulated in PTN-/- mice. The data suggest that LPS- and amphetamine-induced astrocytosis is not directly regulated by endogenous PTN although alterations in the levels of endogenous PTN may cause compensatory mechanisms with some impact on the astrocytic response. Interestingly, we found that 0.5 mg/kg LPS is not sufficient to induce microgliosis in the PFC of PTN-/- and WT mice. However, LPS induced a significant increase in the number of CD11b-positive cells in PTN-Tg mice. On the other hand, amphetamine caused a significant up-regulation of microgliosis only in

the PFC of PTN-Tg mice although this effect was significantly lower compared with LPS-treated PTN-Tg mice. The data demonstrate that the endogenous levels of PTN are critically important to trigger microglial response after different insults and suggest that the known upregulation of PTN levels in different pathologies of the CNS may underlie the characteristic neuroinflammation of these disorders.

Title: Physical deformations of perivascular and meningeal spaces and immune cell activation caused by cortical spreading depression in the mouse

Authors: *A. SCHAIN, R. BURSTEIN;
Anesthesia and Critical Pain, Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: About 16% of the population suffers from migraine, and about a third of those have migraines that are preceded by abnormal sensory perception called aura. This aura is likely due to a brain phenomenon described in rodents as cortical spreading depression (CSD), where cascading neighboring neurons in the cortex become transiently hyperactive and then inhibited. When CSD is induced in rodents, it propagates over the cortex in minutes (at about 2-3 min/mm), and causes activation of meningeal nociceptors only after a delay (20-45 min), that is similar to the delayed onset of headache post aura in humans (20-60 min). It is not known how CSD activates meningeal nociceptors. In this study, we attempt to begin answering this question. Using time lapse multiphoton microscopy in live transgenic mice, we determine the effect of CSD on resident immune cells in the meninges, perivascular space, and intracranial tissues, and the effect of CSD on the these tissues. Using a thin-skull window, we observed CSD-induced phenotypic changes in macrophages, dendritic cells, and T-cells in each cranial layer (the pia, subarachnoid, dura, and skull endeosteum) as well as deformation of perivascular spaces. These findings provide a sequence of anatomical and cellular events that can lead to activation of meningeal nociecptors by CSD.

Title: Disturbance of neurobehavioral performance and dopaminergic neuronal injury in the adult rat brain following neonatal exposure to interleukin-1beta

Authors: ***L.-W. FAN**[1], L.-T. TIEN[4], Y. PANG[1], S. LU[1], H. ZHU[1], J. SHEN[1], J. P. SHAFFERY[2], X. DAI[3], A. J. BHATT[1], R. D. SAVICH[1];

Abstract: Our previous studies showed that interleukin-1β (IL-1β), an inflammatory cytokine, plays important roles in dopaminergic neuronal injury in the neonatal rat brain. To examine whether neonatal IL-1β exposure has long-lasting effects in adult rats, brain injury (postnatal day 70, P70) and motor functions (from P7 to P70) were examined after an intracerebral injection of IL-1β (1 μg/kg) in P5 Sprague-Dawley male rat pups. Our results showed that neonatal IL-1β exposure resulted in disturbances of motor behaviors including hyperactivity in the open field task, and dysfunction in the vibrissa-elicited forelimb-placing, movement initiation, pole and tapered/ledged beam walking tests. However, the impaired motor functions were spontaneously recovered on P70. On the other hand, neonatal IL-1β exposure caused a sustained activation of microglia and elevated IL-1β, IL-6 and Interferon-γ levels, as well as reduced tyrosine hydroxylase expression in the substantia nigra of P70 rats. These results indicate that exposure to IL-1β in the neonatal rats may cause sustained brain inflammatory responses, as well as long-lasting damage to the dopaminergic system in the adult rat brain. The finding that IL-1β induced brain injury was very similar to that induced by lipopolysaccharide (LPS) as we previously reported suggests that IL-1β may play a critical role in mediating brain injury associated with perinatal infection/inflammation.

Title: Diet-induced obesity prolongs neuroinflammation in latent herpes simplex virus-(HSV)-1 infected mice by increasing microglia activation and infiltrating monocytes

Authors: K. A. M. WHITE[1], S. R. HUTTON[2], *J. M. WEIMER[1], P. A. SHERIDAN[3]; [1]Children's Hlth. Res. Ctr., Sanford Res., Sioux Falls, SD; [2]Univ. of North Carolina Neurosci. Ctr., [3]Gillings Sch. of Global Publ. Hlth., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Obesity results in increased inflammation, susceptibility to infection, and has been linked with anxiety and cognitive impairment. Children raised in low socioeconomic status (SES) have diets higher in fat, are at greater risk for anxiety and learning difficulties, and are seropositive for herpes simplex virus-(HSV)-1 at a younger age than their higher SES counterparts. Previous studies from our lab have sought to determine how obesity alters neuroinflammation in mice latently infected with HSV-1. These studies found obesity prolongs inflammation in brains of latent HSV-infected mice, resulting in increased anxiety. In this study, we sought to determine the contribution of infiltrating monocytes to prolonged neuroinflammation in obese, latently infected mice. Weanling C57Bl/6 and $CCR2^{RFP/+}/CX3CR1^{GFP/+}$ mice were placed on a 10% low fat (LF) diet one week prior to receiving an intranasal HSV-1 or mock infection. Fourteen days post infection, mice were randomized to remain on the LF diet or switch to a 45% high fat (HF) diet. At various points following infection, the number and phenotype of infiltrating cells was determined using immunohistochemistry and flow cytometry. In comparison to both latently infected mice on the LF diet and uninfected mice on LF and HF diets, latently infected mice on the HF diet had

greater increased microglial activation and infiltration of inflammatory $CCR2^+$ monocytes in the hypothalamus and dentate gyrus. There was increased VCAM staining indicating an increase in the adhesion molecule expression in the areas of monocyte infiltration ($p<0.05$). Infiltrating monocytes also produced proinflammatory cytokines demonstrating that, along with activated microglia, monocytes contribute to sustained neuroinflammation in latently infected obese mice and may play a significant role in the anxiety phenotype of these mice. Together, these mice provide a useful, testable model to study the biobehavioral effects of obesity and latent HSV-1 infection in regards to anxiety and may provide a tool for studying diet intervention programs in the future.

Title: Acute Hyperbilirubinaemia induces Endoplasmic Reticulum (ER) Stress and NFκB driven neurodegeneration in a mouse model

Authors: *E. SCHIAVON[1], J. L. SMALLEY[2], I. D. FORSYTHE[2];
[1]Univ. of Leicester, Leicester, United Kingdom; [2]Cell Physiol. & Pharmacol., Univ. of Leicester, Leicester, United Kingdom

Abstract: Jaundice is caused by high levels of unconjugated bilirubin in the blood, that when severe cause toxicity and damage in susceptible brain areas (including the cerebellum and auditory brainstem). This results in ataxia and hearing loss and is also associated with cognitive deficits in humans with kernicterus. We developed an acute, rapid onset and reversible model of bilirubin toxicity using CBA/Ca mice. The model exhibits similar neurological problems to those seen in human BIND syndrome (Bilirubin-Induced Neurological Dysfunction) and correlated with deficits in auditory brainstem response (ABR) which is an *in vivo* measure of hearing

function. We compared whole genome gene expression measurements in the human neuronal SHSY5Y cell line and mouse brain tissue following bilirubin exposure, and combined this with Connectivity Mapping to gain mechanistic insights into the toxicity process. We found that bilirubin induces Endoplasmic Reticulum (ER) stress and up-regulation of strategic genes involved in the Unfolded Protein Response (UPR). Additionally there was striking similarity between bilirubin-induced changes and the well-known ER-stress-inducing chemical, Thapsigargin. This mouse model provides a reliable and rapid induction of hyperbilirubinaemia. The results show that bilirubin toxicity causes an inflammation in the auditory brainstem driven by non-canonical activation of NF-kB (Nuclear factor-kB). These observations highlight the role of neuroinflammation in mechanisms of central auditory disease and suggest convergence of common pathological signalling with neurodegeneration.

Title: IL-6 signaling exacerbates brain damage progression but reduces peripheral sickness measures following soman-induced status epilepticus

Authors: *J. IRWIN[1], L. SHUMWAY[1], J. CHANDLER[1], K. LAITIPAYA[1], T. FERRARA-BOWENS[1], M. WEGNER[2], E. A. JOHNSON[1];
[2]Comparative Pathology, [1]USAMRICD, Gunpowder, MD

Abstract: Severe neuropathology and behavioral impairment are a result of prolonged status epilepticus (SE) caused by organophosphorus compounds such as soman (GD). GD, a potent acetylcholinesterase inhibitor, causes prominent cell death in the hippocampus, thalamus, amygdala and piriform cortex, leading to the activation of the neuroinflammatory cascade. Neuroinflammation can exacerbate tissue injury or promote healing, depending on the intricate interaction of multiple cells, inflammatory factors and receptors as the injury progresses, a fact that has complicated the development of effective neuroprotective therapies for CNS injury models. IL-6 is a signaling protein known to be involved in many inflammatory and immune functions in both the periphery and brain and can produce both pro- and anti-inflammatory

effects. To determine which role IL-6 may play in central and peripheral GD effects, this study used wild type and background-matched IL-6 knockout mouse strains to identify changes acute neurodegeneration, mortality, convulsion onset and weight loss following GD exposure. The results showed that attenuation of IL-6 signaling does reduce brain injury following GD exposure though peripheral sickness measures were exacerbated as indicated by a significantly greater 24 hour weight loss compared to wild type controls. These data suggest that the pro- and anti-inflammatory effects of IL-6 may be highly dependent on central/peripheral localization of signals. Regardless, IL-6 inhibition does appear to be a viable neuroprotective strategy though further studies will have to better characterize the varying effects of IL-6 in different organ systems.

Title: Cerebellar inflammation and dysfunction in a rabbit model of cerebral palsy

Authors: *S. NARAYAN, Z. ZHANG, E. NANCE, S. KANNAN;
Anesthesiol. and Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Increasing evidence shows that apart from its motor function, the cerebellum is involved in higher cognitive functions and has functional connectivity to the frontal cortex. We have previously shown that intrauterine lipopolysaccharide (LPS) exposure induced white matter injury in the cerebrum, along with increased microglia and astrocytes activation, resulting in cognitive, motor, and behavior deficits that are consistent with clinical findings of cerebral palsy (CP). We have also shown that targeting activated microglia and astrocytes using dendrimer nanoparticles to deliver anti-inflammatory agents to these cells on PND1 resulted in improvement of their motor function. However, little is known about the presence and role of neuroinflammation in the cerebellum following a maternal intrauterine insult. Given recent data implicating cerebellar involvement in other delayed behavioral and developmental diagnoses, such as autism and cerebral palsy, the goal of this study is to determine whether exposure to

maternal inflammation *in utero* results in inflammation in the immature cerebellum and whether this is associated with motor and cognitive dysfunction in the juvenile rabbit. Time-pregnant New Zealand white rabbits underwent a laparotomy at gestation day 28. Endotoxin group received 8000 EU of LPS injection along the length of the uterus and control saline group received saline injection. Cerebellum from control saline and endotoxin groups were harvested at postnatal day (PND) 1 and 5. Presence and activation of microglia were detected by Iba1 immunohistochemistry staining, morphology characterized using Neurolucida, and inflammatory cytokine profiles were quantified by PCR and ELISA. Cerebellar learning was determined using the eye-blink conditioning response and compared between the CP and age matched control groups. We found that there was increased microglial 'activation,' as evidenced by increased numbers and change in morphology of microglia in the cerebellar white matter and the cerebellar nuclei (deep grey matter) in the PND 1 endotoxin kits when compared with the control saline kits. The potential for targeting activated microglia and inflammation in the cerebellum will be evaluated using dendrimer nanoparticles and localization, and distribution of these nanodevices in the cerebellum will also be determined.

Abstract: Cannabidiol (CBD), the major non-psychoactive constituent from Cannabis sativa, has antioxidant and anti-inflammatory properties which could be of potential therapeutical interest. Peroxisome proliferator-activated receptor (PPAR)-γ is a putative effector protein for CBD actions. Here, we aimed to further explore the mechanisms underlying CBD anti-inflammatory effects using a system model of mouse microglial cells, i.e., the resident immune cells of the brain. More specifically, we wished to determine (i) whether CBD was able to diminish oxidative stress in microglial cells stimulated by the bacterial inflammogen LPS (10 ng/ml) and (ii) whether PPARγ was involved in this effect. Our data show that CBD was able to diminish substantially the activation of microglial cells exposed to LPS (10 ng/ml) for 24 h. More specifically, CBD treatment led to reduced cellular expression of the microglial cell marker Iba-1 and to decreased production of reactive oxygen species measured with the fluorogenic probe CELLROX. Likewise, CBD limited the translocation of the p65 subunit of the major proinflammatory nuclear transcription factor NFκB after an acute stimulation of 30 min with LPS. Interestingly, all anti-inflammatory effects of CBD were antagonized by the PPARγ antagonist GW9662. Altogether, our data indicate that CBD attenuates LPS-induced oxidative stress in microglial cells through the activation of PPARγ and the repression of NFκB translocation.

Title: Toxic role of prostaglandin E2 receptor EP1 after intracerebral hemorrhage in mice

Authors: *J. WANG[1], X. ZHAO[1], T. WU[1], C. CHANG[1], H. WU[1], X. HAN[1], Q. LI[1], Y. GAO[1], T. MARUYAMA[3], J. ZHANG[2];

Abstract: Inflammatory mechanisms mediated by prostaglandins may contribute to the progression of intracerebral hemorrhage (ICH)-induced brain injury, but they are not fully understood. In this study, we examined the effect of prostaglandin E2 receptor EP1 (EP1R) activation and inhibition on brain injury in mouse models of ICH and investigated the underlying mechanism of action. ICH was induced by injecting collagenase into the striatum of middle-aged male and female mice and aged male mice. Effects of selective EP1R agonist ONO-DI-004, antagonist SC51089, and nonspecific Src family kinase inhibitor PP2 were evaluated by a combination of histologic, magnetic resonance imaging (MRI), immunofluorescence, molecular, cellular, and behavioral assessments. EP1R was expressed primarily in neurons and axons but not in astrocytes or microglia after ICH induced by collagenase. In middle-aged male mice subjected to collagenase-induced ICH, EP1R inhibition mitigated brain injury, brain edema, cell death, neuronal degeneration, neuroinflammation, and neurobehavioral deficits, whereas its activation exacerbated these outcomes. EP1R inhibition also was protective in middle-aged female mice and aged male mice after collagenase-induced ICH. EP1R inhibition also reduced oxidative stress, white matter injury, and brain atrophy and improved functional outcomes. Histologic results were confirmed by MRI. Src kinase phosphorylation and matrix metalloproteinase-9 activity were increased by EP1R activation and decreased by EP1R inhibition. EP1R regulated matrix metalloproteinase-9 activity through Src kinase signaling, which mediated EP1R toxicity after collagenase-induced ICH. We conclude that prostaglandin E2 EP1R activation plays a toxic role after ICH through mechanisms that involve the Src kinases and the matrix metalloproteinase-9 signaling pathway. EP1R inhibition could be a novel therapeutic strategy to improve outcomes after ICH.

Title: Quantitative SPECT/CT imaging of neuroinflammation in neurodegenerative disease models

Authors: T. HUHTALA, A.-M. ZAINANA, M. BJÖRKMAN, J. RYTKÖNEN, T. PARKKARI, *O. M. KONTKANEN, P. J. SWEENEY, A. NURMI;
Charles River Discovery Res. Services, Kuopio, Finland

Abstract: Neuroinflammation is associated with neurodegenerative diseases, including multiple sclerosis (MS), Parkinson's disease (PD), Alzheimer's disease (AD), Huntington's disease (HD), and traumatic brain injury (TBI). Activation of the mitochondrial Translocator Protein (TSPO) in neuronal tissue is linked with neuroinflammation and TSPO ligands can be applied to image the progression of neuroniflammation *in vivo* using SPECT or PET. For *in vivo* SPECT/CT imaging of neuroinflammation, 123I-CLINDE was selected as a radioligand. In previous preclinical and clinical studies 123I-CLINDE has been demonstrated to be specific TSPO ligand of inflammation. In the current studies, we assessed inflammatory changes in preclinical models of neuropathic pain, MS, and HD. To study neuropathic pain, the neuritis model was used. Freund's Complete Adjuvant was applied in Surgicel band around sciatic nerve in rats. Tactile and thermal allodynia were evaluated on Days 3, 7 and 9 after the induction. For MS, EAE induction was performed with the delivery with MOG1-125 in female Dark Agouti rats. To study neuroinflammation in HD, the R6/2 mouse strain, was selected. All animal models were selected because they have a well-characterized phenotype that reflects the disease state. In the neuritis model, there was a significant increase in ligand binding in injured hind leg on Day 4 and Day 5 after induction. In the EAE model, animals were assessed on Day 14 and Day 28 post inoculation. A clear accumulation of 123I-CLINDE was seen in cerebellum, brainstem and spinal cord in contrast to naïve animals where no ligand binding in the CNS was observed. Inflammation in the R6/2 mouse model of HD was studied at the age of 10 weeks. A Significant increase in 123I-CLINDE binding was seen in cortex, hippocampus, striatum, medulla and pons indicating activation of inflammation on those areas. In this study, we present usability of 123I-CLINDE combined with SPECT/CT imaging and gamma counter analysis to monitor progression on inflammation in several preclinical rodent models. These data provide support for the use of 123I-CLINDE as a non-invasive, readily translatable method to monitor inflammation.

Title: CD36 signaling in resident brain cells mediates post-ischemic brain injury by promoting free radical production in infiltrating neutrophils

Authors: *L. GARCIA-BONILLA, G. RACCHUMI, M. MURPHY, J. ANRATHER, C. IADECOLA;
Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: The class B scavenger receptor CD36 has been implicated in a wide variety of CNS pathologies (Exp Neurol, 261:633, 2014). After cerebral ischemia, CD36 signaling triggers an inflammatory response associated with brain leukocyte infiltration and damage (J Neurosci, 28:1649, 2008). However, it is unknown if CD36 in resident brain cells or peripheral leukocytes is responsible for its damaging effects. To address this question, lethally irradiated wild type (WT) or CD36−/− mice were transplanted with CD36−/− or WT bone marrow (BM) to generate chimeric mice with selective CD36 expression either in BM-derived cells or in brain cells. Five weeks later, mice underwent transient middle cerebral artery occlusion (MCAO; n=12/group) and injury volume was assessed 3d later in cresyl violet-stained brain sections. CD36−/− mice transplanted with WT BM (WT⇒CD36−/−) had reduced infarct volumes (18±1 mm3; Mean±SE), not different from those of CD36−/−⇒CD36−/− mice (14±1 mm3, p>0.05). Conversely, CD36−/−⇒WT mice had infarcts similar to those of WT⇒WT mice (48±8 mm3 vs. 50±9 mm3, p>0.05). Thus, ischemic damage is independent of CD36 in peripheral leukocytes. Brain flow cytometry was used to determine whether the reduced infarct volume was associated with reduced leukocyte infiltration 3d after MCAO. As anticipated, in CD36−/−⇒CD36−/− mice, in which infarcts are reduced (-72%), post-ischemic leukocyte infiltration (CD45high cells) was attenuated (9±2 x103 vs. 31±7 x103 vs. cell/hemisphere; p0.05), in which infarcts are not reduced. In WT⇒CD36−/− mice, the neutrophil number (CD45high/CD11b+/Ly6G+ cells) in the infiltrate was larger than in CD36−/−⇒CD36−/− mice (2±0.3 vs. 7±1 x103; p0.05). Since neutrophils contribute to ischemic injury by producing reactive oxygen species (ROS) (J. Immunol, 193:253, 2014), we next asked if CD36 in brain cells is required for neutrophil ROS production after MCAO. Despite similar infiltration levels, the number of neutrophils producing ROS in WT⇒CD36−/− was reduced compared to CD36−/−⇒WT mice (15±4% vs. 28±4% dihydroethidium positive neutrophils; p< 0.05). We conclude that CD36 in resident brain cells is required for ROS production by neutrophils and for their neurotoxic effect in the post-ischemic brain. Efforts to suppress post-ischemic CD36 signaling in brain cells may provide new approaches to reduce brain injury by mitigating the harmful effects of oxidative stress.

Title: Neonatal lipopolysaccharide-induced long-lasting learning impairment and hippocampal injury was attenuated by IL-1 receptor antagonist in adult rats

Authors: *L.-T. TIEN[1], Y.-J. LEE[1], J.-A. LEE[2], L.-W. FAN[3];
[1]Fu Jen Catholic Univ., Xingzhuang Dist., New Taipei City, Taiwan; [2]Taipei Med. Univ., Taipei City, Taiwan; [3]Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: We have previously reported that neonatal lipopolysaccharide (LPS) exposure resulted in inflammatory responses, as indicated by an increase in interleukin-1β (IL-1β) content, a hippocampal injury, and cognitive deficits in juvenile and female adult rats. The present study aimed to determine whether an anti-inflammatory cytokine, interleukin-1 receptor antagonist (IL-1ra), protects against the neonatal LPS exposure-induced inflammatory responses, hippocampal injury, and long-lasting learning deficits in adult rats. LPS (1 mg/kg) or LPS plus IL-1ra (0.1 mg/kg) was injected intracerebrally to Sprague-Dawley male rat pups at postnatal day 5 (P5). Neurobehavioral tests were carried out on P21, P49, and P70, while neuropathological studies were conducted on P71. Our results showed that neonatal LPS exposure resulted in learning deficits in rats, as demonstrated by a significantly impaired performance in the passive avoidance task (P21, P49, and P70), and reduced the hippocampal volume and number of NeuN+ cells (neurons) in the CA1 region of the middle dorsal hippocampus of P71 rat brain. LPS induced a sustained inflammatory response in the P71 rat hippocampus, as evidenced by increase in number of activated microglia and elevation levels of IL-1β contents. Neonatal administration of IL-1ra significantly attenuated LPS-induced long-lasting learning deficits, hippocampal injury, and sustained inflammatory responses in P71 rats. Our study demonstrates that neonatal LPS exposure causes a persistent injury to the hippocampus and results in long-lasting learning disabilities related to chronic inflammation in rats, and these effects can be attenuated with an IL-1 receptor antagonist.

Title: Sepsis stimulates gliogenesis but has no significant impact on neurogenesis in the dentate gyrus

Authors: *A. KUNZE[1], P. BLÜMEL[1], B. GRÜNEWALD[1,2], S. KEINER[1], F. WOITKE[1], O. WITTE[1], C. GEIS[1,2], C. REDECKER[1];
[1]Univ. Jena, Jena, Germany; [2]Ctr. for Sepsis Control and Care, Jena, Germany

Abstract: Sepsis is a major cause of mortality and morbidity in intensive care units. Acute and long-term brain dysfunctions have been frequently demonstrated in septic patients. Thereby, pathophysiology of sepsis associated encephalopathy (SAE) remains insufficiently elucidated although there is evidence for inflammatory processes involving endothelial activation, alterations of blood-brain barrier and neurotransmission. Recent experimental studies suggest that cellular dysfunction in neurogenic niches such as the subventricular zone may also contribute to SAE. In the present study, we address the question whether adult neurogenesis in the hippocampus is impaired in an animal model of sepsis. For sepsis induction, adult transgenic pNestin/GFP mice received intraperitoneal injection of faeces on day 0. The precursor cells were labelled either with the thymidine analog BrdU or retrovirus expressing red fluorescent protein on days -4 to -1 prior to sepsis induction. Using confocal microscopy we analyzed the number and location of new born neurons in the dentate gyrus at days 14 and 42 post-sepsis-induction (psi). On days 37 to 41, we investigated spatial memory of mice in a modified Morris water maze which is considered to be a hippocampal-dependent behavioral task. We found that i) the number of BrdU cells significantly increased 6 weeks psi, ii) sepsis mainly stimulates gliogenesis in the dentate gyrus whilst the number of new born neurons increases but without statistical significance, iii) mice reveal no significant impairment of spatial memory psi. iv) preliminary data point towards a disturbance of synaptic integration of new neurons psi. Taken together our study supports the perspective that sepsis has an impact on gliogenesis and neurogenesis in the hippocampus.

Title: Role of thyroid transcription factor-1 in transcriptional regulation of heme oxygenase-1 under neuroinflammation condition

Authors: *B. JEONG[1], J. KIM[2], B. LEE[1];
[1]Biol. science, Univ. of Ulsan, Ulsan-City, Korea, Republic of; [2]Div. of Life Sci., Incheon Natl. Univ., Incheon, Korea, Republic of

Abstract: Hypothalamic inflammation has emerged as a major driver of energy homeostasis dysfunction in both obesity and anorexia. Thyroid transcription factor (TTF-1) is a member of homeodomain-containing transcription factor family, and plays a role in transcriptional regulation of genes expressed in the thyroid, lung and brain. In this study, we found that TTF-1 plays an important role in the transcriptional regulation of heme oxygenase-1 (HO-1) in hypothalamic inflammation. HO-1 is an inducible isoform of the first and rate-limiting enzyme in heme degradation and is a well-known cytoprotective enzyme against inflammation. TTF-1 deficiency resulted in exacerbated inflammatory response in the rat astroglial C6 cells under the presence of tumor necrosis factor-alpha (TNF-α). We found expression of TTF-1 and HO-1 in the mouse hypothalamus by using immunohistochemistry. Furthermore, luciferase assays and chromatin immunoprecipitation assays showed that TTF-1 directly activated HO-1 transcription by binding to its binding domains on the HO-1 promoter. Consistent with these results, mRNA and protein level of HO-1 were increased by overexpression of TTF-1 but decreased by shRNA-mediated inhibition of TTF-1 expression in the C6 cells. Taken together, these results suggest that TTF-1 participates in the hypothalamic inflammation by regulating HO-1 transcription.

Abstract: Systemic Lupus Erythematosus (SLE) is a multifaceted autoimmune, inflammatory disease of unknown etiology that targets joints, skin, heart, kidneys, lungs, blood vessels, and brain. Prevalence is difficult to determine, but is 6-10 times higher in women than men. As many as 80% of adults with SLE experience neuropsychiatric SLE (NPSLE), which comprises 19 syndromes including headache, cerebrovascular disease, seizure, psychosis, mood disorders, and changes in cognitive functioning. People may experience NPSLE in the absence of systemic disease flairs. MRL/MpJ-Fas^{lpr}/J mice (MRL-*lpr*) resulted from a spontaneous autosomal retrotransposon insertional mutation that produces a non-functional variant of the pro-apoptotic cell surface receptor *Fas* and are a model of SLE and NPSLE. They develop autoantibodies to Smith antigen, nuclear proteins, and native single- and double-stranded DNA, but also exhibit changes in cognitive function, emotionality, and motivated behavior associated with autoimmunity. GWAS have suggested variants in some complement proteins may be associated with SLE. The complement cascade comprises several proteins that aid in destroying bacteria and stimulating immune response cells. Inactive complement proteins in the blood are activated by antigen-antibody complexes which initiates a series of cleavage and recruitment steps of other proteins in the cascade. C3 is a central molecule in the complement system that is involved in all three of the complement pathways. It can cause tissue damage by releasing histamine from mast cells to contract smooth muscle and increase vascular permeability. To evaluate C3 as a potential biomarker of NPSLE syndromes, we measured learning, memory, anxiety, anhedonia, and exploration, along with serum C3 using ELISA, in male and female MRL-*lpr* and control strains at pre-symptomatic through severely symptomatic stages of SLE. In males, a decrease in serum C3 was associated with reduced exploratory drive, impaired avoidance learning, and increased preference for sucrose solution. In females, decreased serum C3 levels were associated with impaired memory by novel object recognition and increased preference for sucrose solution. In

group comparisons, C3 levels were reduced in both male and female MRL-*lpr*s compared to MRL-+/+ congenic controls, but were only lower in MRL-*lpr*s compared to MRL-*lpr*2 animals in the males. C3 may be a marker for some NPSLE syndromes, but appears to differ between males and females. This research should be expanded to evaluate serum complement proteins and NPSLE syndromes in humans.

Title: Gestational diabetes mellitus in pregnant rats induces chronic neuroinflammation, synaptic degradation and behavioral changes in the offspring

Authors: B. VUONG[1,2], G. ODERO[1,2], M. STEVENSON[1,2], S. M. KERELIUK[2,3], T. J. PEREIRA[2,3], V. W. DOLINSKY[2,3], *T. M. KAUPPINEN[1,2,3];
[1]Kleysen Inst. for Advanced Med., [2]Univ. of Manitoba, Winnipeg, MB, Canada; [3]the Children's Hosp. Res. Inst. of Manitoba, Winnipeg, MB, Canada

Abstract: Gestational diabetes mellitus (GDM) is the most common complication of pregnancy and population health studies have linked it to impaired cognitive performance in the offspring. GDM and diets containing excess fats and sugars promote inflammatory responses. Prolonged inflammation can impair the neuronal circuitry development in the fetus resulting in lifelong effects on cognitive functions. We hypothesized that GDM causes adverse inflammatory responses in the fetus. This inflammatory environment could disturb the fine-tuning of developing neuronal networks impairing the neurocognitive abilities of the offspring. We induced GDM by feeding female rats a “junk food” diet high in sucrose and fatty acids 6 weeks prior to mating and throughout their pregnancy. Fetal (18.5E) and 15 week-old (young adult) offspring from GDM and lean dams were examined. The neurocognitive abilities of 15 week-old offspring were evaluated in Open field, Morris Water Maze and with Novel Object Recognition

test, and the brains from both age groups were analyzed by immunohistochemistry. Complementary *in vitro* experiments involved analyzing microglial responses to elevated levels of glucose and/or fatty acids. Offspring from GDM dams showed atypical explorative behaviour in open field test. The reduced neurocognitive performance directly correlated to maternal glucose imbalance (fasting blood glucose) during gestation. Analysis of brain tissues derived from the fetal and 15 week-old offspring of GDM dams showed increased astroglial GFAP expression, increased microglial morphological activation, and reduced expression of synaptic vesicle protein. Consumption of a post-weaning high fat and sucrose diet by the GDM offspring further promoted GDM-induced abnormalities. Cultured microglia exposed to high glucose and/or fatty acids transformed into activated, amoeboid morphology, significantly increased nitric oxide production, and changed cytokine release profile. Both *in vitro* and *in vivo* data demonstrate that GDM induces chronic inflammatory responses in the brain of the offspring that persist into young adulthood. Microglia culture experiments confirmed that excess glucose and/or fatty acids induce pro-inflammatory responses. Detrimental pro-inflammatory responses combined with impaired microglial neurotropic functions could explain synaptic degradation that contributes to behavior changes, and memory and learning impairments in the offspring.

Title: Antidepressant effect of Agmatine against lipopolysaccharide induced Depression in mice

Authors: *N. B. GAWALI, V. BULANI, A. CHOWDHURY, P. KOTHAVADE, M. GURSAHANI, A. JUVEKAR;
DEPARTMENT OF PHARMACEUTICAL SCIENCE AND TECHNOLOGY,, Inst. of Chem. Technology, Mumbai, Mumbai, India

Abstract: Preclinical and clinical studies suggest that activation of immuno-inflammatory and oxido- nitrosative stress pathways play major role in the pathophysiology of depression. Increasing evidence has indicated that immune challenge by bacterial lipopolysaccharide (LPS) induces depression and neuro-inflammatory response. The present study was undertaken to investigate the effect of Agmatine pre-treatment on lipopolysaccharide-induced depression,

neuro-inflammation and oxido-nitrosative stress in mice. Mice were challenged with the endotoxin lipopolysaccharide (0.83 mg/kg, i.p.). Agmatine (20 and 40 mg/kg, i.p.) was administered 30 min before LPS. LPS-treated animals presented an increase in immobility time in the forced swimming test (FST) and tail suspension test (TST) when compared to control group 24 hours after endotoxin administration. It was observed that Imipramine (IMI-10 mg/kg, i.p.) and Agmatine at both doses prevented and reversed LPS-induced alterations in the FST and TST. IL-1β content was increased 24 hours after LPS administration in hippocampus (HC) and prefrontal cortex (PFC). IMI and Agmatine prevented and reversed LPS-induced increase in IL-1β level in HC and PFC. IMI and Agmatine pre-treatment prevented LPS evoked oxidative/ nitrosative stress via improving reduced glutathione level along with reduction in the lipid peroxidation and nitrite level in HC and PFC. These results indicate that Agmatine pre-treatment provided protection against LPS-induced depressive which may be mediated by repression of pro-inflammatory cytokines as well as oxido-nitrosative stress in HC and PFC. This study suggests that Agmatine may be an important therapeutic target in the treatment of depression and other pathophysiological conditions which are closely associated with neuro-inflammation and oxido-nitrosative stress.

Title: Modulation of S1P receptors at the Blood Brain Barrier can influence its response to inflammatory stimuli

Authors: *S. F. SPAMPINATO[1,2], B. OBERMEIER[2], A. COTLEUR[2], A. LOVE[2], Y. TAKESHITA[2,3], R. RANSOHOFF[2];
[1]biomed and biotech science, Univ. of Catania, Catania, Italy; [2]Neuroinflam. Res. Center, Dept. of Neurosciences, Lerner Research- Cleveland Clin. Fundation, Cleveland, OH; [3]Dept. of Neurol. and Clin. Neurosci., Yamaguchi University, Japan

Abstract: The importance of the blood brain barrier (BBB) to maintain the principal functions of the brain is well known. Recently the involvement of the barrier in several Central Nervous System(CNS) affections has been demonstrated. In multiple sclerosis (MS) a leaky BBB, together with demyelinated multifocal lesions, constitutes a typical hallmark of the pathology. Several therapeutic approaches have been developed to reduce the migration of leukocytes towards the BBB aiming to reduce the demyelination area. Recently a sphingosine-1 phosphate (S1P) analog, fingolimod, has been introduced in MS treatment. The immunomodulator, acting as functional antagonist for the S1P1 receptor, prevents the egress of T cells from the lymph node, and reduces the onset of new lesions. S1P receptors are as well expressed on endothelial cells and astrocytes, that together with pericytes, are the main cellular constituents of the BBB. Here we investigated whether key BBB properties could be affected by S1P receptor modulation, addressing in particular the role exerted by the immunomodulator fingolimod. For this purpose, we used an *in vitro* co-cultured model to investigate the effects of S1P receptors modulation on endothelial cells and astrocytes. We either examined endothelial cells and astrocytes independently, or in a more physiological condition in which physical contact between the two cell types was enabled. S1P receptors modulation rescued endothelial cells from death upon cytokine challenge, either directly, or indirectly, acting on astrocytes, through the release of trophic factors. When exposed to TNFα and IFNγ in fact astrocytes released granulocytes and macrophages colony growing factor (GM-CSF), able to prevent endothelial cells death induced by cytokines exposure. Finally in an *in vitro* BBB model incorporating shear stress, S1P receptor modulation reduced leukocytes migration across the endothelial barrier. The data here reported point out the possibility that fingolimod, already in use for the treatment of relapsing remitting forms of MS, could also act at the BBB reinforcing it and reducing the damage induced by inflammatory condition and the access of leukocytes in the CNS.

Title: Characterization of lipopolysaccharide-induced TLR4 neuroinflammatory signaling and the effects of fentanyl in CHME-5 human microglial cells

Authors: *L. K. FIGUEROA[1], S. DAS[2], C. W. STEVENS[1], R. L. DAVIS[1];
[1]Pharmacol. & Physiol., [2]Anat. and Cell Biol., Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK

Abstract: Neuroinflammation is a key mediator of neuronal damage observed in various neuropathologies, thus, understanding pro-inflammatory pathways of human glia is important in identifying potential pharmacological strategies to modulate inflammatory signaling in these cells. Microglia-derived cytokines and chemokines are instrumental in neuroinflammation and several pro-inflammatory mediators activate these cells to include bacterial lipopolysaccharide (LPS) that signals through toll-like receptor 4 (TLR4). Even though peripheral TLR4 signaling is well defined, human microglial TLR4 signaling is not. Furthermore, recent studies suggest the ability of opioid agents to modulate immune function in peripheral and central nervous system cells. Therefore, our goals are to characterize the molecular mechanisms of LPS-induced TLR4 signaling, and, elucidate the effects of the mu opioid receptor (MOR) agonist, fentanyl, on this signaling in human microglial cells, CHME-5. In keeping with these goals, LPS-induced tumor necrosis factor (TNF) gene expression, both message, and, intracellular and secreted protein levels were upregulated in a time-dependent manner. Additionally, analysis of phosphorylated NF-κB p65 revealed optimal activation with 100 ng/ml LPS O55:B5 for 90 min in CHME-5 cells. Lastly, dose-dependent co-exposure of LPS with fentanyl significantly upregulated LPS-induced NF-κB binding activity at 10 μM. To date, our data suggest that CHME-5 human microglial cells serve as an experimental model for analyzing the inflammatory actions of human microglial TLR4 signaling, which may be exacerbated by opioid compounds, specifically, fentanyl. Thus, we have also initiated studies to elucidate the effects of LPS, fentanyl and other pharmacological agents on key TLR4 signal transduction proteins. Together, these ongoing studies are expected to further elucidate the mechanisms of LPS-induced TLR4 signaling and the effects of opioid agents in human microglia.

Title: Neuronflammation markers in the substantia nigra associated to L-DOPA-induced dyskinesia

Authors: *E. DEL BEL[1], M. .-. -. -. BORTOLANZA[2], R. KWIATKOSKI[3], F. E. PADOVAN-NETO[3];
[1]Univ. of Sao Paulo- Ribeirao Preto Dent. Sch., Ribeirao Preto, Brazil; [2]MFPb, Univ. of Sao Paulo-FORP, Ribeirao Preto, Brazil; [3]Univ. of Sao Paulo- FORP, Ribeirao Preto, Brazil

Abstract: The major pathological feature of Parkinson's disease (PD) is the progressive degeneration of the nigrostriatal system. It leads to the loss of neurons in the substantia nigra (SN) and subsequent loss of striatal dopaminergic - terminals. The degeneration of the nigrostriatal pathway contributes to the clinical motor symptoms: tremor, rigidity, bradykinesia and postural instability. Long-term l-3,4-dihydroxyphenylalanine (L-DOPA) treatment in PD patients leads to development of abnormal involuntary movements or L-DOPA-induced dyskinesia. As the main target of the nigral dopamine (DA) neurons, the striatum has received much attention in regard to understanding the pathophysiology of LID. It suggests that several dopaminoceptive structures in the brain that are likely to be affected by the exogenously produced DA have received little attention. These regions might play a key role in mediating those L-DOPA-induced abnormal behaviors. Recently, we described an increase of inflammatory markers (GFAP, OX42, iNOS and COX2) in the striatum of hemiparkinsonian rats presenting L-DOPA-induced dyskinesia. To go further on identify neuroinflammatory response specifically related to L-DOPA-induced dyskinesia we report the changes in GFAP, OX42, iNOS and COX2 expression in the SN reticulata/compacta of four groups of rats: hemiparkinsonian, hemiparkinsonian chronically treated with 7-Nitroindazole (7NI- a neuronal nitric nNOS inhibitor), hemiparkinsonian chronically treated with L-DOPA exhibiting dyskinesia, and hemiparkinsonian chronically treated with L-DOPA preceded by 7NI and without exhibiting dyskinesia. Non-dyskinetic parkinsonian animals displayed a rather normalized expression of GFAP and OX42, and no expression of iNOS and COX2 in the studied brain regions. Dyskinetic animals are distinguished by significant changes of the OX42 and GFAP in the SN-compacta ventral and lateral. Also, there was a striking increased expression of the OX42 in the SN-reticulata. The overexpression of GFAP and OX42 in these brain regions correlates with L-DOPA-induced dyskinesia severity. NOS inhibition prevented L-DOPA-induced dyskinesia and either GFAP or OX42 increased expression. Glial cells accumulation in the SN demonstrated that L-DOPA-induced dyskinesia is related to pathological process also occurring in the DAergic cell bodies. We propose that glial cells alterations in the rats presenting LID might reflect a neuroinflammatory reaction underlying neural mechanisms of dyskinesia.

Title: Decreased neutrophil effectiveness and recruitment grants neuroprotection in knockout mice following soman-induced seizure

Authors: *K. LAITIPAYA[1], J. F. IRWIN[1], J. CHANDLER[1], L. SHUMWAY[1], T. FERRARA-BOWENS[1], M. D. WEGNER[2], E. A. JOHNSON[1];
[2]Comparative Pathology, [1]USAMRICD, Gunpowder, MD

Abstract: Severe neuropathology and behavioral impairment are a result of prolonged status epilepticus (SE) caused by organophosphorus nerve agents such as soman (GD). GD, a potent acetylcholinesterase inhibitor, causes prominent cell death in the hippocampus, thalamus and piriform cortex, leading to the activation of the neuroinflammatory cascade. Neuroinflammation can exacerbate tissue injury or promote healing, depending on the intricate interaction of multiple cells, inflammatory factors and receptors as the injury progresses, a fact that has complicated the development of effective neuroprotective therapies for CNS injury models such as SE. Neutrophils are important in propagating the inflammatory cascade, can help resolve damage through many inflammation -related pathways and are one of first subset of leukocytes to respond to brain injury following seizurogenic exposure to GD. In scenarios where extensive damage occurs, neutrophils may become overactive and further exacerbate the injury. In this study, knockout mice missing key recruitment/activation proteins such as intracellular adhesion molecule 1 (ICAM-1), leukotriene B_4 Receptor (BLTR), E-selectin, and neutrophil cytosolic factor 1 (NCF1) were used to determine the role of neutrophils in the progression of acute neuropathology following GD induced seizures. Results indicate that reducing the effectiveness of neutrophil recruitment/activation does attenuate acute GD-induced brain damage. These data suggest that limiting leukocyte activation, in particular neutrophils, may be a viable target for neuroprotection and behavioral recovery. Further studies will investigate the more chronic effects of attenuated neutrophil activity on injury development, resolution and recovery.

Title: Transcriptome data from multiple cell types isolated from adult murine CNS tissue reveals cell type specific response to CNS insults

Authors: *K. SRINIVASAN, B. A. FRIEDMAN, D. HANSEN;
Genentech Inc, South San Francisco, CA

Abstract: Microglia, the primary immune cells of the brain, play a key role in monitoring the brain for any toxic insults that may result in neuronal damage and cell death. Upon sensing any noxious stimuli, microglia respond robustly by secreting inflammatory cytokines and by phagocytosing debris to maintain an optimal environment for neuronal function. Inflammatory signaling in the brain plays a vital role in the pathology of several neurodegenerative diseases, although it is not clear if the inflammatory response is beneficial. In order to fully understand the biology of neuroinflammation, it is critical to tease apart the gene expression changes in neurons and other cell types including microglia, astrocytes and endothelial cells. Here, we present a method to acutely isolate multiple cell types from a single, adult mouse brain without employing any transgenic reporters for the isolation procedure. Using RNA sequencing data from these isolated cell types, we demonstrate the feasibility of this technique in an endotoxemia model and report that the brain's response to endotoxemia is highly cell type specific and that astrocytes require TNFR1 for this response. We next applied this technique to a mouse model of Alzheimer's disease. Transcriptomic analysis of individual cell types revealed hundreds of differentially expressed genes not observed using whole tissue RNA. For example, microglial cells from diseased brains had altered expression of genes involved in Wnt signaling and lipoprotein metabolism. We were also able to detect genes that were downregulated in microglia. These changes are typically difficult to detect in diseased brains due to increased microgliosis, which masks the decreased levels of gene expression. Applying this method to additional models and patient tissues has the potential to transform our understanding of the role of aberrant gene expression in neurological disease or injury.

Title: Inhibition at various locations within the TNF signaling pathway after soman-induced seizures in mice

Authors: *J. K. CHANDLER, T. M. FERRARA-BOWENS, J. F. IRWIN, K. LAITIPAYA, L. J. SHUMWAY, M. D. WEGNER, E. A. JOHNSON;
US Army Med. Res. Inst. of Chem. Def, Aberdeen Proving Ground, MD

Abstract: Exposure to organophosphorus compounds such as soman (GD), a potent acetylcholinesterase inhibitor and chemical warfare agent (CWA), results in prolonged status epilepticus (SE) and severe neuropathology in the hippocampus, thalamus, and piriform cortex. Exposure to GD and similar CWAs has been shown to cause neuroinflammation, which exacerbates damage, reduces cognitive abilities, and decreases overall outcomes. TNF signaling, a prominent pro-inflammatory pathway, appears to exacerbate tissue damage in multiple CNS injury models. Results of previous studies indicate that the loss of normal TNFR signaling does afford neuroprotection in various brain regions and can alter seizure onset times and mortality rates. This study investigated the effects of TNFα, a ligand in the pathway, 24 hours after acute exposure to GD, in comparison to the inhibition of TNFR signaling. Multiple TNF pathway knockout mouse strains were exposed to GD, and changes in acute neurodegeneration, mortality, seizure onset and other physiological variables were compared to those background matched wild-type mice. These results, along with neuroinflammation profiles from the mouse model, will further guide the selection of pathway-specific drugs for testing as well as provide an extended therapeutic window for conventional treatments. Title: Depressed basal neuronal activity in a genetic model of type-1 diabetes is correlated with proinflammatory secretion of HMBG1

Authors: *J. S. THINSCHMIDT[1], M. FEBO[2], L. M. COLON PEREZ[2], S. CABALLERO[1], M. B. GRANT[3];

Abstract: We recently found indicators of hypothalamic inflammation and neurodegeneration linked to the loss of neuroprotective factors including insulin-like growth factor (IGF-1) and IGF binding protein-2 (IGFBP-3) in mice made diabetic using streptozotocin. In the current work, a genetic model of type-1 diabetes (Ins2Akita mouse) was used to evaluate changes in neuronal activity and concomitant changes in the proinflammatory mediator high-mobility group box-1 (HMBG1). We found basal hypothalamic neuronal activity as measured by manganese-enhanced magnetic resonance imaging (MEMRI) was significantly decreased in 8 month old, but not 2 month old Ins2Akita diabetic mice compared to controls. In tissue from the same animals we evaluated the expression of HMBG1 using immunohistochemistry and confocal microscopy. We found decreased nuclear HMBG1 colocalization in the paraventricular nucleus of the hypothalamus (PVN) in 8 month old, but not 2 month old diabetic animals indicating nuclear release of the protein consistent with an inflammatory state. Adjacent thalamic regions showed little change in HMBG1 colocalization and neuronal activity as a result of diabetes. This work extends our previous findings demonstrating changes consistent with hypothalamic neuroinflammation in STZ treated animals, and shows active inflammatory processes are correlated with changes in basal hypothalamic neuronal activity in Ins2Akita mice.

Title: Role of Toll like receptors in neurogenesis

Authors: *S. KRISHNASAMY, S. THAMMISETTY, Y. WENG, M. LALANCETTE-HÉBERT, J. KRIZ;
Inst. Universitaire En Santé Mentale De Québec, Quebec, QC, Canada

Abstract: Aim: The generation of new neurons in the adult brain is mostly associated with two regions, the sub ventricular zone of the lateral ventricles (SVZ) and the sub granular zone of the hippocampal dentate gyrus (SGZ). TLR2 is one of the most prevalent Toll-like receptors in the central nervous system (CNS). In addition to immune cells in the brain, neurons also express TLRs. TLR2 expression was detected on cells that co-express the early neuronal marker, doublecortin (DCX). The finding that TLR2 is expressed in the adult neurogenic niches prompted us to investigate whether it plays a role in neurogenesis in chronic neurodegenerative disorders. In this study we used a TDP43 mice, a valid animal model of Fronto Temporal Dementia (FTLD) to investigate the role of TLRs in neurogenesis. . Objective: The functional plasticity of CNS, including neurogenesis depends on innate and adaptive immunity. We have investigated the role of TLR2 in neurogenesis in the acute and chronic inflammation. Results: Immunofluorescence analysis of nestin, GFAP and DCX expression in SVZ and DG showed that attenuation of neurogenesis in the TL2 KO mice before and after MCAO. *In vivo* imaging of TLR2 expression study reveals that there is increased expression of TLR2 observed in TDP43 mice compared with their wild type mice. Western blot analysis of TL2 showed that there is higher expression in young TDP43 mice. Conclusion: Attenuation of neurogenesis in TLR2 KO mice reveals the impact of TLRs in neurogenesis. Longitudinal *in vivo* imaging results showed that there is increased expression of TLR2 in the young and old transgenic mice compared to the wild type mice.Induction of LPS produced an over expression of TLR2 and cytokines in the transgenic mice.Immunofluorescence analysis of neural progenitors showed that there is significant increase in the both neurogenic regions pre and post symptomatic conditions.

Title: Dysregulation of the astrocytic S100B/RAGE system in ALS models

Authors: *F. MICHETTI[1], C. DONNO[1], P. ANDJUS[2], N. D'AMBROSI[1];
[1]Univ. Cattolica S. Cuore, Roma I-00168, Italy; [2]Ctr. for Laser Microscopy, Univ. of Belgrade, Belgrade, Serbia

Abstract: Astrocytic dysfunction is believed to play a crucial role in ALS neuroinflammatory processes. Most of the toxic astrocytic effects involve intracellular calcium. S100B is a Ca^{2+}-binding protein particularly abundant in astrocytes, behaving as a neuroinflammatory mediator as it is secreted at high concentration by astrocytes under pathological conditions, displaying paracrine toxicity by binding to RAGE. During ALS progression S100B increases in patient astrocytes and, in a rat model of the disease, S100B is augmented in “aberrant astrocytes”, characterized by their neurotoxic potential. The induction of S100B in astrocytes, its release and its interaction with RAGE in motor neurons could represent an hazardous mechanism that takes place during ALS. Main objectives of this work were to investigate 1) if the expression of S100B protein and RAGE change during the course of the disease in rodent models of ALS; 2) if the expression of mutant SOD1 protein per se is sufficient to modify S100B levels in astrocytic cultures. We observed that S100B levels and localization are modulated in the spinal cord and in the brain cortex of rat and mouse models of ALS. We also demonstrated a differential expression of RAGE subunits in SOD1-G93A-derived CNS tissues. Moreover, we induced overexpression of mutant SOD1 in an astrocytic cell line, and observed that the intracellular levels and even the release of S100B increase in these cells. However, overexpression of mutant SOD1 is not enough to induce a differential expression of RAGE in astrocytic culture. Thus, the mere expression of mutant SOD1 interferes with the physiological expression of S100B and with its release at least in cell culture, while the dysregulation of RAGE, which in our conditions is found only in tissues, might be a phenomenon requiring a more complex interplay between different cell types and pathways, or merely involving other cell types different from astrocytes. Overall, these data suggest that S100B may be a toxic mediator released by astrocytes in the ALS-linked neuroinflammatory process, and that its receptor RAGE might be involved in this pathway. This

possibility might even have translational consequences, indicating S100B as a possible candidate to be a therapeutic target for ALS-linked neuroinflammatory processes.

Title: Blood-derived macrophages do not contribute to the inflammatory response after cranial irradiation

Authors: ***W. HAN**[1,2], K. ZHOU[3], T. UMEKAWA[1], C. ZHU[2,3], K. BLOMGREN[1,4];
[1]Dept. of Women's and Children's Hlth., Karolinska Institutet, Stockholm, Sweden; [2]Dept. of Pediatrics, The Third Affiliated Hosp. of Zhengzhou Univ., Zhengzhou, China; [3]Ctr. for Brain Repair and Rehabilitation, Inst. of Neurosci. and Physiol., Univ. of Gothenburg, Gothenburg, Sweden; [4]Dept. of Pediatrics, Univ. of Gothenburg, Queen Silvia Children's Hosp., Gothenburg, Sweden

Abstract: Background: Cranial irradiation (IR) induces loss of neural stem and progenitor cells and is followed by progressive cognitive deterioration in both young and adult patients. Earlier studies have suggested that neuroinflammation contributes to the development of adverse effects, including a shift from neurogenesis to gliogenesis. Given the difficulties distinguishing resident microglia from macrophages derived from blood-borne, peripheral monocytes, the relative contribution after cranial IR of these two evolutionarily different groups of macrophages and antigen-presenting cells is not known. **Methods:** $CX3CR1^{GFP/+}CCR2^{RFP/+}$ mice were used to distinguish resident microglia ($CX3CR1^{+}$; GFP-labeled) from monocyte-derived macrophages ($CCR2^{+}$; RFP-labeled). CCL2 expression and infiltrating monocytes in hippocampus and cerebellum and microglial response in the hippocampus were determined by ELISA and immunofluorescent staining from 6 h through 1 month following a single dose of 8 Gy IR on juvenile (PND 10) or adult (PND 90) brain. **Results:** Our results demonstrate that CCL2 was increased by 360 % in PND 10 and 120 % in PND 90 mice at 6 h and remained elevated for at least 1 month after IR. No peripheral monocyte-derived macrophages could be detected in the hippocampus at any time point investigated (6 h, 1 day, 1 week, 1 month) after IR, neither in juvenile nor in adult mice. In the juvenile brain, the microglia density in the granule cell layer (GCL, including the subgranular zone (SGZ)) increased 6 h, peaked at 1 day, and decreased

thereafter back to the baseline 1 month after IR. In the adult brain, however, the microglia density peaked already 6 h after IR, returned to baseline within 1 day and decreased thereafter. The microglia increase in the juvenile GCL was probably attributed to both proliferation and migration from the molecular layer. Starting from 6 h after IR, microglia in SGZ exhibited amoeboid morphology and expressed the marker CD68. This activation lasted for 1 week in the juvenile brain but only 1 day in the adult brain, indicating a more transient and less pronounced microglia activation in the adult brain after IR. **Conclusions:** In summary, we show here for the first time that peripheral monocyte-derived macrophages do not appear to contribute to the inflammatory response in the hippocampus after IR, neither in the juvenile nor in the adult brain. We also show that the microglia response is more pronounced and protracted in the juvenile brain, and that the inflammation, as judged by CCL2 levels, appears chronic, lasting at least one month after IR.

Title: Time-specific changes in kainic acid-induced mesial temporal lobe epilepsy: transcriptomic and immunohistochemical evaluation

Authors: *M. E. HAMBY, S. M. FALLON, J. A. TAMM, J. SERRATS, M. J. DENBLEYKER, A. ABDOURAHMAN, G. TERRY, R. B. NELSON, B. M. CAMPBELL, P. D. WES, T. MÖLLER, N. BREYSSE;
Neuroinflam. Dis. Biol. Unit, Lundbeck Res. USA, Paramus, NJ

Abstract: Mesial Temporal Lobe Epilepsy (MTLE) is a chronic disease characterized by recurrent unprovoked partial seizures. Current treatments lack long-term efficacy and typically act only to ameliorate the symptomology, rather than to modify the course of the disease. Chronic kainic acid (KA)-induced models of MTLE mimic prominent histopathological and electroencephalographic features of human MTLE, including hippocampal sclerosis, CA1 neuronal loss, astrogliosis, microgliosis, and hippocampal discharges. Here we examined the transcriptional profiles of the hippocampus of KA- vs sham-injected mice from epileptogenesis to the stabilization of spontaneous recurring seizures. KA (1 nmol) or saline (sham) was injected

unilaterally into the dorsal hippocampus of 12 week old C57BL/6J mice, and the ipsilateral (IL) and contralateral hippocampi were isolated for whole-genome expression profiling (Illumina microarray) or immunohistochemistry 7, 28 and 60 d later. Differential gene expression analysis of the IL hippocampus indicated that 1349, 484, and 439 genes were significantly (fdr<0.05) altered in KA compared to sham at 7, 28 and 60 d, respectively. 108 genes were altered at all time-points assessed, while others were altered in a time-dependent manner, indicative of distinct hippocampal gene expression profiles across the course of disease. Ingenuity Pathway Analysis revealed that specific immune cell and inflammatory signaling pathways were upregulated at 7 and 28 d, in support of a role of neuroinflammation in the disease etiology. The top canonical pathways profile at 60 d was quite distinct from that at 7 and 28 d, although certain inflammatory pathways were still prevalent, indicative of pathways involved in the maintenance of the disease. Consistent with a role of neuroinflammation in MTLE, immunohistochemical analyses demonstrated time-dependent changes in both the intensity of immunoreactivity and number of Iba1- and GFAP-positive cells. To reveal gene networks not apparent with differential expression data alone, weighted gene co-expression analysis (WGCNA) was performed. A gene network that highly associated with 7 d IL-KA (but not 28 and 60 d) was identified, which may point to changes involved in the process of epileptogenesis. Another gene network revealed a group of genes highly associated with changes occurring at 28 and 60 d, but not 7 d, which may point to molecules involved in the generation of spontaneous recurring seizures. Collectively, results indicate that specific pathways, including many associated with neuroinflammation, are activated in a time-dependent manner in MTLE.

Title: NPY and CRF induce bi-directional, long-term morphological effects on BLA pyramidal cells as structural correlates of stress resilience and vulnerability

Authors: *S. D. MICHAELSON[1], A. P. MIRANDA[1], H. SILVEIRA VILLARROEL[1], A. MCKINTY[1], K. EPPLER[1], J. WANG[1], Y. QIU[1], J. H. URBAN[2], W. F. COLMERS[1]; [1]Univ. of Alberta, Edmonton, AB, Canada; [2]Physiol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Many brain regions respond to stress with the basolateral amygdala (BLA) regulating emotional processing. Glutamatergic pyramidal cells are the major output neurons of the BLA and mediate behavioral stress responses. These cells respond to stress with dendritic hypertrophy and increased spine densities. Several endogenous neuromodulators alter BLA output cell activity, including the anxiolytic neuropeptide Y (NPY) and the anxiogenic corticotrophin releasing factor (CRF). Daily (5 x d) injections of NPY or urocortin (CRFR1 agonist), induce a persistent state of stress resilience or vulnerability, respectively. While the acute anxiolytic effect of NPY in the amygdala is mediated in part by Y1 receptors, the NPY receptor inducing stress resilience is unknown. We hypothesized that chronic CRF treatment would recapitulate the effects of stress observed on BLA pyramidal cells and NPY treatment would result in the opposite effect, namely, dendritic retraction. We tested this in male rats *in vivo* and using a novel organotypic slice culture preparation of BLA (BLA-OTC) we recently developed. BLA-OTCs (6 w postnatal equivalent age) were treated with NPY, NPYR subtype-selective agonists or CRF for 5 days. Electrophysiological and morphological changes in neurobiotin-filled neurons were analyzed 7-14 days after peptide treatment. In parallel, NPY or a Y1R agonist were injected daily (5 x d) into the BLA of 7 week-old rats; social interaction (SI) was assessed and similar recordings were made in acute BLA slices 4 weeks after the first injection. NPY increased SI time as expected ($\geq$ 4 weeks). Intra-BLA injections of the Y1R ligand increased SI 30 min after injection but did not affect SI long-term. BLA pyramidal cell dendrites were retracted in NPY-treated, but not Y1 agonist-treated rats. In the BLA-OTC, NPY, but not the Y1 agonist, decreased pyramidal cell dendritic length as determined by Sholl analysis, while CRF produced dendritic hypertrophy similar to that seen with stress. Application of the Y5 receptor ligand, (possibly anxiolytic *in vivo*) also caused dendritic retraction, while activation of Y2 receptors, which causes acute anxiety *in vivo*, caused dendritic hypertrophy similar to CRF. The BLA-OTC preparation thus may predict structural changes that accompany stress resilience and vulnerability. NPY and CRF cause opposite effects on BLA dendrites correlating with behavioral changes seen with peptide treatment *in vivo*. The contribution of NPY receptor subtypes to the generation of these changes will be further examined using Y5 and Y2 receptor-selective agonists in rats to determine if they induce long-term behavioral stress resilience or vulnerability.

Title: Characterization of Y2 receptor-expressing cells in the basolateral amygdala

Authors: M. G. DEJOSEPH[1], J. P. MACKAY[2], W. F. COLMERS[2], *J. H. URBAN[1];
[1]Physiol. & Biophysics, Chicago Med. Sch/Rosalind Franklin Univ. Med. & Sci., North Chicago, IL; [2]Pharmacol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Neuropeptide Y (NPY) plays an important role in the buffering of anxiety responses, predominantly through activation of Y1 and Y5 receptor subtypes in the basolateral amygdala (BLA). Conversely, activation of Y2 receptors in this same region has been suggested to be anxiogenic or promote stress-related behaviors. The mechanism and circuitry underlying these diametrically opposed effects of NPY Y2 receptor activation on BLA activity has yet to be elucidated. In this context, we have studied a novel transgenic mouse line (NPY2R-cre x Rosa26-CAG-tdTomato = Y2R-tdTomato) to aid in the characterization of Y2R-related circuitry in the BLA. To determine the neurochemical identity of Y2R-tdTomato-expressing cells in the BLA, brain sections through the amygdala ofY2R-tdTomato mice were incubated with combinations of antibodies to identify glutamatergic pyramidal cells (CaMKII) or interneurons [NPY, somatostatin (SOM), parvalbumin]. tdTomato (putative Y2R)-expressing cell bodies were found throughout the rostral-caudal aspect of the BLA. In the anterior-most BLA, clusters of tdTomato-expressing cells were present within the medial aspect of the nucleus. A majority (>50%; cell counts pending) of these cells were also CaMKII-immunopositive, suggesting that the Y2R may regulate the activity of glutamatergic projection neurons, as occurs in the hippocampus (El Bahh et al, Eur. J. Neuroscience, 22: 1417-1430 (2005). The vast literature indicates that the Y2R may also function as a presynaptic autoreceptor on NPY neurons, which comprise a population of BLA interneurons. All double labeled NPY/SOM-immunoreactive neurons in the BLA and surrounding regions also expressed tdTomato, further reinforcing the role of the Y2R in regulating the activity of NPY neurons. By contrast, parvalbumin-immunoreactive neurons were devoid of tdTomato signal. The presence of Y2R expression in NPY interneurons as well as subclasses of glutamatergic provides a complex and testable circuit to examine the effects of Y2 receptor signaling on the generation of acute as well as persistent anxiety responses.

Title: HCN1 channel expression in the BLA and anxiety-related behavior

Authors: ***M. BOMPOLAKI**[1], W. F. COLMERS[3], J. H. URBAN[2];
[2]Physiol. & BIophysics, [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL;
[3]Pharmacol., Univ. of Alberta, Alberta, AB, Canada

Abstract: The activity of pyramidal neurons in the basolateral nucleus of the amygdala (BLA) is predictive and consistent with the expression of anxiolytic- and anxiogenic-like behaviors in rats. Intra-BLA injections of Neuropeptide Y (NPY) reduce BLA output and are anxiolytic, whereas intra-BLA injections of Corticotropin Releasing Factor (CRF) increase BLA output and are anxiogenic. Previous studies from our laboratories demonstrated that both NPY and CRF act at the neuronal level by mediating the inhibition or enhancement, respectively, of the hyperpolarization activated, depolarizing conductance, the H current, carried by HCN channels (Geisbrecht et al., 2010). These studies, together with anatomical studies, indicated that it is likely that the actions of NPY and CRF result from bidirectional modulation of pyramidal cell HCN1 subunits as their final common pathway. Furthermore, repeated intra-BLA injections of NPY produce prolonged (weeks to months) behavioral stress resilience, as they markedly increase the time treated rats spend interacting in the social interaction (SI) test (Sajdyk et al., 2008). We now have data suggesting HCN1 expression is decreased in the BLA in NPY-induced stress resilience. Therefore, we hypothesize that the expression level of HCN1 in the BLA is important in mediating stress-related behavior. To test this, we used a lentivirus expressing shRNA targeting mRNA for HCN1 to selectively reduce the expression of HCN1 in the BLA of male rats and stress-related behavior was assessed. Animals received injections (2 μL per side; 109 titer units/mL concentration of virus) directly into the BLA of lentivirus expressing either shHCN1 or a scrambled (non-coding) shHCN1 sequence, or vehicle (saline) alone. Four weeks later, immunohistochemistry revealed significant reductions in HCN1 protein levels within the infected region. Social interaction was studied in all groups of injected animals at several times

following the injections. As in chronically NPY-treated animals, SI times were increased in animals that received shHCN1-injections when compared to the other two control groups. All cohorts of animals were also tested in the elevated plus maze (EPM) test. Interestingly, knockdown of BLA HCN1 expression did not have an effect on the performance of these rats on the EPM. These data reinforce our hypothesis that the H current plays a critical role in regulating BLA output, which in turn has significant consequences for regulation of behavioral responses to stress and on the expression of anxiety-related behaviors.

Title: Muscarinic receptors modulate intrinsic GABAergic transmission in the bed nucleus of stria terminalis

Authors: *J. GUO, Y. YANG, D. G. RAINNIE;
Dept of Psychiatry, Yerkes Primate Res. Center, Emory Univ., Atlanta, GA

Abstract: The bed nucleus of stria terminalis (BNST) is an important relay in the circuits regulating emotion. Neurons of the BNST are primarily GABAergic, and are heavily interconnected. Hence, modulation of intrinsic connections within the BNST most likely determines the output of BNST subnuclei to downstream targets. Using a combination of optogenetics and *in vitro* patch clamp recording, we examined intrinsic connections between BNST neurons, and its modulation by acetylcholine (Ach). Application of carbachol (CCh) depolarized BNST neurons, irrespective of cell type, and increased the rate of action potential firing, an effect that was blocked by the muscarinic receptor antagonist, atropine or the M1 receptor antagonist, pirenzepine. Due to the marked intrinsic connectivity, an increased rate of firing in BNST neurons would be predicted to increase local GABA release. As expected, CCh application dramatically increased both the frequency and amplitude of spontaneous IPSCs. Moreover, the CCh effect was blocked by atropine or the sodium channel blocker, tetrodotoxin;

but not by the AMPA receptor antagonist DNQX. Together these data suggest that postsynaptic activation of muscarinic receptors in BNST neurons results in enhanced local inhibitory tone. Paradoxically, CCh was also observed to reduce the frequency but not the amplitude of miniature IPSCs, suggesting that CCh can also inhibit presynaptic GABA release. CCh also decreased the amplitude of stimulation-evoked IPSCs, and increased the paired-pulse-ratio. However, electrical stimulation cannot differentiate between intrinsic GABAergic connections and extrinsic GABAergic inputs. Hence, we used optogenetics to selectively activate intrinsic GABAergic connections by locally injecting an AAV Hsyn-ChR2-eYFP construct into the anterior BNST. As expected light activation of BNST neurons evoked monosynaptic IPSCs that had a reversal potential close to chloride equilibrium potential, and were blocked by GABAA receptor antagonist, SR95531. Light-evoked IPSCs were seen in all three types of BNST neuron. Significantly, the light-evoked IPSCs were attenuated by muscarine, which also increased the coefficient of variation of the IPSCs, suggesting a presynaptic locus of action. Moreover, the effect of muscarine was blocked by atropine. Together these data suggesting that presynaptic muscarinic receptor can modulate intrinsic GABAergic transmission. Experiments are in progress to determine the effects of Ach on extrinsic GABAergic transmission. Differential modulation of intrinsic or extrinsic GABAergic transmission may have important implications for signal processing in the BNST.

Title: Chronic stress modulates synaptic strength in the bed nucleus of the stria terminalis

Authors: *S. E. DEWITT[1], A. MENIGOZ[2], J. GUO[2], D. G. RAINNIE[2];
[1]Behavioral Neurosci. and Psychiatric Disorders, [2]Emory Univ., Atlanta, GA

Abstract: Chronic stress causes a reduction in striatal-enriched protein tyrosine phosphatase (STEP) and an increase in synaptic plasticity in Type III, putative CRF neurons in the dorsal bed nucleus of the stria terminalis (dBNST). STEP opposes synaptic strengthening by inhibiting the activation of ERK and reducing AMPA receptor (AMPAR) insertion in the membrane. The loss of STEP in Type III cells may cause an increase in the ratio of AMPA to NMDA receptors indicative of synaptic strengthening. Although most AMPARs are impermeable to calcium, AMPARs lacking the GluR2 subunit pass calcium and activate the ERK pathway. Chronic stress modulates CP-AMPARs in the BNST of mice however it is unknown if this is differentially affected by cell type. We have begun to determine how chronic stress affects the relative contribution of AMPA, CP-AMPA, and NMDA receptors to the evoked excitatory post-synaptic current (eEPSC) in Type I, II, and III neurons in the dBNST. To this end, we used a 7-day unpredictable shock stress paradigm (USS) on rats. Five days after stress, the AMPA-NMDA ratio (AMPA:NMDA) and CP-AMPA-AMPA ratio were analyzed in the dBNST. Single cell RT-PCR (scRT-PCR) was used to examine the effects of stress on the relative expression of AMPA and NMDA subunits as well as genes involved in the ERK signaling cascade. Our preliminary results have shown a trend towards an increase in the AMPA:NMDA in stress rats (1.5 ± 0.2) compared to controls (1.1 ± 0.2; $p=0.12$). In addition, 1-naphthylacetyl spermine trihydrochloride (NASPM), a CP-AMPA antagonist, reduced the amplitude of the eEPSC at a slower rate (peak response 30% reduction in stress and 44% in controls; interaction between time and stress [$F(19,228) = 1.644$, $P < .05$]) and washed out faster in stressed rats (interaction [$F(21,168) = 1.623$, $P < .05$]. These data are indicative of a reduction in the contribution of CP-AMPARs to the eEPSC in rats exposed to the USS. The preliminary data indicates the reduction in CP-AMPA current specifically occurs in non-Type III cells. In this model, after chronic stress Type III neurons decrease STEP expression leading to an increase in AMPA and CP-AMPA membrane insertion while non-Type III neurons show a reduction in the relative contribution of CP-AMPARs. These differential effects in Type III and non-Type III cells cause an increase of excitability in Type III, putative CRF neurons, while decreasing the excitability of non-Type III cells thereby increasing the anxiogenic output of the dBNST. In a parallel set of experiments, we are using scRT-PCR to examine the expression of GluR1 and GluN1 mRNA in the different cell types to determine if USS induces a cell type specific alteration in receptor expression.

Title: Dopamine (D1R) antagonist suppresses corticolimbic oscillations and fear learning

Authors: *T. E. MADSEN[1], C.-C. HSU[1], C. N. COLLINS[2], J. S. PITTS[3], D. G. RAINNIE[1]; [1]Behavioral Neurosci. and Psychiatric Disorders, Emory Univ., Atlanta, GA; [2]GRU Med. Col. of Georgia, Augusta, GA; [3]Agnes Scott Col., Decatur, GA

Abstract: Activation of dopamine D1 family receptors in the basolateral amygdala is required for successful acquisition of conditioned fear. D1Rs are also critical for the *in vitro* generation of long-term potentiation (LTP), often assumed to be the cellular substrate of learning. Furthermore, dopamine modulates oscillatory activity in the amygdala, which facilitates communication with other limbic brain regions. Delta/theta and gamma oscillations in the basolateral amygdala (BLA) and medial prefrontal cortex (mPFC) have recently been associated with fear learning and expression. We hypothesized that the blockade of fear learning by the D1R antagonist is mediated by its suppression of corticolimbic oscillations. Adult, male, Sprague-Dawley rats were first trained to nosepoke for a food reward, in order to establish a baseline of activity against which to assess freezing as a measure of fear. They were then implanted with microwire recording arrays in the BLA and mPFC. SCH23390 (a selective D1R antagonist) or saline was administered by I.P. injection immediately prior to tone habituation and classical auditory fear conditioning. Fear recall was tested two days later, in the absence of drug. Neuronal spikes and local field potentials (LFPs) were simultaneously recorded in both regions throughout fear acquisition and extinction. Rats that received the D1R antagonist demonstrated significantly less fear recall (freezing and nosepoke suppression) than saline treated rats, despite equivalent responses to acute shock during conditioning. In control rats, the BLA and mPFC displayed significantly increased power, and coherence between regions, in a sharply tuned delta/theta (2-6 Hz) band during successful fear acquisition and recall, as compared to baseline (before habituation tones). Throughout fear acquisition, the mid-gamma (45-60 Hz) range was significantly elevated over baseline in terms of mPFC power, BLA power, and coherence between the two regions. After the shock, there were dramatic increases in high gamma (60-90 Hz) power for the mPFC and in low gamma (30-45 Hz) power for the BLA, as well as mid-gamma within and between both regions. All of these fear-related changes in oscillatory activity were reduced in D1R antagonist treated rats, to the extent that no tone-triggered changes were apparent upon fear recall testing. These results demonstrate a strong correlation between dopamine D1R activation, corticolimbic oscillations, and fear learning, such that we believe D1Rs critically modulate corticolimbic oscillations, which are necessary substrates of fear learning.

Title: High frequency stimulation changes *in vitro* basolateral amygdala excitability

Authors: *B. O'FLAHERTY[1], D. RAINNIE[2];
[2]Behavioral Neurosci. and Psychiatric Disorders, [1]Emory Univ., Atlanta, GA

Abstract: Deep brain stimulation (DBS) of the insular cortex at 130 HZ is an effective treatment of major depressive disorder (MDD) in patients that are unresponsive to traditional MDD therapies such as SSRIs. However, it is currently unknown why DBS is an effective MDD treatment. To date, no one has shown how 130 Hz stimulation affects neuronal activity in limbic areas known to be dysregulated in MDD. For example, the basolateral amygdala (BLA; a key mood area that is hyperactive in MDD patients) receives dense synaptic projections from the infralimbic cortex, and may be a key region influenced by DBS in humans. We thus hypothesize that 130 Hz stimulation of synaptic inputs to the rat BLA would reduce BLA principal neuron excitability. To test this hypothesis, we used *in vitro* whole-cell patch clamp recordings from BLA principal neurons in coronal slices, in conjunction with 130 Hz extracellular stimulation of the external capsule (EC). The EC was stimulated for periods of 2, 4, 6, and 8 minutes. Input resistance, spike threshold, spontaneous synaptic activity frequency / amplitude, and evoked synaptic activity amplitude were measured before and immediately after 130 Hz stimulation. No change in membrane resistance or spike threshold was seen in BLA principal neurons after 130 Hz stimulation. However, we observed a marked decrease in evoked synaptic activity amplitude after 130 Hz stimulation. We interpret the reduced evoked synaptic response as a depletion of readily-releasable synaptic vesicles at cortico-amygdala and thalamo-amygdala synapses. As hyperactivity of the BLA has been implicated in MDD, a reduction in synaptic input into the BLA principal neurons could reduce BLA activity and restore normal functioning. Understanding how 130 Hz stimulation affects the BLA is vital for understanding the clinical efficacy, and to develop more effective and less invasive treatments for treatment-resistant MDD.

Title: Mapping the excitatory afferents onto corticotropin releasing factor neurons in the bed nucleus of the stria terminalis

Authors: ***T. FETTERLY**[1,2,3,4], K. M. HOLLERAN[2,3,4], E. K. AWAD[1], Y. SILBERMAN[1,3,4], D. G. WINDER[1,2,3,4];
[1]Mol. Phys & Biophys, Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Brain Inst., [3]Neurosci. Program in Substance Abuse, [4]Kennedy Ctr., Vanderbilt Univ., Nashville, TN

Abstract: Corticotropin releasing factor (CRF) is involved in the regulation of many behaviors, including feeding, substance abuse and withdrawal, and affective states. Studies, including our own, have implicated excitation of CRF neurons within the bed nucleus of the stria terminalis (BNST) as being of importance in interactions between stress and drugs of abuse (such as cocaine and alcohol). One challenge in studying CRF neurons within the BNST is the complex circuitry and heterogeneity of the brain region. We are utilizing optogenetic and genetically encodable reporter strategies to map excitatory afferents that synapse directly on CRF neurons within the BNST. We have focused on glutamatergic inputs based on two observations. First, qRT-PCR data shows a decrease in BNST CRF mRNA levels in C57Bl/6J mice 24 hours following an injection of ketamine, an N-methyl D-aspartate receptor antagonist. Second, we find that α- and β-adrenergic receptors reciprocally regulate excitatory drive onto BNST CRF neurons and modulate stress-induced fos responses in these cells *in vivo*. Thus, we have stereotaxically injected female CRF-tdtomato reporter mice (strain B6(Cg)-Crhtm1(cre)Zjh/J

crossed with strain B6.Cg-Gt(ROSA)26Sor<tm14(CAG-tdTomato)Hze>/J) with 300 nl of AAV5-CamKIIα-ChR2:YFP into one of three different brain regions with known glutamatergic innervation of the BNST: anterior insular cortex, medial prefrontal cortex (mPFC), or the parabrachial nucleus (PBN). Using whole-cell patch-clamp electrophysiological analysis of excitatory post-synaptic currents (EPSCs) elicited by full field blue light illumination in brain slices containing BNST from tdtomato positive neurons, we have observed EPSCs from mice expressing ChR2 in each of the targeted regions. Curiously, while stimulation of insular (8/8 cells; 4 mice) and PBN (2/2 cells; 1 mouse) projections resulted in light-induced EPSCs in all patched CRF neurons to date, only a small subset of CRF neurons responded to stimulation of the mPFC projection (4/24 cells; 5 mice) projection. One reason for these differences could be the substantial heterogeneity of CRF neurons with the BNST. Using current clamp profiles, our lab and others have shown there are at least three different types of CRF neurons. Data from our lab further exemplifies this heterogeneity by showing that ~24% of BNST CRF neurons are calbindin+ and ~9% of BNST CRF neurons project to the ventral tegmental area. Moving forward, we will work to further understand the role of such divergent afferent circuit connectivity to BNST CRF neurons and how stress and norepinephrine can modulate these glutamatergic inputs.

Title: Guanfacine activates crf-negative bnst neurons: interaction with hcn channels?

Authors: ***N. A. HARRIS**[1,2,3,4], S. A. FLAVIN[1,5], E. K. AWAD[1,2], Y. SILBERMAN[1,3,4], D. G. WINDER[1,2,3,4,5];

Abstract: Stress is a major risk factor for relapse to drug-seeking behavior. The bed nucleus of the stria terminalis (BNST) receives an extensive noradrenergic input and has been shown to be critical in stress-induced relapse to drug-seeking. In rodents, systemic or intra-BNST treatment with α2-adrenergic receptor agonists decreases stress-induced reinstatement behaviors. Clinical studies report that guanfacine, an α2A-AR agonist, curbs cravings for a variety of substances of abuse. We have previously shown that α2A-ARs are heavily expressed in the BNST, and that noradrenergic signaling in the region is dramatically altered in α2A-AR knockout mice. Ongoing studies in our lab suggest that competing inhibitory and excitatory actions of this drug in the BNST could reflect carefully coordinated control of divergent neuronal populations. Consistent with this idea, we find that stress increases c-fos expression in both CRF+ and CRF- cells in the BNST, using a CRF-tdtomato reporter mouse line (strain B6(Cg)-Crhtm1(cre)Zjh/J crossed with strain B6.Cg-Gt(ROSA)26Sor/J). Administration of guanfacine prior to the stress suppresses the c-fos response in only CRF+ cells. Moreover, guanfacine alone enhances the c-fos levels in CRF- cells. Our lab has shown inhibitory effects of guanfacine in the BNST on electrically evoked EPSCs and optically evoked EPSCs derived from parabrachial nucleus (PBN) afferents. This is consistent with canonical Gαi signaling and inhibition of CRF+ neurons. In contrast, in Thy1-COP4 transgenic mice (B6.Cg-Tg(Thy1-COP4/EYFP)18Gfng/J) where ChR2 expression is much reduced in PBN afferents relative to others, bath application of guanfacine enhances optically evoked BNST field potentials. We hypothesize that this novel excitatory effect of Gαi signaling occurs through postsynaptic α2A-ARs in CRF- cells, leading to decreased cAMP-dependent opening of hyperpolarization-activated cyclic nucleotide-gated nonselective cation (HCN) channels. Here we show that bath application of the nonselective HCN inhibitor ZD7288 in *ex vivo* BNST slices from Thy1-COP4 mice enhances optical field potentials by 25%, an effect comparable to that of guanfacine. Furthermore, after systemic guanfacine treatment in a c-fos-eGFP mouse line (B6.Cg-Tg(Fos/EGFP)1-3Brth/J), current clamp profiles of c-fos+ BNST neurons show a significant Ih contribution in 80% of neurons. These converging lines of evidence suggest that excitatory actions of α2A-AR agonism are due to interactions with HCN channels in CRF- BNST neurons. Future studies will elucidate the mechanism of guanfacine enhancement and identify markers of BNST CRF- neurons.

Title: Association of N-cadherin levels and downstream effectors of Rho-GTPases with dendritic spine loss induced by chronic stress in rat hippocampal neurons

Authors: *J. L. FIEDLER[1], P. CATAÑEDA[2], M. A. MUÑOZ-LLANOS[1], G. GARCÍA-ROJO[1], R. MARQUEZ[1], M. GARCÍA-PÉREZ[1], P. S. ROJAS[1], E. ALIAGA[3];

Abstract: Chronic stress promotes cognitive impairment and dendritic spine loss in hippocampal neurons. In this animal model of depression, spine loss probably involves a weakening of the interaction between pre- and postsynaptic cell adhesion molecules such as N-cadherin, followed by disruption of cytoskeleton. N-cadherin, in concert with catenin, stabilizes the cytoskeleton through Rho-family GTPases. Via their effector LIM-kinase, RhoA and RAC-GTPases phosphorylate and inhibit cofilin, an actin-depolymerizing molecule, favouring spine growth. Additionally, RhoA through ROCK inactivates myosin phosphatase through phosphorylation of the myosin-binding subunit (MYPT1), producing acto-myosin contraction and probable spine loss. We evaluated whether N-cadherin/β-catenin and Rho-signalling are sensitive to chronic restraint stress. Stressed rats exhibit anhedonia, impaired associative learning and immobility in the forced swimming test and reduction in N-cadherin levels but not β-catenin in the hippocampus. We observed a reduction in the spine number in the apical dendrites of CA1 pyramidal neurons. Although, the stress did not modify the RAC-LIMK-cofilin signalling pathway, we observed an increase phospho-MYPT1 levels, probably mediated by RhoA-ROCK activation. Our findings suggest that a dysregulation of RhoA-ROCK activity by chronic stress could potentially underlie spine loss in hippocampal neurons.

Title: The Rho-Kinase Inhibitor, Fasudil, prevents depressive-like behavior and hippocampal dendritic spine loss promoted by chronic restraint stress in rats

Authors: *G. GARCÍA ROJO, N. VILCHES, A. GARCÍA, F. AGUAYO, J. L. FIEDLER; Univ. De Chile, Santiago, Chile

Abstract: Brain atrophy accompanied by dendritic arbor simplification and reduction in spine density of the hippocampus, a limbic structure implicated in mood disorders, are factors that seems to contribute to the symptoms of depression. It is plausible that these morphological changes imply alterations in the dendritic cytoskeleton dynamic. RhoA is an important regulator of actin dynamic through its effector ROCK. Transfection of hippocampal pyramidal neurons with constitutively active ROCK mutant produces dendritic simplification and dendritic spine loss. We propose that ROCK inhibitor as fasudil (also known as HA-1077), may prevent both the stress-induced depressive like-behavior in rats and the spine density reduction in the hippocampus. Adult male Sprague-Dawley rats were injected i.p. with saline or fasudil (10 mg/kg) starting four days prior restraint stress procedure, which was conducted 2.5 hrs/day during 14 consecutive days. Control animals were injected with saline or fasudil during 18 days. In order to observe the effect of fasudil on depression- like behavior promoted by stress, we carried out the forced swimming test and conditioned avoidance test. Fasudil prevents the stress-induced immobility observed in forced swimming test. In addition, fasudil prevents the stress-induced reduction in conditioned avoidance responses. On the other hand, control animals treated with fasudil showed similar behavioral patterns as control saline animals. Furthermore, Fasudil prevents the stress spine loss in the dorsal hippocampus promoted by chronic stress. Thus we proposed that Fasudil may prevent abnormal behavior promoted by stress probably blocking the ROCK activity with a concomitant prevention of the spine loss.

Title: Effect of stress on specific microRNAs levels that target genes coding for key proteins involved in spine morphology

Authors: *M. A. GARCÍA PÉREZ[1], M. A. MUÑOZ-LLANOS[1], X. XU[2], J. CIDLOWSKI[2], F. AGUAYO[1], G. GARCÍA-ROJO[1], J. L. FIEDLER[1], A. A. PACHECO[1];

Abstract: MicroRNAs (miRNAs) are small non-coding RNAs that regulate mRNAs translation by matching a seed sequence in the 3'UTR which induces the silencing or degradation of transcripts. MiRNAs are profusely reported in several tissues, cell types and models. They have been postulated as key regulators of relevant processes such as neuroplasticity and brain functions. Recently, we determined the effect of stress on miRNAs levels in the hippocampus. The aims of this study were to (i) verify by RT-qPCR those variations in hippocampus during and after acute and chronic restraint stress sessions (ii) evaluate the putative mRNAs targets relevant for brain function by bioinformatics analyses. Adult male rats were stressed during 0.5 or 2.5 h and sacrificed immediately after restraint session, or 6 and 24 h post stress for acute stress. For chronic stress the rats were stress 2.5 h per day for 14 days and they were sacrificed 24hrs after the last session. We determined that miR-132 and miR-138 did not change in acute stress. Nonetheless, miR-138 showed a significant increase (2 folds) in the chronic stress model. Interestingly, it has been demonstrated that miR-138 has a relevant role in spine morphology and has multiple protein targets relevant in remodeling pathways such as LIMK, ROCK, among others.

Title: Relationship between FMRP and MMP9 in an acute restraint stress model in rats: a possible cross-regulation mechanism

Authors: *F. I. AGUAYO, SR[1], P. ROJAS[2], A. A. PACHECO[1], G. J. GARCÍA-ROJO[1], M. GARCÍA-PÉREZ[1], M. MUÑOZ-LLANOS[1], R. MÁRQUEZ[1], J. L. FIEDLER[1];
[1]Facultad De Ciencias Químicas Y Farmacéticas - Uni, Santiago, Chile; [2]Escuela de Química y Farmacia, Univ. Andrés Bello, Santiago, Chile

Abstract: Proteins of Extracellular Matrix (ECM) are important for development and regeneration of nervous system, besides are important in synaptic plasticity. The Matrix Metalloproteinase 9 (MMP9) participates remodeling proteins of ECM, such as: cytokines, growth factors, membrane receptors, adhesion molecules and other proteases. An increase of MMP9 activity has been associated to pathological conditions such as inflammatory diseases. In contrast, an increase in MMP9 activity has been described during LTP, which is considered as a learning model. The increase in MMP9 activity may occur by an altered transport and stability of mRNA, variations in protein level, secretion and post-translation processing. It has been observed in KO mouse for Fragile X Mental Retardation Protein (FMRP) an increase in the gelatinase activity of MMP9, a deregulation in dendritic spine maturation, alterations in mGluR1/5-dependent LTD and altered social behavior. Interestingly in double KO of Fmr1/Mmp9 mouse all these modifications are prevented; suggesting an interrelationship between the activities of both proteins. Furthermore, the level of MMP9 and the activity of FMRP are regulated by glutamate neurotransmission, while the level of FMRP is sensitive to glucocorticoids, an important stress hormone. We evaluated whether the relationship between MMP9 and FMRP observed in KO mice is preserved in an acute restraint stress model. Adult male wild type Sprague-Dawley rats were stressed by restraint during 0.5 or 2.5 hours, and in order to evaluate the posterior effects of stress on hippocampus, another group was sacrificed after 1.5; 6 and 24 hours post stress. During the first 0.5 h of stress we observe an increase in FMRP levels accompanied by a decrease in the levels of MMP9. After 2.5 h of stress FMRP returned to control levels, while MMP9 increased. We did not observe changes in FMRP phosphorylation. At 24 h post stress both protein levels return to normal. We concluded that the relationship between MMP9 and FMRP observed in KO mice is preserved in an acute restraint stress model. These results suggest a cross-regulation mechanism that involves an inverse relationship between both proteins.

Title: Finding the missing heritability in GWAS: u-statistics of genetically structured data in subgroup analyses of epilepsy, autism and migraines

Authors: *K. M. WITTKOWSKI[1], E. EISING[3], C. DADURIAN[2], B. BIGGIO[2], G. M. TERWINDT[3], M. D. FERRARI[3], I. HEADACHE GENETICS CONSORTIUM[4], A. M. J. M. MAAGDENBERG[3];
[2]CCTS, Biostatistics, Epidemiology & Res. Design, [1]The Rockefeller Univ., New York, NY; [3]Med. Ctr., Leiden Univ., Leiden, Netherlands; [4]IHGC, Helsinki, Finland

Abstract: Background: A decade after the Human Genome Project, the clinical advances hoped for from genome-wide association studies (GWAS) have not yet been realized. Enlarging sample sizes to tens or hundreds of thousands limits the questions that can be addressed, but does not guard against non-functional SNPs differing between non-randomized populations. Combining a novel computational biostatistics approach with decision strategies fine-tuned to GWAS, we can now identify clusters of related gene in groups of hundreds of subjects only. Methods: U-statistics for genetically structured data account for linkage disequilibrium (LD), varying dominance, and compound heterozygosity within a moving window of SNPs. Replacing the conventional fixed 10E−7.5 level with a study-specific cut-off for genome-wide significance accounts for differences in minor allele frequency, the non-randomized nature of GWAS, and for conducting related tests in overlapping diplotypes. Results: The approach was validated by confirming the known targets of epilepsy drugs in a study comparing 185 childhood cases against publicly available controls. Comparing non-verbal vs verbal cases in the two independent stages of the Autism Genome project, suggested the same ion channels as being involved in disruption of active language development (DALD) as in migraines, in support of the hypothesis that preventing “stranger anxiety” from turning into migraine-like experiences might preventing a behavioral maladaptation leading to lack of language (Wittkowski KM Transl Psychiatry 2014, 4:e354). Conclusions: By reducing sample size requirements for GWAS, the genetic data collected over the last decade can now yield profound insights into the etiology of common diseases and subgroup analyses can rescue ‘failed’ phase 3 trials.

Title: Paracrine signaling via connexin hemichannels contributes to the propagation of ionizing radiation-induced DNA damage in brain microvascular endothelial cells

Authors: *E. DECROCK[1], D. HOORELBEKE[1], M. DE BOCK[1], H. THIERENS[2], B. DESCAMPS[3], C. VANHOVE[3], L. LEYBAERT[1];

Abstract: Rardiotherapy is a common treatment for the management of brain tumors. Although modern techniques provide a more precise delivery of radiation, some exposure of normal brain tissue is inevitable. This results in acute vascular damage, primarily characterized by brain microvascular endothelial cell (mEC) dysfunction (activation and cell death) and blood-brain barrier disruption. Importantly, ionizing radiation-induced cellular effects do not remain confined to the cells directly hit by the radiation, but they can be transferred to adjacent non-irradiated cells via intercellular communication pathways, a phenomenon termed the radiation-induced bystander effect (RIBE). Reported RIBE include apoptosis, changes in proliferation, genetic alterations and oncogenic transformation. It is suggested that the propagation of DNA damage, in particular double-strand breaks (DSBs), is a causal agent in these downstream effects. Paracrine factors and direct cell-cell communication via gap junction channels (GJs) are both critical mediators of RIBE. ECs are well-coupled through GJs which are formed by the docking of two hemichannels (HCs). These HCs, i.e. hexameric channels of transmembrane Cx proteins, are commonly closed but may be activated in response to various, mostly pathological, stimuli. They form a diffusive release pathway for paracrine messenger molecules such as ATP into the extracellular environment. We here aimed to explore the role of Cx channels in RIBE in brain mECs. We optimized a set-up in which a well-delineated zone of an adherent rat brain

microvasular endothelial cell line (RBE4) or primary mouse brain capillary ECs was exposed to X-rays (1 and 20 Gy). We investigated kinetics of DSBs (γ-H2AX), in both the irradiated and surrounding non-irradiated bystander zone. The presence of γ-H2AX-positive cells was detected in the bystander zone with a maximum response 3 h post-irradiation, and was reduced in the presence of pharmacological Cx channel blockers or HC-targeting peptides. Reactive oxygen species (ROS) are hypothesized to play a key role in coordinating the RIBE but the mechanism of distant action of these short-lived molecules remains unclear. We here demonstrated that ROS as well as calcium ions (Ca2+) and extracellular ATP are key players in the propagation of the RIBE. We propose that intercellular Ca2+ signaling via Cx HCs (paracrine ATP release pathway) and presumably also via GJs acts as a feed-forward propagation mechanism of ROS production underlying the RIBE. Hence, our results suggest a novel mechanism for radiation-induced damage of brain mECs which involves Cx channels, ATP release and the Ca2+/ROS signaling axis.

Title: Glucocorticoid receptor-regulated transcription of transposable elements

Authors: *R. G. HUNTER[1], B. B. GRIFFITHS[2];
[1]Psychology, Univ. of Massachusetts, Boston, Boston, MA; [2]Developmental and Brian Sci., Univ. of Massachusetts Boston, Boston, MA

Abstract: Stress has been shown to regulate gene expression through epigenetic mechanisms, but little is known about its effects on the 95% of mammalian DNA that does not code for proteins. 50% of this non-coding DNA is comprised of transposable elements (TEs). These elements have been shown to have a number of adaptive roles, including transcriptional regulation and the provision of functional elements in regulatory non-coding RNAs. It has long been proposed that these elements are important in organismal responses to stress. Corticosteroid hormones released in response to physiological and psychological stress are agonists for

glucocorticoid receptors (GRs), which bind to DNA and act as transcription factors. GR binding has been shown to be highly tissue specific. It has been shown in ChIP-sequencing (ChIP-seq) in hippocampal tissue from adrenalectomized, corticosterone challenged rats that only 40% of GR binding is within genes or gene promoters, with the other 60% binding to intergenic regions. Previously, we have shown that some of this intergenic GR binding is to TEs. TE transcription has been shown to be regulated by drugs of abuse, physiological and psychological stress. Further comparison of GR ChIP-seq data with RNAseq data from acute restraint stress and adrenalectomized, corticosterone challenged rats suggests that GR binding results in the altered transcription of TEs in response to acute restraint stress and corticosteroid challenge. While the biological significance of TE transcription resulting from stress-activated GR binding is still largely unknown, it is likely to play a significant role in both the adaptive stress response and potentially in the maladaptive consequences of chronic or uncontrolled stress.

Title: Adult vitamin D deficiency does not alter adult neurogenesis but is associated with impaired performance on a hippocampal-dependent task

Authors: *N. GROVES, R. SULLIVAN, P. JOSH, J. MCGRATH, T. BURNE;
Queensland Brain Inst., St Lucia, Australia

Abstract: Vitamin D has been shown to be important for brain development and function, and vitamin D deficiency may lead to adverse brain outcomes, such as poor cognitive function. To address the link between vitamin D deficiency and cognitive impairment, this study assessed the effects of adult vitamin D (AVD) deficiency on adult neurogenesis in the hippocampus; and learning and memory using a hippocampal-dependent task in mice. Adult male BALB/c mice were fed either a vitamin D-deficient diet or a diet containing vitamin D (1,000 IU/kg) for 10 weeks. One cohort of mice were tested for active place avoidance, which is a hippocampal-dependent learning and memory task. This task requires mice to learn to avoid a shock zone in an arena via extramaze cues over 4 days. A second cohort of mice were treated with BrdU for 10 days, and 32 days later, fixed brains were collected to assess the number of newborn surviving mature neurons and the number of proliferating cells in the dentate gyrus using

immunohistology. Hippocampal brain tissue was collected from a final cohort of mice to assess protein changes using iTRAQ proteomics. In the active place avoidance, control mice learnt the location of the shock zone and over 4 days of testing increased their latency to enter the shock zone. However, there was a significant reduction in avoidance latency in AVD-deficient mice. AVD-deficient mice also showed an increase in distance travelled during the 10 min daily task, despite having no baseline locomotor differences. There was no significant difference in the number of newborn surviving mature neurons or proliferating cells within the dentate gyrus between control and AVD-deficient mice. Proteomic analysis indicated changes in the expression of enzymes involved in the production of glutathione, an important antioxidant for the regulation of oxidative stress. Furthermore, there were changes in the expression of proteins relating to excitatory and inhibitory neurotransmitter systems. Consistent with immunohistological results we identified no expression changes in proteins involved in proliferation or neurogenesis. This study showed that AVD deficiency in mice was associated with impaired performance on the active place avoidance task. However, the AVD-deficient mice did not show a reduction in cell proliferation or hippocampal neurogenesis. Further studies are required to investigate the effects of AVD deficiency on oxidative stress and neurotransmission and how they may relate to cognitive impairment.

Title: Amygdalar miR-15a regulation of FKBP5 is essential for intact behavioral response to chronic stress

Authors: ***N. VOLK**[1,3], J. PAPE[4], S. BEN-DOR[2], R. ZWANG[1], S. GIL[1], E. B. BINDER[4], A. CHEN[1,3];

Abstract: MicroRNAs are important regulators of gene expression and were shown to associate with regulation of various psychiatric disorders; however the identity of specific stress-related

microRNAs (miRs), which are recruited to the Ago2 complex at the time of stress induction has yet to be elucidated. In order to identify a genuine connection between specific miRNAs and their target gene`s 3` UTR following chronic stress, we performed immunoprecipitation of the Ago2 complex and analyzed the identity of the entire population of miRNAs and mRNAs following social defeat in the amygdala. Here, we present evidence that exposure of mice to chronic stress leads to a specific increase of miR-15a levels in the Ago2 complex in the amygdala of stressed mice. A concomitant reduction in the levels of miR-15a predicted target, FKBP5 has been observed. Reciprocally, mice expressing reduced levels of miR-15a in the amygdala alongside chronic exposure to stress, exhibit increase anxiety and depression-like behaviors. FKBP5 is a modulator of glucocorticoid receptor (GR) sensitivity, and thus, the link between both miR-15a and FKBP5 might be functionally important in the stress response. Consistent with methylation-dependent regulation of miR-15a, its levels were elevated following *in vitro* treatment with DNA methyltransferase activity inhibitors. Interestingly, methylations of 7 CpGs, located within the promoter region of human miR-15a, were found to correlate with major depression disorders. Taken together our results support an important role for miR-15a in stress adaptation and the pathogenesis of stress-linked psychopathologies.

Title: Chronic stress modulates the physiological effects of SIRT1 activity in the dentate gyrus of mouse hippocampus

Authors: *D. YU[1], D. HOMIACK[1], L. A. SCHRADER[2,1];
[1]Neurosci. Program, [2]Cell and molecular biology department, Tulane Univ., New Orleans, LA

Abstract: The sirtuins are a family of NAD+ dependent protein deacetylases that are involved in metabolic processes and have been shown to have various functions in neurons, such as DNA

repair and neuronal survival. Previous work in our lab found that chronic variable stress (CVS) significantly increased Sirtuin1 (SIRT1) activity in the dentate gyrus (DG) of rat hippocampus. Direct infusion of sirtinol, a SIRT1 and 2 inhibitor, into the DG prevented CVS-induced memory impairment and depressive-like behavior. The specific function of SIRT1 in the DG, however, is unknown. We hypothesized that SIRT1 activity may affect neuronal properties in the DG of hippocampus slices of control and CVS-treated mice. In this study, we made the surprising finding that pharmacological inhibition of SIRT1 activity increased granule cells excitability in slices from control mice but not CVS-treated mice. This effect in control mice is mediated by voltage- and calcium-dependent large conductance potassium channels (BK channels), as it is blocked by paxilline, the BK channel blocker. In addition, we found that pharmacological inhibition of SIRT1 activity increased spontaneous excitatory postsynaptic current (sEPSC) frequency, but not amplitude, recorded from DG granule cells in slices from control mice. This effect was not observed in CVS-treated mice. The effect on sEPSC frequency in control mice is action potential-dependent. The effect is also blocked by paxilline, suggesting an increase in presynaptic cell excitability mediated by BK channels. On the other hand, pharmacological activation of SIRT1 decreased sEPSC frequency that is TTX-dependent. These results suggest that SIRT1 affects granule cell intrinsic properties and excitatory input through BK channels in control mice but that pathway is impaired in CVS-treated mice. Our previous results showed that SIRT1 activity in the nucleus is increased in CVS, therefore, we propose that CVS-induced long-term SIRT1 over-activity decreases the sensitivity of membrane targets to SIRT1 activity but increases SIRT1 effects in nucleus and transcriptional level. We will investigate this hypothesis in future studies.

Title: Study of a newly identified molecule that respond to a stress hormone, glucocorticoid

Authors: *K. KOIZUMI[1], K. NAKAO[2], H. NAKAJIMA[3];
[1]Kanazawa Univ., Kanazawa-Shi, Japan; [2]Dept. of Physiol., Saitama Med. Univ., Moroyama, Japan; [3]Ageo Central Gen. Hosp., Ageo, Japan

Abstract: Maternal stress during pregnancy increases secretion of stress hormones such as glucocorticoid (GC). A numbers of studies indicate high level exposure to GC during prenatal period affects neural development and stress response after birth. It causes increasing anxiety and behavioral problems for children (Neurosci Biobehav Rev 53:1-24, 2015). Moreover, recent studies suggest it causes psychiatric disorders such as depression (Front Neurosci. 8: 420, 2015), schizophrenia (Psychopharmacology 214: 89-106, 2011) and autism (Neuroscience and Biobehavioral Reviews 32: 1519-1532, 2008). Although detail molecular mechanisms that link between prenatal stress and these psychiatric disorders are not well understood, GC responding molecules are good candidates to play critical roles in this mechanism. Here, we show a newly identified GC responsive molecule, Fam107B. Injection of GC agonist, DEX, or restraint stress on pregnant mice resulted in reduction of Fam107B mRNA expression in the brain of their embryos. To figure out its function, we study effects of RNAi or over expression of FAM107B in neuron-like PC12 cells and mouse neural cells. We found Fam107B negatively regulate effects of DEX on proliferation, differentiation and migration. Possibly, FAM107B is one of the key molecules that respond to stress or GC and give critical effects on neural development in the embryonic brain.

Title: Altered coding- and noncoding RNA expression in the bed nucleus of the stria terminalis of suicide subjects

Authors: *T. M. KLEIN GUNNEWIEK[1], A. JAGER[2], J. C. GLENNON[2], T. KOZICZ[1], A. ASCHRAFI[1];
[1]Dept. of Anat., [2]Dept. of Cognitive Neurosci., Radboudumc, Nijmegen, Netherlands

Abstract: The human stress pathway constitutes a complex system of interconnected brain structures. One of these structures, the bed nucleus of the stria terminalis (BNST), is a limbic region with extensive connectivity with other (sub)cortical brain structures. Previous studies have shown the potential role the BNST plays in processes such as - but not limited to - stress and anxiety, fear learning, and drug seeking behavior. Although changes in expression in various neurotransmitters as well as neuromodulators have been demonstrated in these conditions, a

comprehensive expression profile of the BNST has not yet been made. MicroRNAs (miRNAs) constitute a class of small noncoding units of RNA, each of which able to regulate the expression of up to hundred different genes, and recent studies suggested that they might be involved in fine-tuning gene networks involved in the neuronal stress response. Using Next Generation Sequencing, we analyzed whole transcriptomics of the human BNST, whereby we compared the expression of coding- and noncoding RNA in BNST tissues collected from depressed suicide victims or from individuals who deceased of natural causes (controls). Preliminary results show at least 75 miRNAs with a significant ($P<0.05$) fold change of at least 1.2 changed in depressed suicides as compared to controls. Of these differentially expressed miRNAs we found, 31 were down regulated, whereas 34 were up regulated. Many of these miRNAs identified have been associated with cellular processes involving neuronal stress response, such as mir-34c and mir-124, while others have been linked to cancer (mir-34b, mir-449b), or diabetes (mir-375). In future studies miRNAs with mouse homologs will be validated using qPCR on BNST tissue from stressed- and non-stressed mice. Based on these findings we propose that differentially expressed BNST miRNAs and their associated gene networks may act as critical constituents in the regulation of neuronal stress response.

Title: Chronic early life stress alters circadian clock gene expression in the adrenal glands and liver of neonatal rats with no change in corticosterone secretion

Authors: *C.-D. WALKER[1], S. KIESSLING[2], L. LIN[3], N. CERMAKIAN[1];
[1]Dept Psychiat, [2]Dept of Psychiatry, [3]Dept of Anat. & Cell Biol., McGill Univ., Montreal, QC, Canada

Abstract: Disrupting maternal behavior in early neonatal life is recognized to have long term consequences on anxiety, social behavior and memory, possibly in part through changes in hippocampal synaptic plasticity and neural activity in the amygdala. The limited bedding (LB) model used in several studies of chronic early life stress postulates that fragmentation of maternal behavior is a critical aspect of the stress experienced by the neonates. However, how fragmentation of maternal behavior translates into changes in neural activity and physiological regulation in the pups is unknown. In the present study, we hypothesized that fragmented maternal behavior might disrupt circadian rhythmicity, i.e. clock gene expression (Bmal1 and Per2) in peripheral tissue oscillators in young pups. Mothers were kept either under normal (NB) or limited (LB) bedding conditions between postnatal day (PND)1-9 and tissues from pups were collected on PND10 after 24hrs of constant darkness at various times over the 24 h cycle (circadian time [CT]2, CT8, CT14, CT22). Maternal behavior was observed daily between PND1-9, 4 times during the light:dark cycle and scored for nursing time, pup grooming and fragmentation. Brain expression of Bmal1 in the central circadian clock (SCN), as detected by *in situ* hybridization, was rhythmic and not modified by maternal condition. However, expression of clock genes in peripheral circadian clocks, both adrenal and liver was significantly altered by LB condition. In the adrenals, the rhythm of Bmal1 and Per2 was maintained but the amplitude was increased in LB vs NB pups, while in the liver, rhythms in Bmal1 and Per2 were completely abolished by the LB condition. Plasma corticosterone secretion showed circadian rhythmicity with no significant differences between NB and LB pups. Fragmentation of maternal behavior was higher in the dark phase compared to the light phase and pup grooming behavior was higher in LB compared to NB mothers in the dark phase. Despite no change in nursing behavior frequency between maternal condition, body weight gain of LB pups was reduced compared to NB pups. Significant alteration in peripheral clock gene oscillators in the liver and adrenal in LB condition suggest that important changes in feeding and/or temperature regulation might mediate the effect of fragmented maternal behavior on adrenal and liver function during neonatal life.

Title: 5alpha-reductase mediates stress response circuitry

Authors: *G. L. OSTERHAUS[1], S. C. GODAR[2], L. J. MOSHER[2], C. M. JONES[2], M. BORTOLATO[2];
[1]Univ. of Kansas, Lawrence, KS; [2]Dept of Pharmacol. and Toxicology, Univ. Kansas, Lawrence, KS

Abstract: Stress is a major environmental factor involved in the activation and precipitation of a host of different neuropsychiatric disorders. Ample evidence has shown that stress elicits sexually dimorphic responses, indicating that hormones may be a critical regulatory element of the stress response cascade. For instance, females are more predisposed to depression and anxiety-related behaviors, whereas males are more vulnerable to aggression. However, the underlying molecular mechanisms that govern how steroid hormones shape disease susceptibility and regulate stress responses in a sex dimorphic fashion remain largely elusive. To investigate the role of androgens in stress regulation, we focused on 5alpha-reductase (5AR), the primary enzyme that catalyzes the major rate-limiting step in the synthesis of androgens and several other neurosteroids that mediate stress responses. Notably, 5AR expression is higher in males and is elevated in response to stress. We found that treatment with the 5AR blocker finasteride (FIN) dose-dependently increased depression-like behaviors in both sexes in the forced swim test. Moreover, these changes were accompanied by a significant reduction in the activity of the hypothalamic-pituitary-adrenal axis (HPA), the primary stress response system. In particular, FIN decreased the levels of two central HPA regulatory factors, namely hypothalamic corticotropin-releasing hormone (CRH) and plasma adrenocorticotropin releasing hormone (ACTH). In a separate cohort of animals, we found that FIN markedly reduced saccharin preference, a well-validated paradigm to capture anhedonia, in both male and female rats. Interestingly, FIN-treated animals displayed a progressive reduction in percentage of saccharin consumption throughout the test, suggesting that FIN may block the rewarding properties of saccharin. Taken together, these findings suggest that 5AR may play a critical role in stress response circuitry.

Title: Neurons born during chronic social stress conditions are more vulnerable to a subsequent stress later in life

Authors: *Z. DE MIGUEL[1,2], U. HADITSCH[3], T. D. PALMER[3], A. AZPIROZ[2], R. M. SAPOLSKY[1];
[1]Stanford University. Dept. of Biology, Neurol, Stanford, CA; [2]Univ. of Basque Country. Dept. of Psychobiology, San Sebastian, Spain; [3]Stanford University. Inst. for Stem Cell Biol. and Regenerative Med., Stanford, CA

Abstract: Objective: Numerous studies have examined the effects of stress on the quantity of neurons generated in the adult hippocampus, with most showing a decrease. Few, however, have examined the quality of neurons born during a period of stress. Here we ask whether neurons born despite ongoing stress are like neurons born during control conditions, and whether those neurons are more robust and resilient, or less so to later challenges in life. Methods: CD1 male mice were exposed to dominant cage mates for two weeks with BrdU administration. Ten weeks later, spatial learning was assessed in the Morris water maze. BrdU-ir/NeuN-ir cells, C-fos-ir/NeuN-ir cells, DCX-ir cells and BrdU-ir/NeuN-ir/C-Fos-ir cells were quantified in the dentate gyrus and latencies to find the hidden platform in the spatial learning task were evaluated. In a second experiment newly born cells were labeled using a retroviral vector MLV-CAG-GFP during chronic social stress or control conditions. Eight weeks later animals were exposed to either a second session of chronic social stress or control conditions. Changes in morphology of newly born neurons were examined by determining spine density, dendrite length and number of dendritic branches. Results: Two weeks of social stress increased the number of neurons born during the last five days of stress. Ten weeks after the stress termination, control and stressed animals showed comparable spatial learning acquisition while stressed animals showed a deficit in spatial memory recall. No differences were found in the number of BrdU-ir/C-Fos-ir/NeuN-ir+ neurons. Chronic social stress had no effect on dendritic morphology in neurons born during control conditions; in contrast, such stress decreased spine density and the number of dendrite branches in neurons born during a prior period of stress. Conclusions: Chronic social stress increases the number of neurons generated in the adult dentate gyrus. This effect may be explained by enrichment components inherent to the social interaction that occurs during the social stress model. Despite increased numbers of newly born neurons, the stressed group showed a deficit in spatial memory recall. Additionally, neurons that are born during chronic

social stress conditions may be more vulnerable to recurrent stress experiences later in life. These findings are the first evidence suggesting that newly born neurons during chronic social stress conditions may be more vulnerable to future social stress episodes. However, these findings warrant further examination of whether these effects are intrinsically driven or driven by microenvironmental factors from the niche.

Title: 5alpha-reductase 2 plays a key role in reward and stress

Authors: *S. C. GODAR, G. L. OSTERHAUS, L. J. MOSHER, M. BORTOLATO; Pharmacol. and Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: The stress response system elicits multiple adaptive processes that function on threat appraisal and the enactment of coping strategies. However, a host of studies have shown that both rewarding and aversive stimuli elicit the activation of the hypothalamic-pituitary-adrenal axis (HPA), the primary stress response system. These findings suggest that the HPA is a key substrate for physiological and neurobehavioral adaptive functions. Given the large sexual dimorphism in stress regulation, we investigated the role of neurosteroids in mediating the behavioral and neuroendocrinological responses to different stressors. In particular, we examined 5 alpha-reductase (5AR), the primary enzyme that catalyzes the major rate-limiting step in neurosteroidogenesis. In recent studies, we documented that 5AR blockade with finasteride increased depression-related behaviors and anhedonia, but reduced HPA activation. Finasteride, however, blocks both 5AR1 and 5AR2 isoenzymes, which greatly differ in substrate affinity,

activation requirements and neuroanatomical localization. Despite these differences, the specific contribution of each isoenzyme in stress regulation remains largely unknown. To study the role of 5AR2 in stress regulation, we tested the responses of 5AR2 knockout mice to the forced swim and saccharin preference paradigms, two behavioral tasks that capture depression-like and anhedonic behaviors, respectively. We found that 5AR2-deficient mice showed a marked elevation in depression-related behaviors compared to wild-type littermates. Interestingly, finasteride treatment increased depression-like behaviors in wild-type mice, however this compound did not affect 5AR2 mutants in the forced swim task. These findings were also accompanied by a significant reduction in plasma corticosterone levels in 5AR-deficient mice following forced swim stress. Moreover, we found that 5AR2 mutants exhibited a profound reduction in saccharin preference compared to wild-type animals, suggesting a decrease in responses to reward. Collectively, these results suggest that 5AR2 is a key stress mediator and likely contributes to specific depressive- and anhedonic-like effects of finasteride.

Title: Glucocorticoid receptor and fkbp5 expression and epigenetic variation in teenage and adult suicide

Authors: *H. S. RIZAVI, D. GRAYSON, H. ZHANG, G. N. PANDEY;
Univ. Illinois Chicago, Chicago, IL

Abstract: An impaired HPA stress response has been linked to depression and increased risk of suicide. The feedback regulation of the HPA axis by glucocorticoids is mediated by mineralocorticoid (MR) and glucocorticoid (GR) receptors. GR may play a more important role in the regulation of the stress response when endogenous levels of glucocorticoids are high because of its high affinity for DEX and a lower affinity for endogenous cortisol. GR-mediated

response is regulated by a number of co-factors which interact with GR and regulate its affinity for cortisol. FKBP5 is a co-chaperone protein that, when bound to GR, decreases its sensitivity to cortisol and therefore affects nuclear translocation. In this preliminary study we wanted to analyze the glucocorticoid receptor expression, specifically variant 1F, and FKBP5 in prefrontal cortex samples obtained from a teenage and adult suicide cohort. In addition we also wanted to examine the methylation status of GR1F and FKBP5 promoter in these samples.In adult suicide we observed a decrease in expression of GR1F and an increase in FKBP5 while total GR did not show any change. In teenage suicide total GR and GR1F were both significantly decreased and FKBP5 showed an increase. GR1F promoter region showed a greater increase in methylation in suicide of the teenage group compared to the adult group and a greater demethylation was seen for FKBP5 in suicide of the teenage group compared to the adult. This preliminary study shows that GR and GR related genes may function differentially in teenagers compared to adults. Our data strengthens the idea that epigenetic variation in GR1F and FKBP5 may play an important role in depression and suicidal behavior. In addition, although the sample number was small, variation in methylation status in the GR1F and FKBP5 promoter regions in teenage compared to adult supports the notion that the neurobiology of teenage suicide may be different from adult.

Title: Optogenetic investigation of the anterior bed nuclei of the stria terminalis (aBST) in the inhibition of the neuroendocrine stress response

Authors: *S. B. JOHNSON, R. M. ANDERSON, M. L. HUFF, S. A. ROMIG-MARTIN, R. M. GLANZ, M. C. MILLER, R. T. LALUMIERE, J. J. RADLEY;
Psychology, Univ. of Iowa, Iowa City, IA

Abstract: A vital component of the emotional stress response is activation of the HPA axis, the neuroendocrine signaling cascade that culminates in the release of glucocorticoids (GCs). During emotional stress, upstream cortical limbic regions modulate HPA output via a combination of neuronal and GC-dependent mechanisms. The fact that these regions do not directly innervate

HPA effector cell groups housed within the paraventricular hypothalamic nucleus (PVH), poses challenges for understanding the circuits and mechanisms accounting for how these influences are conveyed to the stress axis. Previous work utilizing functional neuroanatomical and lesioning approaches has identified a putative site within aBST that may serve as one nodal point for conveying stress-inhibitory information from the limbic cortex to PVH. However, as these studies have been largely inferential and have also provided some conflicting information as to the nature of aBST influences over the stress axis, we employed optogenetic approaches to examine the functional role of the aBST–PVH pathways during acute stress-induced HPA activation. Adult rats received bilateral injections of the nonselective light-activated cation channel, channelrhodopsin (AAV5-hSyn-ChR2[E123A]-eYFP; ChR2 group) or control virus (AAV5-hSyn-eYFP; eYFP group) into the aBST followed by bilateral fiber optic implantation immediately dorsal to the aBST. Four weeks later, animals were subjected to an acute emotional stressor (10 min tail suspension; TS) with concurrent 20Hz 473nm laser stimulation for the duration of TS, and repeated blood samples were collected before and after stress exposure for assay of pituitary-adrenal responses. Following photoexcitation of aBST throughout the 10 min period of TS, ChR2 animals showed blunted HPA responses as compared with eYFP controls, evidenced by a significant decrease in ACTH levels immediately after TS (by 30%, $p < 0.05$) as well as a more rapid decline in post-stress corticosterone levels ($p < 0.05$). In a follow-up experiment involving the same procedures with the exception that fiber optic implants were positioned proximally to PVH, photoexcitation of axon terminals originating from aBST recapitulated the HPA-inhibitory effects of aBST cell body stimulation following stress exposure. Immunohistochemical analysis verified that viral-expressing terminals from aBST neurons were GABAergic, and resided in close apposition with CRF-expressing cells within the parvicellular subdivision of PVH. Together, these initial experiments provide a framework for further investigation of aBST involvement in HPA modulation during acute and chronic stress.

Title: Stimulatory action of tobacco-specific carcinogen on the keratinocytes and cancer cells proliferation: neurotransmitters receptor-mediated effects

Authors: *D. G. BERNABE[1], F. VERZA[2], G. MIYAHARA[2], S. OLIVEIRA[3];
[2]Oral Oncology Ctr., [3]Basic Sci., [1]São Paulo State Univ., Araçatuba, Brazil

Abstract: In this study we investigated whether keratinocytes (Hacat) and oral squamous cells carcinoma (OSCC)-derived cell lines (SSC9 and SCC25) are able to produce neurotransmitter norepinephrine (NE) as also the effects of the carcinogen 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) on the NE secretion and OSCC proliferation. Using enzyme-linked immunosorbent assay (Elisa) studies to measure NE concentrations and cell proliferation we demonstrated that supernatant of Hacat, SCC9 and SCC25 showed higher NE levels (6-, 14.9- and 15.1-fold more, respectively) compared to culture media without cells ($p<0.01$). When the cells were stimulated with 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), a tobacco-specific carcinogen, there were increases in the levels of NE secretion in supernatant by Hacat and SCC25 cells ($p<0.05$), but not by SCC9 cells. NNK (10 μM) induced cell proliferation in the Hacat, SCC9 and SCC25 cell lines and these effects were totally inhibited by blocking ß-adrenergic receptors with propranolol ($p<0.05$). The NNK-induced OSCC cell proliferation was also dependent on nicotinic acetylcholine receptors α4 (nAChR-α4) activation (totally in SCC9 cells and partially in SCC25 cells), but not dependent on nAChR-α7 activation. Inhibition of the ß-adrenergic receptors, nAChR-α4 and nAChR-α7 did not block NNK-induced Hacat proliferation ($p>0.05$). Our findings suggest that NNK-induced alterations in OSCC can be associated with imbalance of norepinephrine secretion and neurotransmitter receptors activations.

Title: Drug discovery for the treatment of neuropsychiatric disorders using the zebrafish model system

Authors: *J. BURGSTALLER[1], D. BARBER[2], M. SCHÖNBERGER[2], K. SLANCHEV[1], D. TRAUNER[2], H. BAIER[1];

Abstract: Psychiatric disorders, such as depression, anxiety, schizophrenia and autism, affect a large fraction of the human population. Major depression is characterized by low mood, anhedonia, social withdrawal and other severely debilitating behavioral symptoms. Dysregulation of the hypothalamic-pituitary-adrenal (HPA, "stress") axis is highly correlated with depression and may be a contributing cause to the development of the disease. The identification of a zebrafish (Danio rerio) experimental model with a mutation in the glucocorticoid receptor provides an invaluable tool for research into the pathogenesis of depression, and for the development of potential drug treatments. In this mutant, grs357, the stress axis is chronically elevated (Griffiths et al., 2012), and the homozygous adult animals exhibit behavioral phenotypes reminiscent of an affective disorder (Ziv et al., 2013). Due to their small size, genetic tractability, low cost and quick reproductive cycle, zebrafish have emerged as a new model system for high-throughput *in vivo* screens in search of disease-modifying chemical compounds. We have screened a library of 2,300 biologically active small molecules, at two concentrations, for their acute effects on wildtype and grs357 mutants. Clustering the data by phenotype has revealed a number of novel modifiers of zebrafish larval behavior. Screening of drug X genotype interactions using grs357 is therefore opening up the possibility of identifying novel therapeutic avenues for the treatment of stress-related disorders. In addition, in a more targeted approach, we are exploiting the transparency of zebrafish larvae to explore the utility of photoswitchable, neuroactive compounds to modify behavior. These studies are designed to fulfill the promise of zebrafish as a drug-discovery vehicle for neuropsychiatric disorders.

Title: Imaging the neural circuitry of life threat in prairie voles

Authors: *J. R. YEE[1,3], W. KENKEL[3], A. PERKEYBILE[3], K. MOORE[1], P. KULKARNI[1], S. W. PORGES[5], C. F. FERRIS[2], C. CARTER[4];

Abstract: Encounters with fearful and life threatening situations elicit behavioral changes that aid the organism's adaptation and survival. However, these changes can be directionally opposite, ranging from hypermobilization characteristic of fight/flight responses, to immobilization characteristic of freezing responses. Understanding individual differences in the response to life threat may be critical to improving treatments for trauma-related disorders. Prairie voles exhibit several human-like characteristics that may be relevant to understanding the considerable individual differences in biobehavioral responses to fear, including a predilection for strong social attachments and high parasympathetic tone. In preliminary studies, voles exhibited a high degree of individual variation in behavioral and cardiological outcomes when presented with life threat (i.e. exposure to a live ferret). Thus, we sought to investigate whether such differences are represented by differential patterns of neural activation. Using an awake imaging approach, we examined blood oxygen level dependent (BOLD) changes in response to the odor of a live sable ferret. In comparison to an odor with mild positive valence (i.e. almond, 1% benzaldehyde), ferret odor resulted in significant BOLD activation in over 60 regions of interest (out of 117 total), including regions known to be critical to defense behavior such as the central amygdala and periaqueductal gray. Ongoing imaging work will investigate whether individual differences in the behavioral and physiological response to life threat are represented by distinct patterns of BOLD change throughout the brain.

Title: Characterization of effects of n3- versus n-6 PUFA rich diets in the juvenile period on emotional responses, corticosterone secretion and neuroendocrine pathways

Authors: *J. RAYMOND[1], H. PLAMONDON[2];
[2]Behavioral Neurosci., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Introduction: N-3 PUFAs such as found in fish oil (FO) play an important role in neuronal growth, synapse function and cognitive abilities. Such effects are observable in both adult and adolescent rats. During the adolescent period, the prefrontal cortex undergoes a prolonged course of maturation lasting well after puberty. This region and the interconnected amygdala, hippocampus and mesolimbic/nigrostriatal systems are then vulnerable to positive and negative environmental conditions, including stress exposure and diet. Objectives: The objective of this study is to determine the impact of FO supplementation on behavioural and neuroendocrine responses in adolescent male rats. Methods: Twenty-nine Wistar rats (n=29) were divided in three groups (n=8-10 per group). Control animals receive soybean oil (C-SO, presenting a n-6/n-3 ratio similar to that found in a balanced diet). Experimental groups receive either fish oil (FO, n-3 PUFA rich condition; containing 300 mg/kg/day DHA) or hydrogenated vegetable fat (HVF; rich in total fatty acids with a high n-6/n-3 ratio, including trans fat). A group with no supplement was also added as a control (Home cage - HC; n=5). 0.3g of supplement per 100g body weight was provided daily to each rats for the entire adolescence period (PD27-PD48) by oral gavage. Blood sample level were collected by a tail nick procedure to measure corticosterone (CORT) levels every week and quantify with an ELISA. Locomotion and anxiety was determined using the Open Field and Elevated-Plus Maze tests. Immunohistochemistry analysis assessed corticotropin releasing hormone, CRH type 1 and glucocorticoid receptor receptor expression in interconnected brain regions including the prefrontal cortex, amygdala, hippocampus and nucleus accumbens. Results: Preliminary data indicate reduced anxiety-like behavior in FO-treated rats as well as a reduce secretion of CRH, glucocorticoids and CORT. Immunohistochemical detection is currently being analysed.

Title: Social instability stress in adolescence reduces social interactions with novel peers and improves social memory in male rats

Authors: *T. E. HODGES[1], M. L. MARCOLIN[2], J. L. BAUMBACH[3], C. M. MCCORMICK[3]; [1]Psychology, Brock Univ., St Catharines, ON, Canada; [2]Biol., [3]Psychology, Brock Univ., St. Catharines, ON, Canada

Abstract: Adolescent male rats exposed to repeated social instability stress (SS rats; 1 h isolation + return to an unfamiliar cage partner daily for 16 days from postnatal day (P) 30 to P45) and non-stressed controls (CTL rats) were tested at P46 on a social interaction test in an arena with either their cage partner or an unfamiliar rat. There was an effect of stress group ($p < 0.005$), of partner familiarity ($p < 0.001$), and an interaction of the two factors ($p = 0.02$): SS rats interacted less than did controls when with an unfamiliar partner ($p = 0.004$), and did not differ significantly when with their cage partner ($p = .67$). On P47, rats underwent a social memory test. Rats were provided the opportunity to investigate a rat secluded in a wire mesh cage (familiarization phase), and after a retention interval (30, 60, or 90 minutes long), provided with the opportunity to investigate the familiar rat or a novel rat (test phase). SS and CTL rats spent the same amount of time investigating the rat during the familiarization phase ($ps > .31$), but an interaction of stress group and time spent with the familiar or novel rat in the test phase was found ($p = 0.02$). SS rats showed evidence of social memory, spending more time investigating the novel than the familiar rat at every interval ($p < 0.001$), whereas CTL rats spent the same time investigating each rat at every interval ($p = .74$). The heightened social memory may be related to the sensitized corticosterone response SS rats show to unfamiliar conspecifics (Hodges & McCormick, 2015), which may improve social memory (Timmer & Sandi, 2010). The lack of social memory in controls was not due to inability to discriminate between familiar and unfamiliar peers based on the results from the social interaction test. SS rats may require less encoding time than do controls for social memory. Our results add to our previous findings of atypical social behaviour in SS rats in adulthood, and highlight how adolescent experiences shape the social brain.

Title: Social instability stress in adolescence alters the effects of social context on ethanol consumption

Authors: *M. D. MARCOLIN[1], T. E. HODGES[2], J. L. BAUMBACH[2], C. M. MCCORMICK[2]; [2]Psychology Dept., [1]Brock Univ., St Catharines, ON, Canada

Abstract: Social instability stress [SS; 1 h isolation + new cage partners daily from postnatal days (PND) 30 - 45] in adolescence produces long-lasting changes in the rat's social repertoire and in the behavioural responses to psychostimulants (rev. in McCormick et al., 2014). Because ethanol (EtOH) consumption is greater in adolescents than adults and is influenced by social contexts (rev. in Spear, 2014), we investigated whether SS rats differ from control (CTL) rats in EtOH intake and in the effects of EtOH on social behaviour in three experiments. Expt 1 investigated intake in the home cage after stress under conditions of intermittent access to 10% EtOH + 0.1% saccharin (24 h access, 3x a week, from PND46 to PND66) in a two bottle choice paradigm. SS showed reduced EtOH intake and preference than did CTL rats across weeks. Expt 2 investigated intake of EtOH (first exposure, same solution as in Expt 1) in rats on PND47 in a test arena involving different social contexts (alone, with a familiar partner or an unfamiliar partner from the same or different experimental group, with test pairs separated by wire mesh). SS rats spent less time drinking EtOH than did CTL rats, and rats alone drank less than did paired rats, and those paired with an unfamiliar partner drank more than did the other groups. Although the majority of rats' time was spent at the mesh, the group differences in time at the mesh paralleled the EtOH drinking results, thus one behaviour was not performed at the cost of the other. In Expt 3, rats on PND48 were injected with either saline or 10% EtOH (0.5 mg/kg dose) 30 min before placement in a test arena for 15 min with a non-injected unfamiliar CTL. EtOH increased time spent in social interaction compared with saline in CTL rats, and EtOH decreased time spent in social interactions compared with saline in SS rats. The differences in drinking may involve the altered social repertoire of SS rats or may involve altered EtOH sensitivity (e.g., hedonic value, EtOH metabolism) in SS rats.

Title: The impact of repeated social stress on the juvenile prefrontal cortex: neuronal function and synaptic communication

Authors: *K. R. URBAN[1], J. LI[2], R. J. VALENTINO[1];
[1]Gen. Anesthesia, Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Bioengineering, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Chronic or repeated stress can lead to the development of psychiatric illnesses including depression, post-traumatic stress disorder, schizophrenia, and anxiety.Cognitive function is impaired in these disorders and this is thought to arise in part from stress-induced alterations in cells and circuitry of the prefrontal cortex. Previous studies have shown that an acute stressor can enhance glutamate transmission and cognition, whereas chronic stress reduces glutamate transmission and impairs cognition. However, the bulk of existing research has been performed on adult, male rats, and has not attempted to elucidate distinct age-dependent or sex-dependent mechanisms of stress effects on cognition. Little is known about how age at the time of stress may impact the outcome. Additionally, no studies have examined the effects of social stress, a relevant stressor for humans. In this study, rats were exposed to 5 consecutive days of resident-intruder stress (30 min/day) or control manipulation during early adolescence (32-38 days old, EA), mid-adolescence (42-48 days old, MA), or adulthood (68-72 days old, adult). One day after the final defeat, cellular characteristics of layer 5 pyramidal neurons in the prefrontal cortex were examined using whole-cell patch clamp in 300 μM brain slices. It was found that repeated social stress increased input resistance and half-width of action potentials selectively in MA rats. Although the threshold to fire action potentials was lower in neurons from MA stressed rats, the neurons fired for a much briefer period than those from control rats. In addition, the amplitude, but not frequency, of spontaneous excitatory post-synaptic currents (sEPSCs) was lowered in EA and MA stressed rats, but not in adults. These results suggest that repeated social stress decreases the overall responsiveness of pyramidal neurons potentially by altering the function of both sodium and potassium channels. In addition, the reduced amplitude of sEPSCs suggests reduced expression of postsynaptic glutamate receptors, which could result in impaired plasticity and cognitive function. These data provide the first age-dependent examination of repeated social stress effects on the cellular function of the prefrontal cortex, and suggest that late adolescence/puberty is a period of particular vulnerability to the effects of social stress. They also suggest cellular mechanisms for the cognitive impairments seen following chronic stress.

Title: The effects of food restriction and exercise on anxiety-related behaviors and cognitive functions in male and female adolescent mice

Authors: *Y.-W. CHEN, C. AOKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Adolescence is the least studied stage of brain development and is especially so for females, even though many mental illnesses emerge for the first time among this group. Anxiety is 60% more prevalent in females and is a core feature of many mental illnesses, including anorexia nervosa (AN). The incidence of AN is most common in adolescent females, suggesting an effect of hormones, age, and sex in vulnerability to the disease. There is yet no accepted pharmacological treatment for AN, reflecting our lack of understanding of the underlying neurobiology of AN or of anxiety. Anxiety is a double-edged sword: it can promote a crippling focus upon negative life-events, leading to impairment in cognitive functions, while great reductions of stress-induced anxiety may impair learning and memory. Activity-based anorexia (ABA) is an animal model for identifying the biological basis of excessive exercise and starvation, 2 hallmarks of AN. It was recently shown that 24 hours of food restriction, with or without exercise, reduced anxiety significantly in female adolescent mice. However, the effects of exercise and food-restriction separately or jointly as ABA on anxiety-related behaviors in male adolescents have never been tested. Moreover, how these anxiety-related level changes in adolescence would affect the cognitive functions later in life remains largely unknown. Here,

four experimental groups of C57BL/6 male and female pubertal mice were evaluated: ABA (housed with a running wheel from P36-44 and food restriction from P41-44) and three control groups: CON (control mice with no running wheel experience or food restriction), EX (housed with a wheel from P36-44), and FR (food restricted from P41-44). Three-way ANOVA was run, using food restriction, exercise and sex as the factors. We assessed anxiety-related levels of these animals before ABA (P39, open field), during ABA (P42, marble burying), and after recovery from ABA (P51, elevated plus maze). Spatial and object recognition memory and social preference and recognition of the animals were tested after recovery from ABA (P53-P57). 24 hours of food restriction (at P42) reduced anxiety significantly in both male and female adolescent mice, while exercise had no effect. One week after recovery from ABA, males of the FR, EX, and ABA groups showed increased anxiety compared to CON, but females did not. However, anxiety impacted negatively on spatial memory performance in females, but no such correlation was found among males. This study highlights sex differences in response to food restriction and/or exercise during adolescence and provides the foundation for the next study that will examine the effect of val66met SNP of BDNF.

Title: Leveraging dynamic changes in neural circuitry during adolescence to persistently attenuate fear memories

Authors: *S. S. PATTWELL[1], C. LISTON[2], D. JING[2], I. NINAN[3], R. YANG[2], B. CASEY[2], K. DEISSEROTH[4], F. S. LEE[2];

Abstract: Fear can be highly adaptive in promoting survival, yet it can also be detrimental when it persists long after a threat has passed. Malleability of the fear response may be most advantageous during adolescence when animals are prone to explore novel, potentially threatening environments. Two opposing adolescent fear-related behaviors_diminished extinction of cued fear and suppressed expression of contextual fear_may serve this purpose, but the neural basis underlying these changes is unknown. Using microprisms to image prefrontal cortical spine maturation longitudinally, we delineate dynamic BLA-hippocampal-mPFC circuit reorganization associated with these behavioral shifts. Exploiting this sensitive period of neural development, we devised a behavioral intervention to attenuate adolescent fear memories persistently into adulthood. These findings define a strategy for leveraging dynamic neural changes during adolescence to extinguish pathological fears implicated in anxiety and stress related disorders.

Title: The anxiogenic effects of pre-reproductive stress (PRS) in female rats on their female offspring are partially reversed by maternal post-stress treatment with fluoxetine and NBI 27914

Authors: *H. ZAIDAN, I. GAISLER-SALOMON;
Psychology, Univ. of Haifa, Haifa, Israel

Abstract: Studies in humans and animals indicate that stress can affect behavior and hypothalamic-pituitary-adrenal (HPA) axis function in subsequent generations. We have

previously shown that prereproductive stress (PRS) to female rats in late adolescence impacts her offspring's anxiogenic behavior in a sex-dependent manner. We further showed that stress increases both corticosterone (CORT) levels and corticotropin releasing factor 1 (CRF1) expression in the frontal cortex and oocytes of the exposed females, as well as in their offspring's brain at birth. Here, we aimed to test whether maternal treatment with the CRF1 antagonist NBI 27914 (NBI, 5 mg/ml; 5 days) or the antidepressant drug fluoxetine (FLX, 5 mg/kg, 7 days) would reverse the behavioral alterations induced by adolescent PRS on dams and their offspring. Adolescent female rats (F0) were exposed to a 7-day stress procedure. Twenty four hours later, PRS and control rats were put on a subchronic drug treatment regimen with FLX, NBI or vehicle. Female rats (F0) and their offspring (F1) were weighed regularly, and behavior in dams and offspring was assessed on P60. In F0, PRS increased weight gain and decreased locomotion in the open field (OF), which were unaffected by drugs. In offspring, maternal PRS and drug treatment led to sex-dependent effects. Female offspring of PRS (O-PRS) displayed an increase in the latency to enter the open arms in the elevated plus maze (EPM) as well as abnormal acquisition of fear conditioning (FC), which were reversed by both NBI and FLX treatment. FLX also normalized the maternal PRS-induced increase in freezing in the OF. In males, maternal PRS enhanced open arm frequency in the EPM, and led to less freezing in the acquisition and context retrieval phases of FC. In the OF, O-PRS males displayed enhanced freezing and decreased center time duration. These behaviors were not affected by maternal drug treatment. Interestingly, maternal drug treatment on its own affected offspring weight and behavior in the FC test as well as in assays of novel object and social exploration. In sum, our findings indicate that PRS to adolescent female rats affects offspring behavior, and that administration of FLX and/or NBI immediate after stress reverses some of these effects in female offspring alone. O-PRS males display behavior that may be interpreted as "enhanced risk-taking", and is unaffected by drug treatment. Drug treatment on its own also impacts offspring behavior. These findings indicate that some of the transgenerational effects of pre-gestational trauma may be prevented by post-stress drug treatment, and that different mechanisms may mediate the inheritance of stress to male and female offspring.

Title: Impact of juvenile stress on adult fear learning and dendritic morphology in the basolateral amygdala

Authors: *R. A. SKIPPER[1], C. L. WELLMAN[1], M. R. HERBST[2], J. J. QUINN[2];
[1]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [2]Dept. of Psychology, Miami Univ., Oxford, OH

Abstract: In humans, stress can lead to a host of debilitating outcomes, such as specific phobias, anxiety disorders, and post-traumatic stress disorder. These maladaptive effects have been modeled in rodents, with acute stress resulting in enhanced contextual fear conditioning and dendritic retraction in the amygdala. However, little research has been done to understand the effects of early life stress on emotional learning in adults. We hypothesized that juvenile stress would result in long-term behavioral and morphological effects: enhanced fear conditioning and dendritic alterations in the basolateral amygdala (BLA) in adulthood. Male and female Long-Evans rats were either stressed or unstressed, with equal numbers of males and females in each group. On postnatal day 17 (PND17), stressed rats received 15 mild footshocks in Context A; unstressed controls were exposed to the same context without footshock. All then matured without manipulation until adulthood. On PND90, rats underwent cued fear conditioning (one tone-shock pairing) or no conditioning (one presentation of tone alone) in Context B. On subsequent days, rats underwent tests of contextual fear conditioning (Context B), tone fear conditioning (novel Context C), and memory for early life stress (Context A). In all tests, fear memory was measured as freezing during context or tone exposure. Upon completion of behavioral testing, rats were euthanized and brains were stained using Golgi histology. Dendritic morphology of BLA pyramidal neurons was assessed. Stressed rats showed enhanced contextual fear conditioning compared to unstressed rats. This was accompanied by increased dendritic length and complexity in BLA pyramidal neurons. Overall, cued fear conditioning did not differ between stressed and unstressed rats. However, this could be due to sex differences in fear responding. Preliminary data suggest that males showed more robust cued fear conditioning compared to females, and this difference paralleled differential effects of early stress on dendritic morphology in BLA. These results suggest that the dendritic remodeling implicated in adult stress-induced behavioral changes may also be involved in the maladaptive effects of early life stress. This is relevant to the effects of early life stress and improper fear regulation among humans, including individuals with early-developing post-traumatic stress disorder or those recovering from childhood trauma.

Title: Access to palatable food alters gastrin-releasing peptide and dopamine signalling in the medial prefrontal cortex of adult rats exposed to juvenile stress

Authors: *E. ALI[1,2], J. C. MACKAY[3], M.-C. AUDET[2], J. S. JAMES[2], C. CAYER[2], P. KENT[2,3], Z. MERALI[2,3];
[1]Carleton Univ., Nepean, ON, Canada; [2]Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Stress-exposure during juvenility increases the susceptibility for anxiety and depressive characteristics in adulthood and is also thought to contribute to the growing prevalence of obesity in school-aged children. Stress can increase food intake and a preference for highly caloric palatable food (PF), contributing to weight gain and a risk of developing obesity while PF has stress-buffering characteristics shown in humans and rodents. A feeding peptide called gastrin-releasing peptide (GRP) is involved in stress response and also reduces feeding. GRP receptors (GRPR) are expressed in the medial prefrontal cortex (mPFC), an area implicated in stress and motivated behaviour. Dopamine receptors 1 and 2 (DRD1 and DRD2) are expressed in the mPFC and are involved in reward, motivation and stress. The aim of the study is to reveal the long-term effect of juvenile stress and access to PF on behavioural and metabolic measures and GRP, GRPR, DRD1 and DRD2 mRNA expression in the mPFC. Male Wistar rats that underwent episodic stressor exposure on postnatal days (PD) 27-29 displayed social anxiety that was reversed by consumption of PF. In contrast to the stress buffering effect, PF in combination with previous stressor exposure led to increased weight gain and accumulation of body fat at PD 60. Qualitative polymerase chain reaction revealed an increase of GRP mRNA expression and no change in GRPR expression in juvenile stressed rats with access to PF. The same group also revealed an increase in DRD2 mRNA expression, whereas DRD1 expression was decreased in juvenile stressed rats irrespective of diet. In conclusion, PF mitigates the effects of juvenile stress in adulthood at the expense of increased adiposity in part due to a dysregulation of GRP and dopamine signaling.

Title: Changes in the regulation and function of the HPA axis induced by juvenile social isolation in rats

Authors: ***M. SERRA**[1], G. BOERO[3], F. BIGGIO[2], M. PISU[4];
[1]Univ. of Cagliari, Monserrato (Cagliari), Italy; [2]Univ. of Cagliari, Cagliari, Italy; [3]Univ. of cagliari, Cagliari, Italy; [4]Inst. of Neurosci. CNR, Cagliari, Italy

Abstract: Rearing of rodents from weaning to adulthood in isolation induces various behavioral and neurochemical alterations in comparison with group-housed controls, suggesting that socially isolated rodents represent an animal model of neuropsychiatric disorder. Namely, social isolation results in a decrease in the brain and plasma concentrations of neuroactive steroids that act as positive modulators at GABAA receptors and is accompanied by an enhanced response to the acute administration of ethanol as well as by enhanced neurosteroidogenesis in response to acute stressful stimuli. It also increases the sensitivity of the pituitary to corticotropin-releasing factor (CRF) and impairs negative feedback regulation of the HPA axis. The aim of this research was to study mechanisms that might contribute to the different HPA reactivity to acute stress. We evaluated plasma corticosterone, hypothalamic level of CRF, and the expression of hippocampal and hypothalamic glucocorticoid receptors (GR) at different time point after acute heterotypic stress (foot-shock, 5 min). In group-housed animals plasma corticosterone levels were significantly increased after 5 min, reached at peak at 15 min and returned to baseline 60 min after stress. At variance, plasma corticosterone levels of socially isolated rats were increased at 5 min, after stress, were maximum at 60 min and remained significantly high 7 hours later. In the hypothalamus of group-housed animals no changes in the levels of CRF were detected in any time point measured, while in socially isolated rats a significant increase of hypothalamic CRF levels was found at 15 min, 30 and 60 min after the end of the stress. These data demonstrate that social isolation results in hypothalamic hyperactivity under acute heterotypic stress and suggest that socially isolated rats are much less sensitive to glucocorticoid negative feedback than are

group-housed animals. Social isolation increased basal levels of both hippocampal and hypothalamic membrane GR. Moreover, in group-housed rats GR expression progressively increased with the time after foot-shock exposure, becoming statistically significant 90 min after stress, while socially isolated rats did not show any change in hippocampal and hypothalamic GR expression at any time point examined. These results suggest that dysregulation of GR expression induced by socially isolation stress may cause modifications in the activity of HPA axis and in the negative feedback resulting in prolonged responses to acute stress.

Title: Overcrowding causes variations in hair corticosterone concentration in juvenile male Wistar rats

Authors: ***M. J. ROJAS**[1], D. GONZÁLEZ-UARQUIN[2], L. F. CARDENAS[3], J. S. MEYER[4]; [1]Salud Animal, [2]Grupo de Neurociencias, Univ. Nacional Colombia, Bogota, Colombia; [3]Univ. de los Andes, Bogota, Colombia; [4]Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Chronic stress due to reduction of the minimum living space for an individual during youth triggers several metabolic and behavioral pathologies in adulthood. The aim of this study was to determine whether a chronic stress condition (overcrowding) induces changes on plasma and hair corticosterone concentration from young Wistar rats. The experimental subjects were divided in two groups (control CG, and overcrowded OG); OG subjects were exposed to an overcrowding period from post-natal day (PND) 38 to PND 65. According to the enzyme immunoassay kit, OG showed a higher corticosterone plasma concentration, and also a higher hair corticosterone concentration compared to CG. These results contribute to demonstrate that the concentration of corticosterone in hair from rats is a suitable, and not invasive method for monitoring chronic stress.

Title: Circadian variability of body temperature responses to Methamphetamine (Meth)

Authors: *A. BEHROUZVAZIRI[1], Y. YOO[1], E. MOROZOVA[2], M. ZARETSKAIA[3], D. RUSYNIAK[3], D. ZARETSKY[3], Y. MOLKOV[1];

Abstract: Vital parameters of living organisms exhibit circadian rhythmicity. Despite rats are nocturnal animals, most of drugs of abuse studies in rodents are performed during the day. There is virtually no data on the circadian variability of amphetamine responses. Experiments were performed on male Sprague-Dawley rats implanted with telemetric probes reporting body temperature. Rats received i.p. injections of Meth (1 or 5 mg/kg) or saline at 10-11am or at 10-11pm. Each rat received only one injection of Meth to avoid the effects of repeated administration. The responses were recorded for at least 5 h. The baseline body temperature at night was 0.8ºC higher than during the day. The body temperature increased slightly after injections of saline in both day and night and returned to baseline within 1 h. Both during the day and at night 1 mg/kg of Meth induced monophasic hyperthermia, however, compared to daytime the maximal increase in temperature was half at night. Injection of 5 mg/kg of Meth in the daytime caused a delayed hyperthermic response, preceded by a slight increase of the body temperature immediately after injection. In contrast, the same dose at night produced variable responses with a bias towards a decrease of body temperature. Recently, using mathematical modeling, we showed that the complex dose-dependence of day-time temperature responses to Meth results from a delicate balance between inhibitory and excitatory drives which have different sensitivity to the drug (Molkov et al. Am. J. Physiol. 2014). In this study, we extended

our model by introducing circadian inputs to interpret the night time data above. We have found that during the night the baseline activity of the excitatory response component is greater than during the day. Besides, during both day and night, the equilibrium body temperature after either dose of Meth was noticeably lower than the body temperature observed before injection. The suppression of the hyperthermia/conversion to hypothermia in response to Meth at night is explained by a combination of two factors. First, the excitatory drive appears partially saturated, and, thus, is activated by Meth to a lesser extent. This evokes smaller increase of body temperature in response to low doses of Meth, or the excitatory components becomes overpowered by the inhibitory drive in response to the higher dose. Second, the reduction of the equilibrium temperature leads to gradual cooling which counteracts the hyperthermia/facilitates hypothermia. We speculate that the reduction of the equilibrium body temperature by Meth reflects a suppression of spontaneous locomotor activity underlying circadian variations of body temperature.

Title: N-methylserotonin from Japanese pepper (Zanthoxylum piperitum), soy isoflavones, black cohosh extract, and combinations thereof regulate skin temperature in a female rat model of menopause-related hot flash

Authors: ***M. J. WEISER**[1], V. GRIMSHAW[1], K. WYNALDA[1], M. H. MOHAJERI[2], C. M. BUTT[1];
[1]Biol. Models, DSM, Boulder, CO; [2]Biol. Models, DSM, Kaiseraugst, Switzerland

Abstract: Oral administration of soy isoflavones or black cohosh extract for the relief of menopause symptoms have some clinical support, but the data are mixed. Soy isoflavones such as genistein can regulate menopause-related hot flashes, but the mechanisms for this activity are not completely understood. Similarly, black cohosh contains N-methylserotonin (NMS) as a minor component, and NMS has selective agonist activity at the 5-HT_7 serotonin receptor subtype that is involved in thermoregulation. Soy isoflavones and black cohosh are commonly used as homeopathic approaches to menopause symptoms, but it is unknown whether they work

together in additive or synergistic fashions. We have performed three studies that sought to determine the effects of dietary NMS, or its combination with soy isoflavones and black cohosh, on induced hot flash and measures of mood in female rats. All three studies used ovariectomized (OVX) female rats that were fed diets containing different levels of NMS, soy isoflavone concentrate, or black cohosh extract. OVX animals given estradiol implants served as positive controls. Locomotor activity (open field), anxiety-like behaviors (elevated plus maze; EPM), and depression-like behaviors (forced swim test) were assessed first, and then skin temperature was monitored during experimental hot flashes that were induced with intravenous calcitonin gene-related peptide. None of the dietary manipulations affected OVX-induced weight gain, uterine growth, or mood-related behaviors, but estradiol implants increased the time spent in the center of the open field and on the open arm of the EPM. Furthermore, synthetic NMS, NMS contained in Japanese pepper (*Zanthoxylum piperitum*; a 25-fold more efficient source of NMS than black cohosh), black cohosh extract, soy isoflavones and estradiol implants all individually blunted the hot flash response. Dietary combinations of Japanese pepper with isoflavones, black cohosh, or isoflavones + black cohosh also reduced the hot flash response, but the pepper alone and the pepper + isoflavones combination were the most effective. These three separate studies provided replication and confirming results that a natural dietary source of NMS was equivalent to synthetic NMS in reducing the hot flash response, that soy isoflavones and black cohosh can have similar, but less robust, effects on hot flash, and that some benefits may be conferred by combinations of these natural products. These *in vivo* findings also support NMS as a component of black cohosh and Japanese pepper that may reduce menopause-related hot flashes while avoiding the potential side-effects of phytoestrogens or hormone replacement therapy.

Title: Amphetamine enhances endurance by increasing heat dissipation

Authors: *Y. YOO[1], E. MOROZOVA[2], A. BEHROUZVAZIRI[1], M. ZARETSKAIA[3], M. B. BROWN[4], D. RUSYNIAK[3], D. ZARETSKY[3], Y. MOLKOV[1];

Abstract: Amphetamine is widely used among athletes to enhance performance despite how poorly understood are its ergogenic mechanisms. This study sought to determine if amphetamine may impart performance benefit by impacting thermoregulation during exercise. Two groups of six rats were tested during the experiment, one group (Amph) was injected with amphetamine (2 mg/kg i.p.) and the other group (Saline) – with a saline. Following dosing, rats performed an incremental treadmill test to exhaustion at room temperature (24^{o}C with workload (speed and incline) increases in three minute stages. Continuous recordings of core body temperatures (T_c) via implantable telemetry, and oxygen consumption (VO_2) via analysis of expired gases were performed. Time to exhaustion (mean±SE minutes) for Amph (17.3±0.6) was longer than for Saline (14.8±0.8). T_c in Amph was lower than in Saline at every treadmill workload, however, with the longer running time in Amph, final T_c was not significantly different between groups. Interestingly, for Saline rats T_c increased at a constant rate, while for Amph rats the rate of increase in T_c was increased with workload. Total heat produced, which was calculated from VO_2, was not significantly different between Saline and Amph at every treadmill workload. To further examine these findings, we extended a previously constructed mathematical model with two heat producing compartments – core body and skeletal muscles. Using Bayesian approach we quantified separately the heat generation in the core and muscles, and the heat dissipation, and then compared these parameters between Saline and Amph. The model satisfactorily reproduced and explained the difference of body temperature dynamics between groups. Modeling revealed that amphetamine increased the heat dissipation from the core body. At exhaustion, the mean T_c in both groups were approximately 40 °C. However, muscle temperature in Amph, which was predicted by the model, was higher than in the Saline group, vs. . We concluded that amphetamine (2 mg/kg) increases heat dissipation during exercise thereby slowing down rise in core body temperature. Given the limitation imposed by high core body temperature on time to exhaustion, amphetamine may increase endurance performance by delaying hyperthermia. However, running under the influence of amphetamine may increase risk for skeletal muscle-specific heat injury.

Title: Estradiol modulates temperature regulation in the female mouse

Authors: E. M. BLACKMORE[1], S. J. KRAJEWSKI-HALL[1], *N. E. RANCE[1,2];
[1]Pathology, Univ. of Arizona Col. of Med., Tucson, AZ; [2]Evelyn F. McKnight Brain Inst., Univ. of Arizona, Tucson, AZ

Abstract: Hot flushes are due to estrogen withdrawal and are characterized by the episodic activation of heat dissipation effectors. Despite the vast numbers of individuals affected, there is little understanding of how estrogen modulates thermoregulation in any species. There is also limited information on how estradiol regulates body temperature in the mouse, a valuable research model because of the availability of transgenic lines. In this study, we report a method to record tail skin temperature (T_{SKIN}) in freely-moving mice. Mice were ovariectomized (OVX) and implanted s.c. with silastic capsules containing vehicle or 17β-estradiol (E_2) producing low levels of serum estradiol. Core temperature (T_{CORE}) and activity were measured with an i.p. telemetry probe and T_{SKIN} was measured with a data-logger protected by a Delrin housing, similar to a method we developed for the rat (Williams et al. Endocrinology, 2010). In the first experiment, T_{CORE}, T_{SKIN} and activity were recorded continuously over a five day period in mice housed in their home cages (12 hour light/dark) with ambient temperature ($T_{AMBIENT}$) at approximately 24.0°C. Days 3-5 after capsule implantation, E_2 significantly lowered the T_{CORE} during the light phase (OVX 36.8 ± 0.11°C, n = 10 vs OVX + E_2, 36.4 ± 0.08°C, n = 9, mean ± SEM) but not the dark phase (OVX, 37.9 ± 0.11°C, n = 10 vs OVX + E_2, 37.7 ± 0.06°C, n = 9). Continuous recording of T_{SKIN} revealed wide fluctuations in vasomotion and diurnal rhythms. There was no effect of E_2 on T_{SKIN} or activity during the circadian rhythm recordings. In a second experiment, T_{CORE}, T_{SKIN} and activity were recorded (during the light phase) in mice exposed to a wide range of $T_{AMBIENT}$ (20 - 36°C) in an environmental chamber. OVX + E_2 mice maintained T_{CORE} at a lower level at nearly all $T_{AMBIENT}$, compared to vehicle controls. In addition, the overall T_{SKIN} of OVX + E_2 mice was lower than that of OVX mice, with significant

differences at $T_{AMBIENT}$ of 21, 23, 25 and 26°C. There was no significant difference in activity between the two groups. Overall, our studies show that E_2 treatment of OVX mice consistently lowers T_{CORE} during the light phase. These findings are different than those previously observed in the rat, where T_{CORE} is only lowered by E_2 during heat stress. Our methods to record T_{SKIN} in freely-moving mice will enable further research on the effects of E_2 on thermoregulation in transgenic mouse models.

Title: Heat shock factor 1-deficiency affects systemic control of body temperature

Authors: *A. STAHR[1], M. INGENWERTH[1], E. NOICHL[2], H.-W. KORF[2], H. REINKE[3], C. VON GALL[1];
[1]Heinrich-Heine-University, Inst. of Anat. II, Düsseldorf, Germany; [2]Goethe-University, Dr. Senckenbergische Anatomie, Inst. of Anat. II, Frankfurt, Germany; [3]Heinrich-Heine-University, Inst. of Clin. Chem., Düsseldorf, Germany

Abstract: The hypothalamus controls the autonomous nervous system as well as the endocrine system and regulates metabolic processes, circadian rhythms, behaviour and body temperature. The heat shock (HS) pathway, mediated by the transcription factor HSF1, is an essential defensive mechanism against acute heat exposure and is involved in many cell-signalling pathways to maintain cellular homeostasis. However, little is known about the role of HSF1 in the systemic control of energy homeostasis. Therefore, we analysed core body temperature and spontaneous locomotor activity in HSF1- deficient ($HSF1^{-/-}$) and wildtype littermates ($HSF1^{+/+}$). $HSF1^{-/-}$ mice showed a decrease in locomotor activity and an increase in core body temperature, suggesting a role of HSF1 in the systemic control of energy expenditure. HSF1 is expressed in various hypothalamic brain regions which are involved in regulation of energy metabolism and co-localized with tyrosine hydroxylase, the rate limiting enzyme in dopamine synthesis. HSF1-deficient mice show decreased prolactin levels and increased expression of uncoupled protein 1 in brown adipose tissue. In conclusion, we showed for the first time that HSF1 plays a role in systemic regulation of energy expenditure, hypophyseal prolactin release and peripheral UCP1

expression. Thus, HSF1 might be involved in hypothalamic temperature-mediated feedback regulation of energy metabolism.

Title: Nitrous oxide evokes neuroendocrine stress and heat conservation responses

Authors: S. AL-NOORI[1], A. CIMPAN[2], Z. MALTZER[1], J. ZOU[3], K. J. KAIYALA[1], *D. S. RAMSAY[1];
[1]Dept of Oral Hlth. Sci., Univ. Washington, Seattle, WA; [2]Div. of Biol. Sci. Sch. of STEM, Univ. Washington, Bothell, WA; [3]Dept. of Biochem., Univ. Washington, Seattle, WA

Abstract: Despite the extensive use of nitrous oxide (N2O) in dentistry and anesthesiology as well as its status as an abused inhalant, remarkably little is known about N2O's mechanisms of action. We hypothesized that as with many drugs of abuse, N2O activates neuroendocrine stress responses. As N2O also promotes hypothermia during initial administration, we hypothesized that the drug initially inhibits thermogenesis via brown adipose tissue (BAT) while promoting heat loss via the tail, major organs of thermoregulation in rodents. Finally, because N2O evokes hyperthermia following serial administrations, we hypothesized that elevated BAT thermogenesis plays a role in this thermoregulatory sign reversal. To assess hypothalamic-pituitary-adrenal (HPA) axis neuroendocrine responses and sympathetic autonomic neuroendocrine responses during initial N2O administration, we measured plasma corticosterone (CORT), norepinephrine (NEPI), and epinephrine (EPI) during an initial 2-h 60% N2O session (N=5 male rats, values are mean ± SE). CORT (ng/ml) increased from 38±25.3 at baseline to 528±174.5 during N2O (p=0.09). NEPI (pg/ml) increased from 237.0±34.9 at baseline to 387±42.2 (p=0.04). EPI (pg/ml) increased from 170.0±51.4 at baseline) to 316±132.2 during N2O (p=0.15). Accordingly, acute N2O administration appears to evoke classic neuroendocrine

stress responses. In a separate study, using dual probe telemetry implants and infrared (IR) thermography, we assessed the effects of nine repeated N2O administrations compared to control (con) administrations on core temperature (Tc), BAT temperature (Tbat) and tail temperature (Ttail). Telemetry revealed that both Tc and Tbat were reduced significantly during initial N2O administration (Tc: n=11 con, 12 N2O; N2O minus con difference averaged over 90 min (DT) = -0.5±0.12 C, p=0.001. Tbat: n=8 con, 8 N2O; DT = -1.1±0.18 C; p <0.001). IR thermography revealed that acute N2O administration unexpectedly inhibited Ttail (n=6 con, 7 N2O; DT = -1.6±0.36 C; p = 0.001). In the 9th session, N2O inhalation increased Tc (DT = 0.7±0.23 C; p = 0.007) indicative of a hyperthermic sign reversal, yet neither Tbat nor Ttail were different from control (Tbat: DT = 0.04±0.33 C; p = 0.9; Ttail: DT = 0.07±0.91 C; p = 0.9). Thus, acute 60% N2O evokes classical HPA and sympathetic neuroendocrine stress responses, and may promote hypothermia via reduced BAT thermogenesis accompanied by tail vasoconstriction as a compensatory mechanism to limit body heat loss. After repeated N2O administrations rats exhibit a hyperthermic Tc but a normalized Tbat, suggesting induction of a hyperthermia-promoting thermogenic adaptation of undetermined origin.

Title: Predator odor rapidly increases skeletal muscle thermogenesis in rats

Authors: ***N. Y. MAVUNDZA**[1], M. E. SMYERS[2], R. M. CAMP[2], J. D. JOHNSON[2], C. M. NOVAK[2];
[1]Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH

Abstract: Neural pathways in the brain integrate internal metabolic and external stimuli to effect behavioral and metabolic changes to optimize fitness. Hypothalamic pathways modulate metabolism of several peripheral systems including skeletal muscle through the sympathetic

nervous system. Activation of the ventromedial hypothalamus (VMH) is associated with increased muscle glucose uptake, insulin sensitivity, and fat oxidation. Although the VMH is widely known to integrate internal metabolic cues, external environmental stimuli also impact behavior and associated metabolic changes through their action on the VMH. The central/dorsomedial VMH is an integral part of the medial hypothalamic defense circuit and has recently been implicated in the behavioral and autonomic aspects of the predator response. Therefore, the overlap in structure suggests that there may be an interaction between these functions of the VMH - metabolic and defense. We have found an increase in skeletal muscle thermogenesis in rats following exposure to predator odor. This response was rapid, increasing muscle temperature 1° C by 2 min, and 1.8° C by 10 min after exposure to predator odor. It is unlikely that this was secondary to a general stress response because a shock stimulus induced a lower magnitude change in temperature. Predator odor - induced muscle thermogenesis is likewise not completely secondary to increased physical activity as the elevated muscle temperature persisted even when activity was held constant using a treadmill. Lastly, predator odor has the potential to significantly impact energy balance as energy expenditure was increased by 46% in the first hour after exposure. Based on these findings, we hypothesize that exposure to predator odor acts as an external environmental cue to optimize survival by activating not only the innate defense response but also coordinated metabolic and physiological responses.

Title: Ventromedial hypothalamic melanocortin receptor activation differentially impacts skeletal muscle energetic pathways in lean vs. obesity-prone rats

Authors: *C. K. GAVINI[1], S. L. BRITTON[2], L. G. KOCH[2], C. M. NOVAK[1];
[1]school of biomedical sciences, Kent State Univ., Kent, OH; [2]Dept. of Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Rats selectively bred for high intrinsic aerobic capacity (HCR) are lean, resistant to obesity, and consistently more active than low-capacity runners (LCR), which are prone to metabolic syndrome. We have shown that HCR have elevated total daily energy expenditure (EE), primarily due to elevated physical activity (PA) plus low economy of activity in HCR wherein those excess calories are dissipated by skeletal muscle as heat. We focus on the ventromedial hypothalamus (VMH), part of a pathway regulating energy balance (EB) through its actions on peripheral glucose and lipid allocation, modulating respiratory quotient (RQ) and thermogenesis. The central melanocortin (MC) system also plays a vital role in modulating EB, increasing EE and PA, and decreasing appetite. We have demonstrated that activation of MC receptors in the VMH lowers RQ and increases activity EE both by increasing PA and lowering work efficiency, and that it more effectively impacts metabolism in HCR compared to LCR via differential activation of the sympathetic nervous system (SNS). Based on this, we hypothesize that MC receptor activation in the VMH will alter skeletal muscle metabolic pathways and this will be greater in HCR than in LCR. Male HCR/LCR rats (n=32; 8/group) with guide cannulae aimed at the VMH received microinjections of MC receptor agonist Melanotan-II (MT-II, 20pmoles/200nl) or vehicle (aCSF).We examined mRNA and protein expression of metabolic mediators in skeletal muscle, brown adipose, white adipose, and liver. Compared to vehicle microinjection, intra-VMH MT-II induced a significant increases or trends in mRNA expression of mediators of EE (UCPs, PPARs, PGC1a) with an increasing trend in protein expression; and a trend toward greater activation in HCR than in LCR. There were no significant changes in mediators of energy conservation (K+ATP channels, MED1). These results support the hypothesis that the brain-muscle pathway, modulated by MC receptors in the VMH, more effectively impacts metabolism in HCR compared to LCR, and may underlie the elevated activity EE in the lean phenotype.

Title: Neuronal regulation of vitamin B12 metabolism under selenium-biased versus glutathione-biased redox conditions

Authors: *Y. LI[1], R. DETH[2];
[1]Pharmaceut. sciences, Northeastern Univ., Boston, MA; [2]Nova Southeastern Univ., Fort Lauderdale, FL

Abstract: Vitamin B12, also known as cobalamin (Cbl), is an essential micronutrient and neurologic dysfunction is a primary clinical manifestation of Cbl deficiency. Methylcobalamin (MeCbl) and adenosylcobalamin (AdoCbl) are active Cbl species, serving as enzyme cofactors, and it has been observed that the ability of cells to generate MeCbl and AdoCbl from other Cbl species depends on cellular redox status. The brain is present in a closed compartment surrounded by the blood-brain barrier with a unique redox environment. Both selenium-containing selenoproteins and glutathione (GSH) play important roles in the brain redox system. Availability of the GSH precursor cysteine is very limited in the brain, with a level in cerebrospinal fluid that is < 10% of the level in blood. Moreover, the transsulfuration pathway, which converts homocysteine to cysteine, is partially blocked in the brain. However, the brain exhibits a superior ability to retain and utilize selenium, which correspondingly compensates for the relative shortage of GSH. In order to investigate the effects of GSH-biased and selenium-biased redox conditions on neuronal cobalamin metabolism, we modified serum-free cell culture media with defined combinations of different cysteine and selenium concentrations to create GSH-biased vs. selenium-biased redox environments. Using the SH-SY5Y human neuroblastoma cell line as a neuronal cell model, we measured levels of individual Cbl species and a series of thiol metabolites with HPLC/electrochemical detection analysis. We found that the level of cyanocobalamin (CNCbl) was significantly decreased when both selenium and cysteine levels were low, suggesting that the cellular Cbl uptake was impaired, since CNCbl was the Cbl source in culture media. In addition, levels of both AdoCbl and MeCbl showed selenium and cysteine dependence, but cysteine in the culture media had a more profound effect on the level of MeCbl than selenium, which may be due to the fact that cysteine level could quickly and directly influence the level of GSH and subsequently affect formation of glutathionylCbl, a precursor of MeCbl. Consistent with this notion, the GSH level and the ratio of GSH to its oxidized form GSSG were more directly dependent on cysteine concentration than selenium concentration. To date there has been very little effort to identify the key brain-specific elements of antioxidant metabolism. Our findings begin to address this critical gap in knowledge and they indicate differential roles for GSH vs. selenoproteins in maintaining redox and MeCbl-dependent methylation status in the brain.

Title: Cerebral IL-17A improves glucose metabolism through AKT signaling

Authors: *J. YANG[1], J. KOU[1], J.-E. LIM[1], R. LALONDE[2], K.-I. FUKUCHI[1]; [1]Cancer Biol. & Pharmacol., Univ. of Illinois Col. of Med. At Peoria, Peoria, IL; [2]Dept. of Psychology, Univ. of Rouen, Rouen, France

Abstract: Interleukin-17A (IL-17A) is well known as a proinflammatory factor involved in many auto-immune diseases and metabolic disorders. Emerging studies have shown the connection between obesity and IL-17A in IL-17A knockout mice. However, the role of IL-17A in glucose metabolism is unclear. In this study, we found that both IL-17A and IL-17 receptor A are present in the mouse brain. Overexpression of IL-17A in the brains of mice via recombinant adeno-associated virus serotype 5 (rAAV5)-mediated gene delivery gave rise to loss of body weight and adipose tissue mass and an improvement in glucose tolerance and insulin sensitivity while overexpression of IL-17A in the skeletal muscles led to only a comparable improvement in glucose tolerance. Moreover, IL-17A enhances glucose uptake in PC12 cells by activation of AKT. Our results provide evidence for the first time that IL-17A in the brain plays a predominant role in regulating glucose metabolism, body weight and adipose tissue mass, particularly, enhancing glucose uptake by neurons via activation of AKT.

Title: NF-κB regulates neuronal bioenergetics *in vitro*

Authors: *W. SNOW[1,2], S. K. ROY CHOWDHURY[1], J. DJORDJEVIC[1], D. MCCALLISTER[1], C. CADONIC[1,3], P. FERNYHOUGH[1,2], B. C. ALBENSI[1,2,3];
[1]Div. of Neurodegenerative Disorders, St. Boniface Hosp. Res. Ctr., Winnipeg, MB, Canada; [2]Pharmacol. & Therapeut., [3]Biomed. Engin., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Objective: Although considered important for immunity, the transcription factor nuclear factor kappa B (NF-κB) is also implicated in learning and memory. Mice lacking the p50 subunit of NF-κB display learning and memory deficits. NF-κB levels are altered after the induction of long-term potentiation (LTP), an experimental model of cellular learning and memory. Conversely, LTP is altered after blockade of NF-κB in hippocampal brain slices. In addition to synaptic plasticity, the regulation of neuronal bioenergetics is also central to learning and memory. NF-kB modulates cellular energy regulation (i.e., mitochondrial dynamics, glycolysis) in cancer biology. Whether NF-κB exerts similar influences on energy production in neurons, however, is not well established. NF-κB is present in the mitochondrial matrix in neurons. Further, the antioxidant manganese superoxide dismutase (MnSOD), localized to mitochondria, is a downstream target of NF-κB. This study investigated the effects of NF-κB blockade on cellular respiration and glycolysis in neuronal cultures as a means of investigating its role in neuronal energy homeostasis. **Methods:** Cortical neurons from embryonic CD1 mice (E15-16) were cultured in 24-well Seahorse (Seahorse Biosciences) culture plates (300,000/well). After 24-hr treatment with NF-κB inhibitors sulfasalazine and SN50 at DIV 8-9, oxygen consumption rates (OCR) and glycolysis (extracellular acidification rates; ECAR) were measured in real time using the XF24 Analyzer (Seahorse Biosciences) and compared to untreated controls. Western blots were used to detect levels of NF-κB and MnSOD after NF-κB blockade. **Results:** Treatment (24 hr) with 1 mM sulfasalazine decreased maximal respiration ($p<0.05$) in neurons. SN50 decreased maximal respiration rates in a dose-dependent fashion ($p<0.05$). Sulfasalazine had no effect on ECAR at baseline. Glycolysis, however, was diminished in neurons treated with varying doses (300 uM-1 mM) of sulfasalazine ($p<0.001$), as was glycolytic capacity ($p<0.01$). Western blot experiments are ongoing. **Conclusions:** These data establish a novel role for NF-κB in neuronal bioenergetics. Such results have important implications for the treatment of disorders in which brain energy regulation and memory are compromised, including Alzheimer's disease. **Acknowledgement:** Funding from Natural

Sciences and Engineering Research Council (NSERC, BA), Research Manitoba (WS and BA), St. Boniface Research (BA), and the Everett Endowment Fund (BA).

Title: Modulation of neuronal mitochondrial motility and calcium responses by solutions enriched with oxygen nanobubbles

Authors: ***M. V. IVANNIKOV**, M. SUGIMORI, R. LLINAS;
NYU Sch. of Med., New York, NY

Abstract: Mitochondrial motility is believed to be driven by changing ATP needs in spatially segregated neuronal domains, and regulated by increases in cytosolic calcium levels. In previous studies we showed that treatments with solutions enriched in oxygen nanobubbles (RNS60, ~ 55±5 ppm O_2), as opposed to hyperbaric oxygen solutions (ONS60, ~ 55±5 ppm O_2), lead to significant increases in neurotransmitter release in the squid giant synapse (Choi et al., 2014) and in mouse diaphragm muscle preparations (Walton et al., 2014). These were both accompanied by increases in cellular ATP levels. Moreover, such changes could be completely abolished by mitochondrial inhibitors (Choi et al., 2014). Our preliminary data in differentiated PC12 and cultured cerebellar granule neurons show that the rise in cytosolic ATP levels with RNS60 leads to increased mitochondrial motility. Mean mitochondrial velocity in RNS60 treated cells was 0.31±0.05 um/sec (n=12) compared to 0.17±0.03 um/sec (n=12) in controls at room temperature. Additionally, the cytosolic area affected by mitochondrial motility measured over 10 min time period was also significantly increased by RNS60. RNS60 did not affect resting cytosolic calcium levels measured with fura-2AM in cerebellar granule neurons. However, the amplitude of cytosolic calcium transients evoked by brief applications of 60 mM potassium chloride Tyrode's solutions in fluo-4AM loaded cerebellar granule neurons was increased by 16.3± 4.8 % (n=6). Taken together, these findings suggest that stimulation of mitochondrial ATP production

with oxygen nanobubbles likely leads to a partial dissipation of intracellular ATP and ADP gradients despite increased cytolic calcium influx, which disinhibits mitochondrial motility.

Title: Mouse chronic subordination stress to model eating disorder-based metabolic dysfunctions

Authors: ***M. RAZZOLI**[1], V. SANGHEZ[2], A. BARTOLOMUCCI[1];
[1]Integrative Biol. and Phisiology, Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Pediatric, LABiomed Res. Inst. at Harbor UCLA Med. Cente, Torrance, CA

Abstract: Eating disorders and their physical and psychiatric co-morbidities appear to have causal factors including stressful life events and negative affect. By far the most common, binge eating disorder (BED) is defined by eating in a discrete period of time a larger than normal amount of food, a sense of lack of control over eating, and marked distress. Its underlying mechanisms are still unknown, in part due to the lack of appropriate animal models. We developed a naturalistic murine model of chronic subordination stress (CSS)-induced hyperphagia linked to metabolic disturbances. Subordinate male mice become hyperphagic and vulnerable to weight gain, show high leptin, low adiponectin, dyslipidemia and tissue-specific down-regulation of the insulin and peroxisome proliferator activated receptors pathways, indicative of insulin resistance. Furthermore, when high fat diet is allocated to hyperphagic subordinate mice their metabolism is further aggravated to pre-diabetes-like state. Since subordinate hyperphagic behavior is at the core of the described metabolic phenotype we sought to characterize it towards BED. In dedicated experiments, CSS was associated to the automated acquisition of subordinate food intake for meal pattern analysis. Additionally, we tested the hypothesis that the manifestation of obesity and metabolic syndrome could be prevented by limiting hyperphagia applying a pair-feeding protocol to subordinate mice. CSS disrupted the

architecture of feeding: subordinate mice ingested a disproportionate amount of food at higher rate and with shorter satiety ratio than control mice, in analogy to BED diagnostic criteria. Either hunger or acute stress were able to further exacerbate subordinate mice hyperphagia, suggesting a stress over-reactive state. Notably, preventing hyperphagia by pair-feeding abrogated the obese phenotype but not the fasting hyperglycemia of subordinate mice, probably due to a greater hunger-stress sensitivity. Overall these results support the validity of mouse CSS to model binge eating disorder addressing the contribution of the individual socioeconomic status on health in the development of eating disorders and their metabolic sequelae. Further characterization of the subordinate phenotype will help identify the molecular mechanisms involved in the regulation and the control of food intake in a psychologically and metabolically challenging context to generate knowledge-based innovative therapies.

Title: Behavioral, metabolic, and iron defects associated with loss of Ncb5or in the mouse cerebellum

Authors: *M. A. STROH;
Neurosci., Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Loss of NADH cytochrome b5 oxidoreductase (Ncb5or), a ubiquitously expressed flavoheme oxidoreductase, has been shown to result in pancreatic beta cell death, increased oxidative stress, altered lipid metabolism, as well as iron dyshomeostasis, hypermetabolism, and hyperactivity in mice. We recently conducted radioactive iron (Fe-59) pulse feeding experiments on global knockout (KO) mice and found that, while total brain iron content was unchanged, the amount of radioactive iron present in the brains of KO mice was significantly increased, suggesting an increased iron flux. To further investigate the effects of Ncb5or deficiency on neural tissue we generated a conditional knockout (CKO) mouse that lacks NCB5OR in the

cerebellum. Early longitudinal behavior tests reveal hind-limb clasping associated with changes in proprioceptive processing as early as 3 weeks of age in CKO mice. At 7 weeks of age, dietary iron deficiency results in alterations in locomotion and coordination in both wild type and CKO mice. However WT and CKO mice display opposite trends, with WT mice becoming hyperactive and CKO mice becoming hypoactive compared to age and genotype matched chow fed mice. Assessment of molecular markers in the cerebellum of CKO mice at age 7 weeks reveals changes in transcript levels in many genes associated with the maintenance of iron homeostasis as well as iron-sulfur containing proteins of the mitochondrial electron transport chain. Finally, intraperitoneal injection of 14C labeled 2-deoxyglucose revealed a significantly increased uptake of 2-deoxyglucose in the cerebellum of CKO mice as early as 7 weeks of age. Taken together, these findings suggest an important role for Ncb5or in maintaining iron homeostasis as well as potential influence over metabolic processes. A longer longitudinal study is currently underway to determine the behavioral effects of Ncb5or deficiency during brain aging.

Title: Contribution of centrally acting hormones amylin and ghrelin on the adipose tissue transformation in burn victims

Authors: *M. K. SARAF[1,2], D. N. HERNDON[2], C. PORTER[2], R. RADHAKRISHNAN[3], M. CHONDRONIKOLA[3], T. CHAO[3], L. S. SIDOSSIS[2];
[1]P.G.I.M.E.R., Chandigarh, India; [2]UTMB, SHC, Galveston, TX; [3]UTMB, Galveston, TX

Abstract: Severe burn injury causes massive metabolic abnormalities including catecholamine surge, lipolysis, and hormonal imbalance in burned children. We have recently demonstrated morphological changes and increased UCP1 expression in subcutaneous white adipose tissue (WAT) of human burn survivors (i.e. browning of WAT). Rodent studies suggest that amylin and ghrelin may be involved in the regulation of thermogenesis and energy expenditure, possibly by triggering sympathetic nerve activity innervating WAT. This study investigated the association between amylin and ghrelin hormones and the browning of WAT in burn victims. Subcutaneous WAT and blood samples were collected from twelve burned children (13±6yrs; 57% total body surface area burned) and nine healthy children (9±5 yrs). Hormones were measured by 'magnetic bead panel based multiplex' assay kit. Histology, immunohistochemistry, RT-PCR and mitochondrial respiration measurements were performed in WAT. Higher UCP1 mRNA ($p < 0.01$), UCP1 protein (22.9±4.5ng/mg vs 2.7±0.3; $p<0.001$), UCP1 immuno-staining, interleukin-6 (1307±282pg/ml vs 36±24; $p<0.001$) and mitochondrial respiration (1.5±0.3 vs 0.6±0.1 pmol/sec/mg, $p<0.05$) of burn WAT compared to healthy controls, indicates browning of WAT. Tissue norepinephrine level (53±20 pg/mg vs 15.2±10.2 pg/mg) was increased in WAT of burn victims after two week of post burn as compared to early days, indicating persistent adrenergic stimulation. We found high amylin (123.6±18pg/ml vs 24.7±4.6 pg/ml; $p<0.01$) and low ghrelin (15.2±3.5 pg/ml vs 27.8±7.3; $p<0.05$) level in plasma of burn victims. Amylin levels were significantly correlated with mitochondrial respiration ($R2=0.53$, $p<0.05$). Hence we conclude that centrally acting amylin and ghrelin may contribute, at least in part, to the WAT transformation.

Title: The effect of early life methyl donor supplementation on obesity development

Authors: *S. E. MCKEE[1], T. M. REYES[2,1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Nearly 50% of women with a normal pre-pregnancy body mass index gain more weight than recommended during their pregnancy. This excessive gestational weight gain (GWG) significantly increases the risk for the development of obesity in the offspring. Excessive GWG can be modeled in animals by feeding pregnant dams a high fat diet, leading to increased maternal weight gain and obesity-promoting phenotypes in the offspring. Using a mouse model of excessive GWG, we have documented in the offspring an increased preference for sucrose and fat, increased expression of genes that underlie reward-related behaviors, and both global and gene specific decreases in DNA methylation. These changes in reward-related neural circuitry may contribute to the increased risk for the development of obesity in the offspring by altering the animal's response to highly palatable, energy dense foods. Methyl donor supplementation (MDS) during pregnancy can reverse some of these obesity-promoting phenotypes in offspring, yet it is unknown whether postnatal MDS can reverse these phenotypes. To determine this, offspring from dams fed either a high fat diet (HFD) or control diet during gestation were fed a methyl donor supplemented diet during early life (3-6 weeks). We find that postnatal MDS significantly decreased body weight in both male and female adult HFD offspring, and does not alter body weights of control diet offspring. Further, postnatal MDS can normalize adult male fat preference and contributes to region specific normalization of DNA hypomethylation. Continued assessment of obesity development, preference for palatable foods, metabolic phenotypes, and expression changes of genes underlying homeostatic and hedonic feeding will elucidate whether early postnatal nutritional interventions can be utilized as a therapy to offset adult obesity risk.

Title: Fast-cyclic voltammetry reveals altered oxygen homeostasis in the nucleus tractus solitarii of the spontaneously hypertensive rat

Authors: *P. S. HOSFORD[1], J. MILLAR[2], A. G. RAMAGE[1], A. V. GOURINE[1], N. MARINA[1];
[1]Univ. College, London, London, United Kingdom; [2]QMUL Sch. of Med. and Dent., London, United Kingdom

Abstract: We have recently shown that in spontaneously hypertensive rats (SHRs) pO_2 of the brainstem parenchyma is lower compared to that of normotensive animals. We hypothesized that in conditions of decreased pO_2 astrocytes release ATP and L-lactate which contribute to the development of arterial hypertension by increasing activity of pre-sympathetic circuits (Marina et al., 2015). In this study, we investigated pO_2 homestasis in a brainstem area important for the control of blood pressure. We used fast-cyclic voltammetry to detect real time changes in tissue pO_2 in the nucleus tractus solitarii (NTS) in response to electrical simulation of the vagus nerve in α-chloralose anesthetized SHR (n=7) and Wistar (n=6) rats. Resting parenchymal pO_2 was determined in the NTS at natural arterial blood pressure (BP) for both strains (SHR; BP ~150, Wistar; ~100mmHg) and was found to be significantly ($P<0.05$) lower in the SHRs (51±4 vs 71±6 mmHg). Electrical stimulation of the central end of the vagus nerve (0.8mA, 1ms, 20s) caused a decrease in blood pressure and heart rate accompanied by a biphasic change in tissue pO_2 characterized by an initial decrease followed by an 'overshoot' above the baseline value. The initial pO_2 decrease was found to be significantly smaller in the SHRs compared to Wistar rats when stimulated at 3Hz (-5 ± 3 vs -18 ± 6 mmHg) and 5Hz (-7±3 vs -23 ±3 mmHg), respectively. However, there was no difference in the amplitude of the pO_2 overshoot. Animals subsequently received a ganglionic blocker (chlorisondamine, 1mg kg^{-1}) and mean arterial BP was clamped at 100mmHg by phenylephrine infusion (~20μg min^{-1}). In these conditions blood pressure and heart rate changes evoked by vagal stimulation were abolished; the initial decrease in tissue pO_2 was still significantly smaller in SHRs compared to Wistars when stimulated at 5Hz (-1 ± 1 vs -11 ± 4 mmHg) and 10Hz (-6 ± 2 vs -17 ± 5 mmHg). However, pO_2 overshoot became significantly higher in SHRs when stimulated at 5Hz (14 ± 2 vs -8 ± 1mmHg) and 10Hz (12 ±1

vs 6 ± 3 mmHg). In summary, at the normal level of the arterial BP the NTS of SHRs display smaller decreases in tissue pO_2 in response to increased neuronal activity but larger overshoots than Wistars. Further, SHR have a lower resting parenchymal pO_2. The evidence obtained indicates that oxygen homeostasis is altered in the SHR. The profile of pO_2 changes triggered by enhanced neuronal activity is also different which may reflect differences in vascular anatomy and/or perfusion between the two strains.

Title: Changes in brain melanocortin system with calorie restriction-induced adaptive thermogenesis and suppressed physical activity

Authors: *S. MUKHERJEE[1], S. L. BRITTON[3], L. G. KOCH[3], C. M. NOVAK[2];
[1]Biol. Sci., [2]Dept. of Biol. Sci., Kent State Univ., Kent, OH; [3]Anesthesiol., Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Obesity, a growing problem in today's society, can be reversed by energy restriction, but this causes metabolic compensations hampering continued weight loss. During weight loss, energy expenditure (EE) is suppressed beyond what is predicted by reduced body weight, a phenomenon termed adaptive thermogenesis. For our experiments we used rats artificially selected for high and low intrinsic aerobic capacity (HCR, LCR) which respond differently to 50% calorie restriction (CR), specifically with respect to suppression of physical activity and activity-related EE. Here, we examined changes in the brain melanocortin (MC) system over 21 days of calorie restriction in male HCR and LCR. In the arcuate nucleus (ARC), opposing anorexigenic POMC/CART (proopiomelanocortin/cocaine- and amphetamine-regulated transcript) neurons and orexigenic NPY/AgRP (neuropeptide Y and agouti related-peptide)

neurons modulate energy balance homeostasis, partly through neuropeptide actions on MC receptors. To determine if this system changes in association with adaptive thermogenesis, micropunching was employed to extract hypothalamic regions including the ARC, paraventricular nucleus (PVN), perifornical lateral hypothalamus (PeFLH), dorsomedial hypothalamus (DMH), and ventromedial hypothalamus (VMH) from frozen brain sections. QPCR was performed to examine the RNA expression of the melanocortin receptor subtypes 3, 4, 5 (MC3R, MC4R, MC5R). Comparisons were made between HCR and LCR at ad libitium feeding and after 50% CR at 2 days and 21 days. Expression of MC3R in the PVN decreased in HCR at 21-day CR. This is consistent with our findings demonstrating that MCR activation in the PVN promotes physical activity, and that physical activity decreases in HCR (but not LCR) after 21 days of CR. Changes were also seen in MC4R in VMH, where HCR increased expression throughout the course of CR. Whereas for MC5R there was a significant interaction between HCR and LCR in the ARC where HCR showed an increase, but LCR showed a decrease, after 2 days of CR. AgRP expression increased in both HCR and LCR by 21-day CR. Thus, just as energy restriction results in different degrees of activity-associated adaptive thermogenesis and physical activity suppression in HCR vs. LCR, we also find that 21-day CR differentially affects some, but not all, aspects of the brain MC system. These changes may result from opposing effects of CR on the two peptides-melanocortins and AgRP-that act on the same receptors, suggesting a possible role of orexigenic AgRP in changes in activity during energy restriction, especially long-term restriction.

Title: Metabolic glucose, insulin and leptin circadian rhythms are altered by perinatal cafeteria diet in rats

Authors: D. J. BUSTAMANTE-VALDEZ, *P. DURAN;
Facultad De Ciencias, UNAM, Ciudad de Mexico, Mexico

Abstract: The SCN receives information of the metabolic status of the body using input from the paraventricular nucleus,as well it is known to be the master clock in mammals.The food intake in quantity, quality and time is related to the correct use of metabolic hormones, and in the energy balance. Proper nutrition is one of the factors involved in the health and development of animals. The quantity and quality of the nutrients must satisfy the vital needs of the individuals, so that an imbalance in these causes changes at different levels which are hormonal, metabolic and organizational into the nervous system, depending on the moment in which it is established, can influence in the critical periods of brain and somatic development in the short, medium- or long-term. The aim of the present study, was to evaluate and to establish differences in daily profiles as well as in the rhythm amplitude and acrophase of plasma glucose, insulin, and leptin concentrations, levels of corticosterone were also evaluated as a control to stressors and circadian profile of a non-metabolic hormone in hypercaloric malnourished juvenile male rats. Sprague-Dawley female rats were randomly divided into 2 nutritional protocols (control -CO and high calorie/low protein malnutrition-MHp) with water and food ad libitum, three week prior the mating and through the gestation and lactation periods. The postnatal development of the offspring was observed, and pups from MHp group showed a decrease in size and weight, as well as an area significantly minor under the curve on the glucose tolerance test. Analysis of plasma glucose, insulin, and leptin parameters threw an imbalance in energy metabolism during 24 hours, a Cosinor test was performed to evaluate the daily rhythms insulin and leptin which occurred in CO but not in MHp group, glucose 24hr rhythms was present in both groups. We found a difference in the model of homeostatic assessment (HOMA) over 24hr, HOMA-IR (insulin resistance), was significantly greater in ZT4 and ZT20 of CO compared to MHp. HOMA-B (beta pancreatic cells) was significantly higher in ZT4 and ZT16 in MHp vs CO. Therefore it can be inferred that the disparity presented in MHp compared to CO in the daily rhythm of glucose, insulin and leptin, as well as the delay in growth are due to perinatal exposure of the high calorie/low protein diet known as “cafeteria diet”. Nutritional conditions during early stages of development have an influence on the energy balance in later stages, a disparity in the daily rhythmicity of glucose, insulin and leptin can be related to conditions or diseases at later stages.

Title: Brain glycogen fuels the exercising brain to maintain endurance capacity

Authors: *T. MATSUI, H. OMURO, Y.-F. LIU, T. SHIMA, M. SOYA, M. HAMASAKI, S. MIYAKAWA, H. SOYA;
Univ. of Tsukuba, Ibaraki, Japan

Abstract: During exercise, energy supply for active organs such as skeletal muscles and brains is essential issue to maintain endurance capacity. Although muscle glycogen, the glucose storage molecule, is the essential energy source in exercising muscles, energetics in the exercising brain is still largely unknown. Since brain glycogen stored in astrocytes, a source of lactate as a neuronal energy source, decreases during prolonged exhaustive exercise, we hypothesized that brain glycogen plays an important role in exercise endurance through energetic contributions in the exercising brain. To test this hypothesis, we here employed a rat model of prolonged exhaustive exercise on the treadmill with high-power microwave irradiation (10 kW, 1.2 sec), which is a sacrificing method as the gold standard for detecting brain metabolites including glycogen *in vivo*. Prolonged exhaustive exercise increased blood lactate levels and induced hypoglycemia, muscle glycogen depletion, and decreases, but not depletions, in brain glycogen levels together with increased neuronal monocarboxylate transporter (MCT2) protein levels. At the end of exhaustive exercise (time to exhaustion, 84.4 ± 2.9 min), metabolomics revealed increases in brain lactate levels, but not in muscle, with sustained concentrations of glycolytic sources. Simultaneously, brain ATP levels were maintained, while muscle ATP levels was depleted. Last, blockade of brain glycogenolysis and MCT2 during exercise by icv-injection with 1,4-Dideoxy-1,4-imino-d-arabinitol (DAB) and α-cyano-4-hydroxy-cinnamate (4-CIN), respectively, decreased endurance capacity associated with brain ATP levels. Our findings demonstrated for the first time that lactate from brain glycogen fuels the exercising brain to retain endurance capacity, providing a new understanding of brain energetics during exercise. Residual brain glycogen is a potential defense mechanism for maintaining brain ATP during exhaustive exercise.

Title: Role of TRPV4 in prediabetic obese peripheral nerve

Authors: C. AVOUNDJIAN, B. COOPERMAN, *L. R. BANNER;
Biol., California State Univ. Northridge, Northridge, CA

Abstract: Overconsumption of food and inactivity on a regular basis are risk factors for developing prediabetic obesity. According to the American Diabetes Association, prediabetes affects over 86 million Americans which, if not taken care of, may cause type II diabetes. This disease state is characterized by higher than average blood sugar levels and depending on the severity, may lead to a number of problems in immune and nervous systems. Although studies are limited, prediabetes has been shown to induce complications in the peripheral nervous system (PNS) - a common complication in diabetic patients. Prediabetic neuropathy causes differences in the conduction of motor and sensory nerves as well as abnormalities in nerve function. Transient Receptor Potential Vanilloid 4 (TRPV4), is a cation channel responsible for sensing a variety of stimuli and is found within the spinal cord and sensory neurons of the peripheral nervous system. Recent studies have demonstrated a role for TRPV4 in regulating peripheral neurite growth. The expression of TRPV4 in prediabetic peripheral nerves may play a role in establishing differences in the nerves of prediabetic obese and normal mice. In order to examine the effects of TRPV4 in the sciatic nerves of prediabetic obese mice, we measured the quantity of the ion channel present within the nerves of high fat fed and control fed mice. Six-week-old C57BL6/J bred mice were placed on a 60% high fat or 10% control diet for 19 weeks. Blood glucose and weight measurements were then used to determine prediabetic condition. Animals fed a high fat diet weighed significantly more and displayed elevated blood glucose levels than mice fed the control diet. Sciatic nerves from these animals were extracted for protein, quantified with the BCA kit, and used for Western blot analysis. Our preliminary analysis revealed higher TRPV4 levels in the sciatic nerves of diet induced obese mice relative to the levels of TRPV4 in control fed mice. This suggests that the upregulation of TRPV4 produced from a high fat diet may have an effect on prediabetic nerve function. Nerve conductions studies will be performed following agonist and antagonist application to address the role of TRPV4 in diet-induced prediabetic neuropathy.

Title: Implicit motor learning in the absence of sensory-prediction errors

Authors: *D. GRAEUPNER[1], P. A. BUTCHER[1], J. A. TAYLOR[2];
[1]Dept. of Psychology, [2]Dept. of Psychology; Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Recent studies have shown that learning in visuomotor adaptation tasks results from the interplay between implicit learning of a forward model, driven by sensory-prediction errors, and explicit learning, driven by target errors (Taylor, Krakauer & Ivry, 2014). Sensory-prediction errors are thought to be dependent on cursor feedback, while target errors are thought to be a proxy of a reward signal; however, the relationship between these two error sources with respect to implicit and explicit learning remains unclear. The goal of the current study was to systematically manipulate cursor feedback and reward feedback, and measure their relative contribution to implicit and explicit learning. Here, we employed a 2-by-2 factorial design, manipulating type of error signal (Endpoint vs. Scaled reward) and number of training targets (One vs. Eight) in a visuomotor rotation task. Explicit and implicit learning were distinguished by asking participants to verbally report their intended aiming direction on each trial. In the Endpoint conditions, error feedback was given in the form of a red circle indicating hand position, while in the Scaled reward conditions, error feedback was delivered as points (0-100) indicating the distance between an unseen cursor and the target. Additionally, we varied the number of target locations in each group: using either One or Eight targets. For the Eight target conditions, the targets could appear at one of eight locations that were separated by 45° along a numbered ring. We found that participants in all conditions learned to counter the rotation to a similar degree. Participants in the Endpoint feedback conditions showed similar traces of explicit and implicit learning, although, consistent with prior work from our lab, their relative contribution differed with respect to the number of targets. Surprisingly, implicit learning was also present in the Scaled reward feedback condition when training was limited to one target. In fact, here the time course of implicit learning was similar between Endpoint and Reward feedback conditions. When training at eight targets with reward feedback, implicit learning was greatly diminished. These findings suggest that the time course of implicit learning is itself

composed of multiple processes that evolve over the course of training in a similar manner. However, reward feedback is not sufficient to induce implicit learning when training throughout the workspace. In summary these findings indicate that implicit learning under reward feedback may be consistent with operant conditioning or use-dependent plasticity as opposed to a forward model.

Title: Modifying the discrete sequence production task for a multi day tdcs study in young and older adults

Authors: *B. GREELEY[1,2], J. BARNHOORN[5], W. VERWEY[5], R. SEILDER[1,2,3,4];
[1]Sch. of Kinesiology, [2]Dept. of Psychology, [3]Neurosci. Program, [4]Inst. of Gerontology, Univ. of Michigan, Ann Arbor, MI; [5]Univ. of Twente, Enschede, Netherlands

Abstract: The discrete sequence production (DSP) task is an explicit motor learning sequence task where two 6-item sequences are presented one item at a time. Over many repetitions, participants eventually execute a 6-item sequence as 2 or more segments, an indication of distinct motor chunks. Previous work has demonstrated that older adults exhibit a reduction in chunk length and have an impaired explicit memory, relative to young adults. Right and left dorsolateral prefrontal cortex (DLPFC) have been demonstrated to be involved in early explicit sequence learning as well as early adaptation. Primary motor cortex (M1) has been shown to be involved in explicit sequence learning and retention. Further, premotor cortex has been shown to be involved in memory consolidation in sequence learning. Here, we use transcranial direct current stimulation (tDCS), a non-invasive form of brain stimulation, to facilitate early learning and chunking in both younger and older adults in a truncated version of the traditional DSP task. Participants attend three sessions over the course of a week, and are randomized into one of five tDCS conditions (right DLPFC, left DLPFC, M1, premotor, or sham). Over the three sessions, participants complete a battery of cognitive and motor tasks that correlate with motor learning ability and executive functioning in order to characterize the participant, use later as covariates in

analysis, and understand how these cognitive and motor tasks might change from baseline as a function of the tDCS condition. Participants also practice the DSP task while receiving tDCS for up to 25 minutes during sessions 1 and 2. During session three, participants are tested on their ability to remember the sequence of the DSP task without stimulation. We hypothesize that tDCS to right DLPFC will facilitate early learning in both older and younger adults, with older adults receiving the most benefit from the tDCS stimulation. We also predict that tDCS over premotor cortex will help facilitate chunking in older adults, relative to older adults in the sham group. We expect that stimulation to M1, left DLPFC, and premotor in younger adults will change the rate of motor learning relative to young adults in the sham tDCS group. Our preliminary results suggest that younger adults without tDCS are still able to chunk with fewer trials in the DSP task over three sessions.

Title: Fine motor control is associated with individual fitness level in older adults

Authors: *C. VOELCKER-REHAGE[1,2], L. HUEBNER[1,2], B. GODDE[1];
[1]Jacobs Univ. Bremen, Bremen, Germany; [2]Technische Univ. Chemnitz, Chemnitz, Germany

Abstract: A physically active lifestyle positively influences cognitive performance as well as corresponding brain structures and functions in elderly persons (e.g., Colcombe & Kramer, 2003). Recent studies showed a positive influence of a high fitness level on motor performance (e.g., Claudino et al., 2013). Fitness level was assessed by a physical activity questionnaire. The aim of the current study was to explore whether high fit older adults exhibit better performance than low fit participants also in a visuomotor tracking task requiring fine motor control, when fitness status is quantitatively measured with a cardiovascular exercise test. Data were collected from 52 older adults ranging from 67 to 83 years of age. Participants were assigned into two extreme groups based on their VO_2-peak from a cardiovascular spiroergometry on a bicycle ergometer (low fit group: VO_2-peak $\leq$ 1.10 l/min, n = 12; high fit group: VO_2-peak $\geq$ 1.50 l/min, n = 9). Fine motor control was assessed with a visuomotor precision grip tracking task.

Participants had to track two different irregular sine wave patterns with their right dominant hand (16 trials of 15 seconds each). Tracking variability was operationalized by use of the root mean square error (RMSE). All participants completed the Montreal Cognitive Assessment (MoCA) to control for cognitive decline (scores ranging from 21 to 30). A significant correlation of MoCA score and fine motor performance was found (r = -.035, p = .011), therefore further analyses were controlled for MoCA score (ANCOVA: 2 fitness (low fit, high fit) × fine motor control performance (RMSE) with MoCA score as covariate). High fit older adults performed better in the visuomotor tracking task revealed by a smaller RMSE (F (1, 20) = 5,476, p = .031, η^2_p = .233) as compared to the low fit group. MoCA score was significant (F (1, 20) = 7.600, p = .013, η^2_p = .297) indicating a moderating effect of cognitive performance on fine motor control. These results indicate that the performance in our visuomotor tracking task is, besides cognitive status, positively influenced by a high fitness level. Thus fitness might compensate not only for cognitive, but also for manual decline. Currently, analysis of corresponding EEG data is in progress. We expect to find supporting evidence by differences in electrophysiological correlates of high and low fit older adults. Claudino, R., Mazo, G. Z., & Santos, M. J. (2013). Title: Motor plasticity in assembly-line workers: effects of repeated work task changes on manual dexterity and related brain function

Authors: *B. GODDE[1], J. OLTMANNS[1], C. VOELCKER-REHAGE[1], U. M. STAUDINGER[2]; [1]Jacobs Univ., Bremen, Germany; [2]Columbia Aging Ctr., New York, NY

Abstract: Work demands have a strong influence on brain and cognition. It has been assumed that particularly cognitive challenges in confrontation with unknown problems and novel situations facilitate positive plasticity in adult development [1,2]. We recently provided evidence

that also repeated confrontation with novelty at work at low levels of job complexity (indicated via repeated work-related task changes; WTC) positively affects cognitive flexibility and brain structure in adults across the working life span [3]. Here we were interested whether repeated WTC facilitate motor plasticity in long-term assembly-line workers. Of 3.500 workers from a production company in northern Germany who had been full-time employed with that company over the last 16 years, 179 persons returned a screening questionnaire. This allowed us to identify 10 (n=20) pairs of participants who differed in WTC (high/low) but were optimally matched for age, sex, job complexity as well as academic performance, openness to new experience and leisure time activity in young adulthood. In order to investigate long-term effects of WTC on manual dexterity and related brain function, we compared functional MR images from the participants while they performed a manual visuomotor force tracking task. First results revealed that participants with high WTC did not differ in motor performance levels and learning slopes from their low WTC matched counterparts. However, similar performance was associated with different brain activation patterns. While high WTC participants revealed focal activations in contralateral sensorimotor and parietal brain areas, low WTC was associated with much more distributed and diffuse activations in bilateral, also frontal brain areas. Interestingly, activation patterns found in low WTC participants resembled those previously found in older as compared to younger adults. Thus we conclude that repeated WTC facilitate motor plasticity in construction workers and might delay aging of the motor system. References: [1] Bowen CE, Noack CMG, Staudinger UM (2010). Title: Task-related alpha power during a fine motor control task in young and older adults

Authors: *L. HUEBNER[1,2], B. GODDE[1], C. VOELCKER-REHAGE[1,2];
[1]Jacobs Univ. Bremen, Bremen, Germany; [2]Technische Univ. Chemnitz, Chemnitz, Germany

Abstract: Task-related alpha power over sensorimotor and parietal areas decreases during the execution of a motor task (Manganotti et al., 1998). Others reported that older adults require increased prefrontal resources during motor control tasks (Berchicci et al., 2012). This study aimed to investigate whether age effects on alpha power differ in prefrontal and motor regions. 46 participants were recruited, 16 young participants ranging from 19-29 years of age and 30 older adults ranging from 67-83 years of age. Participants performed a visuomotor precision grip tracking task with a 6-axis-Mini-Model-force transducer (8 trials of 15 seconds each). Tracking variability was operationalized by use of the root mean square error (RMSE). Task-related power (TRPow) in the lower (8-10 Hz) and upper (10-12 Hz) alpha frequency band was calculated for the following electrodes of interest: contralateral motor cortex (C3) and prefrontal electrodes (Fp1, Fp2, AF3, AF4). Older adults showed lower fine motor control performance as compared to young participants. First analyses revealed that in the lower alpha band $TRPow_{C3}$ did not differ between age groups, whereas in analyzed prefrontal electrodes older adults revealed a smaller TrPow decrease than young adults. This smaller decrease mainly resulted from smaller alpha power at rest of the older participants. In the upper alpha band older adults exhibited a significantly smaller $TRPow_{C3}$ than young adults. In contrast to the lower alpha band, no age effect was found in the upper alpha band for frontal electrodes. Task-related power in lower and upper alpha bands seems to reflect different (sensorimotor/cognitive) processes. Our results fit to the findings that the upper alpha frequency band reflects activity in sensorimotor areas (Manganotti et al., 1998), whereas lower alpha might be linked to cognitive performance (Klimesch, 1999). Further, diminished alpha power and TRPow decrease seem to be responsible mechanisms of age-related performance decline. Both cognitive and motor processes seem to be involved in performing the visuomotor tracking task and are both diminished in older adults.

Title: A cognitive framework for explaining serial processing and sequence execution strategies

Authors: *W. B. VERWEY[1,2], C. H. SHEA[2], D. L. WRIGHT[2];
[1]Univ. of Twente, Enschede, Netherlands; [2]Dept. of Hlth. and Kinesiology, Texas A&M Univ., College Station, TX

Abstract: Behavioral research produced many task-specific cognitive models that do not say much about the underlying information processing architecture. Such an architecture is badly needed to understand better how cognitive neuroscience can benefit from existing cognitive models. This problem is especially pertinent in the domain of sequential behavior where behavioral research suggests a diversity of cognitive processes, processing modes and representations. Inspired by decades of reaction time (RT) research with the Additive Factors Method, the Psychological Refractory Period paradigm, and the Discrete Sequence Production task, we propose the Cognitive framework for Sequential Motor Behavior (C-SMB). We argue that C-SMB accounts for cognitive models developed for a range of sequential motor tasks (like those proposed by Keele et al., 2003; Rosenbaum et al., 1983, 1986, 1995; Schmidt, 1975; Sternberg et al., 1978, 1988). C-SMB postulates that sequence execution can be controlled by a central processor using central-symbolic representations, and also by a motor processor using sequence-specific motor representations. On the basis of this framework we present a classification of the sequence execution strategies that helps researchers to understand better the cognitive and neural underpinnings of serial movement behavior.

Title: Age effects on the transfer of sequence knowledge between different types of movements

Authors: *J. S. BARNHOORN[1], F. DÖHRING[2], E. H. F. VAN ASSELDONK[1], W. B. VERWEY[1];
[1]Univ. of Twente, Enschede, Netherlands; [2]Saarland Univ., Saarbrücken, Germany

Abstract: The goal of the current study was to determine whether age influences the ability to transfer sequential knowledge between two different types of motor responses. During practice of a discrete sequence production task, participants responded either by unimanual key presses (KP) on a standard computer keyboard, or by moving a lever with a flexion extension (FE) motion of their right arm. Sequence knowledge was then tested with the other type of responses. Stimulus presentation was identical over the whole task. Sequence learning theory suggests that performers first develop a cognitive representation and with additional practice a motor representation. Based on this insight and on previous research, we hypothesized that elderly would be able to transfer sequence knowledge between the two response modes. Because KP responses are less precise, we expected this condition to be more cognitively controlled than the more difficult FE condition, and therefore also hypothesized more transfer from practice using KP followed by a retention test using FE than vice versa. We tested 32 right-handed elderly (65 - 74) and 27 young people (18 - 30). Individual characteristics were described using the MOCA, a visuospatial working memory task, a digit symbol substitution task and a general health questionnaire. The experiment started with familiarization with KP and FE. Then, two 6-element sequences were practiced with KP or FE for a total of 288 trials. Participants were instructed that two fixed sequences were presented, but not that a test on transfer to another response mode would follow. After an explicit sequence knowledge questionnaire, the test phase with the remaining type of movements followed. The test phase consisted of one block of 24 familiar trials and one block of 24 random trials. Transfer was defined as the percentage speed difference between the familiar and random test blocks. After FE practice, both age groups showed transfer of sequence knowledge. This effect was larger for young participants than for elderly. After KP practice, only young participants showed signs of transfer, which was smaller than the amount of transfer after FE practice. Because there was no difference in the amount of explicit sequence knowledge between the practice conditions, we conclude that there is either more implicit spatial sequence learning in the FE than in the KP response mode, or that KP responses are a more sensitive measure of implicit sequence knowledge. We found that elderly are indeed able to transfer sequence knowledge but to a lesser extend than younger people and that in both age groups response mode plays an important role in measuring such effects.

Title: Age related differences in scheduling observational and physical practice

Authors: *F. DÖHRING, S. PANZER;
Human Movement Sci., Saarland Univ., Saarbruecken, Germany

Abstract: Aging is associated with changes in the neuronal structures, which result in cognitive and motor slowing. Observational practice (OP) can be an important tool for motor skill learning especially when the performer has restrictions in executing the task as a result of his physical or cognitive constitution. Thus it might be of particular relevance for elderly. Little attention has been drawn to OP and aging (Celnik et al., 2006). The present experiment was designed to determine whether older (OA) and younger (YA) adults benefit from different OP schedules in learning a sequential motor task. YA (20 to 30 years) and OA (65 to 75 years) had to execute a 10-element movement sequence with their dominant right arm. They used a horizontally mounted lever to control a cursor on a projector screen with motions of flexion and extension. The goal of the task was to move the cursor as quickly and accurately as possible between the illuminated targets. YA and OA were randomly assigned to one of two different practice schedules, a blocked version (BLO) with OP first followed by physical practice (PP) and an alternated version (ALT) with a continuous change between OP and PP. PP consisted of 16 blocks of 10 consecutive sequences for a total of 160 sequences. OP consisted of a video session composed of additional 16 blocks observing a learning model. A 2x2x16 (age-group, schedule, block) ANOVA with repeated measurements for the mean element duration revealed an interaction of Block x Schedule, $F(15,630) = 7.64$, $p < .01$, $\eta^2 = .15$, a main effect in block, $F(16,630) = 93.05$, $p < .01$, $\eta^2 = .69$, and a main effect of age-group, $F(1,42) = 130.44$, $p < .01$, $\eta^2 = .76$. While YA were superior in movement time, both age-groups increased their performance regardless of their schedule. In addition the schedules induce the same pattern without differences in relation to the age-group; subjects in the BLO showed only an advantage in performance compared to subjects in the ALT until bock 4 after which both schedule lead to similar outcome. The difference in performance between YA and OA is consistent with the phenomenon of age-related general slowing. The advantage induced by the BLO can be explained by the greater amount of information provided to the subjects. That YA and OA showed the same pattern of results indicates that both age-groups were able to extract equal information form observing the model, but OA performed slower on the executive level. Further research should address the question whether these effects are more cognitive or motor related.

Title: Functional Connectivity patterns in the cerebellar-thalamic-cortical network predicts retention in locomotor adaptation

Authors: *L. SHMUELOF[1], S. BAR-HAIM[2], F. MAWASE[3,4];
[1]Motor Performance Lab, Dept. of Neurol., [2]Physical Therapy, [3]Biomed. Engin., Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel; [4]Dept. of Physical Med. and Rehabil., Johns Hopkins Univ., Baltimore, MD

Abstract: Locomotor adaptation has been studied extensively in recent years as a model for rehabilitation of walking deficits and for motor adaptation. While behavioral results in the lab suggest that locomotor adaptation shares key similarities with reaching adaption, the neural basis of locomotor adaptation is still largely unknown. We investigate the neural basis of locomotor adaptation and retention by examining the relationship between functional connectivity in resting state fMRI activation and the ability to learn and retain novel locomotor patterns. In light of previous results in human patients and nonhuman primates, we focus on the connectivity within the cerebellar-thalamic-cortical pathway, which have shown to be involved in forming and learning motor memories. We were specifically interested in asking whether baseline connectivity levels are indicative of the ability of subjects to learn and retain novel locomotor

patterns and how functional connectivity between regions of interest changes following learning. Thirteen subjects participated in a protocol of three consecutive days. In the first day, subjects did a baseline session in which they were instructed to walk on a split-belt treadmill with no speed perturbations. Subjects were then transported to the MRI scanner and underwent anatomical, functional and structural MRI. In the second day, subjects adapted to the split-belt treadmill with the belts of the treadmill moving at different speeds, and then transported to the scanner and underwent another MRI session. On the third day, in order to evaluate the level of task's retention, subjects performed a behavioral session of adaptation-washout-readaptation protocol. We found that the baseline connectivity between cerebellum and thalamus predicted savings (i.e. rate of relearning) across individuals while baseline connectivity between thalamus and motor cortex predicted the retention (i.e. initial bias of relearning) of the motor task across individuals. These results suggests that the formation of new motor memories is not affected only by the activation of the cerebellar-thalamic-cortical network during the learning, but also by the pattern of connectivity between these areas before learning began. Moreover, we detected a significant change in functional connectivity both between the cerebellum and thalamus and between the cerebellum and motor cortex following motor learning, indicating that the consolidation process is associated with connectivity changes that occur following the learning.

Title: Error estimation training enhances motor learning in older adults

Authors: *Y.-T. CHEN, M. KWON, A. CASAMENTO MORAN, M. W. BEIENE, B. G. GRUBBS, F. T. FIOL, K. GAUGER, E. A. CHRISTOU;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Error estimation, defined as the ability to detect the difference between the desired and actual motor performance, is a crucial part of motor learning. Nonetheless, it is unknown whether training that emphasizes error estimation could improve motor learning in older adults. The purpose of this study, therefore, was to determine whether error estimation training enhances

motor learning in older adults. Twenty seven older adults (71.3 ± 9.1 yrs) participated in this study. They were randomly assigned into three groups (error estimation training group, N=9; typical training group, N=9; and control group, N=9). The error estimation training group practiced 100 trials of a rapid goal-directed task with the ankle joint and estimated their own performance by reporting the endpoint coordinates (space and time) of the peak displacement after each trial. The typical training group practiced the same task for 100 trials but without estimating performance after each trial. The control group did not practice the task with the ankle joint. All the participants were tested one day later with elbow flexion (ipsilateral transfer). The goal of the task was to accurately match a spatial-temporal target. The spatial target was 9º for ankle dorsiflexion and 18º for elbow flexion and the time target was 180 ms. Visual feedback of the position trajectory and target was provided for 5s for all the participants after each trial. We quantified endpoint error as the shortest distance between the peak movement and the target. Participants in the error estimation training group exhibited greater endpoint error than the typical training group (39.8 ± 3.9% V.S. 29.8± 2.6%) during task acquisition (ankle dorsiflexion). In contrast, the error-detection training group (40.6±3.0%) exhibited lower endpoint error than the typical training (55.2.6±7.6%) and control (56.2.3±8.1%) groups during ipsilateral transfer. In summary, these results suggest that error-detection training can enhance motor learning in older adults.

Title: Rapid learning of higher-order statistics in implicit sequence learning

Authors: K. R. THOMPSON[1], *P. J. REBER[2];
[1]Psychology, [2]Dept Psychol, Northwestern Univ., Evanston, IL

Abstract: Implicit learning involves extracting experienced regularities and statistical variation from the environment in order to improve behavior. Because knowledge of environmental structure is acquired outside of awareness, it is challenging to determine the precise nature of the

information that is obtained from experience. A commonly used paradigm to study this implicit learning process is perceptual-motor sequence learning in which a covertly embedded sequence is used to create statistical structure across sequences of actions. It is somewhat intuitive to hypothesize that participants acquire the simplest possible statistics, which should be the least computationally demanding to track across time. In most sequence learning experiments, this means learning second-order conditional probabilities (or trigrams). In the current experiments, we manipulated the statistical information available to participants during training on an implicit sequence learning task. Participants were either trained with a traditional 12-item repeating sequence, or with probabilistic, pseudo-randomly mixed 6-item fragments of that sequence constructed to match the lower-order (trigram) statistics of the repeating sequence condition. If only the simplest necessary statistics are learned, we would expect participants to display equal sequence learning across conditions. We found that participants who trained on full repetitions of the sequence exhibited robustly better sequence learning than participants who completed fragment training. This implies that some higher-order statistics are acquired rapidly during repeating sequence practice. We built a computational simulation model to test specific hypotheses about candidate learning processes. The best-fitting statistical learning model incorporated immediate acquisition of fourth-order conditional probabilities, two orders of magnitude more complex than strictly necessary to learn the sequence. A third behavioral experiment confirmed that fragments training led to equivalent learning as repeated sequence training when fourth-order information was matched. This is particularly striking considering the exponential increase in storage capacity necessary to compute higher-order statistics among all elements of the environment. While our results do not rule out other approaches to the computationally difficult problem (e.g., chunking mechanisms), both the behavioral and modeling data suggest that participants rapidly learn higher-order statistics from sequential information.

Title: The influence of biomechanics and cognitive demands on locomotor sequence learning

Authors: G. BORIN, *J. T. CHOI;
Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Visual information is naturally used to modify our walking patterns. Voluntary control must be integrated with locomotor pattern generation to control precise stepping movements. Here we challenged walking control by presenting stepping targets of varying spatial complexities (i.e., random vs. ordered), and determined how biomechanical factors (i.e., step length, step width) and cognitive demands (i.e., dual task) affect the rate and magnitude of locomotor sequence learning. Thus far, we tested 8 healthy subjects (27 ± 3 yrs, 2M/6F) walking at 2.0 m/s. The learning paradigm was derived from the serial reaction time task, introduced by Nissen and Bullemer (1987). Performance was measured across 7 blocks that each consisted of 100 steps (Fig. 1a). Blocks 1, 2 and 6 were called random blocks (R1, R2, R3); stepping targets appeared in randomly selected series of location. Blocks 3-5 and 7 were called sequence blocks (S1-S3, S4); subjects were presented with a repeating sequence (e.g., short-long-normal-long-short-normal, narrow-wide-normal-wide-narrow-normal). Sequence-specific learning was calculated as the difference in performance between training block S3 and random block R3; non-specific learning was calculated as the difference between random blocks R2 and R3. We tested two different biomechanics conditions: one required step length modification along the anterior-posterior axis, and the other required step width modification along the mediolateral axis. In addition, a separate group will be tested to determine the effects of a dual cognitive task on the rate and magnitude of locomotor sequence learning (Fig. 1b). The results suggest that both step length and step width sequences could be learned over 300 training steps. Group averaged performance improved over training blocks S1 to S3. The decrease in performance in the last random block R3 indicates sequence-specific effects rather than non-specific learning effects. Moreover, endpoint error in the mediolateral direction was consistently smaller compared to that in the anterior-posterior direction.

Title: Transfer of sequence-specific and non-specific motor skills after constant and variable training

Authors: *D. M. MUSSGENS[1,2], F. ULLÉN[2];
[1]NINDS, Bethesda, MD; [2]Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Retention of motor skills is known to be affected by the schedule under which a motor skill is practiced, with variable practice (i.e. varying practice between different tasks) typically being superior to constant practice (i.e. repeating the same task in large blocks). However, it is less clear whether variable practice is similarly beneficial for skill transfer and which components of task performance are transferred between tasks. To determine how practice schedule affects transfer of implicitly learned motor sequence skills we trained two groups of participants on an implicit serial reaction time task and evaluated performance on transfer sequences before and after practice. Participants in the Constant training group practiced 10 blocks of the same 12-element sequence, whereas the Variable group practiced a total of 10 blocks, but alternating between two different 12-element sequences. We evaluated three different types of transfer: task-general transfer to a structurally non-overlapping sequence, inter-manual transfer to a perceptually identical sequence performed with the untrained hand, and sequence-specific transfer to a novel sequence that shared 3 sub-sequences (triplets) with the trained sequences. All sequences were carefully balanced for salient structural properties and transfer was quantified as reaction-time decreases after training as compared to baseline. We found less task-general transfer to the non-overlapping sequence after constant practice than after variable practice, but no difference between groups for inter-manual and sequence-specific transfer. Further, we found evidence for transfer of sequence-specific knowledge in both groups. Transfer was larger to the structurally overlapping sequence than to the non-overlapping sequence and improvements on predictable sequence elements (i.e. the last elements of shared triplets) were greater than those on comparable unpredictable elements (i.e. the first elements of shared triplets). These results suggest that variable practice is more beneficial than constant practice for task-general transfer of sequential skills, possibly by reducing negative interference from implicit sequence expectations. Further, the presence of sequence-specific transfer in both groups suggests that knowledge of sequence structure can, at least partially transfer to novel sequences, independent of practice schedule.

Title: Explicit knowledge in a motor sequence depends on strategy

Authors: *M. JAYNES, M. SCHIEBER, J. MINK;
Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Explicit knowledge of a motor sequence is defined as the ability to describe rules or underlying patterns in the movements that make up the sequence. In experimental paradigms this knowledge may be promoted by specific instruction or developed with practice. Depending on the motor task, explicit knowledge may hinder, benefit, or have no obvious effect on performance. Despite comparable performance improvement, some healthy subjects fail to attain explicit knowledge of underlying patterns in a certain motor sequence. Cognitive and procedural differences between subjects who reach and subjects who do not reach explicit knowledge are unknown. We investigated whether attainment of explicit knowledge in a sequence depends on motor strategy. Healthy adult human subjects performed a battery of finger tapping sequences while wearing a CyberGlove. The tapping tasks included changing visual stimuli that prompted the same finger movements. We instructed subjects to tap the sequences as quickly and accurately as possible but made no insinuation of the common motor sequence. 47% of subjects attained explicit awareness of the underlying pattern in at least one set of motor sequences. A generalized procrustes analysis of the velocity-acceleration plot of each fingertip revealed that subjects who reached explicit knowledge tapped with more consistent finger trajectories throughout the experiment than did subjects who did not reach explicit knowledge. This consistency was present even on sets of motor sequences before the acquisition of explicit knowledge. Despite these differences in the ability to declare underlying patterns in the sequences, there was no difference between groups in performance improvement as measured by tapping speed. Explicit knowledge of an underlying pattern in a finger tapping task is promoted by kinematic consistency, and this kinematic consistency suggests a difference in motor strategy.

This finding suggests that a motor learning strategy resulting in more consistent and automatic movement may be advantageous in motor tasks that benefit from explicit knowledge.

Title: Long-term stability of implicit sequential memory: One-year consolidation of probabilistic sequence learning

Authors: ***A. KÓBOR**[1], K. JANACSEK[2,3], Á. TAKÁCS[3], D. NEMETH[2,3];
[1]Brain Imaging Ctr., Res. Ctr. For Natural Sciences, HAS, Budapest, Hungary; [2]Inst. of Cognitive Neurosci. and Psychology, Res. Ctr. for Natural Sciences, Hungarian Acad. of Sci., Budapest, Hungary; [3]Inst. of Psychology, Eötvös Loránd Univ., Budapest, Hungary

Abstract: Probabilistic sequence learning (PSL) underlies the efficient processing of statistical patterns in our environment and it is therefore crucial in many day-to-day activities. PSL is acquired gradually; however, only limited information is available about its long-term retention. Former studies emphasized the role of frontostriatal circuits in PSL. The aim of the present study was to investigate the plasticity of these circuits involved in the consolidation and one-year retention of PSL. Healthy young adults (N = 46) performed the Alternating Serial Reaction Time (ASRT) task, which separately measures the sequence-specific and general skill learning component of PSL. The task was administered in three testing sessions: before and after a 24-hour delay and after a one-year delay. We found evidence for improved PSL after 24-hour delay. Specifically, sequence-specific performance was higher at the beginning of the second session than at the beginning of the first session, which also excludes the possibility of simply relearning sequential regularities. Crucially, results showed the one-year retention of this sequence-specific knowledge indicated by similar performance during the second and third sessions. In contrast, general skill learning decreased after one year. The degree of sequence-specific retention for one year was not associated with working memory or frontal lobe functions suggesting the

independence of automatic and controlled adaptive processes. In sum, these results highlight the long-term plasticity of frontostriatal circuits mediating formation, consolidation, and retention of memory traces related to sequential regularities. In addition, findings give insight to the dynamic change of multiple processes that occur during an offline learning period within a longer stretch of time.

Title: Changes in NREM2 sleep spindle frequency play a causal role in motor sequence learning consolidation

Authors: ***S. LAVENTURE**[1], S. FOGEL[2], G. ALBOUY[3], O. LUNGU[1], C. VIEN[1], P. SÉVIGNY-DUPONT[1], C. SAYOUR[1], J. CARRIER[1], H. BENALI[4], J. DOYON[1];

Abstract: Motor sequence learning refers to the process by which simple, stereotyped movement elements come to be performed effortlessly as a unitary sequence through multiple sessions of practice. Past studies have shown that motor sequence learning goes through different phases during practice, hence allowing the memory trace to become more stable over time, a process called motor memory consolidation. Numerous researches have convincingly demonstrated that sleep plays a critical role in motor sequence learning consolidation. Yet there is no consensus regarding the sleep stages implicated in this type of memory consolidation. Evidences indicate that NREM2 sleep, and spindle activity in particular, are critical for motor memory consolidation to occur but most of these studies are only correlational in nature. To probe the possible causal role of NREM2, we implemented a targeted memory reactivation (TMR) protocol. We conditioned a first group of participants (n = 25) with a rose-like odor during learning of a sequence of finger movements, and re-exposed them to the odor during subsequent NREM2 sleep (Cond-NREM2). A second group (n = 23) was conditioned with the same odor and was re-

exposed during REM sleep (Cond-REM). Finally, a third group (n = 28) was not conditioned, but was exposed to the olfactory stimulus during NREM2 sleep (NoCond). In order to measure the effect of cuing on consolidation of the novel task we retested all subjects in the morning. We found significant difference of gains in performance between the experimental groups ($F2, 71 = 5.855$, $p = .004$). More precisely, the Cond-NREM2 group had significantly higher gains in performance than both the Cond-REM and NoCond groups. Importantly, Cond-NREM2 showed significant increases in sleep spindles of several characteristics over parietal regions when comparing periods of sleep before and during stimulation. More importantly, however, we found that the change in frequency of sleep spindles at Pz during stimulation was specific to the 13.5 to 14 Hz frequency band, and mediated the relationship between our experimental groups and the offline gains. These findings strongly suggest that NREM2 sleep is causally implicated, through the activity of sleep spindles, in the consolidation of motor sequence memories.

Abstract: Many complex behaviours involve the ability to learn and reproduce sequences of events in their correct temporal order. Some of these sequences can occur embedded in continuous streams of information. Therefore, we often extract sequences from background

information without any prior knowledge about the timing of sequence on- and offsets. While recent theoretical and empirical work indicate that the sequential structure of inputs may be inferred from perceived transitional probabilities, the ability to exploit such statistical information seems to be highly variable. A mechanistic account of what is causing such differences in behaviour, however, is still missing. Here we address how the brain extracts the statistical regularities embedded in temporal sequences and whether inter-individual differences in sequence learning can be predicted from fluctuations of brain activity. Building on previous electrophysiological studies, we hypothesised that rhythmic brain activity supports the representation of behaviourally relevant sequences in neuronal activity as well as their consolidation in memory. Our findings suggest that transitional probabilities embedded in temporal sequences are tracked by oscillatory activity in multiple frequency bands (1-50Hz). Finally, we observed that individual differences in sequence learning can be predicted with high accuracy from delta (1-4Hz) coupled beta (15-20Hz) oscillations.

Title: The impact of predictability on implicit motor and perceptual sequence learning

Authors: L. KATZ, B. FLYNN, C. SINGH, C. SEMERJIAN, L. IZRAYLOV, M. MALABANAN, J. CUDIA, *L. H. LU;
Psychology, Roosevelt Univ., Chicago, IL

Abstract: This study aimed to evaluate if the rate of implicit sequence learning differs across motor and perceptual modalities, and how the predictability of a sequence affects learning. We used a serial response time (SRT) paradigm and assessed learning via a decrease in reaction time (RT). Motor and perceptual modalities were decoupled: participants “caught” an auditory cue (A, B, C, or D) by pressing the key corresponding to one of the four locations on the screen that matched the auditory target. In the motor condition, the motor response to “catch” the target location repeated in a 7-digit sequence. In the perceptual condition, the auditory cues repeated in a 7-digit sequence, but there was no sequence to motor responses corresponding to auditory targets. Sequences were primarily first order conditional (FOC), where knowing one digit sufficiently predicts the next sequence, or second order conditional (SOC), where two digits are

needed to predict the next in the sequence. The first four blocks were learning blocks, the fifth block was composed of unpredictable trials (random), and the sixth block was identical to the learning blocks. Right-handed healthy adults participated (n=40; 37 females; age=23.67, sd=6.40). Across blocks 1-4, we evaluated for learning by a within-subject 2 (modality) x 2 (predictability) x 4 (blocks) ANOVA. We found main effects for predictability ($F(1,39)= 14.95$, $p < .01$), block ($F(3,117)= 11.17$, $p < .01$), and modality by predictability interaction ($F(1,39)= 4.88$, $p = .03$). Participants responded faster to the FOC sequence and across blocks. The FOC advantage was only observed in the motor sequence. These findings indicate that learning occurred regardless of sequence modality, though FOC yielded faster RTs when learning a motor sequence. We also examined the stability of learning by comparing RT to the learned sequence after a block of random trials. This within-subject 2 (modality) x 2 (predictability) x 2 (block 5 vs. 6) ANOVA yielded main effects for predictability ($F(1,39)= 14.99$, $p < .01$), block ($F(1,39)= 26.01$, $p < .01$), and predictability by block interaction ($F(1,39)= 12.07$, $p < .01$). Participants responded faster to the FOC sequence and to block 6. The interaction showed that RT decreased more for the FOC sequence than for the SOC sequence. Altogether, these results suggest that sequence predictability affects implicit sequence learning, but there was no evidence to support that motor and perceptual sequences have different rates of learning.

Title: Fluctuations in processing time are reflected in the shape of early visual evoked potentials

Authors: ***M. J. RIBEIRO**[1], J. S. PAIVA[2], M. CASTELO-BRANCO[2];
[1]Univ. Coimbra, Coimbra, Portugal; [2]IBILI, Fac. of Med., Univ. of Coimbra, Coimbra, Portugal

Abstract: Fluctuations in sustained attention lead to moment-to-moment fluctuations in task performance. Even in easy repetitive visuomotor tasks, human performance fluctuates with time. These variations in performance have been linked to fluctuations in the activity of the attention networks. Attention has an impact in early stimulus processing, yet, the relationship between

moment-to-moment fluctuations in task performance and early stimulus processing is still not clear. In this study, we explored this relationship by taking advantage of the high temporal resolution of EEG signals, and adopting a within-subject, whole time course analysis of single trial ERP data. We studied the neuronal correlates of reaction time variability in a simple visuomotor two-choice reaction time task. The task was chosen in order to minimize speed-accuracy tradeoffs while maintaining the requirement for overt attention on the visual stimulus. We acquired EEG recordings during task performance, from healthy young adults, using a 64-channel Neuroscan system. In order to determine if trial-to-trial differences in visual evoked responses might be caused by slight shifts in the position of gaze fixation at the time of stimulus onset, we also recorded gaze position during task performance with a dark pupil eye tracking system, iView X (SensoMotoric Intruments - SMI). Our results revealed that visual evoked potentials in a time window between 150 and 300 ms after stimulus onset correlate with reaction time on a trial-by-trial basis. Within this time window, the visual evoked potentials presented a marked negative peak with bilateral occipito-parietal topography (N1/N170). Trials associated with faster responses, presented a sharper N1 potential, with a narrower distribution in time and higher peak amplitude, while slower trials were associated with smaller amplitudes and a broadening of the N1 shape in time. Eye gaze position at time of stimulus onset did not correlate with these ERP amplitude values, suggesting that these differences were not related to differences in external input but, most likely, were related to moment-to-moment differences in internal state. In conclusion, our observations suggest that fluctuations in reaction time reflect trial-to-trial differences in the amplitude of visual evoked potentials as early as 150 ms after stimulus onset. The time course and topography of these neural responses suggest that these originate in the ventral extrastriate cortex, a visual area sensitive to feature-based attention.

Abstract: Visual attention allows individuals to preferentially process relevant stimuli and suppress processing of irrelevant stimuli during perceptual decision making tasks. Steady-state visual evoked potentials (SSVEPs) are defined as narrow band EEG responses at flicker frequencies of visual stimuli. Steady-state responses have been previously shown to reflect differing attentional abilities between subjects. In this study we were able to predict individual differences in specific psychological processes during visual decisions by comparing subjects' SSVEP responses, a proxy for visual attention. Subjects were asked to perform a novel two-alternative forced choice task as accurately as possible within a time constraint. On each trial subjects decided whether a Gabor was drawn from a distribution of high or low spatial frequency and indicated their choice using a response box. SSVEPs were evoked during the experiment at both 20 and 30 Hz in the EEG spectrum, corresponding to the flicker frequency of the Gabor and the visual noise respectively. Individual differences in accuracy and reaction time are shown to be predicted by individual differences in the phase information of the SSVEPs, specifically the phase-locking index (PLI) across trials at 20 and 30 Hz, especially in electrodes over the parietal and occipital lobes. This predictive ability is thought to be due to differences in individuals' ability to suppress visual noise and enhance visual signal. Furthermore these individual differences in attention ability predict specific psychological parameters of the diffusion model, a model of speeded decisions that assumes specific psychological processes on each trial. By modeling reaction time and choice as a diffusion process, we reparameterized responses into a distribution with parameters that provide the average evidence accumulation rate, variance in evidence accumulation, non-decision time, and decision criterion per trial. Subjects who suppressed visual noise well (i.e. had small 30 Hz PLIs) had faster within-trial evidence accumulation rates as well as faster visual preprocessing times. While subjects who enhanced the visual signal (i.e. had large 20 Hz PLIs) had larger within-trial evidence accumulation variance and faster preprocessing times. The accuracy and reaction time of out-of-sample subjects was well predicted given their attentional response to the noise and signal stimuli, as measured by SSVEPs, when using estimated parameters of the diffusion model. Our modeling paradigm with the use of simple EEG measures has the potential to identify individuals that will be best at specific tasks that require visual attention.

Title: Individual differences in ERP components associated with signal detection and distractor resistance

Authors: H. WILLIAMS[1], K. KIM[4], W. J. GEHRING[2], *C. LUSTIG[3];
[1]Psychology, [3]Dept. of Psychology, [2]Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Responding to the world around us involves detecting important signals, often in the face of distraction. Processing sensory stimulation, deciding whether to attend to it, and responding all result in changes in brain activity that can be using event-related potentials (ERPs). We examined ERP components in 29 healthy young adults while they tried to detect a small, briefly presented signal against either a stable background or a moving background that created distraction resulting in slower and less accurate responses. Approximately 40% of subjects failed to show the N200 component, often associated with early stages of signal detection, in either condition. Behaviorally, these participants had lower scores on measures of signal sensitivity and processing efficiency. In contrast, the P300 component, typically associated with later processing stages including decisions about stimuli (e.g., “is this a signal I should respond to?”) was robust across subjects and sensitive to the distractor manipulation (smaller amplitude, longer latency). Correlational analyses indicated that greater P300 amplitude and shorter latency were associated with better signal sensitivity and processing efficiency. Together the results suggest that early perceptual-attention processes may be important for overall signal detection sensitivity, whereas later attentional components more associated with cognitive control play a role in resisting distraction.

Title: Distinct mechanisms for distractor suppression and target facilitation

Authors: *M. P. NOONAN[1], N. ADAMYAN[3], A. PIKE[2], F. PRINTZLAU[2], B. CRITTENDEN[2], M. G. STOKES[2];
[2]Dept. of Psychiatry, Oxford Ctr. for Human Brain Activity, [1]Univ. of Oxford, Oxford, United Kingdom; [3]Lab. Psychologie de la Perception, Univ. Paris Descartes, Paris, France

Abstract: It is well established that preparatory attention improves processing of task-relevant stimuli (Desimone and Duncan, 1995). Although it is often more important to ignore task-irrelevant stimuli, comparatively little is known about preparatory attentional mechanisms for the inhibition of expected distractions (Ruff and Driver, 2006, Navalpakkam and Itti, 2007). Here, we first establish behaviourally that distractor inhibition is not under the same top-down control as target facilitation. Using a four-location variant of the Posner paradigm, participants were cued to either the location of a target stimulus, the location of a distractor or were provided no predictive information. In addition to varying the presence of the distractor, we critically manipulated the flexibility of cueing: spatial cues were randomised on each trial in one version of the task (Flexible), or fixed for a block of trials (Blocked). In Experiment 1, we found that participants (n=24) were able to use target-relevant cues to facilitate target processing in both blocked and flexible conditions, but distractor cueing was only effective in the blocked version of the task. In Experiment 2, we replicate these findings in a larger sample of participants (n=71), and leveraged the additional statistical power to perform individual differences analyses to tease apart potential underlying mechanisms. We found no evidence for a correlation between these two types of benefit, suggesting that flexible target cueing and distractor suppression depend on distinct cognitive mechanisms. In Experiment 3, we use EEG (n=20) to show that preparatory distractor suppression is associated with a diminished P1 and altered N2pc components, but we found no evidence to suggest that this effect was mediated by top-down control of oscillatory activity in the alpha band (8-12Hz). We conclude that flexible top-down mechanisms of cognitive control are specialised for target-related attention, whereas distractor suppression only emerges when the predictive information can be inferred directly from past experience. This is consistent with a predictive coding model of expectation suppression that is selective for task-irrelevant information. Title: Can top-down control override learning experience?

Authors: *A. SCHUBÖ, H. KADEL, T. FELDMANN-WÜSTEFELD;
Philipps Univ., Marburg, Germany

Abstract: Recent findings have challenged the classic dichotomy of bottom-up vs. top-down as control mechanisms in the guidance of visual attention and have suggested past selection history, e.g. evident in learning experience, as a third source of selection bias (Awh, Belopolsky, & Theeuwes, 2012). The present study has used event-related potentials to examine how learning experience affects the deployment of visual selective attention, in addition to, and in interaction with top-down control. Learning experience was differentially induced by having participants perform a visual categorization learning task which was combined with a visual search task in the course of the experiment. One group of participants had to respond to color in categorization learning; a second group had to respond to shape. In the search task, all participants had to report the orientation of a line embedded in a shape singleton that served as target. In some trials, an additional color singleton distractor was presented. The crucial manipulation involved the presentation of a cue at the beginning of a trial. The cue indicated what type of task had to be performed so that participants could prepare for the task in an upcoming trial before stimulus onset. The main questions to be investigated were whether learning affected performance in the search task and whether resulting differences in performance could be overcome when the cue allowed task preparation. Results showed that color distractors slowed down performance in the visual search task to a greater extent when color rather than shape was determined as being predictive in the learning task. Disentangling the mechanisms underlying this behavioral effect by means of lateralized ERP components showed differential attention deployment: ERPs in the color group indicated that color distractors captured attention in the search task (as indicated by the ND component) before they could be actively suppressed (as indicated by the PD component). ERP results in the shape group indicated that color distractors did not capture attention (no ND) and that suppression was possible earlier in time (early PD). Interestingly, the findings were virtually the same when a cue indicated the task at the beginning of each trial and allowed participants to prepare for the upcoming task. These results provide direct evidence of

preferential attention deployment towards stimuli with high predictive value in learning, even if these are irrelevant for the search task and participants had the opportunity to actively prepare for the search task in advance.

Title: ERP evidence of reafferent priming of V1 feedforward circuits by spatial attention during dynamic vision

Authors: ***A. ROYSTON**[1], J. NAPAN[1], K. ANDERSON[1], A. HABERMAN[1], S. J. LUCK[1], S. A. HILLYARD[2], W. M. USREY[1], G. R. MANGUN[1];

Abstract: Efficient selection of task-relevant information and suppression of irrelevant information is crucial for successful goal-directed behavior in everyday life. Classic visual selective attention paradigms in humans often employ briefly flashed stimuli (e.g., Posner Cueing, RSVP), and have shown modulations of visual evoked activity with attention. However, these designs fail to capture the dynamics and complexity of continuously-visible real world visual scenes, leaving open questions concerning the application of these findings to more natural viewing scenarios, perhaps failing to reveal key mechanisms. For example, although electrophysiological studies in nonhuman primates and fMRI studies in humans have reported clear, replicable effects of spatial selective attention in striate cortex and LGN, ERP studies of this issue in humans have yielded inconsistent results. We hypothesize that in natural vision, the presence of continuous inputs may trigger an attention-related reafferent priming of feedforward circuitry in V1 such that subsequent feedforward inputs benefit from enhanced attentional modulation at this early cortical locus. To test this, we presented continuous bilateral stimuli to human subjects who covertly attended to one hemifield in order to detect occasional targets

(contrast decrements) in dynamic and static stimulus conditions. Our preliminary findings using these designs provide support for our hypothesis, showing a significant modulation of ERPs generated in V1 (i.e., the C1 component of the visual ERP) in the dynamic, ongoing stimulus conditions compared with the static stimulus conditions. Our findings suggest that reafferent priming enhances processing of feedforward inputs in human V1 during selective attention to ongoing, dynamic stimulation, which is more similar to the conditions faced in natural vision.

Title: Learning-dependent changes in neural mechanisms underlying selective attention

Authors: *S. ITTHIPURIPAT[1], K. CHA[2], A. BYERS[2], J. SERENCES[1,2];
[1]Neurosciences Grad. Program, [2]Psychology, UCSD, La Jolla, CA

Abstract: Competing theories have been proposed to describe neural mechanisms underlying selective attention. These include sensory gain, noise modulation, and efficient read-out mechanisms. While these mechanisms are not mutually exclusive, different studies have demonstrated that one mechanism may outperform another in terms of predicting attention-induced changes in behavioral performance. We hypothesized that these discrepancies may arise in part from changes in attentional modulations during learning. To test this hypothesis, we simultaneously tracked changes in psychophysical contrast thresholds and neural responses using electroencephalography (EEG) while human subjects performed a contrast discrimination task over one month. During the early stages of learning, focused attention increased the multiplicative response gain of the early sensory P1 component as well as the decision-related late positive deflection (LPD or P3). Quantitative modeling reveals during this early phase, gain amplification of the P1 and LPD sufficiently accounted for attention-related improvement in

behavioral performance. However, at later learning stages (after ~17 days), there was no attentional gain modulation in the P1 component. Quantitative modeling revealed that noise-reduction models best accounted for the link between P1 responses and behavior. However, there was sufficient gain amplification of the LPD component that predicted attention-related improvements in behavioral performance. Collectively, these results suggest that neural mechanisms underlying selective attention are stage-dependent: selective attention increases gain amplification of early sensory signals only during initial phases of learning, whereas modulations of the LPD are observed throughout learning stages.

Title: Predictability or relevance for the task... Who drives spatial attention? An EEG study

Authors: ***N. DO CARMO BLANCO**[1], J. JOZEFOWIEZ[1], J. J. B. ALLEN[2];
[1]Psychology-SCALab, Univ. De Lille, Villeneuve D Ascq Cedex, France; [2]Psychophysiology Lab., Univ. of Arizona, Tucson, AZ

Abstract: Being able to detect contingencies between events is essential for a wide range of cognitive functions, from motor control to social interaction. This learning process, widely accepted to be prediction driven, could happen even without awareness, when it is not relevant to the task at hand. Prediction is also at the core of the efficient processing of statistical regularities described by predictive coding theories, where neural signals are related to the extent to which stimuli are predicted. This framework is supported by studies showing increased BOLD activity for unpredictable outcomes. Nevertheless, those results could reflect an enhancement of attention when a stimulus is not expected. Here we used the event-related potential N2pc component, widely recognized to reflect allocation of spatial attention, to study how outcome predictability affects attention. If contingencies are learned even when they are task-irrelevant, could such implicit associations also modulate attention? We used an associative learning paradigm where

we manipulated contingency (predictiveness) and relevance of the association upon streams of cue-outcome visual stimuli, while stimulus characteristics and probability were held constant. At the end of each stream, participants had to assess the association between one of the two possible cues and one of the two possible outcomes. To elicit the N2pc component, participants had to indicate the orientation of a random feature of every outcome, which was embedded among distractors. We found that outcomes predicted by a cue showed an increased spatial attention as indexed by the N2pc component, in accordance with a predictive coding model. Surprisingly, this effect was found even when this association was irrelevant. These results show that spatial attention is enhanced by predictability during learning, even when the association is irrelevant to the main goals of the task at hand. Moreover, it indicates that non-contingent outcomes capture spatial attention less efficiently, which suggests that the enhanced BOLD activity found for unpredictable outcomes is not related to attention, supporting a predictive coding framework. The current study confirms the remarkable ability of the brain to extract and update predictive information and the modulation of encoding by top-down processes.

Title: Mnemonic target representation in a visual detection task

Authors: **N. MYERS**[1], G. ROHENKOHL[2], V. WYART[3], M. WOOLRICH[1], A. NOBRE[1], *M. STOKES[1];
[1]Oxford Univ., Oxford, United Kingdom; [2]Ernst Strüngmann Inst. (ESI) for Neurosci., Frankfurt, Germany; [3]Lab. de Neurosciences Cognitives (Inserm U960),, Paris, France

Abstract: Many perceptual decisions require the current input to be matched up with an internal decision criterion, or template. Classic studies of visual attention have typically attributed its representation either to raised baseline activity in sensory neurons tuned to the template's features, or to changes in synaptic gain of those neurons. More recent studies, however,

complicate this explanation: the encoding of stimulus features, either in visual and prefrontal neural populations, or in activation patterns distributed across the cortex, changes rapidly from moment to moment, tracing a complex but stereotyped trajectory through activation state space. This prompts a re-evaluation of when in time, and in what representational format, stimulus and template codes are compared. We measured magnetoencephalography as human participants performed a match-to-template orientation task, and measured the temporal dynamics of stimulus representation, template representation, and how both representations interact at the decision stage. Our findings run counter to some classic findings in visual attention, since we did not see a tonic activation of the template, and saw only short-lived cross-generalization in the coding between stimuli and templates when using the same coding space. Instead, template information transiently emerged around the time of stimulus onset, and quickly returned back to baseline, in keeping with an account of template encoding in synaptic weight changes that do not require persistent activity. In addition, we found that the trial-to-trial match between template and stimulus (i.e., the decision variable) was represented in the MEG signal, and that it emerged around the time that template coding began to subside. Intriguingly, we found that the task-irrelevant signed difference between template and stimulus was also encoded at this stage. We argue that this task-irrelevant representation can be explained readily by a probabilistic population code underlying the decision stage. We conclude that a simple, multi-layered architecture based on population codes can provide a framework for bringing together findings across visual attention, working memory, and decision-making.

Title: How does spontaneous brain activity interact with evoked activity? Non-additive interaction, phase-dependence and scale-free properties

Authors: *Z. HUANG[1], J. ZHANG[2], A. LONGTIN[1], G. DUMONT[1], N. W. DUNCAN[1], J. POKORNY[3], P. QIN[1], R. DAI[2], F. FERRI[1], X. WENG[2], G. NORTHOFF[1];
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Hangzhou Normal Univ., Hangzhou, China; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Investigations on both cellular and regional levels of neural activity showed trial-to-trial variability reduction after stimulus-onset, highlighting the central role of spontaneous brain activity and its ongoing nature during task-evoked activity. However, evidence is still lacking on elucidating the exact relationship between spontaneous and task-evoked activity. On the other hand, to understand this interaction, one may have to trace back to the unique temporal structure of spontaneous activity. Being ubiquitous in nature, scale-free properties (power-law distribution) has been observed in neural activity across many different spatiotemporal scales including the infraslow frequency fluctuations (<0.5 Hz) of spontaneous activity. This property is also characterized as long-range temporal correlations (LRTCs). However, the functional significance of LRTCs and their relationship to spontaneous and task-evoked activity remain unknown. The aim of our study was to use functional magnetic resonance imaging (fMRI) to investigate how spontaneous brain activity interacts with task-evoked activity, as well as how the LRTCs of spontaneous activity relate to this interaction. Using an extremely sparse event-related design, a novel correction approach (accounting for spontaneous fluctuations by pseudo-trials) and phase analysis of fMRI signals, we demonstrate that (i) stimuli presented at a lower magnitude of preceding spontaneous BOLD activity produce a stronger response than stimuli presented at a higher magnitude, which explains trial-to-trial variability reduction after stimulus-onset; (ii) this non-additive interaction was further characterized by phase-dependent excitability of spontaneous activity, i.e. different temporal excitability for trough vs. peak and fall vs. rise phases; (iii) the degree of the phase-dependent excitability is related to the degree of LRTCs of spontaneous activity, as indexed by the power-law exponent. This suggests that the temporal structure of spontaneous activity shapes the non-additive interaction between spontaneous and task-evoked activity. To the best of our knowledge, we have provided, for the first time, direct evidence for a non-additive interaction between spontaneous and task-evoked activity and its underlying mechanism of phase-dependent excitability, as well as its relationship to the temporal structure of the spontaneous activity. Our findings not only contribute to our understanding of spontaneous brain activity and its scale-free properties, but also bear important implications for neural activity in general.

Title: Task-independent correlations predict task-evoked BOLD response similarity in frontoparietal association cortex

Authors: *M. L. WASKOM[1], A. D. WAGNER[2];
[1]Dept. of Psychology, [2]Dept. of Psychology and Neurosciences Program, Stanford Univ., Stanford, CA

Abstract: Anatomical and functional connectivity measurements suggest that primate association cortex is organized into distributed large-scale networks. In humans, this has been most effectively demonstrated through analyses of task-independent low-frequency fluctuations in the BOLD signal. Multiple approaches for extracting network structure from these measurements, including clustering, community detection, and independent components analysis, have revealed network definitions that are largely convergent. Moreover, patterns of results in the task-based literature often bear a striking resemblance to these networks. Despite such observations, the precise relationship between task-independent and task-evoked signals remains a controversial issue. To address it, we analyzed fMRI data that were collected while humans performed a demanding perceptual discrimination task with a fast event-related design. We estimated task-evoked responses across different parcellations of frontoparietal association cortex by fitting finite impulse response models to BOLD timeseries data. This produced, for each region in a given parcellation, an evoked response waveform and a timeseries with residual, task-independent variance. We then estimated correlation coefficients within pairs of response waveforms and pairs of residual timeseries. Results showed that estimates of task-evoked similarity and task-independent connectivity were strongly related. Moreover, while response waveforms in much of association cortex were highly reproducible across splits of the data, the responses in some regions markedly differed from canonical models of the hemodynamic response function. Despite being distributed throughout cortex, regions with similar non-canonical responses showed high levels of task-independent connectivity. The strength of the relationship between task-independnt and task-evoked measures also depended on the

parcellation scheme used to define regions: the relationship was stronger when regions were defined using population atlases of task-independent networks than when defining regions with common anatomical landmarks. Together, these results indicate that task-independent connectivity is meaningfully related to task-evoked processing and provide support for efforts to understand cortical organization through the lens of large-scale task-independent networks.

Title: Stimuli-based phasic components of task-induced deactivation during sustained attention

Authors: ***K. SHATTUCK**, J. W. VANMETER;
Georgetown Univ., Washington, DC

Abstract: Background: Task-induced deactivations (TIDs) observed in functional magnetic resonanace imaging (fMRI) studies are recognized as an important component of brain activity during externally focused cognition. In particular, the magnitude of TIDs in the ventromedial prefrontal cortex (vmPFC-TIDs) increases with attentional effort, working memory, and episodic memory formation. Clinical implications include decreased vmPFC-TIDs correlating with symptom severity in depression and schizophrenia. Though TIDs are commonly considered the result of top-down attentional control, there has been a lack of investigation into stimuli-driven, bottom-up TID responses. Using a hybrid block and event-related task design, we investigated both the task-based tonic component and stimuli-based phasic component of vmPFC-TIDs during the Sustained Attention Task (SAT) at two levels of difficulty. Methods: Ten (7 female, 18-39 years) healthy, right-handed subjects with normal or corrected-to-normal vision performed 84-second blocks of the SAT and a version of the SAT with distraction-induced challenge (dSAT) interpersed with 30-second periods of rest while undergoing fMRI scanning. Both the SAT and dSAT briefly presented (40-75 ms) a small visual target on 50% of randomly selected trials (6-8s ISI), and subjects pressed one of two buttons to indicate target detection; the dSAT added flashing background illumination (10 Hz). Results: Group results showed vmPFC-TIDs

from rest that were greater for dSAT than SAT blocks. The group deactivation from rest provided a region-of-interest for a within-task event-related analysis that showed stimuli-related deactivations were greater for target trials than non-target trials. Conclusions: Phasic, stimuli-driven TIDs should be considered as a component of cognitive responses to external stimuli and may provide additional information to our understanding of attention, memory, and disease.

Title: Intracranial Gamma-band coherence is influenced by task and experience

Authors: *T. LIVNE[1], A. DAITCH[2], C. HACKER[3], N. SZRAMA[3], G. SHULMAN[3], E. LEUTHARDT[3], M. CORBETTA[3];
[1]Radiology, Washington Univ. Sch. of Med. In St. Lo, Saint Louis, MO; [2]stanford school of medicine, Stanford, CA; [3]Washington Univ. Sch. of Med. in St. Louis, Saint Louis, MO

Abstract: Cortical gamma band activity (above 30Hz) has been hypothesized to be related to attention allocation, conscious perception, and to the integration of information into a unified representation. A possible mechanism by which local gamma activity can support coordination between remote cortical sites is synchronization. By synchronizing or desynchronizing gamma activation between sites the brain can flexibly create and adjust functional networks to account for changing demands. The fast high-gamma frequency band (65-115 hz) may be especially useful for quickly recruiting and maintaining multiple concurrent networks. To test the hypothesis that high-gamma coherence is adaptively modulated during task performance we computed a network level coherence change from ECoG electrodes implanted in 4 epileptic patients while they performed a task designed to establish audio-visual associations. During each trial subjects categorized a visual stimuli as a body or a tool. Each of these categories was uniquely preceded by auditory stimuli from a specific category (bird songs or musical tunes). A third neutral auditory stimulus was followed by either visual category and was used to emphasize the regularity of the other two auditory categories. Each subject completed multiple task runs (6-8 runs). An additional resting state signal was recorded in a separate run. To evaluate whether

gamma synchronization was modulated by entering a task state and was further shaped by our patients' experience with the task and the novel associations it promoted, we performed two comparisons of pair-wise LFP high-gamma band correlation across all electrodes in each patient: 1) coherence during task vs. coherence during rest; and, 2) and coherence during the first task run vs. coherence during the last task run. Our results show that in both comparisons a larger than chance number of pairs exhibited a coherence change, indicating that gamma coherence is indeed modulated by task and experience. Furthermore, similar electrodes were the most modulated in both comparisons, suggesting that the network that was initially created to perform the task was being actively modulated with experience. These results support the hypothesis that high-gamma band coherence might be a mechanism by which the brain coordinates the integration of information between different cortical sites to support efficient cognitive functioning.

Title: Gamma-band synchrony measures indicate differential prefrontal and parietal contributions to signal detection and top-down control

Authors: ***K. KIM**[1], H. WILLIAMS[2], W. J. GEHRING[2], M. SARTER[2], C. LUSTIG[2]; [1]Univ. of Texas Houston, Houston, TX; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Correct detection of environmental cues and resisting distraction are important for successful behavior. These abilities are supported by frontoparietal networks in both humans and rodents, with rodent studies further indicating the crucial role of cholinergic innervation. Gamma-band synchrony may provide an important bridge between the human animal findings, as human encephalogram (EEG) studies link increased gamma-band synchrony to the hemodynamic changes underlying BOLD fMRI, rodent local field potential studies show its modulation by acetylcholine (ACh), and findings from both species indicate its association with both bottom-up and top-down attention. We therefore examined changes in gamma

synchronization in healthy young adults performing a modified version of the distractor condition sustained attention task (dSAT) developed for cross-species studies of signal detection and distractor resistance (Demeter et al., 2008). The major modification was the use of a shifting-grid distractor that more clearly provided a competitive input for attention, as opposed to whole-field changes in luminance that may also challenge lower-level perceptual processes. As expected gamma synchrony increased during task performance and was further increased during the distractor. However, these increases were primarily in left parietal regions rather than the right prefrontal regions predicted from rodent studies. Instead, right prefrontal gamma dispersion was associated with increased response-time variability during distraction, suggesting that this region contributes to signaling the need for top-down control rather than its implementation. Occipital regions showed significant distractor-entrained oscillation patterns, with greater entrainment during "miss" trials, indicating attention misdirected to the distractor. Correlational analyses suggested modulation of distractor entrainment by left-parietal gamma, further implicating parietal cortex as an important component in top-down control. In summary, the present findings are consistent with previous human and rodent studies implicating frontoparietal networks in attention and distractor resistance, but suggest that right prefrontal cortex may be more involved in signaling a need for control, and parietal regions with its implementation.

Title: Feature-based attention modulates correlated BOLD activity in the visual cortex

Authors: *Y. LIU[1,2], H. J. ALITTO[2,3], A. ROYSTON[1,4], G. R. MANGUN[1,4,5], W. M. USREY[2,3,5];

Abstract: An important neural mechanism underlying top-down selective attention is the modulation of synchronous neural activity across brain areas. Attention-induced modulations of interareal synchrony within the visual cortex have been suggested to promote effective transmission of goal-relevant information across neuronal assemblies representing such information. While most prior literature examined attention-related changes in interareal connectivity under spatial attention, it is less understood how feature-based attention modulates activity along specific visual pathways representing the attended features. Here we addressed this issue via functional magnetic resonance imaging when human participants performed a cued-attention task during which an auditory cue instructed them to attend covertly to either the direction of motion or color of a moving-dot stimulus. We found that compared with a passive-viewing condition, blood-oxygen-level-dependent (BOLD) activities within the extrastriate areas, including V3, V3A, hV4, and MT+, were enhanced following an attentional cue. Preliminary analyses of interareal correlations in cue-induced BOLD activities reveal that attention modulated the overall correlation of trial-to-trial fluctuations in BOLD responses across the visual areas. Interestingly, reductions in correlated BOLD activities were observed among areas along the dorsal visual stream when participants attended to the color instead of the direction of the dots. These results are consistent with the view that feature-based attention enhances the representation of goal-relevant sensory information by modulating connectivity both among the entire visual system and along specific visual pathways.

Title: Causal role of IPS and TPJ in selective attention in multi-target environments

Authors: *M. PRAß, H.-O. KARNATH, B. DE HAAN;
Ctr. of Neurology, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Visual extinction is a neuropsychological deficit that can follow unilateral, most commonly right hemispheric, brain damage. Extinction patients are able to detect contra- and ipsilesionally presented single targets, but fail to report contralesional targets when an ipsilesional target is concurrently presented. The existing literature suggests a critical role for both the right temporo-parietal junction (TPJ) and the right intraparietal sulcus (IPS) in the ability to attend and respond to multiple targets simultaneously, however, the precise role of each of these areas in this ability is currently unclear. In this study we combined the Theory of Visual Attention (TVA) with continuous theta burst stimulation (cTBS) in neurologically healthy subjects to directly investigate the role of the right TPJ and IPS in attentional selection in multi-target environments. Specifically, we investigated the TVA processes impaired after temporary inhibition of neural activity at either the right TPJ or the right IPS and the relation of these TVA processes to the ability to attend and respond to multiple targets simultaneously. Additionally, we measured the effect of cTBS on the motor evoked potential (MEP) in each individual subject to obtain an individual estimate of the strength of cTBS inhibition. Our results suggest that cTBS to the IPS modulated top-down attentional selection. However, cTBS to the TPJ failed to induce a change in TVA parameters. We conclude that the IPS plays a crucial role in top-down attentional control, while the function of TPJ remains unclear. This suggests that the IPS may modulate attention in multi-target environments and its failure in extinction via top-down prioritization of targets over distractors.

Title: Attention alters animal and action representation in highly-distributed, functionally-defined cortical parcels

Authors: ***S. A. NASTASE**[1], M. VISCONTI DI OLEGGIO CASTELLO[1], Y. O. HALCHENKO[1], A. C. CONNOLLY[1,2], N. N. OOSTERHOF[1,3], M. I. GOBBINI[1,4], J. V. HAXBY[1,3];

Abstract: Attending to particular semantic features of a complex, naturalistic stimulus may require attentional mechanisms to operate across highly-distributed neural populations. Here we apply simple models of representational space to extensive, functionally-defined cortical parcels to evaluate how attention reshapes the distributed neural representation of animal and action categories. Functional MRI was used to measure neural responses while participants viewed brief naturalistic video clips of animals behaving in their environments. Stimuli comprised five different folk animal taxa (primates, ungulates, birds, reptiles, insects) each performing four different actions (eating, fighting, running, swimming) in a fully-crossed design for 20 total conditions. In each run, participants performed a 1-back task requiring them to selectively attend to either the animal or action types. Whole-brain surface-based searchlight hyperalignment based on neural responses to a 1 hr nature documentary was used to rotate participants' response patterns into representational correspondence. Instead of relying on anatomical boundaries or functional localizers to constrain our multivariate analyses, we used an unsupervised learning algorithm to cluster cortical searchlights based on shared representational geometry. We cross-validated cluster solutions across participants to identify particularly stable parcellations at several scales. We then used representational similarity analysis to evaluate how the similarity between response patterns for the 20 conditions within each parcel related to several target similarity structures. We found that attending to action information increases the discriminability of action category representations in intraparietal and pericentral cortices. Attending to animal information increased animal category discriminability in ventral temporal cortex. These effects were driven by both decreased within-category distances and increased between-category distances. For both action representation in the dorsal visual pathway and animal representation in the ventral pathway, representation was more robust in earlier visual areas when attention was directed elsewhere, suggesting that attention selectively increases depth of processing. The action category model better fit neural representation than did animal category and animacy continuum models in most cortical parcels. Surprisingly, this advantage was also quite large in ventral temporal cortex, suggesting that the representation of animal behavior may eclipse that of animal form in the ventral visual pathway in the context of naturalistic vision.

Title: Semantic relationships of real-world objects bias visual attention

Authors: *G. L. MALCOLM[1], C.-I. NAH[2], S. SHEREMATA[3], S. SHOMSTEIN[2];
[1]Dept. of Psychology, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. of Psychology, The George Washington Univ., Washington, DC; [3]Dept. of Psychology, Florida Atlantic Univ., Boca Raton, FL

Abstract: We primarily attend to objects when observing the environment, making object properties an integral component in constraining attentional allocation. While extensive research has investigated object properties in relation to space and low-level features, recent evidence from our lab suggests that high-level, semantic relationships between objects influence allocation of attentional resources, even when these relationships are task-irrelevant. Behavioral results found that, when three objects were presented, attention was biased to the semantically related object (Malcolm & Shomstein, 2014). Here, we investigated the neural mechanisms that prioritize semantic relationships between real-world objects to bias attentional allocation. We specifically focused on investigating whether early visual cortex (areas V1-V4) and object-sensitive lateral occipital cortex (LOC) showed semantic-based modulation of sensory response. Additionally, we examined whether retinotopically organized regions within the inferior parietal sulcus, areas IPS0-2, are the regions responsible for eliciting early sensory modulations consistent with semantic relatedness. Participants viewed three objects arranged in a triangle, or 'triad', with one object just above fixation and one in each periphery, below the midline. Critically, one of the peripheral objects was always semantically related to the central object while the other was not (e.g., if the central object was a lamp, one peripheral item was a light bulb and the other an envelope). After the triads remained on the screen for an average of 4s, a target along with two distractors appeared (one on each object). Targets occurred on all three objects equally, making the semantic relationship between the objects irrelevant to the task. Participants were asked to discriminate the target while keeping their eyes fixated on a central cross. We observed that neural activity was biased toward the semantically related object throughout visually responsive cortex. Importantly, semantic based modulation of visual responses was observed despite the fact that semantic relationships were task-irrelevant. The results demonstrate that semantic relationships between objects modulate visual cortical activity even at the earliest stages, biasing spatial attention.

Title: Alpha oscillation as a clock for visual processing -Illusory jitter frequency correlated with individual alpha frequency-

Authors: *S. MINAMI[1,2], K. AMANO[2,1];
[1]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [2]CiNet, Osaka, Japan

Abstract: Introduction: Recent studies have demonstrated the possible involvement of alpha oscillations (8-13 Hz) in visual processing (Jensen et al., 2012). To further elucidate the functional role of alpha oscillations, we utilized an illusion called motion-induced spatial conflict (Arnold and Johnston, 2003). In this illusion, a moving isoluminant border placed in close proximity to moving luminance-defined borders appears to jitter. In a previous study, we found that the frequency of illusory jitter perception (~10 Hz) matches that of neural oscillations whose amplitudes are modulated during jitter perception. However, a causal link between alpha oscillations and illusory jitter perception has not been demonstrated. Here, we tested the hypothesis that alpha oscillations contribute to the generation of illusory jitters by examining inter-individual differences in peak alpha frequency (PAF) and perceived jitter frequency. Methods: PAF was measured during the resting state using magnetoencephalography (MEG). Subjects opened and closed their eyes in response to a cue sound in a dark room. In a separate psychophysical experiment to measure perceived jitter frequency, subjects judged whether illusory jitter stimuli in the upper visual field jittered faster than a physical jitter stimulus at a random frequency (4-13 Hz). The perceived jitter frequency was defined as the frequency at which the response rate was 50%. Results and Discussion: We found that the perceived jitter frequency of each subject was highly correlated with the PAF during the resting state, regardless of eye-opening. Given that an illusory jitter stimulus was not presented during the alpha frequency measurement, the PAF was unaffected by illusory jitter perception, and reflects the intrinsic alpha frequency of each subject. Therefore, the correlation between the perceived jitter frequency and PAF suggests that alpha oscillations are involved in the generation of the illusory jitter perception. The PAF during the perception of illusory jitter also correlated with the perceived jitter frequency, indicating that the intrinsic alpha is sustained during jitter perception. The perceived jitter frequency did not correlate with the peak frequency of other oscillations including beta. Based on these findings, we propose that alpha oscillations act as a clock for visual processing. In the case of illusory jitters, dissociation between motion-based delayed

position representation in the dorsal stream and the object-based, physically correct position representation is resolved at the alpha frequency.

Title: Reconstructing spatial attention maps from EEG alpha activity

Authors: ***J. J. FOSTER**[1], D. W. SUTTERER[1], J. T. SERENCES[2,3], E. K. VOGEL[1], E. AWH[1]; [1]Dept. of Psychology, Univ. of Oregon, Eugene, OR; [2]Dept. of Psychology, [3]Neurosciences Grad. Program, UCSD, San Diego, CA

Abstract: Past work has demonstrated a clear link between oscillatory neural activity in the alpha band (8-13Hz) and covert spatial attention. For example Rihs, Michel, and Thut (2007) found that the topographic distribution of alpha activity across the scalp covaried with attended location in a spatial cueing task. Here, we show that alpha topography - measured using electroencephalography (EEG) - can be used to precisely track the locus of covert attention in a time-resolved fashion. We used an encoding model to reconstruct spatially-specific population response profiles following the onset of central cues that prompted endogenous shifts of spatial attention. In Experiment 1, a central cue (87.5% valid) directed participants to one of eight placeholders arranged in a circle around fixation. After 1250 ms, a search array was presented and participants were asked to find the digit among letters. Robust enhancements of target discrimination at the attended locations confirmed the efficacy of the central cues. We observed robust spatially-specific tuning functions (TFs) that tracked the covertly attended locations. These TFs emerged 400-500 ms after cue onset, a time-course that dovetails with past behavioral and neural estimates of the latency for endogenous spatial orienting. We observed the same empirical pattern with both physically-congruent spatial cues (oriented bars indicating the cued position) and symbolic cues (letters and digits) that had no pre-experimental association with the cued positions. A further control experiment ruled out biases in eye position as a potential source of this spatially-specific neural signal. Together, these results highlight the role that alpha activity plays in the deployment of covert spatial attention, and suggest that alpha-based TFs

provide a robust approach for tracking the deployment of spatial attention with excellent temporal resolution.

Title: Task-dependent change of alpha oscillation frequency and its functional significance

Authors: ***I. BABU HENRY SAMUEL**, C. WANG, M. DING;
J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Neuronal oscillations are characterized by amplitude and frequency. In the case of human alpha oscillations (8 to 12 Hz), whereas the modulation of alpha amplitude by task conditions have been extensively studied, the frequency of alpha in a given individual is often considered a trait-level variable. Task dependent changes of alpha frequency and its functional relevance has not been fully established. We addressed this problem by recording high-density EEG from subjects performing a modified Sternberg working memory task. In this task the subject was shown a set of digits (0 to 9) on a CRT monitor for 1s (encoding) which was followed by a 3s retention period. At the end of retention a probe digit was presented and a “yes” (index finger in the dominant hand) or “no” (middle finger) button press was required to indicate whether the probe digit belonged to the set. Memory load was controlled by the size of the digit set which in this experiment was chosen to be 1, 3 or 5. We showed that (i) Alpha Frequency (AF) is modulated by memory load, (ii) the load modulation is different across different functional states (encoding versus retention), and (iii) high alpha frequency is associated with slower reaction times and vice versa. There is also evidence indicating that the visual p1 evoked component has smaller amplitude and higher latency when the pre-probe AF is high. These results suggest that alpha frequency is a task dependent variable and its increase signals

increased inhibitory activity. Finally, attempts were made to explain alpha frequency modulation within the two-alpha (high versus low alpha) framework.

Title: Modulation of visual perception by low frequency oscillations

Authors: ***S. NELLI**, J. SERENCES;
UC San Diego, San Diego, CA

Abstract: Selective attention can prioritize the processing of behaviorally relevant visual stimuli. Oscillatory modulation of neural excitability may play a role in this ability by altering information processing both within early visual areas and between early visual areas and downstream regions. One putative oscillatory mechanism of attentional control is anticipatory desynchronization of EEG alpha rhythms (8-12 Hz) in visual cortex. Decreases in alpha power in task-related regions may result in enhanced task performance by allowing increased neural firing. In addition, prestimulus differences in alpha phase have also been associated with task performance, suggesting differential information processing at separate phases of the alpha cycle. Together these findings support the hypothesis that alpha oscillations affect perception through rhythmic inhibition of cortical activity. However, it is not clear if alpha oscillations play a role in directly regulating the quality of sensory processing, or if alpha oscillations impact behavior by altering the efficacy of information transfer from early to later stages of processing. Here we examined the impact of alpha oscillations on behavioral performance in a discrimination task in which subjects had to report the orientation of a temporally unexpected and briefly flashed (~8 ms) orientated grating. The contrast of this grating was determined before the start of the experiment for each subject so that accuracy was fixed between 60% and 65%. Performance on this task was then evaluated as a function of alpha power and alpha phase (as assessed with scalp EEG). We observed that alpha activity during the post-stimulus period strongly predicted behavior, consistent with a role for alpha in mediating the relay of sensory signals to downstream areas.

Title: EEG phase shift caused by visual-spatial attention accompanies ventriloquism effect

Authors: T. KUMAGAI, *H. MIZUHARA;
Kyoto Univ., Kyoto-shi, Japan

Abstract: The brain, in nature, accepts and integrates different information sources. However, multisensory spatial information is not always combined correctly. One example is the "ventriloquism effect," which is the illusion whereby we misunderstand the source of a sound, attributing it, as it were, to the dummy rather than to his human partner. The neural basis of this effect remains an open question. In the present study, we examined the ventriloquism effect according to the hypothesis that visual-spatial attention causes an electroencephalographic (EEG) phase shift in the auditory cortex, indicating that auditory attention is critical to the input of auditory position. Our research applied exogenous or endogenous visual spatial attention as the main factor behind the ventriloquism effect. We used sound stimuli which lent themselves to virtual location by interaural time difference, and employed a two-alternative forced-choice paradigm. After looking at salient visual stimuli, participants were asked whether the sound source was located on their left or their right side. We obtained EEG measurements while participants conducted the localization task. The behavioral task showed that the sound position was preferentially detected as if originating from the position to which exogenous or endogenous visual attention was attracted. In the exogenous attentional condition, EEG oscillation in the theta frequency range was more likely phase-coupled for the ventriloquism effect. The topography showed the phase-locking at the contralateral occipital/temporal electrodes site in the visual-cue hemifield. On the other hand, we found no laterality of EEG phase-locking in the non-ventriloquism-effect condition. Moreover, in the endogenous spatial-attentional condition, we did not find any laterality of phase-locking with or without the ventriloquism effect. This result suggested the following: (1) that upon exogenous visual-spatial attention, the phase shift arising from the visual cortex is transmitted to the ipsilateral auditory cortex, and thus the visual-spatial-attention-enacted auditory space added to the visual space causes the ventriloquism effect; (2)

that endogenous visual-spatial attention induces the ventriloquism effect without the phase shift of exogenous attention.

Title: Attention modulates large-scale synchronization of low-frequency oscillations in multisensory processing

Authors: ***J. DAUME**[1], U. FRIESE[1], F. GÖSCHL[1], P. WANG[1], P. KÖNIG[2], A. K. ENGEL[1]; [1]Dept. of Neuro- and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. of Cognitive Sci., Osnabrück Univ., Osnabrück, Germany

Abstract: Directing attention towards relevant multisensory events is crucial to cope with the vast amount of information reaching our sensory systems. However, the mechanisms underlying attentional modulations of information processing remain unknown. Here, we used MEG to study large-scale synchronization across distant brain areas as a putative mechanism by which attention might modulate the processing of congruent or incongruent audiovisual stimuli. Healthy participants were presented with stimuli composed of a circular drifting grating accompanied by a complex sound. On every trial, brief simultaneous near-threshold changes in sound volume and visual contrast occurred twice during the 2.5 seconds lasting presentation. Each of these changes was either congruent (increase or decrease in both modalities) or incongruent (increase in one modality and decrease in the other modality). Prior to stimulation a cue indicated whether the first or the second multisensory stimulus change would be task-relevant. Participants were instructed to specify whether both modalities varied congruently or incongruently for the attended change. For the analysis of oscillatory brain activity we focused on a 400 ms time window following the first amplitude change. Spectral power in source space was examined using beamformer algorithms, and revealed strong influences of attention on low- and high-frequency oscillations. Gamma-band power was increased for attended versus

unattended bimodal changes in visual and auditory cortices as well as parietal and frontal brain regions. Significant decreases in power related to the allocation of attention were observed across posterior cortex regions in the beta-, alpha-, and theta-band. Analyses of functional connectivity revealed that attention was associated with increased theta-band coherence in right frontopolar cortex, bilateral inferior frontal cortex and in bilateral temporal regions. Attention also led to decreased alpha-band coherence in bilateral occipital and parietal cortex. Finally, beta-band coherence was lower for congruent as opposed to incongruent bimodal stimulation in mid-cingular cortex and right superior temporal cortex. Our results demonstrate that directing attention towards bimodal events modulates oscillatory activity in large-scale cortical networks comprising early auditory and visual as well as multisensory areas. Notably, during attended multisensory processing low-frequency coherence increased in a fronto-temporal network. These findings indicate that large-scale synchronization might orchestrate the functional integration in multisensory brain networks.

Abstract: Multisensory process is an ability to combine cues from various modalities, and a basic feature of brain function. Such a process directly contributes to forming perception. To

reveal multisensory processes occur in unisensory stage, recent studies focus on onset mechanism. In the next step, therefore, how and where sustainable multi-sensory processes are implemented should be answered. To investigate this issue, interpreting “the cocktail-party effect” in a broad sense, we designed an audio-visual speech matching task, and investigated detailed binding mechanism, using magnetoencephalography (MEG). In our task, two films were presented simultaneously, which consisted of two different sentences spoken by the identical person. To accomplish our task, participants were required to attend to not only auditory stimuli but also mouth movement persistently. We acquired MEG data during the task using a 306-ch whole-head MEG (Neuromag) from 15 healthy volunteers. First, source estimation analysis showed persistent activations in temporal pole (TP). We used wavelet transform for source data of TP, which revealed the activations consisted of multiple frequency components, especially delta (3-5Hz) and beta (15-30 Hz). To examine these frequency bands coordinate, we quantified phase amplitude coupling (PAC), which revealed a novel PAC pattern between delta phase and beta amplitude in TP (Fig. 1). Finally, measuring coherence, we confirmed TP operated together with motor area, especially the post-central area by the medium of delta (Fig. 2). In short, these results can be interpreted as following: previous studies report TP is a convergent hub of somatosensory, visual, auditory and language network. Visual and auditory information might be converged in TP. Second, delta is reported as one of the most adequate oscillations for encoding speech information, and beta as motor related oscillations. To support this idea, we confirmed TP coordinated with motor area. Thus, we propose PAC in TP is a part of mechanism to integrate audio-visual information.

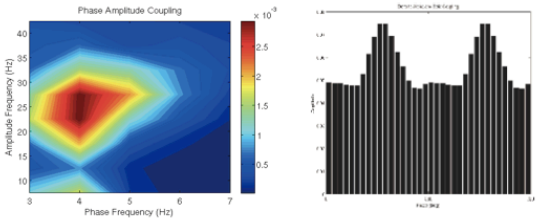

Figure 1. Phase-amplitude comodulogram. In left, vertical line denotes amplitude, horizontal line does phase. In right, Bars indicate delta phase bins from 0-720 degree. Therefore, each bin denotes 20 degree respectvely.

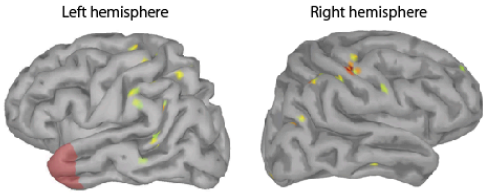

Figure 2. Imaginary coherence. Significant clusters tend to overlap with parietal lobe especially the post-central areas bilaterally. Red color denotes TP in the left hemisphere. This region is used as the seed region in calculating coherence values.

Title: The representational similarity of face morphs predicts performance in an independent visual search task

Authors: *J. LEE, J. J. GENG;
Ctr. For Mind and Brain, UC Davis, Davis, CA

Abstract: The representation of task-related information determines the speed of attentional selection and distractor suppression. However, it remains unclear how the neural representation of stimulus similarity affects attentional processes. We investigated this problem by examining the relationship between brain regions that encode categorical representations of face identity and performance in an independent visual search task. Functional magnetic resonance imaging (fMRI) data were acquired during a task in which face morphs between two famous face identities were classified as one or the other person. In addition, a house or a scrambled face image was sometimes presented and required the third "non-face" response. Representational similarity analysis (RSA) was used with a whole-brain searchlight procedure to identify regions with patterns of activation that correlated with identity classification (using the Spearman rank correlation coefficient). The results confirmed that face selective areas in the ventral temporal cortex and inferior occipital gyrus contained highly similar patterns of activation for all faces, which were dissimilar from all non-face stimuli. However, patterns of activation in the right middle frontal gyrus and the left inferior parietal cortex were highly consistent with the classification of face identity. Interestingly, performance in an independent visual search task in which one of the face identities served as the target and the various face morphs appeared as distractors was predicted by the behavioral and neural patterns during the classification task: reaction times to select the target increased as the classification similarity between the target and the distractor morph increased. These results suggest that the contents of the attentional template, which determine the speed of attentional selection, reflects the categorical structure of target stimuli that is represented in frontal and parietal areas as well as in stimulus-specific perceptual areas.

Title: Effortful control relates to intrinsic functional connectivity in dlPFC and dACC

Authors: *N. THAI, B. C. TABER-THOMAS, M. MAGGI, K. E. PEREZ-EDGAR, P. M. COLE;
Dept. of Psychology, The Pennsylvania State Univ., University Park, PA

Abstract: Effortful control, as measured through self-reports developed by Rothbart and colleagues (2001), has been studied in relation to many important developmental achievements. For example, effortful control is positively related to success in school, higher levels of empathy and prosocial behaviors, greater ability to resolve conflict, and lowered risk for pathologies such as conduct disorder, substance abuse and antisocial behavior (Ellis et al., 2004; Rothbart et al., 1994). During adolescence, the structure and activity of the anterior cingulate has been found to correlate with self-reports of effortful control (Posner et al., 2007). Resting state, or task-free analysis of intrinsic functional connectivity (iFC), may help elucidate broader neural architectures that support effortful control in children. iFC in executive control and salience networks has been associated with emotional functioning (e.g., internalizing and externalizing problems), as well as with behavioral traits (e.g., empathy) (Vaidya & Gordon, 2013). iFC continues during sleep and does not require active cognitive processes (Fukunaga et al., 2006). The current study investigates links between children's intrinsic functional connectivity and the temperamental trait of effortful control. 16 children (9M) ages 6-10 years (MAge = 8.35 SDAge = 1.37) provided resting state data during sleep. A voxelwise measure of global iFC was obtained for each participant by computing the average connectivity of each voxel with all other voxels in the brain. These maps were then entered into a whole-brain regression analysis to reveal regions where effortful control related to global iFC (cluster corrected p FDR < 0.05, with voxelwise $p < 0.005$). Effortful control was positively related to global iFC in left dlPFC and dACC. These findings are consistent with the extant literature on iFC relating to executive functions. Posner and Fan (2008) have identified an executive network, consisting of the anterior cingulate and prefrontal cortex, which is involved in resolving conflict among response tendencies. Other research has supported the cognitive role of the ACC in processing errors and conflict (Kerns et al., 2004; Menon et al., 2001). Effortful control, in turn, facilitates error and conflict monitoring. Intrinsic connectivity involving dlPFC has been associated with executive

attention (Posner & Rothbart, 2009). Taken together, we found support for individual differences in intrinsic connectivity involving dlPFC and dACC to be associated with effortful control, implicating that effortful control engages both the central executive (anchored by dlPFC) and salience (anchored by dACC) networks.

Title: Monitoring, extracting, and encoding indicators of cognitive workload(MEDIC)

Authors: ***B. K. BRACKEN**[1], N. PALMON[2], B. D. FREDERICK[3], N. J. COOKE[4], V. ROMERO[2], D. KOELLE[2], J. PFAUTZ[2];
[1]Cognitive Systems Div., [2]Charles River Analytics, Cambridge, MA; [3]McLean Hospital/Harvard Med. Sch., Belmont, MA; [4]Arizona State Univ., Mesa, AZ

Abstract: Background: The success of emergency medical personnel in saving lives depends on their acting quickly and effectively, as individuals and as teams. Training must go beyond individual skills to include team member interactions, and how skills transfer to stressful environments. Currently, trainers must infer competence by observation alone_a challenging task. Automatically sensing indicators of cognitive workload can augment performance observations, offering insight into factors underlying that performance. Method: We designed and demonstrated a system to augment training by Monitoring, Extracting, and Decoding Indicators of Cognitive workload (MEDIC). MEDIC combines a multimodal suite of unobtrusive, field-ready neurophysiological, physiological, and behavioral sensors; complex event processing to extract and fuse the best indicators of cognitive workload and team dynamics from the multiple, high-volume data streams originating from the sensor suite; and probabilistic modeling to interpret those indicators for easy understanding. Results/Conclusions: We designed a head-mounted device to measure cognitive load, a body band device to measure physical activity, and a user interface (UI) for trainers to take notes and record time-tagged photos and videos as the scenario unfolds. During our pilot study, we successfully extracted and fused data

from two individuals across both physically (simulated CPR) and cognitively (arithmetic and n-back cognitive task) demanding conditions. We concisely identified complex sequences of events in raw data using complex event processing. MEDIC is capable of processing both continuous (heart rate, oxygenated hemoglobin) and discrete (communication events, trainer observations on performance) variables. We explored five methods of data modeling, and determined that for our pilot data weighted averaging was most accurate for estimating individual state (stress and cognitive workload), but Causal Influence Models were most accurate for team state (team dynamics). Finally, we designed a separate UI that displays interpreted data after the simulation, including information about each state for each individual and for the team. Future work will include validation of each component of MEDIC using laboratory studies and testing in realistic training environments. Title: Reward pays the cost of noise reduction in cognitive and motor control

Authors: *S. G. MANOHAR[1,2], K. MUHAMMED[2], M. HUSAIN[2];
[1]Dept. of Exptl. Psychology, Oxford, United Kingdom; [2]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: The speed-accuracy trade-off is a fundamental principle in animal and human behaviour. Classically, this is explained by an optimal balance between the benefits of obtaining a goal sooner, and the disadvantages of speed, e.g. energetic cost and lower signal-to-noise ratios. However, recent reports suggest that motivation by reward can break the orthodox trade-off. We studied this with an incentivised speeded distractor-avoidance task. We found that

reward improved cognitive control over distraction, but simultaneously reduced reaction time. In the motor domain, reward increased both the velocity and accuracy of movements. To account for these effects, we consider a new factor, the cost of control. Mathematically, we propose that there is a fixed cost for a proportional increase in the signal-to-noise ratio. We suggest that, similar to motor control signals, a precision signal that attenuates noise might carry a cost. For example in rise-to-threshold models of decision-making, the noise might be attenuated relative to signal, but this gain incurs an economic cost that must be weighed against the benefits. The cost of control model fitted the data better than models without this component. Since rewards are signalled by dopamine, which is also thought to play a part in motivating effortful behaviour, we hypothesised that states of dopamine depletion may exhibit an increased cost of control. To test this, 19 patients with Parkinson's disease, a condition associated with dopamine depletion, were tested on the oculomotor task. The effects of reward were weaker in these patients, and within the model corresponded to an increased cost of control. Further, the model predicted that larger commands, being subject to greater noise, will be more amenable to noise reduction by reward. To test this, we varied the amplitude of saccades. High rewards increased both speed and accuracy, but reward effects were stronger for larger movements. This supports the hypothesis that signal-to-noise ratios can be improved at a cost, and that this cost applies proportionally to the amount of noise present.

Title: Inferior parietal lobules plays an important role in individual differences in executive function: a study with fMRI and SNP

Authors: *Y. UEDA[1], Y. KIKUNO[2], H. YAMAMOTO[1], J. SAIKI[1];
[1]Kyoto Univ., Kyoto, Japan; [2]Nagasaki Univ., Nagasaki, Japan

Abstract: Focusing on relevant information with ignoring irrelevant (distracting) information is an important skill to facilitate an efficiency of our behavior. This skill is called executive function. This function is realized with co-activation of cingulo-frontal-parietal cognitive/attention network (CFP network; Bush and Shin, 2006) in brain and has large individual differences. In this study, we replicated their experiment and investigated brain regions whose activity was correlated with interference task performance to reveal which brain regions contribute to individual differences in executive function. Furthermore, we also investigated the relationship between brain activations and single nucleotide polymorphisms in the dopamine receptor D4 gene (DRD4 rs1800955) and acetylcholine receptor subunit α-4 gene (CHRNA4 rs1044396) to reveal the mechanisms of the individual differences. In the experiment, 96 participants underwent the multi-source interference task (Bush and Shin, 2003, 2006), in which they were asked to identify the oddball digit among three digits with a button press. In the control condition, position of the oddball digit was congruent with its response position on the button box whereas in the interference condition, it was incongruent with its position on the box. Moreover, in the interference condition, the distractor digits were chosen randomly from the oddball targets in other trials. The results indicated that CFP network showed robust activity in the interference condition than in the control condition. Notably, brain activity correlated with the task performance was found in the left dorsolateral prefrontal cortex and the bilateral inferior parietal lobules (IPLs). In these regions, activations were stronger for participants who showed longer reaction times in the interference condition. Regarding to the gene-cognition relationships, participants with the TT and CC genotype in DRD4 and CHRNA4, respectively, showed reduced interference from distractors than other genotyped participants. Factorial analysis controlled with task performance revealed that their activities in bilateral IPLs and thalamus were significantly increased during the task than other genotyped participants. Altogether, these findings suggest that individual differences in executive function may depend on the susceptibility of these regions and/or their connectivity, which in turn were controlled by DRD4 and CHRN4.

Title: Development of functional networks supporting delay of gratification in young children

Authors: *A. T. PARK, P. K. SAXLER, A. B. CYR, J. D. E. GABRIELI, A. P. MACKEY; Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Delay of gratification during early childhood has been linked to important future academic outcomes. Although the developmental trajectory of delay of gratification has been examined at the behavioral level, few neuroimaging studies have been done with young children to investigate the nature and development of the functional networks underlying these behavioral differences. In this study, 36 participants between the ages of 4 and 7 performed a delay of gratification task (the "marshmallow test") and completed structural and resting state fMRI (rs-fMRI) scans. 23 participants were able to delay gratification (6.5 years, 9 males), i.e., wait for the larger reward, and 13 participants were not able to wait (5.8 years, 8 males). The groups differed by age ($t(34) = 2.02$, $p = .05$) but not gender ($\chi2(1, N = 36) = 1.7$, $p = .2$). Rs-fMRI preprocessing steps included: realignment, slice timing correction, spatial smoothing, bandpass filtering (.01-.1 Hz), physiological noise correction (aCompCorr), and outlier detection and regression (ART). The groups did not differ in number of motion outliers (delayers: 3.5, non-delayers: 4.2, $Z = .25$, $p = .8$). We chose inferior frontal gyrus pars opercularis (IFG) as a seed due to its involvement in delay of gratification in adults. IFG was defined from each participant's individual structural scan (FreeSurfer 5.3), and registered to functional space. Group-level analyses controlled for number of motion outliers. Controlling for age, children who were able to wait showed significantly less connectivity between left IFG and reward-related regions, the ventral striatum and substantia nigra. Delayers also showed significantly greater connectivity between left IFG and left precentral gyrus. Taken together, these results suggest that successful delay of gratification in early childhood is linked to differences in functional connectivity between cognitive control areas and brain regions responsible for processing rewards and initiating actions. The parallels between our results and fMRI findings in adults 40 years after performance of the "marshmallow task" (Casey et al., PNAS, 2011) suggest that individual

differences in these functional networks may arise early in development and persist into adulthood in the absence of targeted intervention. Future work will investigate the behavioral and neural impacts of educational programs that aim to improve cognitive control in young children.

Title: Influence of gender performance stereotype on the error-related negativity

Authors: *D. S. LELAND, K. A. ROLEFSON, S. E. BADOUR, G. L. BYE, C. M. BRENNAN, R. S. BELOTT;
Psychology, Univ. of Wisconsin-Eau Claire, Eau Claire, WI

Abstract: Gender stereotype threat refers to the fear of confirming the negative stereotypes of one's gender. We predict that the salience of task errors will be influenced by participants' expectations regarding which gender generally performs better on the task. We are testing this using the flanker task, where participants indicate the direction of a central arrow in a series of five arrows. We have replicated classic findings of an error-related negativity (ERN; a frontocentral negativity larger when evoked by errors than correct responses) and will present preliminary findings on how the ERN is modulated by gender performance stereotype. We predict that when participants are told that their gender (as opposed to the opposite gender) has a performance advantage for the flanker task, they will be more concerned about errors and thus generate larger ERNs.

Title: Mindfulness-of-breathing exercise affects eeg alpha-power measures of self-monitoring

Authors: H. BING-CANAR, J. PIZZUTO, *R. COMPTON;
Dept. of Psychology, Haverford Col., Haverford, PA

Abstract: The present study assessed how a brief mindfulness induction affects neural markers of self-monitoring and task engagement during a speeded cognitive performance task. Participants (n = 33) were assigned to either engage in a 14-minute mindfulness-of-breathing audio exercise or attend to a control listening exercise. They then completed a six-choice Stroop task of selective attention while EEG was recorded. EEG measures of performance monitoring included quantification of alpha power in the 1280-ms inter-trial interval following button-press responses. Prior evidence has found transient but robust increases in alpha power following correct responses and suppressed alpha following error responses, suggesting a pattern of "mental relaxation" after correct responses specifically (Carp & Compton, 2009). In the present study, participants in the mindfulness condition demonstrated this effect to a greater extent than controls. Alpha power during the window of stimulus processing did not differ between mindful versus control groups, arguing against the possibility of generally increased alpha power consistent with an overall relaxation effect. Instead, the results suggest that alpha power changed more dynamically across trial events in the mindful participants, such that greater alpha power (and greater inferred mental disengagement) was evident during brief "relaxation" periods between trials in the mindful group while at the same time stimulus processing and error processing evoked engagement that was equivalent across groups. Event-related potential markers of error-monitoring, including the error-related negativity and error positivity, were not affected by the mindfulness manipulation but were predicted by individual differences in self-reported mindful awareness and anxiety. Together the results suggest that a mindfulness-of-breathing exercise may promote more dynamic patterns of engagement during task performance.

Title: Withholding a reward-driven action: studies of corticospinal dynamics and the effect of cognitive depletion

Authors: *S. FREEMAN, D. LU, A. ARON;
UCSD, San Diego, CA

Abstract: Controlling an inappropriate response tendency in the face of a reward-predicting stimulus likely depends on the strength of the reward-driven activation, the strength of a putative top-down control process, and their relative timing. We developed a rewarded Go/NoGo paradigm to investigate such dynamics. Participants made rapid responses (on Go trials) to high versus low reward-predicting stimuli and sometimes had to withhold responding (on NoGo trials) in the face of the same stimuli. Behaviorally, for high vs. low reward stimuli, responses were faster on Go trials ($p<0.001$) and there were more errors of commission on NoGo trials ($p<0.001$)_showing that the value of the stimulus modulated response prepotency even on trials where responses were not permitted. We used single-pulse Transcranial Magnetic Stimulation to map out the corticospinal excitability dynamics. We found that, for NoGo trials, there was an early rise in motor activation that was then sharply reduced beneath baseline. This activation-reduction pattern was more pronounced for high versus low reward trials and in participants with greater motivational drive for reward (determined by their average response times). Those participants who had relatively more activation compared to reduction also made more NoGo errors ($r=0.44$, $p=0.02$). These results suggest that an effortful control process 'kicks in' to mitigate early reward-related response activation. A follow-on experiment tested whether the reduction phase reflects such a top-down control process that is related to the strength of the preceding activation and could potentially be depleted by a separate effortful task. Participants underwent the rewarded Go/NoGo task, then a high or low load working memory task, and then the rewarded Go/NoGo reward task again. In the high load group, we observed a significant pre-to-post increase in the NoGo error rate for high reward trials ($p=0.02$), which was significantly greater than the pre-to-post change for low reward trials ($p=0.02$). This was not the case for the low load group ($p's>0.2$), most likely because top-down resources were not depleted. Taken together, these studies show that when a response is inappropriate, reward-predicting stimuli induce early motor activation, followed by a top-down effortful control process (which we interpret as response suppression) that depends on the strength of the preceding activation. Our findings provide novel information about the activation-suppression dynamics during control over rewarding stimuli, and they illustrate how fatigue or depletion leads to control failures in the face of reward.

Title: Sex differences in neural processing during fMRI monetary incentive delay performance

Authors: ***M. R. MITCHELL**[1], P. D. WORHUNSKY[1], I. M. BALODIS[1], M. C. STEVENS[2], G. D. PEARLSON[1], M. N. POTENZA[1];
[1]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Olin Neuropsychiatry Res. Center, Hartford Hosp., Hartford, CT

Abstract: Men and women differ in various psychopathological conditions, including addictions. For example, men are more likely to develop an addiction but women are more likely to telescope into an addiction and are also more likely to relapse. Sex differences in the neural mechanisms of various aspects of addiction (e.g., reward processing) have yet to be fully understood. In order to investigate sex differences in reward processing, we recruited healthy male and female participants to perform a monetary incentive delay task while undergoing functional magnetic resonance imaging (fMRI). Seventy-nine healthy male (n=41) and female (n=38) participants matched on age, race/ethnicity, and education completed a monetary incentive delay (MID) task during fMRI. The MID task consists of trials during which participants press a button in response to a target object in order to win, or avoid losing, monetary rewards of $0, $1, and $5. The MID task allows investigation of neural activity associated with different temporal phases of reward-processing, including reward-prospect,

reward-anticipation and reward-receipt. During win-anticipation women display greater ventral striatum (VS) and decreased posterior cingulate cortex (PCC) relative to males. In response to winning outcomes women exhibited reduced activation in the ventromedial prefrontal cortex (vmPFC), PCC, and anterior cingulate cortex. During loss-anticipation, women display greater activation in the cerebellum, PCC, mFC, inferior frontal gyrus (IFG), and VS. In response to a loss outcome, women displayed decreased activity in the dorsal striatum and increased activity in the middle temporal gyrus (MTG) than men. Sex-differences were also displayed during neutral trials, with women showing increased activity across reward-processing phases in the VS, IFG, vmPFC, and MTG. Taken together, these results suggest that men and women process rewards differently in that they have differential recruitment of brain regions during anticipatory and outcome phases. Importantly, sex differences were also observed during the neutral conditions (i.e., in the absence of a monetary incentive) with women exhibiting patterns of increased activity in reward-circuitry. Thus, men and women differ not only in their reward processing, also in their baseline activity during task performance. Such findings emphasize the need for a better understanding of the differences in neural processing between men and women with respect to various behavioral aspects of addiction such that better, and potentially sex-dependent, treatment options can be developed.

Title: Prefrontal activation across time during executive tasks in young adults: A NIRS study

Authors: J. K. LANGE, *A. L. SMILEY-OYEN;
Kinesiology, Iowa State Univ., Ames, IA

Abstract: Introduction. We examined activation of the prefrontal cortex while performing two executive processing tasks using near-infrared spectroscopy (NIRS). We tested young adults to assess changes in underlying activation from task initiation to completion. While change across time has not been reported, fMRI studies indicate right lateralized activation during inhibition tasks and bilateral activation during tasks that require manipulation or updating of information (working memory). Methods. Changes in concentration of dorsolateral prefrontal blood oxygenation were assessed while 38 young adults (ages 18 to 25) completed the Stroop inhibition task and N-Back-1 and N-Back-2 working memory tasks. Results. Young adults exhibited right-lateralized prefrontal activation throughout the duration of the Stroop task. They exhibited increasing bilateral prefrontal activation during the N-Back 2 task. In addition, greater activation was elicited during the N-Back 2 task compared to the Stroop. Discussion. Prefrontal activation throughout the duration of executive task performance in young adults has not been previously studied. Task-related differences in activation appear to be the result of the cognitive effort necessary to perform executive tasks that require inhibition or working memory. Assessing the changes in activation throughout the course of executive tasks can provide new insights about distinct patterns of activation during executive function. These data provide a basis for future examination of changes in underlying activation in the prefrontal cortex that are age- and disease-related.

Title: Orienting- and executive control deficits after exposure to life-threatening events

Authors: *C. S. SKAFTNES[1], A.-K. SOLBAKK[2,3], T. ENDESTAD[1];
[1]Dept. of Psychology, Univ. of Oslo, Oslo, Norway; [2]Dept. of Neuropsychology, Helgeland Hospital, Mosjøen, Norway, Mosjøen, Norway; [3]Dept. of Neurosurgery, Oslo Univ. Hospital-Rikshospitalet, Oslo, Norway, Oslo, Norway

Abstract: Background: Several studies using tasks involving cognitive control (e.g., Stroop, Flanker, and Go/No-Go) have demonstrated significantly increased interference effects in posttraumatic stress disorder (PTSD) patients. However, it is still unclear whether the impairment is related to dysfunctions in proactive or reactive control. Moreover, as studies often use diagnosed PTSD as the main inclusion criterion, the observed alterations in performance may be driven by trauma exposure rather than being unique to PTSD. **Methods:** Using the Attention Network Task (ANT; Fan et al., 2002) we examined task performance in 28 adolescents who survived the terror attack in Norway (Utøya) on the 22nd of July 2010, compared to a non-trauma exposed control group (N = 22). Our main goal was to investigate whether the effects of valid versus invalid target location cues differed between groups, rather than target congruency. We predicted that an invalid cue would affect performance, measured by reaction times to a larger degree in the Utøya sample, compared to our control group. **Results:** The results revealed a main effect of both target congruency, $F = 212.20$, $p < .0001$, and cue validity, $F = 179.85$, $p < .0001$. Confirming our predictions, there was a significant interaction between cue validity and group, $F = 7.51$, $p = .009$, in that the trauma exposed group showed a significantly larger cue-dependent performance. However, the target congruency x group interaction was not significant, $F = .22$, $p = .644$. **Conclusion:** The results show that participants exposed to life-threatening events had more cognitive interference by an invalid cue compared to the non-exposed control group. Considering that the invalid cue was always centered, and could thus never be valid, our findings suggest that increased interference effect on cognitive control tasks may be a result of impaired proactive preparation effects by cues rather than lessened reactive control.

Title: fMRI activation of dorsal and ventral right inferior frontal cortex in a context-dependent stop signal task indicates different roles in motor control

Authors: *K. Z. XU[1], A. W. SALI[1], B. A. ANDERSON[1], S. YANTIS[1,2,3], S. M. COURTNEY[1,2,3];
[1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]F.M. Kirby Ctr., Kennedy Krieger Inst., Baltimore, MD

Abstract: Human lesion and imaging (fMRI) studies have demonstrated that the right inferior frontal cortex (rIFC) is critical for stopping action, but the specific function of rIFC activity in stopping is debated. While some argue for a direct role of rIFC in response inhibition, others have argued for a role of rIFC in either guiding attention to external events, or in encoding behaviorally-relevant task rules. To test these hypotheses, we administered a context-dependent stop signal task to humans. Each participant received 3 types of trials: Go trials, Stop trials, and Continue trials, presented in a pseudo-randomized order. All trials started when participants acquired central fixation at a context cue. The shape of the context cue (square or triangle) indicated the stimulus-response rule mapping on that trial, and was visible briefly before it was replaced by a central fixation point. The fixation point was then extinguished and, simultaneously, a peripheral target appeared. On Go trials, participants were required to generate a speeded saccade to the target. On Stop and Continue trials, a yellow or blue point appeared at the center of the screen after a variable delay. In one context, a yellow point cued the participants to cancel the saccade while a blue point cued the participants to complete a saccade to the peripheral target. In the other context, the rules were reversed. The context alternated every 8,10 or 16 trials, randomly and without prior warning. Reaction times in Continue trials were longer than in the Go trials, and the Failed Stop trials yielded the shortest reaction times. Increased BOLD activity in dorsal rIFC was observed in both Stop and Continue trials compared to Go trials, but there was no activation magnitude difference between Stop and Continue trials. On the other hand, multivariate pattern analysis (MVPA) was able to classify, with above chance accuracy, the meaning of the instructional stimulus for that trial (i.e., Stop signals vs. Continue signals), but not the color of the stimulus (i.e., yellow vs. blue). These results suggest that dorsal rIFC 1) detects signals that are behaviorally relevant, and 2) represents the current stimulus-response association. In contrast, ventral rIFC demonstrated increased BOLD activity relative to Go trials, only in Stop trials, yet there was no activation magnitude difference between Failed and Successful Stop trials. Thus, contrary to some previous claims, these results suggest that the ventral rIFC detects signals that are stop-relevant, yet does not control motor inhibition per se.

Title: Distinct roles for left and right rostrolateral prefrontal cortex in information integration: A multivariate fMRI study

Authors: *T.-R. HUANG[1], R. C. O'REILLY[2];
[1]Dept. of Psychology, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. of Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: The most anterior part of the brain is often referred as the rostral prefrontal cortex or frontal pole, which is primarily occupied by the Brodmann Area 10. In the literature of human executive control, the rostromedial prefrontal cortex (RMPFC) is implicated in mentalizing and multitasking, whereas the rostrolateral prefrontal cortex (RLPFC) is implicated in retrieval and integration of memory. For RLPFC, some laterality differences have been observed. For example, Bunge, Helskog, Wendelken (2009, NeuroImage) reported engagement of left, but not right, RLPFC in relational integration. However, the nature of such a laterality difference is not entirely clear from univariate analysis--left RLPFC may supervise rather than serve information integration, or vice versa. To examine the representations and functional roles of left and right RLPFC, we carried out a human functional magnetic resonance imaging (fMRI) study in that participants were challenged by a relational matching task, which is known to engage RLPFC. We then applied a multivariate pattern analysis (MVPA) to search for brain areas that encode task-specific information. Contrary to the results from univariate analysis in earlier studies, our preliminary data (N=6) from multivariate analysis show that right, but not left, RLPFC encodes both first-order and second-order relations, suggesting a direct contribution of right RLPFC to serve information integration. To provide further evidence, a more detailed and complete analysis (N=20) is being pursued.

Title: Tracking changes in EEG, mindful awareness, stress, and neuro-phenomena as personal perspective changes to universal perspective through Guided Subtraction Meditation

Authors: *G. K. SCHEINER[1], G. Z. SOGHOYAN[2], R. J. GOUGELET[2], A. M. VAHID[3], J. A. PINEDA[2];
[1]Cognitive Sci., UCSD, LA Jolla, CA; [2]Cognitive Sci., [3]Psychology, Univ. of California San Diego, La Jolla, CA

Abstract: We investigated the effects of the Guided Subtraction Meditation(GSM) practice, a new and unique meditation practice originating from South Korea. This practice focuses on dissociating from the egoic mind through a method they call subtraction. In this method, practitioners recall images and thoughts pertaining to past, present, and future experiences and discard or let go of them for the purpose of dissociating from these mental schema. Purportedly, after 100-150 hours of GSM, practitioners experience a state where the separation between the observer and observed dissipates, called the Universe Mind by the practice. We longitudinally tracked practitioners of this meditation(n=15) alongside non-meditating control subjects(n=20) from the start of their meditation practice to their 300-350th hour of meditation practice. At three timepoints(start, 100-150 hrs, 300-350 hrs or every 8-14 weeks for non-meditators), we administered the Philadelphia Mindfulness Inventory(PMI) and asked practitioners to fill out neurophenomenological reports(NPR). We also recorded EEG during 3 conditions, an eyes closed baseline, a session of GSM meditation, and a "stillness" task in which practitioners were asked to keep their mind free of thoughts. Between start and mid- treatment timepoints for the meditation group, we found significant trait increases in mindful awareness through the PMI and observed alterations in self experience related to ego dissolution and a feeling of universal oneness during the "stillness" task in practitioners' NPRs. The all electrode power spectrum showed significant increases in Theta, Alpha peak, and Beta peak power between start and mid-treatment timepoints across all conditions. While practicing GSM, Theta power decreased and Alpha power increased compared to baseline. These patterns are consistent with those seen during cognitive tasks that engage the DMN and increase cognitive load. This suggests that during GSM, the DMN may be engaged in a unique way while practitioners recall and actively dissociate from memories, thoughts, and feelings while simultaneously inhibiting mind-wandering and self-referential thought processes. During the "stillness" task, when practitioners reported experiencing the Universe Mind, Alpha spread over areas implicated with the ego body-self association in the TemporoParietal Junction, suggesting a potential neural basis for this change in self experience. Our observations suggest that this practice may be an effective method to induce rapid global changes in mental function which include increased awareness and alterations in self experience which seem to be safe and potentially healthy.

Title: The wandering brain: Individual differences in grey and white matter structure predict frequency of goal-related and emotionally positive mind-wandering

Authors: ***K. C. FOX**, M. S. JARRETT, M. GIRN, A. RAUSCHER, K. CHRISTOFF;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Mind-wandering (or 'spontaneous thought') has been most famously tied to activity in brain regions of the default mode network (DMN). However, almost nothing is known about how the brain's anatomical structure might vary in individuals with differing overall patterns of mind-wandering. For instance, individuals show marked differences in the frequency with which their spontaneous thoughts are goal-related (vs. unrelated) and emotionally positive (vs. neutral or negative) - but are these individual patterns of spontaneous thinking reflected at the level of neuroanatomy? We sought to explore the relationships between these individual propensities and both grey matter concentration (using high-resolution T1 anatomical MRI scans) and white matter integrity (using diffusion tensor imaging). During an MRI scan, we allowed subjects to rest and think freely, interrupting their thinking at random intervals with occasional thought probes. A total of 120 probes asked subjects about (i) whether their thoughts arose spontaneously, or whether they were intentionally directing them; (ii) whether thoughts were related to their current concerns and goals in life, or not; and (iii) whether they were emotionally pleasant, unpleasant or neutral. Overall individual difference scores were calculated for each participant (e.g., proportion of positive thoughts), and correlated with whole-brain grey matter concentration and tract-based white matter integrity. We found distinctive patterns of both grey and white matter structure correlated with individual propensity toward spontaneously arising vs. intentionally directed thoughts; thoughts related vs. unrelated to current concerns and goals; and emotionally pleasant vs. unpleasant thoughts. Moreover, these differences were observed in many regions beyond the DMN. Our results suggest that distinctive individual tendencies in the content and valence of spontaneous thinking are linked to correspondingly distinctive brain

anatomy. Our findings also speak to clinical disorders involving persistent and dysfunctional forms of spontaneous thought, e.g. depressive rumination: our results show that the brain structure of people who tend to have negative, non-goal-related thoughts is quantitatively distinct from those who tend to spontaneously produce positive, goal-related thinking.

Title: Time course of conflict processing modulated by brief mindfulness meditation

Authors: *Y. TANG[1], R. TANG[2], M. POSNER[3];
[1]Psychology, Texas Tech. Univ., Lubbock, TX; [2]The Univ. of Texas at Austin, Austin, TX; [3]Univ. of Oregon, Eugene, OR

Abstract: Resolving conflict is a pivotal self-control ability for human adaptation and survival. Although some studies reported meditation may affect conflict resolution, however, these studies were not randomized and could not provide conclusion on causality. Moreover, the neural mechanisms of resolving conflict following meditation are poorly understood. Based on our series of studies using mindfulness meditation, we here conducted a fully randomized 5 hours trial of one form of mindfulness meditation - Integrative Body-Mind Training (IBMT) in comparison to a relaxation training control. Thirty-five healthy and right-handed undergraduates (mean age=21.31, 17 male) without any prior meditation or relaxation training experience participated in this study. The experiment was approved by a local Institutional Review Board, and informed consent was obtained from each participant. Before and after training, all subjects performed a Stroop word-color task while their brain activity was measured using a high-density electroencephalography system. Eighteen subjects had 10 consecutive IBMT sessions with about 30 min per day (5 h in total), seventeen subjects were given the same amount of relaxation training. These two training sessions were conducted in parallel. During the Stroop word-color task, IBMT group produced significantly faster resolution of conflict compared to relaxation group, a smaller N2 and an earlier and larger P3 component of the event-related brain potentials (ERPs). Source analysis using sLORETA showed that the P3 localized bilaterally to the dorsal part of the anterior cingulate cortex (ACC, BA 24/BA 32). These results indicate that brief

mindfulness meditation induces a brain state that modulates the activity of ACC and improves information processing including the resolution of Stroop conflict. These findings are compatible with the idea that IBMT improves cognitive flexibility and reduces habitual response via enhanced self-control. Title: Is increased beta band power in the subthalamic nucleus related to global suppression of cortico-spinal excitability during behavioral response inhibition?

Authors: *A. GHAHREMANI[1,2], J. R. WESSEL[3], K. UDUPA[1], U. SAHA[1], M. HODAIE[1,2,4], A. M. LOZANO[1,4], S. K. KALIA[1,4], A. R. ARON[3], R. CHEN[1,5];

Abstract: Behavioral response inhibition is often studied with the stop-signal task, in which participants prepare a quick response to a go-stimulus, and then sometimes try to stop the initiated movement on trials in which a stop-signal occurs. Several studies in humans show that rapid behavioral response inhibition has global effects on the skeletomotor system. For example, when participants stop, corticospinal excitability (CSE), assessed with single pulse Transcranial Magnetic Stimulation (TMS), is reduced not only in the target muscle that needs to be stopped, but also in task-unrelated muscles as well. Rapid stopping recruits the subthalamic nucleus (STN) of the basal ganglia, one signature of which is increased beta band power of local field potentials in the STN of Parkinson's disease patients. Given also the suggestion that the STN has a broad effect on basal ganglia output, we hypothesized that broad skeletomotor suppression

during stopping (as assessed with TMS) could relate to the increase of beta band power in the STN. To test this, we measured STN local field potentials from deep brain stimulation electrodes implanted in six Parkinson's disease patients. Subjects performed a verbal stop-signal task, while their CSE was concurrently measured with TMS pulses to the motor cortex and EMG from their right hand (which was task-unrelated). Behavioral stop signal performance was good. The mean Go RT was 708ms and the speed of stopping (SSRT) was 361ms. The probability of stopping was .54. In line with several reports (Ray et al. NeuroImage 2012; Alegre et al. Exp.Neurol 2013), there was increased STN beta-band activity for successful stop trials compared to failed stop trials and go trials ($F(2/10) = 5.18$, $p < 0.03$). Also, in line with several studies in healthy young participants (Wessel et al. J Neurophys 2013; Cai et al. Brain and Language 2012, Badry et al., J Neurophys 2009), CSE was reduced from the task-unrelated hand for successful stop trials compared to failed stop trials and go trials ($F(2/10) = 5.94$, $p < 0.02$). Preliminary analysis showed that trials with stronger STN beta-band activity had numerically stronger CSE suppression measured at the hand, but this did not reach statistical significance in this incomplete sample. Thus, consistent with prior reports, rapid action stopping increases beta band power in the STN and produces global skeletomotor suppression. Preliminary evidence suggests these may be related, providing some evidence for the idea that global motor suppression is mediated via the STN.

Title: Effects of socioeconomic status on executive impairment in young smokers

Authors: R. L. ANTONIO[1], *S. POMPEIA[2];
[1]Psychobiology, Univ. Federal de São Paulo - UNIFESP, São Paulo, Brazil; [2]UNIFESP, São Paulo, Brazil

Abstract: Cigarette smoking elicits deleterious effects on cognition and is the leading cause of preventable death worldwide. Eighty percent of the one billion smokers worldwide come from developing countries, with high rates of income inequality. Low socioeconomic status (SES) is not only associated with higher rates of smoking as with poorer cognitive stimulation, which negatively affects cognition including executive functioning, also reported to be impaired in smokers. However, details are lacking regarding which type of executive functions are affected by SES and smoking. This is so because the term executive function encompasses many domains related to control of behavior, which can be evaluated by tasks that assess inhibition, shifting, updating, planning, access to long term memory, dual tasking (cold executive domains) as well as impulsivity (hot executive function, which can be measured by tests or questionnaires), related to poorer inhibitory control and higher risk taking. Here we studied whether SES would mediate executive impairment in young smokers. In an ongoing study, 60 young (aged 18-35), healthy smokers (> 10 cigarettes a day for 1 year) and nonsmokers of high and low SES were assessed regarding cold executive functions considering the above mentioned domains (Stroop Test, Category Switch Test, Number Memory Test, BADS Zoo Map, verbal fluency, dual task), impulsivity (Barratt Impulsivity Scale, BIS-11; delay discounting) and control measures sensitive to SES (working memory capacity measured by the Counting Span Test). Effects of acute nicotine administration and withdrawal were controlled through a test battery that lasted 90 min and by having smokers carrying out the tasks 30 min after the last cigarette (less than two hours of abstinence). Testing sessions were carried out in the morning. We found that irrespective of smoking status low SES participants had worse scores in the control measures of working memory capacity, confirming the deleterious effect of lower cognitive stimulation. Inhibition, shifting, updating and access to long term memory were also impaired in the low SES participants in relation to the high SES group. Regarding hot executive functions, lower SES participants also reported worse control of impulsivity in the BIS-11 and higher delay discounting. Negative effects of smoking were only found in the BIS-11 (motor impulsivity, non-planning, and BIS total score) and it did not interact with SES. Our preliminary findings suggest that low SES impairs many cold and hot executive abilities and high SES does not protect smokers against the negative effects of tobacco use on impulsivity.

Title: Cognitive control modulates task representations in occipital and prefrontal cortex

Authors: *L. S. LOOSE[1,2,5], D. WISNIEWSKI[3,2,5,6], M. RUSCONI[1], J.-D. HAYNES[1,2,6,4,7]; [1]Bernstein Ctr. for Computat. Neurosci., Charité Universtitätsmedizin Berlin, Berlin, Germany; [2]Berlin Ctr. for Advanced Neuroimaging, [3]Bernstein Ctr. for Computat. Neurosci., [4]Excellence Cluster NeuroCure, Charité - Universitätsmedizin, Berlin, Germany; [5]SFB 940 Volition and Cognitive Control, Technische Unviersität Dresden, Dresden, Germany; [6]Berlin Sch. of Mind and Brain, Humbolt Univ. zu Berlin, Berlin, Germany; [7]Dept. of Psychology, Humboldt Univ. zu Berlin, Berlin, Germany

Abstract: Alternating between different tasks is effortful and requires the recruitment of executive control functions. On trials following a task switch, as compared to task-repeat trials, reaction times are slower, which is known as a switch cost. Previous research on task preparation has compared global signal differences between switch and repeat trials. These studies often report a prefrontal network to be more active in switch-conditions than in stay-conditions. Recently, it has been shown that task sets are encoded in spatially distributed patterns of brain activity. So far, however, it has remained unclear whether these neural task representations are modulated by the increased control demands in switch trials. In this experiment, we used multivoxel pattern analysis (MVPA) in order to to compare the task-related neural information that is decodable in switch versus repeat trials. 40 subjects performed an event-related task switching paradigm, while functional magnetic resonance imaging (fMRI) was acquired. On each trial, subjects were cued to perform one of two different tasks. Trials either repeated the previous task or switched to the other task. Tasks were cued by abstract visual symbols presented on screen. The design allowed us to orthogonalize switch and repeat trials for both tasks. We used multivariate searchlight decoding to identify task-related processes information separately for switch and repeat conditions. To control for the influence of visual cue-related information, MVPA-classifiers were trained on data from one cue and tested on data from the other cue (cross-classification). In order to avoid overfitting, we applied leave-one-run-out cross-validation. We found that tasks could be decoded with higher accuracies in switch as compared to stay trials. In switch trials, task information was found in occipital lobe and the inferior frontal gyrus, pars triangularis, whereas analyses of repeat-trials yielded no regions with significant task-information. These results indicate that cognitive control seems to strengthen task representations under conditions of switching, primarily in occipital lobe and prefrontal cortex.

Title: Dissociable electrophysiological correlates of proactive and reactive control during response inhibition

Authors: *K. FUKUDA, J. D. SCHALL, G. F. WOODMAN;
Psychological Sci., Vanderbilt Univ., Nashville, TN

Abstract: The countermanding paradigm has been extensively used to examine our ability to inhibit a planned action. Theories propose that response inhibition is accomplished by two types of executive control. Proactive control uses endogenous expectations to inhibit actions, whereas, reactive control is exerted to fully terminate actions in response to the external cues (e.g., Verbruggen & Logan, 2009; Aron, 2011; Bisset & Logan, 2011; van Belle, et al. 2014). We recorded scalp EEG while human participants performed a manual countermanding task. We found that proactive and reactive control were instantiated by two distinct neural responses observed at different stages of the task. Proactive control occurred with a larger amplitude sustained negativity observed across frontal channels prior to target presentation. Reactive control occurred with a transient increase in alpha power observed at parieto-central channels following the stop signals. In Experiment 2, we found that these two mechanisms of executive control interact. Using pre-trial cues to indicate the probability of an upcoming stop signal modulated the sustained frontal negativity of proactive control. However, responses were successfully inhibited when the parieto-central alpha power of reactive control compensated for the level of proactive control following the cue. Our findings reveal novel neural metrics of

proactive and reactive control with high temporal precision and demonstrate the interaction of these mechanisms as subjects control responses.

Title: Training divides neural representations to conquer multitasking costs

Authors: ***K. G. GARNER**, P. E. DUX;
Sch. of Psychology, Univ. of Queensland, St. Lucia, Australia

Abstract: The present "Information Age" is replete with complexity and frequently requires that we manage multiple tasks concurrently. It is thought that humans are poor at multitasking because frontoparietal and subcortical (FP-SC) brain regions both serve a broad range of mental functions and are limited information processors. Thus, performing multiple tasks exceeds the capability of the system, and performance impairments are incurred. Training is known to improve multitasking ability by influencing the activity of FP-SC areas. However, it is not well understood how the functional organisation of this system changes to improve multitasking performance. To address this, we characterized the functional changes of the FP-SC system that predict multitasking-training outcomes. Participants (N=100) performed single and multiple tasks in pre- and post-magnetic resonance imaging (MRI) sessions that were interspersed by either a multitasking or an active-control training regimen (inefficient visual-search task). Using functional imaging and a multivoxel pattern analysis (MVPA) approach, we found that the divergence of FP-SC blood-oxygen-level-dependent (BOLD) response patterns across voxels to the trained tasks predicted multitasking improvements. Importantly, this was only observed for participants who trained on the multitasking regimen, and not for the active-control group. Therefore, the FP-SC system supports enhanced multitasking behavior by segregating representations for the constituent tasks, thereby reducing neural competition between them.

Title: Greater distribution of executive control networks supports cognitive reserve in bilingual older adults

Authors: ***T. B. WENG**[1], E. GUZMÁN-VÉLEZ[1], G. COOKE[2], A. Z. BURZYNSKA[2], C. N. WONG[2], E. MCAULEY[2], A. F. KRAMER[2], D. TRANEL[1], M. W. VOSS[1];
[1]The Univ. of Iowa, Iowa City, IA; [2]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: A wealth of research supports the notion that bilingualism protects the aging brain by attenuating the cognitive declines that accompany healthy aging and by delaying the onset of dementia. These findings are consistent with the cognitive reserve hypothesis, which postulates that there are individual differences in the ability to adaptively cope with the decline in brain integrity and maintain cognitive functioning. How might bilingualism enable such cognitive reserve? One view posits that a lifetime of managing two languages produces flexibility between multiple brain networks, enabling a larger repertoire of paths for cognitive processing. Accordingly, we predicted that brain regions in the executive control network (ECN) of bilingual older adults are more functionally connected to regions from other cognitive networks when compared to their monolingual peers. In the current study, we tested this prediction by analyzing resting-state functional magnetic resonance imaging (rs-MRI) data from healthy bilingual (n = 10) and monolingual (n = 10) older adults matched in their age, years of education, and sex. With high spatial precision and test-retest reliability rs-fMRI measures functional connectivity, as expressed by temporal correlations of brain activity during the resting state, among multiple brain regions without the constraints of specific task demands. Thus, rs-fMRI permits one to observe the organization of spatially distributed brain regions into functionally connected networks. Consistent with our predictions, we found that, compared to monolinguals, the ECN of bilinguals was more functionally connected to the salience network (SAL), a network proposed for detecting behaviorally-relevant stimuli, and to the dorsal attention network (DAN), a network proposed for driving goal-driven attention ($p < 0.05$). However, we observed that a network comprised of classical language regions is more functionally differentiated from other networks (default network and ECN) for bilinguals compared to monolinguals ($p < 0.05$), suggesting greater functional specialization of language regions in bilinguals. We interpret these results as

reflecting a possible neural mechanism underlying the extended cognitive reserve found in bilingual older adults. We suggest that bilingualism is associated with greater integration of networks involved in executive control and attention accompanied by greater specialization of regions involved in language.

Title: Subcortical response increase to uncertainty and deviations from expectation

Authors: *A. MESTRES-MISSE[1], R. TRAMPEL[2], R. TURNER[2], S. A. KOTZ[1,2];
[1]Univ. of Manchester, Manchester, United Kingdom; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Optimal behavior often requires a precise balance between automatic and controlled processing. In a dynamic noisy environment, it is not only beneficial to automatize routinely reliable behavior, but also to allow flexibility to deal with uncertainty and unexpected events. The present 7T-fMRI study investigated the role of subcortical structures in regulating this automatic-controlled processing mechanism, especially necessary when our expectations are violated. For this purpose, a new task was designed, in which participants learned to calculate the outcome of different sequences of geometrical figures. The design included three types of sequences, which provide unambiguous, ambiguous and incongruent contextual information, and two outcomes, probable and unlikely. After three consecutive days of training in calculating the value of the sequences, participants judged the correctness of the sequences in the scanner. We hypothesize that when there is a difference between the expected and actual outcomes, cognitive control mechanisms are needed to override the anticipated response, re-evaluate the evidence, and select an appropriate, albeit less likely, alternative (if possible). The results showed increased dorsomedial striatal and ventral anterior thalamic nucleus activation for ambiguous and unambiguous subordinate sequences; additionally, ambiguous sequences displayed also larger

activation in bilateral centromedian-parafascicular thalamic nucleus and red nucleus; and finally, dorsolateral and posterior dorsomedial striatum showed increased activation for incongruent sequences. These results demonstrate how different subcortical structures modulate deviations from expectation as well as highlight their critical function in cognitive control and the automatic-controlled processing balance.

Title: Cognitive control by disinhibition: a cortical model of decision making and multiple-item working memory

Authors: *D. STANDAGE, M. PARE, G. BLOHM;
Queen's Univ., Kingston, ON, Canada

Abstract: Recent data provide evidence for the control of cortical processing by interneuron-targeting interneurons (Pi et al, Nature, 2013). We hypothesize that such disinhibition is a fundamental mechanism of cognitive control, testing our hypothesis with a biophysically-based model of a local circuit in association cortex. It is widely believed that several association cortical areas (e.g. dorsolateral prefrontal cortex and the lateral intraparietal area) play an important role in decision making and working memory, but these two cognitive processes make conflicting demands of neural circuitry. Competition between neural populations encoding choice alternatives is crucial to decision making, but competition between populations encoding memoranda entails forgetting. We propose that disinhibition modulates the competition between neural populations, allowing the same circuitry to support cognitive tasks with different processing requirements. Our local-circuit model is a network of simulated pyramidal neurons and inhibitory interneurons, connected by AMPA, NMDA and GABA synapses. All biophysical parameters are justified by electrophysiological data, including the structure of synaptic connectivity, the relative strengths of synaptic conductance, and the high-conductance state of neurons due to background synaptic bombardment. We simulate disinhibitory control by modulating the strength of the inhibitory background conductance onto interneurons. In simulations of visual discrimination tasks, weak disinhibition reproduces signature

characteristics of neural and behavioural data, including the time-evolution of decision-correlated neural activity, and psychometric and chronometric curves. Disinhibition also controls the speed-accuracy trade-off, where a weaker disinhibitory signal produces slower, more accurate decisions for a given task difficulty and number of alternatives. In simulations of visual working memory tasks, strong disinhibition supports working memory capacity consistent with that of experimental subjects, qualitatively reproducing neural data from association cortical areas. Our disinhibitory signal further controls network performance in a third task, in which multiple stimuli are presented simultaneously, but none are chosen. Many decision making and working memory tasks include an interval of this description. Overall, our model provides compelling evidence for disinhibition as a source of cognitive control, accounting for a large volume of neural and behavioural data under a single set of parameter values, and making predictions for future experimental studies of cognition.

Title: Examining changes in cortical activity associated with switching attention between tasks of different modalities

Authors: *J. L. TOMLIN, W. E. MCILROY;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: With modern technology advancing, humans are constantly trying to perform multiple tasks at the same time. Such multitasking commonly involves switching attention between two tasks. This ability to disengage from one task and engage in another is an executive function allowing for cognitive flexibility in a dynamic environment. Attention switching can, however, result in decreased level of performance as measured as a behavioural switch cost. This switch cost is the difference in reaction times between trials involving a task switch and trials in which a single task is performed (no switch). The current study is focussed on advancing an approach to reveal the temporal properties of this attention switching and the underlying electrophysiological correlates. The rationale for this study was a precursor prior to evaluating exercise-induced

changes on the temporal characteristics and electrophysiological events associated with attention switching. In the current study, participants switched from a near-continuous background auditory task to a primary visual simple reaction time task. The background auditory task involved a choice reaction using the left hand based on the frequency of two auditory tones. The switch task was a simple visual reaction time task involving a right wrist flexion response to a left arrow. This background task was chosen so participants were continuously engaged in a task (with a 600 ms interval between auditory tones) and then must rapidly switch to the visual task at an unpredictable time point. The timing of the visual reaction times during switch and non-switch trials were compared to determine switch cost. Continuous EEG was examined while switching between these tasks as well as during the performance of the visual task repetitively. ERPs time-locked to the visual stimulus were examined. Preliminary results revealed a delayed P3 latency in the switch condition, indicating the stimulus evaluation stage of information processing is longer when switching attention between two tasks. Further analysis will investigate earlier ERP components to examine cortical activity differences in early stages of information processing comparing switch and non-switch trials. This research hopes to reveal which stages of information processing are altered in timing when switching attention between two tasks and the factors that modulate capacity for attention switching.

Title: Effects of tolcapone and bromocriptine on cognitive flexibility in an anti-saccade task

Authors: *I. G. CAMERON[1], D. WALLACE[2], A. AL-ZUGHOUL[3], A. S. KAYSER[2], M. D'ESPOSITO[3];
[1]Ctr. for Cognitive Neuroimaging, Donders Inst. for Brain, Cognition and Behavio, Nijmegen, Netherlands; [2]Univ. of California, San Francisco, San Francisco, CA; [3]Univ. of California, Berkeley, Berkeley, CA

Abstract: In terms of executive functions, it has been suggested that the prefrontal cortex (PFC) is important to task maintenance, but that the basal ganglia (BG) are important to task flexibility. Tolcapone and bromocriptine are dopaminergic drugs that can be used to investigate such assumptions. Tolcapone, a COMT inhibitor, should affect behaviors that rely on PFC function, because by inhibition of COMT, more dopamine remains at the synapse (COMT has greater importance for PFC compared to striatal dopamine metabolism). In contrast, bromocriptine, at D2 agonist, should affect behaviors, such as task switching, that more explicitly recruit PFC-BG circuits, due to the relative dominance of D2 receptors in the BG than in the PFC. We used a pro- (look towards) /anti- (look away) saccade task that included the requirement to switch suddenly to the opposite task mid-trial. Our hypothesis was that task maintenance depends on the PFC; therefore, tolcapone would improve performance on non-switch trials, however it would impair performance on switch trials. Conversely, bromocriptine would facilitate switch trials, but would impair non-switch trials. 16 subjects participated in a 3-session double-blind experiment counterbalanced for tolcapone, bromocriptine or placebo. 40 % of the trials were non-switch trials and 60 % of the trials were switch trials. Target stimuli were presented pseudorandomly to the left or right. A measure of "efficiency" (percent correct / reaction time) was used to assess overall performance. We did not find a significant Drug X Switch Condition interaction ($P = 0.06$), though this trend indicated that non-switch trials were less efficient under tolcapone. Tolcapone reduced efficiency overall (main effect of Drug, $P < 0.01$), and efficiency under tolcapone was different from placebo ($P < 0.05$). To further explore this, we divided subjects based on COMT Val/Met polymorphism (Val results in a more active COMT enzyme), to determine if there was a Drug X Genotype interaction. This interaction was not significant ($P = 0.26$), but there was main effect of genotype ($P < 0.05$), such that Val/Val subjects were the most efficient and there was a Genotype X Switch Condition interaction ($P < 0.01$), as Val/Val subjects also exhibited less of a loss in efficiency on switch relative to non-switch trials. We suspect that the nature of the task (2 Tasks, 2 Switch Conditions and 2 Target Locations) requires trial-by-trial flexibility. Thus, optimal performance necessitates subjects to be governed by the task stimuli: programming an initial response, and switching if, and only if, instructed explicitly. The results suggest that greater PFC dopamine impedes cognitive flexibility.

Title: Efficiency of brain network dynamics associated with cognitive ability

Authors: *D. H. SCHULTZ, M. W. COLE;
CMBN, Rutgers-Newark, Newark, NJ

Abstract: The efficiency of the human brain is remarkable. It is able to exceed modern computers on multiple computational demands (e.g., language, planning) while consuming the wattage of a mere light bulb. The mystery of how the brain can be so efficient is compounded by recent evidence that all brain regions are constantly active as they interact with each other in so-called resting-state networks (RSNs). In order to investigate the brain's ability to efficiently process complex cognitive demands we used data from the Human Connectome Project (WU-Minn consortium, N=100) to compare functional connectivity during rest and several highly distinct tasks (as previously described; (Barch et al., 2013)). We previously found that RSNs are present during a wide variety of tasks, and that tasks only minimally modify functional connectivity patterns throughout the brain (Cole et al., 2014). Here we tested the hypothesis that, while subtle, these task-evoked functional connectivity changes from rest nonetheless strongly contribute to behavioral performance. Surprisingly, we found across three diverse tasks (language, relational, and working memory tasks) that high performing individuals exhibited more efficient brain connectivity updates (smaller changes in functional network architecture between rest and task). These results suggest that individuals with more efficient brain connectivity updates have especially effective network configurations for general task performance. The brain's efficiency therefore appears to be a key feature contributing to both its network dynamics and general cognitive ability.

Abstract: Introduction: Early experiences are critical for the Brain development in Children, and maturation of their cortical areas. When children are exposed to different kinds of threaten, for example work in the street on an average of 6 or 7 hours per day, plus the lack of education, an unhealthy environment, due a low socioeconomic status (SES). These children suffer an affectation on their Neurocognitive functions development, which will bring serious consequences in their future. **Objective:** The aim of this work is to compare the performance of executive functions and cognitive process in children aged from 7 to 11 years old, considering the SES, gender, as well the school status. We looked to describe the Neuropsychological profile of children in a street social context. **Methods:** Participants were 40 children from 7 to 11 years old, based on the downtown of Guadalajara city, were divide in two groups, 20 inside of a street context, and 20 from a structure family context with a medium SES. We used the Neuropsychological Questionnaire school maturity (CUMANES) this questionnaire have 13 sub tests, and 8 sub tests from the neuropsychological battery of executive functions (BANFE), which evaluate different neuroanatomical areas of the prefrontal cortex. **Results and Discussion:** We completed a sample of 20 Children in groups, 10 girls and 10 boys, the group from a street context presented a low Neuropsychological development index compared with the other group, they showed problems in planning abilities, working memory, and semantic tasks. Although a few subjects of street context group present a different range but maybe is for ethnic characteristics. The lack of Neuropsychological skills increased, with the differences age in the street context group, presented alterations in different neuropsychological domains**.**

Title: Cognitive effort and the opportunity cost of time: a behavioral examination

Authors: *R. OTTO, N. DAW;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: A spate of recent work demonstrates that humans seek to avoid the expenditure of cognitive effort, much like physical effort or economic resources. Less is clear, however, about the circumstances dictating how and when people decide to expend cognitive effort. Here we adopt a popular theory of opportunity costs and response vigor and to elucidate this question. This account, grounded in Reinforcement Learning, formalizes a trade-off between two costs: the harder work assumed necessary to emit faster actions and the opportunity cost inherent in acting more slowly (i.e., the delay that results to the next reward and subsequent rewards). Recent work reveals that the opportunity cost of time--operationalized as the average reward rate per unit time, theorized to be signaled by tonic dopamine levels, modulates the speed with which a person responds in a simple discrimination tasks. We extend this framework to cognitive effort using established “cognitive control” tasks, for which 1) the amount of cognitive effort demanded from the task varies from trial to trial and 2) expenditure of cognitive effort holds consequences in terms of accuracy. In one experiment, 50 subjects completed a Simon task while available rewards varied randomly on a trial-to-trial basis. Echoing previous results, we found that subjects tuned their response speeds in accordance with the experienced average reward rate: when the opportunity cost of time was high, subjects responded more quickly. On response-incongruent trials--for which correct responses demand cognitive effort--this reward-rate-dependent speeding was accompanied by a reduction in accuracy. That is, expenditure of cognitive effort appeared to be modulated by the opportunity cost of time. Further, and consistent with our account, the strength of this modulation covaried with individual differences in efficacy of cognitive control, operationalized as response slowing on incongruent trials. Taken together, our results provide an initial look the circumstances dictating how and when people expend cognitive effort.

Title: Measuring the subjective cost of physical effort

Authors: *P. S. HOGAN[1], C. D. FRYDMAN[2], V. S. CHIB[1,3];
[1]Biomed. Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]USC Marshall Sch. of Business, Los Angeles, CA; [3]Kennedy Krieger Inst., Baltimore, MD

Abstract: We constantly make decisions about what types and how much effort we exert. One factor that could influence these decisions is our subjective preferences for effort (i.e. how effortful a task feels). In this experiment we characterized individuals' subjective preferences for physical effort costs and their underlying neural mechanisms. To accomplish this we scanned subjects with fMRI while they performed a physical effort task that required exertion in the form of gripping a hand-clench dynamometer. Subjects first learned an association between force produced and a numerical scale ranging from zero to one-hundred relative to subjects' maximum voluntary contraction. They then performed a series of risky binary gambles involving varying levels of force to be exerted. During each choice subjects made a decision between exerting a low amount of effort with certainty or a gamble that could result in a high level of exertion or a zero level of exertion. We found that the majority of subjects exhibited convex subjective effort cost functions, indicating that the marginal subjective values of the cost associated with the task increased as more effort was required. A total of 20 subjects have been scanned and subsequent analysis will look for brain regions with activity associated with individuals' subjective preferences for physical effort.

Title: The influence of habitual physical exercise on effort discounting in decision making

Authors: *J. BERNACER[1,2], E. LUIS[3], I. MARTINEZ-VALBUENA[2], M. MARTINEZ[3], N. PUJOL[4], D. RAMIREZ-CASTILLO[2], M. A. PASTOR[3,2];

Abstract: Effort-based discounting on decision making has been demonstrated to correlate with sedentary behavior. In the present contribution, we hypothesize that changing sedentary lifestyle for habitual physical exercise may reduce effort-based devaluation, resulting also in functional brain changes during decision making. To test this hypothesis, we recruited 22 young participants (age 18-24) with a sedentary behavior according to the GPAQ test (World Health Organization), and included them in a 3-month mild physical activity program (3 days a week, 30 minutes per day). They completed several neuropsychological tests (RYFF, TCI) and were tested using BOLD fMRI before and after the program while performing a decision-making task as follows: subjects were presented pairs of options that differed in probability (odds to win) and effort (minutes running on a treadmill) to earn a fixed payment (30 euros), so the volunteers had to balance high probabilities of winning with their willingness to run. They were instructed that one of the pairs of options (out of a total of 315) would be randomly selected by a lottery and they had to perform the selected amount of exercise in order to get the money. The neurocomputational analysis of fMRI data revealed that, before following the physical training plan, two clusters located in the dorsal anterior cingulate cortex and dorsomedial prefrontal cortex positively correlated with uncertainty (computed as Shannon entropy) and subjective value, respectively (both $P<0.05$, FWE corrected for multiple comparisons at cluster level). After completing the program, subjects tended to choose the high probability option of the pair irrespective to the physical effort (paired t-test before vs after the program, $P<0.05$). We also found robust changes in the fMRI coding of uncertainty and effort discounting (voxel-by-voxel paired t test): 1) uncertainty values (Shannon entropy) showed a significant positive correlation with BOLD signal in the precuneus after the program, compared with before the program ($P<0.05$, FWE corrected for multiple comparisons at cluster level); 2) effort-discounting values significantly positively correlated with BOLD signal in the ventromedial prefrontal cortex after the program, compared with before the program ($P<0.05$, FWE corrected for multiple comparisons at cluster level). In all, our experiment confirms that habitual physical exercise done

by formerly sedentary subjects impacts on effort-based decision-making both at behavioral and neural levels.

Title: Option generation and option switching decision-making in apathy - a disorder of motivation

Authors: ***Y. ANG**, M. HUSAIN;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Apathy or lack of motivation to act is a profoundly disabling clinical condition that also occurs in milder form in healthy people. The mechanisms underlying its manifestations are largely unknown, but it has been suggested that it might arise from deficits in decision making. Here we examined the relationship between apathy and (i) option generation, and (ii) option switching in healthy young and older adults. We used two novel paradigms implemented on a touchscreen computer while level of motivation in participants was indexed using a modified version of the Lille Apathy Rating Scale. In the first task, participants (young: N = 40; elderly: N = 25) were required to produce, in four minutes, as many different paths as possible between a start-point and an end-goal. Three conditions were tested, with different levels of effort required (0, 4 or 8 barriers). In each condition, the number of paths generated correlated strongly with motivation, independent of age, baseline motor ability and IQ. In the second task, participants (young: N = 25; elderly: N = 20) had three minutes to maximise rewards earned by producing as many paths as they could, but now they had a choice between two goals. Each path was drawn from a start-point to either a (i) high reward goal that became progressive harder to reach with new barriers appearing each time a path was drawn to it, or (ii) low reward goal with no barriers. Compared to motivated people, apathetic individuals actually allocated more effort during the task. They persevered longer on going to the high-reward goal (which progressively became harder to reach), switching to the easier, low-reward option much later than more motivated

participants. Yet, as a result apathetic people earned less credits. Using each individual's movement time to reach the low-reward goal, we also computed the optimal number of paths to the high-reward goal before a participant should switch to the low-reward goal. Deviation from the optimal strategy scaled negatively with motivation level, i.e. apathetic people were less able to initiate effective responses, deviating more from the optimal strategy. These findings demonstrate that lack of motivation is associated with both impaired option generation and option switching goal-directed behaviour. Apathetic people were not only slower at generating options, but were also less able to switch effectively between them. These simple tasks serve as tools to probe disrupted decision-making mechanisms underlying motivational deficits, providing objective methods for examining pathological apathy in brain disorders.

Title: Neural processes underlying reward-saving behavior in human amygdala and prefrontal cortex

Authors: *L. ZANGEMEISTER, F. GRABENHORST, W. SCHULTZ;
Dept. of Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Saving behavior has a profound influence on markets and entire economies. Contrary to common binary inter-temporal choice paradigms, deliberate saving requires internal planning and repeated postponement of consumption across time. We recently showed that, during reward-saving, single neurons in the monkey amygdala exhibit planning activity related to single-step economic choices (Grabenhorst et al., 2012) and longer-term internal reward goals (Hernadi et al., 2015). We designed a saving paradigm and used fMRI to explore the neural mechanisms underlying internally planned reward-saving in humans. Healthy volunteers (N = 24) freely set reward goals and subsequently performed choice sequences of up to three minutes to attain primary rewards (milk-based drinks). To elicit variation in saving behavior we used different reward types (high/low fat content) and rates of reward increase during saving (high/low growth). Reward type and growth rate were cued at the start of each choice sequence

allowing subjects to form an internal saving plan. Before sequence initiation, subjects reported their willingness-to-save. During a sequence, subjects chose trial-by-trial to save the reward for later or to spend (i.e. consume) immediately. Individual saving behavior reflected subjective valuations of reward type, growth rate and their interaction. Subjects did not always follow their initially reported plan, which allowed us to distinguish neural activity related to stated intentions from activity predictive of the eventually executed saving sequence. Analysis of fMRI data showed that amygdala activity reflected both subjects' internal saving plans and trial-by-trial choices ($P < 0.05$, cluster-level corrected). At sequence start, amygdala planning activity more strongly encoded the future executed saving sequence than reported willingness-to-save. During sequence execution, amygdala activity encoded trial-by-trial save-spend choices and current sequence value. We also found planning activity, sequence valuations and tracking of sequence progress in medial and lateral prefrontal cortex and anterior cingulate cortex. Our results identify neural processes related to the formation and pursuit of internal economic saving plans and point to an important role for the human amygdala in planning for distant rewards. Title: Ventrolateral prefrontal activity reflects increases in object value induced by larger choice sets

Authors: *J. FUJIWARA[1], N. USUI[2], S. EIFUKU[1], T. IIJIMA[3], M. TAIRA[2], K.-I. TSUTSUI[3], P. N. TOBLER[4];
[1]Fukushima Med. Univ., Fukushima, Japan; [2]Tokyo Med. and Dent. Univ., Tokyo, Japan; [3]Tohoku Univ., Sendai, Japan; [4]Univ. of Zurich, Zurich, Switzerland

Abstract: The act of choosing between objects generally increases the subjective value of the chosen object. However, it is unclear whether this increase in value is due to having chosen the object or to simply owning the object after choosing it. In this study, we dissociated these two

possibilities by varying the size of the choice set under the assumption that this manipulation would increase choice-related value but have no impact on ownership-related value. In the scanner, participants selected options from choice sets of various sizes (1, 2, 4, or 8 options) and of differing value (low or high, based on pre-choice attractiveness ratings), whereby size and value were manipulated independently. After an option was selected, participants re-rated the attractiveness of the chosen option. By comparing post- with pre-choice ratings, we found that the subjective value of options chosen from larger choice sets increased more than that from smaller sets, and activation of the ventrolateral prefrontal cortex reflected this change in value. Control analyses showed that this revaluation effect is specific to the influence of set size and independent of the influence of ownership. These data further elucidate why we like things we have chosen ourselves.

Title: Neural Representation of Value of Information

Authors: ***K. KOBAYASHI**, M. HSU;
Univ. of California, Berkeley, Berkeley, CA

Abstract: In many types of decisions, an agent acquires some piece of information over the course of time, e.g. reading abstracts to select which posters to visit. Information is often associated with some cost (e.g. reading time), and the agent has to decide whether to acquire information by comparing its value against its cost. Because information in these cases has no intrinsic value, its value only comes from the ability to make a decision more adaptively in the future. According to decision theory, normative value of information is expected marginal gain from making an informed decision, and requires simulation of the self's choice and its expected utility under all possible contents of information. Although proper valuation of such pure information is fundamental to a variety of decision problems, we still know little about its neural basis. We conducted a behavioral experiment to examine the extent to which value of

information conforms to normative predictions, and an fMRI experiment to investigate neural representation of value of information. The experiments involved a series of gambles. Each gamble was consisted of two possible monetary outcomes, one gain and one loss, and their probability was (50%, 50%). Subjects chose whether to play each gamble. Next, we presented an additional piece of information for each gamble. When purchased, the information provided more precise prediction of outcomes by updating probability distribution, based on which subjects could choose whether to play the gamble. For example, the information could reveal that probability over outcomes was either (33%, 67%) or (67%, 33%), instead of (50%, 50%). We displayed potential probability distributions by the orientation of a partition line overlaid on a roulette wheel, and asked subjects to choose whether to buy the information at some monetary cost. Behaviorally elicited value of information was largely consistent with normative predictions; value of information was larger when more precise prediction were supplied, and when potential outcomes were larger. Critically, when the information would not change probability, most subjects reported it as valueless. From fMRI, we found that activation in medial prefrontal cortex and striatum was correlated with value of information. We also found a number of regions which activation was correlated with expected value of gambles. Critically, these two types of representation were overlapped in medial prefrontal cortex. These results suggest that value of information, which depends on simulation of own choice, shares some neurocognitive processes with other types of valuation, consistent with the "common currency" hypothesis.

Title: Neuroanatomical correlates of economic rationality in aging - Testing GARP

Authors: *H.-K. CHUNG[1], A. TYMULA[3], P. GLIMCHER[2];
[1]Psychology, [2]Inst. for the Interdisciplinary Study of Decision Making, New York Univ., New York, NY; [3]Economic, Univ. of Sydney, Sydney, Australia

Abstract: The population of people above 65 years old is growing and work investigating their physical ability, cognitive function and decision making is of increasing importance. We previously (Tymula, et al., 2013) found that highly functional older adults are surprisingly likely to make fundamental choice errors in economic situations (more likely to violate "first-order stochastic dominance") compared with all younger subjects. The number of these errors increases even further as elders age. While such choices are clearly detrimental to older people's financial wellbeing, there is no biomarker for this "irrational performance" at the individual level, and insufficient evidence on the effects of neuroanatomical aging on decision making. In this study, we recruited healthy elders so as to relate the degree of error in their choice behavior to brain structure. We adopted the behavioral paradigm designed by Harbaugh and colleagues (2001) to estimate the number of violations of the generalized axiom of revealed preference (GARP) in each individual as a measure of these errors. In a typical choice from our design subjects chose one of two collections (bundles) of goods. For instance "2 boxes of milk and 3 pieces of chocolate" or "4 boxes of milk and 2 pieces of chocolate". Assessing many such choices, an economically rational agent must both obey transitivity prefer increasing amounts of any good to decreasing amounts of that same good (within reason). In sum, the task allows us to calculate the number and strength of violations of GARP to quantify the degree of irrationality in choice for each individual. We then relate this behavioral measure of economic irrationality to individual brain structure. Our goal is to use whole brain voxel based morphometry (VBM) analysis to determine where the gray matter volume correlates with the behavioral measure of irrationality in choice. In a recently published study we found that grey matter density in the posterior parietal cortex predicts risk attitudes with surprising accuracy. Our ex ante hypothesis is that thinning beneath some threshold in this area gives rise to economic irrationality. Our preliminary results indicate that the paradigm works well. Older subjects with what would be considered normal cognitive ability according to popular cognitive function scales, violate GARP at different rates allowing us to rank them based on the degree of economic irrationality in their choice. Ongoing imaging of 40 subjects should allow us to rapidly test our ex ante hypothesis.

Title: The diversity of distributed decisions

Authors: *M. E. WHEELER[1], E. J. PETERSON[2];
[1]Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]UCSD, San Diego, CA

Abstract: The integration of evidence over time is associated with accumulator signals in neural populations. Empirical and theoretical arguments suggest these accumulators act as general cortical computational mechanism, and therefore are a crucial component in decision making. Past work studying cortical responses in animals has focused on select frontal and parietal regions, showing that some neurons in these regions indeed behave similar to a formal drift diffusion model. However fMRI studies of evidence integration, which provide whole-brain measures of blood-oxygen-level-dependent (BOLD) signal, indicate that accumulation signals are widespread. These same fMRI studies also show that there are a variety of BOLD response profiles that appear to predict reaction time but do not take on the characteristic accumulator shape, defined here as a reaction-time-dependent ramping of activation as sensory evidence arrives and ceasing just prior to the commitment to a choice. The diversity of apparent reaction time predictive signals motivated this MVPA reanalysis of 5 fMRI studies spanning more than 80 participants. We report here our efforts to use the BOLD signal to predict reaction time. The two key results are, (1) while reaction time predictive signals are widespread in human cortex, the regions that are most predictive are highly task dependent and, (2) while accumulator-shaped time courses are important predictors of human behavior, many of the strongest signals took on a range of other profiles. Although direct neuronal recordings are needed to fully confirm our results, we conclude that the neural correlates of human evidential decision making are highly diverse, distributed, and task dependent.

Title: Dorsal anterior cingulate and ventromedial prefrontal cortex have inverse roles in both foraging and economic choice

Authors: *A. SHENHAV, M. A. STRACCIA, J. D. COHEN, M. M. BOTVINICK; Princeton Neurosci. Institute, Princeton Univ., Princeton, NJ

Abstract: Research has grown increasingly interested in contrasting sequential foraging choices and economic choices between simultaneously presented options. Kolling et al. (2012, Science) [KBMR] proposed that these choice types are subserved by different circuits, with dorsal anterior cingulate (dACC) vs. ventromedial prefrontal cortex (vmPFC) driving foraging vs. economic choice. To support this account, they scanned human subjects while making a foraging choice between exploiting a current offer or swapping for potentially better rewards (Stage 1 of a trial [S1]) or an economic choice between two reward-probability pairs (S2). KBMR found different roles for dACC and vmPFC during the two task stages: in S1 dACC primarily tracked the relative value of foraging (RVF), and vmPFC the value of exploiting (especially when choosing to exploit); in S2 dACC tracked the relative similarity of chosen and unchosen values and vmPFC tracked their relative difference. We recently showed that dACC's role in S1 choices is better described by the difficulty of choosing (i.e., value similarity) than by RVF when correcting for choice biases and testing a sufficiently broad set of RVFs (Shenhav et al., 2014, Nat Neuro). Here we attempt to rule out a third possibility, that dACC tracks both choice difficulty and RVF. In doing so we address concerns about our study design that may have reduced sensitivity to an RVF effect (over and above a difficulty effect), in particular our use of (a) primarily numeric stimuli, (b) a free response paradigm (rather than an enforced delay to response), and (c) a moderate sample size (N=14). We further test an additional hypothesis regarding vmPFC: that its previously reported role in foraging may also be identical to its role in economic choice, and inverse to that of dACC. Specifically, we hypothesize that this region of vmPFC tracked the relative ease of choosing between the options presented. We scanned 31 subjects while they performed KBMR's task, including a response delay but using a wide range of RVFs and playing cards as reward-related stimuli. Replicating our previous findings, we find that dACC activity during both task stages is similarly well described by choice difficulty, and find no evidence of an RVF effect over and above this. Conversely, we find an inverse pattern in vmPFC, whereby activity during both task stages is associated with the ease of the current choice. The latter finding may reflect a value signal associated with choice ease, relative chosen value, or simply greater time off task prior to the response cue. Nevertheless, these findings further argue against the theory that foraging and economic choice are subserved by separate neural circuits.

Title: Neural mechanisms of demand avoidance

Authors: *C. Z. SAYALI, B. CIULLO, D. BADRE;
CLPS, Brown Univ., Providence, RI

Abstract: When people are presented with two options of cognitive labor that differ in the level of effort they require, they choose the less demanding task. It has been observed that increased cognitive effort is associated with decreased responses in reward circuits but increased activity in areas related to cognitive control. Thus, it has been suggested that demand avoidance is a result of disutility associated with cognitive effort, and what makes a task more effortful is the presence of response conflict. However, these studies adopted categorical designs that rely on a subtractive approach which limits sensitivity to detect the shape of the behavioral and neural response functions. Therefore, the current study parametrically modulated the level of difficulty within a demand selection paradigm. Further, we separated choice from execution phases which allowed us to separate parametric responses driving decisions about what course of cognitive effort to take versus those related to execution of an effortful task itself. We hypothesize that what causes demand avoidance is the conflict associated with choosing the more effortful task. Therefore, we predict to see parametric changes in areas of medial prefrontal cortex related to conflict monitoring during the execution phase. Further, these responses should be related to decreases in ventral prefrontal and striatal reward systems during the choice phase. During the first phase of the experiment, participants performed multiple runs of 13 trials that varied according to six levels of difficulty which were modulated by the frequency of task-switching. Prior to each run of a given difficulty level, participants saw a symbolic cue that they selected to begin the run. In this way, each difficulty level came to be associated with a unique cue. In the second phase, participants were forced to choose which of two runs they wanted to perform by selecting between two associated symbols. They then complete the associated run of trials with the selected difficulty. The behavioral results have shown that participants consistently choose the easier task. The proportion of selecting the easier task increases linearly with increasing levels of difficulty difference between tasks. Also, selecting the more difficult task yields slower response times, indicating that choosing the more difficult task typically reflects a harder decision. Preliminary fMRI results show that MPFC tracks changes in selected difficulty. During

the execution phase, difficulty is tracked by a fronto-parietal network related to cognitive control.

Title: Risky decision-making in college smokers

Authors: *J. S. RODEFER;
Psychology, Valdosta State Univ., Valdosta, GA

Abstract: Cigarette smoking and tobacco-related illnesses result in approximately five million deaths around the world each year, with smoking being responsible for more almost one-half million deaths (approximately 20% of total) in the United States each year. Previously published research has suggested that smokers display poorer self-control as compared to non-smokers, and self-control training experience has been associated with greater success rates in smoking cessation. Yet, some data suggest that robust and reliable differences in risk-taking behavior do not exist between groups of smokers and non-smokers. The Iowa Gambling Task (IGT) is a computerized decision-making task that employs individual decks of cards that have different rewards and costs associated with each individual deck (A, B, C, D), and has been used with both clinical and non-clinical populations. One possible explanation for these data is that the association between smoking and risky decision-making may be related to the ability to delay gratification and resist temptation. Thus, a main goal of these experiments was to evaluate the hypothesis that magnitude of smoking deprivation contributed to risky decision-making. The present experiments examined both pattern of risky decision-making performance and specific deck selection in undergraduate smokers and non-smokers that were recruited from a university setting. Smokers were asked to either abstain or not abstain from smoking overnight before coming into the laboratory the following day. Adherence to abstinence request was ascertained by measuring CO levels in exhaled breaths. The risky decision-making performance was divided

into early learning (trials 1-40; learning) and later performance (trials 41-100; performance) blocks of trials for each of the individual decks. Individuals who successfully abstained from smoking overnight chose more frequently from riskier decks during the later blocks of trials. There was a general trend for increased choice from suboptimal desks in later trials. In contrast, smokers who did not abstain demonstrated an increased preference for decks representing optimal decision-making. When taken in sum, these data suggest that nicotine abstinence, as measured by CO levels, may contribute to risky decision making in the IGT.

Title: Episodic memories predict adaptive value-based decision-making

Authors: *L. E. HUNTER[1], O. FELDMANHALL[1], V. MURTY[1], L. DAVACHI[1,2], E. A. PHELPS[1,2,3];

Abstract: Prior research illustrates that memory can guide value-based decision-making. For example, during reinforcement learning, the value associated with an option is incrementally learned across multiple exposures, suggesting that memories guide stimulus response learning. However, other types of memories, such as episodic recollections, may also contribute to value-based decision-making. Using a novel behavioral paradigm, here we test to what extent value based decision-making is influenced by episodic recollections for past rewarding experiences (i.e. stimulus-reward associations). Participants completed a task where they first learned the value associated with lotteries. After a short delay, they completed a decision-making task in which they choose whether they wanted to re-engage with previously encountered lotteries. Finally, participants completed a surprise memory test for the lotteries and their associated values. Results indicate that participants chose to re-engage more often with lotteries that resulted in high versus low rewards. This type of adaptive decision-making is only seen when individuals have contextually embedded memories for the reward values associated with

individual lotteries, suggesting that adaptive decision-making is associated with detailed, episodic recollections of prior experiences. Further, we find that this reliance on episodic memory for adaptive decision-making generalizes to more complex, ecologically valid choice behavior, such as social decision-making. These findings provide an important integration of declarative memory and decision-making literatures to better understand key mechanisms supporting adaptive behavior.

Title: Market experience attenuates the endowment effect through modulation of anterior insula: A training study

Authors: *L. TONG[1], K. J. YE[2], H. C. NUSBAUM[1], A. HORTACSU[2];
[1]Dept. of Psychology, [2]Dept. of Econ., The Univ. of Chicago, Chicago, IL

Abstract: Consumers ask a greater price for goods that they own than they are willing to pay for otherwise identical goods, a phenomenon known as the endowment effect. Previous fMRI research indicates that lower insula activity during selling is related to a reduced endowment effect in experienced compared to inexperienced traders. The present study extends this research by experimentally manipulating market experience. Inexperienced traders (n=13) made trading decisions while undergoing fMRI before and after the treatment of short-term selling experience. In a pretest session prior to market experience, and in a posttest session after the market experience treatment, participants made a series of decisions to buy or sell products at high and low prices during neuroimaging. Between the two scanner sessions, participants were given incentives to trade consumer goods on eBay over the course of two months. Trading experience reduced both the endowment effect behaviorally ($p<0.05$), and right anterior insula activation when presented with lowball offers during selling ($p<0.05$). Moreover, insula activity during low selling offers positively predicted the endowment effect, and partially mediated the effect of trading experience on the endowment effect. These results provide causal evidence that selling

experience reduces the salience of selling at a loss, consistent with behavioral evidence that market experience attenuates economic biases.

Title: The effects of incentive valence on instrumental performance

Authors: ***J. GALARO**, P. CELNIK, V. S. CHIB;
Johns Hopkins Univ., Baltimore, MD

Abstract: Incentive mechanisms reward favorable performance and punish unsuccessful performance. In this experiment we examined how prospective monetary gains and losses influence both motor cortical excitability and instrumental performance. During the experiment participants were presented with possible gains or losses of different magnitudes, where payout was contingent on successful performance of a motor reaction task involving a simple, visually cued movement of the finger. Behavioral heuristics (e.g. reaction time) were computed to measure performance vigor. Our behavioral results indicated that participants exhibited increased vigor for increased reward magnitude in both the gain and the loss domain. Moreover, we found a more pronounced increase in vigor metrics for losses as compared to gains, which was related to participants' differential subjective valuation of gains compared to losses (i.e. individuals' loss aversion). Further analyses will examine the relationship between motor cortical excitability and reaction time and subjective preferences for incentive. Specifically we will test if motor cortical excitability mediates relationships between individuals' subjective preferences for incentives and resulting motor performance and vigor.

Title: Why do we take so long when faced with two good options?

Authors: *J. DRUGOWITSCH, S. TAJIMA, A. POUGET;
Dept. of Basic Neurosciences, Univ. of Geneva, Geneva, Switzerland

Abstract: In every-day ambiguous and noisy environments, decision-making requires the accumulation of evidence over time. In perceptual decision-making tasks (e.g., discriminating a motion direction), choices and reaction times are well-fitted by drift diffusion models (DDMs). These models represent the accumulated belief about the difference in sensory evidence as the location of a diffusing particle that triggers a decision once it reaches one of two decision boundaries. Recently, DDMs have been shown to also fit human behavior in value-based decisions, where subject compares the endogenous values of possible options (e.g., deciding between two lunch options). In this case, the DDMs only represent the difference in values, such that they predict behavior that is insensitive to the absolute values of the compared options. This is counterintuitive because, intuitively, choosing between two highly-rewarded options will yield high rewards for either choice, such that these choices should be made more quickly to save time and effort. To resolve this conundrum, we sought for the theoretically optimal strategy to maximize the reward rate per unit time in such value-based decision paradigms. Using dynamic programing, we found that this optimal strategy indeed reduces for simple, but realistic, scenarios to a particular class of DDMs that feature “collapsing boundaries”. That is, the distance between the decision boundaries shrinks over time, thus urging a decision. Interestingly, the speed of boundary collapsing is greatly modulated by the a-priori reward distribution. If the two options are highly rewarded on average, the boundary should collapse more rapidly. This collapse ensure that average reaction times depend on the absolute values even if decisions within individual trial are only guided by the relative value between options. Moreover, the speed of the boundary collapse for value-based decision tends to be larger than the ones that is optimal for standard perceptual decision tasks in which subjects try to maximize the number of correct answers. These results clarify the difference between value-based and perceptual decisions, and may reconcile the ongoing debate on when subject should have collapsing boundary in decision-making.

Title: Value-based biasing of decision variable dynamics under speed pressure

Authors: K. AFACAN[1], A. BLANGERO[2], *S. KELLY[3];
[1]Biomed. Engin., The City Col. of New York, New York, NY; [2]Oxford Univ., Oxford, United Kingdom; [3]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland

Abstract: Sensory-instructed behaviors are biased in favor of actions that are more valuable than the alternatives. Under situations of intense speed pressure where the time available to act is short with respect to the timeframe over which sensory selectivity grows to a level sufficient for accurate perception, such biases become central to adaptive strategies for reward maximization. Cognitive modeling work based on the principle of sequential sampling provides a natural account of how such prioritization takes place: a "decision variable," which diffuses between two alternative decision bounds with a drift tendency governed by sensory evidence, is started closer to the more valuable bound. In this project we provide behavioral and neural evidence for a distinct mechanism of prioritization, whereby the decision variable is not just started closer to, but initially, actively launched toward, the more valuable decision bound, and is then dynamically re-routed by the incoming, discriminatory sensory information. In our task, subjects manually reported on a two-alternative fixation color change using their left and right hands within a very strict deadline, with more points rewarded for correct discrimination of one color than the other. A model in which drift rate was subject to the additive influence of linearly-growing sensory evidence and a constant value-based bias provided a closer fit to reaction time data than more typical starting-point bias or constant drift rate models. Further, lateralized motor preparation signals in the human event-related potential exhibited a characteristic "turn-around" in trajectory for slow, correct, low-value actions as predicted by the model. Ongoing analyses are being conducted to explore inter-individual differences and potential mixed strategies that combine starting point and drift biases.

Title: Investigating cortical networks to characterize neural dynamics of reward based decision making

Authors: *H. COURELLIS[1,2], J. IVERSEN[2], D. PETERSON[3], H. POIZNER[3], G. CAUWENBERGHS[1,3];
[1]Bioengineering, [2]Swartz Ctr. for Computat. Neurosci., [3]Inst. for Neural Computation, UCSD, La Jolla, CA

Abstract: Reward based decision making is a complex process that requires the participation of both cortical and subcortical networks and involves dopaminergic neurons in the basal ganglia connecting to structures in the frontal lobe to drive higher level decision making processes. To investigate cortical networks associated with reward based decision making, we analyzed the EEG of individuals performing a reward based decision task, identified Regions Of Interest [ROIs] (and their corresponding anatomical structures), and examined causal relations among them. 64 channel EEG was collected by Peterson et al. (Neuroscience 163 (2009) 1092-1101) from 11 healthy individuals of ages of 58-72, while they performed a task that tested their ability to make reward based decisions. Between two images on a screen, they selected the image that would give them more money using their knowledge from previous decisions. First the reward based decision making cortical network of a single participant was investigated. The individual's EEG data were analyzed employing Independent Component Analysis and subsequent identification of causal interactions among the resulting Independent Components (ICs). A functional decision making network was identified, linking the visual, anterior cingulate, and motor cortices in a manner consistent with the requirements of the image selection task performed by the participant: visualizing the images, making a decision, and reaching to select the chosen image. Subsequently, EEG data from all 11 participants were analyzed and generalized ROIs were identified, populated by clusters of ICs drawn from the group's EEG data. IC clustering features, which included scalp maps, Event Related Potentials (ERPs), Event Related Spectral Perturbation, Inter-Trial Coherence, power spectra, and dipole locations were preprocessed using principle component analysis. A competitive layer neural network was employed to perform the clustering that resulted in 12 IC clusters. Average ERPs for each resultant cluster and cluster tightness were used to identify ROIs and their correspondence to

anatomical structures potentially relevant to the decision making network was identified. The main structures of interest were the Anterior Cingulate, Orbitofrontal, Prefrontal cortices, and the Inferior Frontal Gyrus, all of which have been associated with the activity of decision making networks. Activity in these ROI's is determined through anatomically constrained low resolution electromagnetic tomography, generating source activations in the same locations for all participants, thus allowing for causal connections between these ROI's to be evaluated.

Title: Value aftereffects: evidence for dynamic adaptation in the valuation process of human subjects

Authors: *M. KHAW, P. W. GLIMCHER, K. LOUIE;
Neural Sci., New York Univ., New York, NY

Abstract: While standard theoretical frameworks for decision-making assume stable and unchanging preferences, empirical observations of context-dependent choice behavior suggests a relative process of valuation. Recent evidence points towards a flexible and adaptive value coding in neural systems, scaling to the range of recent rewards (Padoa-Schioppa, 2008) or the value of alternative offers (Louie et al., 2011). Context effects driven by aspects of the current choice set are well-characterized by value normalization (Louie et al, 2013); however, whether analogous temporal value context effects exist in human behavior is unknown. Here, we investigate bidding behavior with a value-based adaptation manipulation. In sensory processing, classic adaptation paradigms elicit history-dependent changes in perception. For instance, prolonged viewing of curved lines biases subsequent judgments of concavity, and prolonged viewing of visual motion produces an opposite motion aftereffect in subsequent static stimuli (the waterfall illusion). Analogous to visual aftereffects, we hypothesize that subjective valuations *shift* after prolonged exposure of the subject to different value quantities. The experimental protocol consisted of two adaptation blocks interspersed between three test auction

blocks. 44 adults (24 female, mean age = 23.43 years) participated. During bidding blocks, subjects were asked to declare a willingness-to-pay (WTP) for snack items via an incentive-compatible Becker, Degroot & Marschack auction. During adaptation blocks, subjects were asked to evaluate repeatedly (300 trials per block) the pleasantness of either high- or low-value snack items (as determined from the first bidding block). Consistent with a temporal form of value normalization, we find that bids following a history of high-value adaption are lower on average than bids following low-value adaptation. The bids themselves exhibit a regression toward the mean from the very first block as trials elapse. A linear regression of bid deviations on past bid values reveals a significant positive effect of the last immediate bid. In contrast, there is a significant negative effect of a longer-running aggregate of past values. These relationships also appear to vary over time, with the negative effect of a long-running average being strongest at the start of bidding blocks, and vice versa for the effect of immediately past bids. Our results indicate that the subjective valuation of goods - much like perceptual judgments - is dynamically affected by the recent history of experiences. Thus, adaptation may be a general phenomenon across both sensory and valuation domains.

Title: The representational space of value-based decisions during model-based and model-free reinforcement learning

Authors: *M. N. HEBART, G. E. WIMMER, J. GLÄSCHER;
Dept. of Systems Neurosci., Hamburg, Germany

Abstract: A major line of research in decision neuroscience is aimed at characterizing the computational and neural principles of the learning systems that underlie human and animal choice behavior. Previous seminal studies have focused on identifying model-derived neural computations of model-based learning (Gläscher et al., 2010, Daw et al, 2011) and have demonstrated the existence of an efficient neuronal algorithm for learning state transitions in complex environments. What remains unknown is the exact neural representation of these

complex state spaces that are shaped by such computations. Here we suggest that probabilistic state spaces can be characterized in terms of representational distance, which enables humans to choose the action that is representationally the closest to the desired state. To investigate this principle, we devised a modified version of the popular two-step task (Daw et al., 2011), varying transition probabilities between initial and terminal states and reward values of terminal states. Bayesian model comparison revealed that participants' behavior could be best explained by hybrid model-based and model-free learning with eligibility traces and a persistence parameter biasing softmax action selection. Using multivariate pattern decoding, we identified representations of states in visual cortex as well as other cortical brain areas. Building up on these findings, we used pattern-component modeling (Diedrichsen et al., 2011) - an extension of representational similarity analysis - to deconstruct the representational similarity between initial and terminal states into components of (1) state transition probability, (2) expected reward value, and (3) their interaction. Our results demonstrate separable representations of each of these components in the human brain, suggesting that humans may base their model-based choices on an integrated representation of state-state and action-state similarity. Our approach provides a first step in identifying the neural foundation of complex state representation and the forces that shape them.

Title: Neural mechanisms supporting persistent maladaptive food choices

Authors: ***K. E. FOERDE**[1], J. STEINGLASS[2,3], D. SHOHAMY[4], B. T. WALSH[2,3];
[1]Psychology, New York Univ., New York, NY; [2]Div. of Clin. Therapeut., New York State Psychiatric Inst., New York, NY; [3]Psychiatry, Columbia Univ. Med. Ctr., New York, NY; [4]Psychology and Kavli Inst. for Brain Sci., Columbia Univ., New York, NY

Abstract: People routinely make poor choices, to the detriment of their health and well-being. Yet, despite knowledge of the negative consequences, maladaptive choices persist. Such behavior is particularly common in choices about which foods to eat, but the neural mechanisms that support persistently poor food choices and how they relate to everyday behavior are unknown. We examined these issues in individuals with Anorexia Nervosa (AN), whose

persistent choice of low calorie foods poses a serious and sometimes fatal threat. Participants with AN were receiving treatment aimed at weight restoration to a medically healthy weight, and were tested within 24 of hours of hospitalization. We used functional magnetic resonance imaging (fMRI) to examine brain activity while individuals with AN and healthy controls made decisions about which foods to eat. The task comprised three phases. In the first two phases, participants rated the healthiness and the tastiness of high- and low-fat food items. Next, in the third phase, each participant was asked to make a series of choices between a reference item, randomly selected among items rated by the individual as neutral in both the health and taste rating phases, and each of the other foods. Participants were informed that, immediately following the task, they would be served one of their choices as a snack and were expected to consume it - creating a real-world contingency for their choices. This paradigm allowed an individual's ratings of food to determine the reference item, which was critical in comparing behavior of healthy controls with individuals with AN, as the two groups were expected to rate the health and tastiness values of food differently. To determine whether choice responses in the task were related to actual eating behavior, we compared responses on the food choice task with caloric intake in a lunch-time meal the next day in which participants were presented with a buffet-style array of foods and asked to eat whatever they wished. Food was weighed before and after and amount consumed in grams and kcal was calculated. Using fMRI, we found that the dorsal striatum was more strongly associated with food choices in AN relative to controls, whereas ventral striatal activity did not differ between groups. Moreover, fronto-striatal connectivity during the experiment predicted the amount of food consumed in a meal the next day. These findings demonstrate that activity in fronto-striatal brain circuits is related to the persistent restrictive intake seen in AN, and may relate to persistent maladaptive behavior more broadly.

Title: A systematic comparison of models of generosity

Authors: *C. DI TELLA, P. GLIMCHER, W. MA;
Ctr. for Neural Sci., NYU, New York, NY

Abstract: Objective: Decisions that affect other people's outcomes are a fundamental aspect of social behavior. In non-strategic contexts, such decision-making processes are formalized as models of "other-regarding preferences", which measure how much a person is willing to sacrifice to help or hurt others. Many models of other-regarding preferences have been proposed, but there has not been convincing evidence in favor of any particular one. Moreover, MRI studies of other-regarding preferences typically assume a model without justifying their choice. The goal of our project was to empirically identify the best model from amongst the leading models of other-regarding preferences, using optimal trial design and Bayesian model selection procedures. In addition, we assessed the effect of social distance on the parameters of the other-regarding preferences. Methods: We conducted two studies consisting of an incentive-compatible modified dictator game with two possible recipients, one a friend and one a stranger. Previous studies of generosity have handpicked trials believed to be informative about models or parameters. Here, we took a more systematic approach. In Study 1, we selected trials to maximize mutual information between the data and the model, i.e., our ability to determine which of three classes of models (Charness-Rabin, Cobb-Douglas and Rawlsian) best accounted for the behavior of our subjects. In Study 2, we selected trials to maximize mutual information between the data and the parameters within the best fitting model in our population. Results: Study 1: Several model comparison measures identified the Charness-Rabin model as by far the best descriptor for our population. The Charness-Rabin model posits a linear utility function, with a weight on the other's welfare that depends on whether the decision maker is better or worse off; the Fehr-Schmidt model is a subclass of Charness-Rabin. Study 2: This study revealed that, regardless of context (better or worse off), the weights placed on the welfare of a friend are higher than those placed on the welfare of a stranger. Moreover, the pattern of weights by context is markedly different for friends and strangers: subjects tend to display classical difference aversion with strangers, with negative weights when the subject is worse off, and positive weights only when better off. By contrast, the weights for friends tend to be always positive, albeit lower when worse off than when better off. We interpret these results as evidence of a tendency towards prosocial difference aversion when it comes to friends and antisocial difference aversion when it comes to strangers.

Title: Gender difference in the performance of cheater-detection in social exchange: an eye-tracker study

Authors: *M. WATABE[1], Y. UEDA[2], T. KATO[3], M. SHINADA[4], T. YAMAGISHI[5]; [1]Monash Univ., Bandar Sunway, Malaysia; [2]Kyoto Univ., Kyoto, Japan; [3]Kyushu Univ., Fukuoka, Japan; [4]Tokyo Gakugei Univ., Tokyo, Japan; [5]Hitotsubashi Univ., Tokyo, Japan

Abstract: Introduction: Cheater detection (CD) is a cognitive ability to find free-riders in social exchange. CD has been considered as one of the most essential abilities for humans to survive as social groups (Cosmides Cognition, 1989). Experimental studies have demonstrated the existence of this ability across cultures and ethnicities, but individual differences of this ability has been unexamined. Our previous research (Watabe et al., 2014) has suggested that the detection ability would differ between males and females. It revealed that male participants show higher detectability for male cheaters than female participants. In this study, we replicated this experiment with an eye-tracker system to investigate more detailed process of cheater detection performance. **Method:** We herein collected 18 male and 17 female university students' data and investigated how they detect cheaters by watching self-introduction video with cheaters and cooperators. Participants watched video streaming, a pair of same-sex persons (one is a cheater and the other is a cooperator) appeared simultaneously on the display, introducing themselves without audio for 30 seconds (Shinada et al. 2010). Then, participants were asked to detect which one is the cheater. They did this task for 36 pairs (18 male pairs and 18 female pairs). **Results:** The results show again that male participants show higher detectability for male cheaters than female participants. According to the analysis of the eye-tracking data, males who spent longer time to look at the cheater's face showed higher detectability, and female who spent longer time to look at the eyes of videotaped persons showed lower detectability. We also found that females who spent longer time to look at the mouth (and around) showed higher detectability. **Discussion:** The present results confirmed the previous findings of gender difference on CD performance. Also, the results of eye-tracking data suggest that males and females adopt different strategies for detecting cheaters. Males tend to look at the target's face overall whereas females tend to look at parts of the target's face. The female's detectability would depend on which part of the face she focus on.

Title: Mechanisms of decision making in criminal trials

Authors: J. R. LAW[1], J. A. G. SKENE[1], J. M. PARELMAN[4], D. H. BESKIND[2], N. VIDMAR[2], R. M. CARTER[5], J. M. PEARSON[3], *J. SKENE[1];

Abstract: During a criminal investigation and trial, decisions by police officers, prosecutors, judges, and jurors are governed by established procedures and rules. These procedures reflect well-accepted assumptions about how humans weigh evidence about the guilt or innocence of a defendant. However, research has shown that traditional models of decision-making cannot adequately account for the behaviors actually observed during complex cognitive tasks. Here, we demonstrate an experimental task that quantifies the effects on judgments of guilt of factors commonly seen in criminal prosecution. Using descriptions of crime scenarios that differ in evidentiary and potentially biasing content, we asked participants to rate the likelihood of guilt and the punishment deserved for each scenario. We targeted two populations, representing different participants in the legal system: potential jury members (assessed using MTurk participants) and legal professionals (assessed in a law student population). We then used a generalized linear mixed model to evaluate the effect of each type of evidence and each crime type on ratings of guilt and deserved punishment. Across populations, we found that the accumulation of evidence linking a defendant to a crime was the strongest determinant of confidence in guilt. DNA and other physical evidence had the largest effects, with a lower effect for eyewitness testimony. In contrast, prescribed punishment correlated strongly with the type of crime, but was minimally affected by the amount of evidence implicating the accused. Surprisingly, prior convictions for a related crime_conventionally viewed as strongly prejudicial for criminal defendants_had only a modest influence on judgments of guilt. While the results were similar for law students and MTurk participants, law students showed a significantly lower overall confidence in guilt and larger effects of physical evidence and witness testimony. Although the legal system seeks to determine guilt solely on the basis of evidence, we found that type of crime significantly influenced confidence in guilt, independent of evidence linking the defendant to the crime. This baseline confidence was positively correlated with subject ratings of the amount of punishment each crime deserved. Previous studies have shown that moral

judgments of deserved punishment may be mediated by a neural circuit that integrates perceived threat or harm to the victim with the intent of the perpetrator (theory of mind). Our results suggest that elements of this "punishment" circuitry can modulate processes involved in the rational evaluation of evidence directly implicating someone accused of a crime.

Title: The effect of testosterone on the Ultimatum Game: A single-dose administration study

Authors: *E. KOPSIDA, J. BERREBI, P. PETROVIC, M. INGVAR;
Clin. Neurosci., Karolinska Insitute, Stockholm, Sweden

Abstract: In recent years studies on the Ultimatum Game have successfully shown that human beings forfeit, under certain circumstances, the rule of profit maximisation and act contrary to their financial gain, by rejecting unfair offers. A possible explanation for this behaviour could be that unfair offers elicit negative emotions to the responders, who punish the unfair proposer by rejecting the offer. Neuroimaging studies have shown that unfair offers are associated with activity in insula, anterior cingulate cortex (ACC), dorsolateral prefrontal cortex (dlPFC), and amygdala. A potential role of testosterone on the Ultimatum Game has also been proposed, albeit with inconsistent findings. In the present study, we sought to further investigate the role of amygdala and testosterone on the Ultimatum Game, by conducting a double-blinded, single-administration study (N=68; 28 women). 60mg of Tostrex was administered to male and female healthy volunteers, three hours prior to undergoing an fMRI session, during which they played a standard version of the Ultimatum Game. This dose was sufficient to significantly increase participants' testosterone levels compared to placebo ($Z=-5.755$, $p=.000$). The behavioural analysis revealed a statistical trend, as participants in the testosterone group tended to accept a greater number of unfair offers than participants in the placebo group ($Z=-1.483$, $p=.138$), irrespectively of gender. The main contrast unfair>fair offers yielded activation in areas previously associated with the Ultimatum Game ($p<.05$, FWE). To test our primary hypothesis

that testosterone would increase amygdala activation in relation to unfair offers, the contrast unfair>fair offers was compared between groups. A non-significant trend towards greater bilateral amygdala activation on the testosterone group was observed (left: Z=1.86, p=.03, uncorrected; right: Z=1.79, p=.03, uncorrected). Furthermore, the testosterone group displayed a greater activation in the right dlPFC (Z=4.07, p=.000, uncorrected) than the placebo group. Finally, a non-significant trend towards higher left amygdala activation was shown for rejection of unfair offers compared to acceptance (Z=2.10, p=.018, uncorrected). The present study was the first to investigate the effect of testosterone on both genders using the same experimental protocol. The findings indicate that testosterone administration could be related to a greater acceptance of unfair offers, potentially by acting on the dlPFC.

Title: Making better decisions by predicting others' minds

Authors: ***N. MA**[1], N. HARASAWA[1], K. UENO[2], N. ICHINOHE[4], M. HARUNO[5], K. CHENG[3,2], H. NAKAHARA[1];

Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]The Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Osaka, Japan

Abstract: In everyday life, humans often not only predict what others decide but also use the predictions for making their own better decisions. It is so essential in social cognition and how they predict others are often examined, however, how the prediction is used for better decisions remains elusive and also, what the underlying neural mechanisms and computations are. To address this issue, we conducted human fMRI, devising a novel experimental paradigm, combined with computational modeling. The paradigm is composed of three tasks, building on value-based decision-making (choosing one of two options for maximizing their monetary rewards). In main task, the subject did value-based decisions for oneself, but each option's value

changes based on others' choices, so that the task required one to decide based on the prediction of others' decisions. Two control tasks examined each component in the main task; subject performed ordinary value-based decisions (self task) and also predicted others' decisions (other task). This setting allowed us to construct models of the two components and then build a non-parametric model to examine how they were combined for the choices in the main task. Using different models for different hypotheses, we had three findings in behavior (n = 24). First, we found that the subject's choice behavior is certainly modulated by their predictions of others' decisions. Second, they used the prediction in a particular way, that is, generating hypothetical sets of the subject's options based on the prediction, i.e., somewhat in a Bayesian way. Third, however, their behavior is further modulated by the attraction or interaction over the options between the hypothetical sets, leading to their actually suboptimal decisions. These results were further confirmed by computational models with free parameters which account for individual difference in decision-making. We are currently collecting and analyzing human fMRI data, using model-based analysis. Our preliminary results (n = 13) showed differential brain circuits for predicting the others (in other task) and using the prediction for better decisions (in main task). These findings together indicate the hierarchical mechanisms from predicting the others to making better self-decisions, using the predictions.

Inst. of Neuroscience, NCNP, Tokyo, Japan; [8]Ctr. for Information and Neural Networks, NICT, Osaka, Japan

Abstract: Human makes decisions guided by one's reward expectation, but also in social setting, adjusted frequently in favor for rewards to others. This nature leads to fundamental debates in the social sciences, such as altruism. A large literature exists on the debate, however, evidence is scarce for a perhaps simpler and basic question in neuroscience, that is, how the others' reward takes part in the process of one's own reward-based decision-making and what the neural mechanisms are, especially whether they are social-domain specific or non-specific. To address these issues, we combined human fMRI with computational modeling in reinforcement learning paradigm. Our experimental task is composed of three conditions (three types of trials.) In standard condition, the subjects performed ordinary value-based decisions between two options, each of which is associated with reward probability and magnitude. In other and bonus condition, extra reward to others and the self was attached to either option and it was always given when the option was chosen. In behavior, we found that others' reward influenced the choice behavior in the subjects' majority, although the influence is weaker than that by bonus in the same face amount. Using logistic regression in behavior, we quantified each value (standard, others', and bonus value) and decision value (final value difference between the options including extra values). Using the quantification, we analyzed BOLD signals for identifying neural correlates of each and decision values, and the processes to integrate others' value into decision value. First, the significant neural correlates of both others' and bonus values are found in the dorsomedial and dorsolateral prefrontal cortices (dm/dlPFC). But the correlate of only others' value is found in right temporoparietal junction (rTPJ). Decision value, and standard value difference, is found in the ventromedial prefrontal cortex (vmPFC). Second, by further analyses on others' value, we found that the right dlPFC and dmPFC activation is elevated particularly when the option with others' reward is chosen and not chosen, respectively, whereas the rTPJ activation does not distinguish the choices. Third, psychophysical interaction analysis indicated that the vmPFC activation is significantly correlated with those in rTPJ and right dlPFC when decision value involves others' reward. Taken together, these findings demonstrate neural pathways for encoding others' reward and using it for a final decision, in parallel to but also uniquely from that for processing bonus, or self-additional reward.

Title: Neural correlates of creative thinking

Authors: *K. UEDA[1], R. HIKICHI[1], M. NAKAO[1], T. NODA[2];
[1]Grad. Sch. of Engineering, The Univ. of Tokyo, Tokyo, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: Creative thinking is connected to various mental processes, including relaxation of mental constraints and activation of memory networks. In this study, we focus on analytical and verbal processes, especially the intuitive and nonverbal processes, involved in creative thinking, and clarify the underlying neural mechanisms. Eight healthy experimental participants underwent functional magnetic resonance imaging (fMRI) while they carried out creative thinking tasks requiring them to conceive creative ideas. Verbal- and image-recall tasks were also performed for comparison. A significant activation was observed in the left inferior frontal gyrus (BA44) during the verbal-recall compared with the image-recall task. In addition, a significant activation was observed in the superior occipital gyrus (BA19) during the image-recall compared with the verbal-recall task. On the other hand, a significant activation was observed in the left middle temporal gyrus, angular gyrus, precuneus, and lingual gyrus during creative thinking tasks compared with the verbal and image-recall tasks. Thus, our results clarify the relationship of verbal and nonverbal processes with creative thinking.

Title: Same costs cost different: the effect of prosociality on third-party punishment using feedback-related negativity

Authors: *Y. CHENG[1,2], C. QU[2];
[1]Dartmouth Col., Hanover, NH; [2]Sch. of Psychology, South China Normal Univ., Guangzhou, China

Abstract: While in dictator games a third party can give costly punishment to the dictator when confronted with unfair distribution, previous studies have found that inequality aversion and reciprocal altruism might account for this. However, little research has focused on people who are rarely inclined to give third-party punishment. Prosociality as an individual difference determines behavior in economic games and many real-life situations. This study investigates how prosociality (prosocial or individualist) influences third-party punishment. Event-related potential (ERP) was collected to explore the neural correlates of outcome evaluation on allocation offer. We used a behavioral task to identify people with different prosociality. Sixteen prosocials and sixteen individualists took part in the ERP experiment. In the adapted dictator game, Player A had an endowment of 100 points and would transfer 10 to Player B, who had no endowment. Participants, the third party, were endowed with 50 points, and had the option of punishing Player A with 5 or 15 points (the cost was decided by the computer) after the observation. Observing the distribution outcomes (90:10), participants could punish player A with two costs, which resulted in a fair distribution (50:50). For feedback-related negativity (FRN) analysis, we measured the average amplitude in the 250-350 ms time window for distribution feedback that was localized to frontalcentral electrodes (Fz, FCz, Cz). Behavioral results found that a lower cost caused more third-party punishments. Prosociality influenced third-party punishment: facing unfair offers, prosocials made more costly punishments than individualists. For prosocials, there was no obvious difference between their punishments at different cost levels. However, individualists' made more third-party punishments when costs were less. ERP results revealed that FRN was modulated by prosociality. For both prosocials and individualists, low costs elicited a significant larger FRN than high costs. On the same high cost condition, however, prosocials elicited larger FRN than individualists. Results were interpreted in terms of expectancy deviation theory: more negative amplitudes are presumed to be related to paying more attention to dictator's allocation and outcome. The current results suggest that high cost leads to less attention to dicator's allocation and outcome for individualists because they like to maximize the sum of resources for oneself, whereas both high and low cost do not decrease prosocials' attention to dictator's allocation and outcome because they prefer to maximize resources for oneself and others.

Title: Differences in people choosing cooperatively versus competitively during social dilemmas: an EEG spectral analysis

Authors: *A. J. WILSON[1], B. S. ROBINSON[2], N. J. A. WAN[2], K. E. JORDAN[2];
[1]Western Illinois Univ., Macomb, IL; [2]Psychology, Utah State Univ., Logan, UT

Abstract: The neural intricacies of cooperation between humans is limited. The Prisoner's Dilemma (PD) has been used to study behavioral differences in cooperation and competition for decades, but only a small amount of research has been produced about the neural correlates of cooperation and competition within the framework of PD. Furthermore, other social dilemma games, such as Snowdrift (SD), have also been studied from a behavioral standpoint, but far fewer studies have researched the neural differences between people within SD. In this study, we investigate the differences in choice between PD and SD and also between people who are behaviorally cooperative and behaviorally competitive within these games. Since SD is a less risky social dilemma game in comparison to PD, we expect to find differences between games in choice behavior and level of neural activation recorded by EEG. Furthermore, we expect to find neural differences between people who are cooperative than people who are competitive. We analyze activation in alpha (8-12Hz) and beta (12-24Hz) within our regions of interests (ROIs): the prefrontal cortex (PFC) and inferior parietal lobule (IPL). We found behavioral differences between PD and SD, where people cooperate more during SD (~50%) than for PD (~30%); we did not find differences in activation for choice between games for either alpha or beta, in either ROI. This suggests choice between social dilemma games are no different on a neural level -- or rather, we use the same amount of activation for any social dilemma game even though the scenario or the payoffs are different. We also found differences in beta PFC for people who are cooperative as opposed to people who are competitive. People who are cooperative elicit greater beta PFC activation when cooperating than when defecting whereas people who are competitive do not show this difference. This can be related to risk assessment during the riskier choice of cooperation and also taking into consideration the future outcomes of a partner's choice. Further investigation into how robust this particular beta PFC finding is across social dilemma games can reveal support for PFC as an area related to risk assessment in social situations or risky decision scenarios.

Title: Distinct neuronal bases involved in the proposer and responder condition of the ultimatum game

Authors: *S. K. HORAT[1], G. FAVRE[1], F. R. HERRMANN[2], P. MISSONNIER[1,3], M. C. G. MERLO[1];
[1]Univ. of Fribourg, Fribourg, Switzerland; [2]Univ. Hosp. of Geneva, Geneva, Switzerland; [3]Mental Hlth. Network Fribourg (RFSM), Marsens, Switzerland

Abstract: The behavior of humans in economic decision-making is well established in literature. The Ultimatum Game (UG) is a typical paradigm to investigate this issue. In this task, a "Proposer" has a certain sum of money at his disposal and has to propose a share to the "Responder", and the goal is to gain the maximum amount of money. The responder can either accept or reject this offer. If the responder accepts the proposal, the share is done accordingly whereas if he refuses, both players end up with nothing. However, the underlying cognitive processes are poorly studied yet. Therefore, we aimed to examine the neuronal bases of the proposer and responder condition performing event related potentials (ERP), independent component analysis (ICA) and source reconstruction. Two major ERP components, the P2 and feedback-related negativity (FRN) were observed in a time range of 150 to 400 ms after stimulus onset at medial electrode sites in both conditions. Although no significant differences were found for the FRN component, a significant shorter latency and increased amplitude of the P2 component for the proposer condition was observed. Moreover, ICA analysis showed a supplementary independent component activated in the P2 ERP time-range, modifying the P2 ERP morphology in proposer condition only. Additionally, the electrical source localization showed higher activity in the mid-frontal gyrus and anterior cingulate cortex for the proposer condition in the same time-range of the P2 ERP. Together, these results indicate an involvement of distinct neuronal bases at slightly different time points during decision-making suggesting that cognitive processes are engaged differently depending on the task condition although the goal is the same.

[3]Psychology, Univ. of Colorado, Boulder, CO

Abstract: Successful human interactions depend upon the interpretation of an agent's behaviors and intentions in order to support strategic control of behaviors and decisions. Interpreting others' actions requires many elements of social cognition, including more complex functions like theory of mind. Although there is some consistency in the neural substrates identified as supporting these functions (e.g. the medial-prefrontal cortex and temporal-parietal junction, TPJ), most tasks employ static or sequential interactions that do not allow investigation of differing levels of social-cognitive engagement on a short time scale. In this study, we adapted a dynamic, competitive game modeled on a simplified penalty kick, wherein humans (N = 29) controlled a ball, attempting to score against a human- or computer-controlled goalie, while measures of brain activation were obtained using functional magnetic resonance imaging (fMRI). This allowed us to quantitatively characterize subjects' strategic interactions with their opponent - and how these strategies change over short and longer time scales. K-means clustering on the difference between the y position of the subject-controlled ball and human-controlled goalie revealed that participant behavior reduced to two clusters, one pair representing early feints and misdirections (i.e., separation between participant and opponent near the start of the trial) and the other representing strategies intended to hide the kicker's intention for as long as possible (i.e., separation only at the end of the trial). These clusters - each further separable into pairs of upward or downward movements - correspond to distinct behavioral strategies. Play against a computer opponent served as a non-social baseline with similar strategic interactions. Using multivariate pattern analysis (MVPA), we examined whether local brain regions carried information that predicted trial features (e.g., opponent, outcome, strategy). Confirmatory analyses found that visual regions can be used to classify human from computer opponents at the time the opponent is revealed. MVPA of strategic interaction focused on the neural response differences between the two strategy-defined clusters. Using this dynamic task allows distinction of strategic elements of deception (e.g., timing of movement) from the conditions that elicit deception, the nature of the opponent, and the outcome of the action. The use of dynamic tasks facilitates the study of strategic social interaction on short timescales, opening avenues for causal studies of the supporting neural substrates.

Title: Functional connectivity reveals network abnormalities during explicit and implicit moral reasoning in psychopathy

Authors: *K. J. YODER, J. DECETY;
Univ. of Chicago, Chicago, IL

Abstract: Psychopathy is a strong risk factor for immoral behavior and is characterized by reduce empathy, remorse, guilt, and callous disregard for rights and welfare of others. It is also marked by abnormal attention which has downstream consequences on emotional processing. The current study used functional magnetic resonance imaging (fMRI) to examine the influence of task demands on moral evaluations in 88 incarcerated males (28 with Psychopathy Checklist-Revised (PCL-R) scores above 29). Participants viewed dynamic visual stimuli depicting interpersonal assistance and interpersonal harm in implicit and explicit moral reasoning tasks. In the first, psychopathy scores negatively predicted activity in striatum and dorsolateral prefrontal cortex, as well as functional connectivity seeded in right amygdala and right temporoparietal junction with anterior cingulate, anterior insula, striatum, and ventral prefrontal cortex. During the explicit task, psychopathy scores were negatively associated with response in anterior cingulate and amygdala. They also predicted decreased functional connectivity to striatum and temporal pole, but greater connectivity to dorsal anterior cingulate. These findings provide the first direct evidence for the role task demands play in the association between psychopathic traits and the salience network when viewing morally laden behaviors.

Title: Within-trial repetitive transcranial magnetic stimulation affects belief bias in conditional reasoning

Authors: *M. ROSER[1], J. S. T. EVANS[2], L. S. CARROLL[2], N. A. MCNAIR[3], G. FUGGETTA[4], A. KHARKO[2];
[1]Sch. of Psychology, [2]Plymouth Univ., Plymouth, United Kingdom; [3]The Univ. of Sydney, Sydney, Australia; [4]Univ. of Leicester, Leicester, United Kingdom

Abstract: Human reasoning is affected by numerous biases. When asked to decide on the logical validity of conditional (if-then) statements, many people exhibit a bias towards endorsing inferences drawn from believable statements as logically valid. This is known as belief bias and it is hypothesized to involve neural systems for working memory and inhibition. To investigate the neural sources of belief bias we used brief within-trial repetitive transcranial magnetic stimulation (rTMS), guided by neuronavigation, to transiently disrupt activity in frontal brain regions identified as active in a large functional magnetic resonance imaging (fMRI) experiment of belief bias in conditional reasoning. Group fMRI results were warped into individual-subject space to identify cortical targets. The inferior frontal gyri (IFG, associated with inhibition) and dorsolateral prefrontal cortex (DLPFC, associated with working memory) bilaterally, and vertex, were targeted with 500ms of stimulation at 10Hz and 80% of active motor threshold at two separate stages (major premise and minor premise) of trials in which participants were instructed to conclude on the logical validity of conditional statements. Logical validity was crossed with the (independently-rated) believability of conditional statements in a design which has been shown to reliably produce belief bias. The experiment was run in six blocks of 24 trials with each block corresponding to stimulation of a different cortical site, the order of which was randomised. At the stage of Major-premise presentation, at which believability of the statement can be assessed, rTMS over the IFG increased belief bias relative to a sham condition. Stimulation of DLPFC at this timepoint did not affect belief bias. At the later stage of Minor-premise presentation, at which premises can be integrated and logical reasoning is possible, rTMS over IFG and DLPFC had no effect upon belief bias. These results suggest that belief bias arises as a result of insufficient inhibition of beliefs based on real-world knowledge at an early stage of the reasoning process.

Title: Disgust sensitivity and pupillometric responses independently predict the effect of disgust stimuli on moral judgments

Authors: ***J. Z. LIM**[1], M. LEE[2], K. WONG[1], O. MULLETTE-GILLMAN[2,4,3];
[1]Neurosciences and Behavioral Disorders, Duke-Nus Grad. Med. Sch., Singapore, Singapore; [2]Psychology, [3]Singapore Inst. for Neurotechnology, Natl. Univ. of Singapore, Singapore, Singapore; [4]Neurosciences and Behavioral Disorders, Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: Disgust stimuli alter moral judgment, but it is unclear if this modulation is due solely to disgust, or if physiological arousal may underlie this effect. Recently we demonstrated that disgust modulation of moral judgments across different domains is a bi-directional function of individual disgust sensitivity (DS). Here, we test whether arousal plays a mediating role in this relationship using pupillometry as a measure of state arousal. Participants (N=39) underwent pupillometry while judging the moral acceptability of utilitarian harm in personal moral dilemmas. Before each scenario, a disgust or neutral facial expression was presented for gender discrimination. Participants completed the Disgust Sensitive Scale (Revised) and the Affect Intensity Measure (AIM), a measure of trait arousability. First, we replicated that disgust sensitivity determines the degree and direction of the change in moral judgment, with significance in a one-way ANCOVA of change in ratings across disgust and neutral conditions with DS as a covariate ($F_{1,37} = 4.34$, $p = .04$, partial eta-squared = .11). We then examined whether arousal, as measured by pupillometry, could account for this modulation of moral judgment. We focused on a window 2-4s after the onset of facial primes; where prior studies have shown emotional stimuli modulate pupil dilation. We averaged the pupillometric difference between disgust and neutral conditions as a measure of the manipulated change in state arousal,

and examined whether this change could account for the change in moral judgment. This was accomplished through a multiple regression with both this arousal factor and individual DS as predictors of change in moral judgment. Both arousal and DS independently influence changes in judgment (Model R-squared = .195; DS: ß = 0.36, t = 2.50, p = .02; Pupil size difference: ß = 0.36, t = 2.46, p = .02). Our results show that both state arousal and disgust independently modulate moral judgments, and that arousal does not mediate the relationship reported in our first bidirectional function. This finding demonstrates that moral decision-making is not only the interplay of reason and emotion (disgust, moderated by individual sensitivity), but that additional physiological factors also play a critical role.

Title: Choking under pressure due to high incentives as a change in state distinct from motivated performance

Authors: *T. G. LEE, D. A. BARANY, S. T. GRAFTON;
UC Santa Barbara, Santa Barbara, CA

Abstract: One of the paradoxes in human motivation is performance failure that is seen in situations involving relatively large rewards or high motivational states. One strategy for understanding why a high reward could lead to performance failure (i.e. “choking under pressure”) is by mapping the underlying neural systems that are recruited during high pressure conditions. Using functional magnetic resonance imaging (fMRI), we recently found that activity in the dorsolateral prefrontal cortex and its functional connectivity with motor cortex is involved in modulating the extent to which participants choke under pressure during high incentive trials in a bimanual motor task. However it still remains an open question whether performance vulnerability under high incentive is due to a qualitatively separate “choking state” or is an effect

of a motor system that is 'overdosed' with too much arousal or other influence but otherwise functions the same as in low pressure states. By using a multi-voxel pattern analysis technique, we examined whether patterns of BOLD activity that are predictive of performance during a pre-movement preparatory period are similar across three different levels of incentive. Our results show that, across several brain regions including frontal and motor cortex, the activity patterns that lead to successful performance are similar at both low and medium levels of incentivized performance. In contrast, these patterns of activity fail to generalize in predicting performance at the highest level of incentive. This suggests that it is unlikely that choking under pressure simply reflects the higher end of a continuum of incentivized performance, but rather that performance vulnerability is due to a maladaptive state that is qualitatively distinct from usual performance situations.

Title: Predicting the preferences of others relies on self- and other-related prediction errors

Authors: *G. ROSENBLAU[1], C. KORN[2], B. VANDER WYK[1], K. PELPHREY[1];
[1]Yale Univ., New Haven, CT; [2]Dept. of Psychiatry, Psychotherapy, and Psychosomatics; Univ. of Zurich, Zurich, Switzerland

Abstract: Many of our efforts in social interactions are dedicated to optimizing our predictions of others' preferences, mental states, and behaviors, also referred to as Theory of Mind (ToM). Although much research has been devoted to identifying the neural implementation of ToM, it remains unclear how humans integrate self- and other-related information to predict others' preferences and how they optimize their predictions over time. Here, we utilize a novel preference task to investigate neural mechanisms involved in updating social predictions and learning from prediction errors. To ensure high ecological validity, the task involves real social feedback. Participants (N=21) are asked to predict the preferences of three different people for a number of items (food types, beauty products and leisure activities). They subsequently receive trial-by-trial feedback about the other's actual preference ratings. After completing the task,

participants rate their own preferences for the same items. On the single subject level, we modeled participant's trial-by-trial prediction errors (the absolute difference between participant's rating of the other person's preference and the person's actual preference rating) and the perceived self-other difference (the absolute difference between participant's ratings of their own preference versus that of the other person). Trial-by-trial computation of prediction errors and of perceived self-other differences was associated with activity in ventral and dorsal parts of the medial prefrontal cortex (MPFC). The computation of prediction errors versus perceived self-other differences elicited a stronger neural response in the dorsal part of the MPFC, superior temporal sulcus and in the ventral striatum. The opposite contrast yielded activity in the ventral MPFC and bilateral amygdala. We show that when participants infer another person's preferences, they encode the task-irrelevant difference between their own and the other person's preferences. Moreover, our results are in line with the notion of a dorsal-ventral functional gradient in the MPFC, distinguishing between other- versus self-relevant social processing. In a next step, we will apply computational learning models to delineate participants' individual social learning capacity by using past feedback to improve predictions for future items.

Title: The use of strategy during social dilemmas: an EEG spectral analysis

Authors: *N. J. A. WAN[1], B. S. ROBINSON[1], A. J. WILSON[2], K. E. JORDAN[1];
[1]Psychology, Utah State Univ., Logan, UT; [2]Psychology, Western Illinois Univ., Macomb, IL

Abstract: The neural intricacies of strategy-driven choice within humans remain largely unknown. Using The Prisoner's Dilemma (PD), three types of strategies emerge: tit-for-tat (TFT), win-stay-lose-switch (WSLS), and no strategy. These strategies are also applicable in other social dilemma games, such as Snowdrift (SD). In this study, we investigate the behavioral and neural differences between TFT, WSLS, and no strategy across two social dilemma games, PD and SD. We expect to find people with strategies will perform better than people without strategies, regardless of the game. Neurally, we expect to find people with strategies to have

differences in prefrontal cortex (PFC; related to decision making) and/or inferior parietal lobule (IPL; related to social perception) activation. Lastly, we expect to find neural differences between two strategies, TFT and WSLS: TFT is a more socially-oriented strategy and should have increases in IPL versus PFC activation, whereas WSLS is more economically-oriented and should have increases in PFC vs IPL activation. We use EEG and analyze neural activation for alpha (8-12Hz) and beta (12-24Hz). Our results indicate greater behavioral scores for people with strategies as opposed to people without strategies, as predicted. Those with strategies have increased alpha desynchrony in IPL, suggesting the use of a strategy requires more neural resources than using no strategy. Those without strategy had differing activations by choice, in that cooperation showed greater alpha desynchrony than defection. Activation by choice was not different when choosing with a strategy. This suggests that processing a choice is more efficient for people with strategies, since activation for switching between choices is not different, whereas people without strategies have markedly different activation patterns for cooperation and defection, creating a larger difference in neural activation when switching between choices. Differences within strategies are notably found in the fronto-parietal network, where people choosing with TFT have increased beta PFC activation for cooperation as opposed to defection, whereas people choosing with WSLS show the opposite. Both strategies activate beta IPL greater than those without strategies. This PFC difference may indicate a relationship between economical decision making and social decision making: TFT can be framed as a more social-centric strategy, with increased beta for cooperation possibly indicating a theory-of-mind-type of assessment; WSLS can be framed as a more economical-centric strategy, with increased beta for defecting possibly indicating a cost-benefit-type of assessment.

Title: Modeling social influence on human decision-making with reinforcement learning theory

Authors: *L. ZHANG, J. GLÄSCHER;
Inst. of Systems Neurosci., Univ. Med. Ctr. Hamburg Eppendorf, Hamburg, Germany

Abstract: Most human decision-making takes place in a social context which influences individual decisions. In addition to making choices according to the action-outcome association, humans tend to align themselves with others, even without any direct social interaction. A long tradition of economic and social psychological studies has demonstrated a robust effect of social influence and conformity on perceptual decision-making (Asch, 1951). However, little is known about how the human brain computes value-based decisions when social influence is present. To fill this gap, we developed a novel experimental paradigm that allows for real-time interaction between multiple players. In the present study, groups of five participants were asked to perform a probabilistic reversal learning task, in which the reward probability switched after a certain number of trials. Following their initial choice, they were also required to place a post-decision wager between 1 and 3 (i.e., 1, 2 or 3) affecting their final payoff. After each participant had seen the choices from other four co-players via intranet, they were able to adjust both their choice and wager. In the end, monetary reward was displayed depending on the reward probability, and participants' goal was to maximize their payoff. Behaviorally, we observe an increased switch probability of choices as a function of group coherence levels (i.e., 2:2, 3:1 or 4:0) when their initial choice was in inconsistent with the collective decision of the others and an increased change in post-decision wagering along the group coherence when the initial choice was in agreement with the others. Using reinforcement learning, we built two "social" variants, in which the other players' choices could influence the subject's 2nd choice, and two "non-social" variants, in which subjects' 2nd choices were not affected by others. We employed Bayesian hierarchical estimation to fit these models to the behavioral data and used the deviance information criterion for model selection. The social models outperformed the non-social models. Between the social models, a variant that updates interim expected values by the weighted group coherence prior to the 2nd choice outperformed another model, in which the individual cumulative reward history was taken into account. Comparing the coherence model's action probability with the actual choice probability revealed that this model indeed provides robust prediction. These preliminary findings suggest that participants parse social information simply in terms of number of players (dis)agreeing with their initial choice rather than maintaining individual models of the others' decision-making process.

Title: Astrocyte-neuronal lactate metabolism in memory formation during rat development

Authors: *E. CRUZ, A. TRAVAGLIA, C. M. ALBERINI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Previous studies from our laboratory demonstrated that hippocampal astrocyte-neuronal lactate shuttling is critical for the consolidation of inhibitory avoidance (IA) memory in adult rats. Because the mechanisms underlying memory formation varies across age, and the transport of lactate from blood into the brain is higher during development, here we investigated the astrocyte-neuronal lactate metabolic mechanisms during memory consolidation across development. Specifically, we have focused on two developmental ages, postnatal day 17 (PN17), when the rats rapidly forget hippocampal-dependent memories (a phenomenon known as infantile amnesia), and PN24, when they are able to form strong and long lasting memories comparable to those of adult rats. We compared both groups to adult rats. We found that the hippocampal expression of lactate dehydrogenase A (LDHA), the enzyme that converts pyruvate into lactate, was significantly increased in total hippocampal extracts of both PN17 and PN24 rats compared to adult rats (PN80). Furthermore, the levels of hippocampal monocarboxylate transporter 4 (MCT4), a lactate transporter selectively expressed in astrocytes, and of MCT2, which is selectively expressed in neurons, were significantly lower in the synaptoneurosomal fraction of the P17 group compared to that of P24 and P80 rats. No differences were observed between the expression of the MCTs in P24 and P80. Furthermore, preliminary findings show that hippocampal infusions of the inhibitor of glycogen phosphorylase and synthase activity 1,4-dideoxy-,4-imino-d-arabinitol (DAB) at P24 impaired long-term memory, similar to the findings previously reported in adult rats. This data suggest that hippocampal lactate metabolism is developmentally regulated. This project was funded by NIMH R01 MH100822 to CMA

Title: High fat diets negatively impact female rodent learning and memory early in development and is counteracted by enriched environments

Authors: *I. C. SUMAYA, A. K. SUTER, S. HUSSAIN, N. RAMIREZ, C. DAWSON, S. MOMI, S. WILLIAMS;
Psychology - 24 DDH, CSU, Bakersfield, Bakersfield, CA

Abstract: The positive impact that enriched environments have on laboratory rodents has been well documented. Namely, rats kept in enriched environments have consistently shown improvements in learning and memory paradigms. Because the underlying mechanism of action of learning improvements is thought to be hippocampal neurogenesis, important to our research are the emerging data showing a reduction in neurogenesis in rats fed a high fat diet (Biotard et al., 2012; Valladolid et al., 2010). In line with these results, previously, we found high fat diets to negatively impact learning memory in male rats and used enriched environments to ameliorate these effects (Sumaya et al., 2014). Because there have been reports showing a high fat diet effects neurogenesis differently in male and female rats, we wanted to investigate the effects of a high fat diet on learning and memory in females. As we have done previously with males, we first placed female rats in either standard cages or enriched environments at 2 months of age and then fed them either Regular Chow (11% fat) or a Western Diet (39% fat, 44% carbs, 17% protein kcal, Modified AIN-93G, Research Diets) for 55 days then measured errors in the 8-arm radial maze at 4, and 10 months of age. Errors in the 8-arm maze task (averaged over the 8 days: 1 trial per day) were significantly greater in the high-fat group having its most detrimental effects in the groups that were housed in standard cages at 4 months of age (High Fat: 7.80±1.07 errors vs. Regular Chow: 3.13±0.63 errors). However, at 10 months of age, rats kept in standard cages and fed a high fat diet did not differ on learning errors as compared to their controls on regular chow. And, regardless of diet and age, the rats housed in enriched environments showed the least amount of errors at all testing points (Standard Chow at 4 months: 3.13±0.63 errors; 10 months: 1.44±0.41 errors) (High Fat at 4 months: 4.80±0.62 errors; 10 months: 2.20±0.50 errors). These data provide first time evidence that 1) increases in fat intake contributes to deficits in female rodent learning and memory at the early developmental stages, and 2) enriched environments can counteract the negative effects of a high fat diet on female rodent learning and memory.

Title: Effects of enriched environment in persistence of social memory

Authors: *L. F. JAIMES, A. R. P. CAIXETA, A. F. S. ALMEIDA, G. S. PEREIRA;
Federal Univ. Minas Gerais, Belo Horizonte, Brazil

Abstract: Introduction: The enriched environment (EE) increase neurogenesis and improve performance of mice in many memories. Social memory is a capacity to recognize to co-specific and is crucial for reproduction, territorial defense and establishment of hierarchies in natural contexts. Previous studies in our laboratory demonstrated that 7 days of enrichment before training produce 10 days of persistence in social memory. However, other investigations proved that, after consolidation, neurogenesis induce by enrichment and pharmacological agents promotes forgetting in adult and young mice in a model of contextual fear. So our aim is determine effects of EE after a consolidation in a persistence of social recognition memory. Methods: Training session (TR) the Swiss juvenile male mice were used as intruder and were presented to the resident subject (with 30 minutes of habituation in the cage) inside a transparent acrylic cylinder during five minutes. The test session (TT) consisted in reintroducing the intruder juvenile mouse ten days after training to evaluate memory persistence. Adult male Swiss mice (8- to 12-weeks old) and juvenile male Swiss mice (25- to 30-days old) were maintained in two types of conditions with control of temperature and handling. Standard-housed (SH) consist in groups of five in a standard plastic cage. Enriched environment (EE) consist in groups of five in a larger plastic cage containing one plastic shelter, two cardboard rolls, three toys, and ribbons with distinct textures. Animals were divided into four experimental groups: EE+SH (7 days EE + TR + 10 days SH + TT), EE+EE (7 days EE + TR + 3 day SH + 7 days EE+ TT), SH+EE (7 days SH + TR+ 3 days SH+ 7 days EE+TT) and SH+SH (7 days SH+TR+ 10 days SH +TT). The social recognition index and social investigation time were analyzed by ANOVA and T-test when appropriated. Results: The groups with EE 7 days before training have persistence of social memory, so EE+EE (0.38±0.03) and EE+SH (0.36±0.03) remember the intruder, $p<0.05$. However, the EE after TT did not change the behavior of the animal on the task, then SH+EE (0.48±0.04) group did not remember the juvenile. Moreover, EE+EE did not show a statistical difference with EE+SH. Conclusions: This study could reproduce that 7 day of EE are enough to produce 10 day of social memory. However, EE after consolidation of social memory did not show influence in the remembering. Finnacial Support: CAPES, CNPq and FAPEMIG.

Title: Age curve for memory expression: adult rats perform better than juvenile and middle-aged animals in the precision of fear conditioning context discrimination, Morris water maze and object location

Authors: ***A. P. CRESTANI**[1], L. DE OLIVEIRA ALVARES[2], J. HAUBRICH[2], F. SANTANA[2], R. O. SIERRA[2], J. QUILLFELDT[2];
[1]Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil; [2]Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil

Abstract: The present study aims to investigate the performance of rats at three different ages in different types of memory. Specifically, we evaluated the precision of context discrimination in a fear conditioning task, Morris water maze learning and object location retention in juvenile (pubertal), adult and middle-aged rats. Our results show that animals at the two ends of the age curve retrieve memory traces with lower precision compared to adult animals. In the fear conditioning, adult animals were able to discriminate between the conditioned and the novel context when tested at 2 or 14, but not at 28 days after training: this replicates the classical trace generalization - with precision loss - that is characteristic of systems consolidation. However, juvenile animals could not discriminate contexts earlier, at 14 days, and middle-aged ones have lost this ability only 2 days after training. A similar “inverted U-shape” age-performance curve was observed in two tasks of a different nature, Morris watermaze and object location, where only adult animals were able to express adequate long-term retention. The converging results of three different, hippocampus-dependent memory tasks, suggests that memory deficits may not be restricted to aging animals - a classically established phenomenon - but is also a temporary

condition during ontogeny. To this point, these findings cannot be interpreted in terms of putative mechanisms, but it is reasonable to suppose that the qualitatively poorer memory of juveniles is due to some degree of immaturity of the involved brain areas, such as the hippocampus; a different mechanism would take place in the senescent brains, despite the similar performance observed. To our notice, this is the first study investigating differences of memory precision exhibited at distinct ages that not only encompasses juvenile animals in the full behavioral screening, but also found a deficit that is similar, but probably not related to the classical one observed in aging animals.

Title: Assessing the development of spatial memory consolidation in juvenile and adolescent rats

Authors: *N. TZAKIS, N. GILL, T. BOSNIC, M. R. HOLAHAN;
Carleton Univ., Ottawa, ON, Canada

Abstract: The neural mechanisms by which environmental stimuli are consolidated and stored as stable, long-lasting memory representations in the brain remain elusive. Investigations into the neural structures that mediate memory processing, and the development of connectivity patterns within those structures, have provided the foundation required to gain insight into the memory consolidation process. An understanding of how memories are stored, consolidated and used during the juvenile period will provide the next step to answering the fundamental questions concerning the transference of short-term memories into remote stores. Therefore, the main objective of the current work was to gain insight into the development of memory consolidation capabilities by examining and comparing memory consolidation processes between two developmental time points (juvenile and adolescence) based on the expression of spatial memories acquired either recently or remotely. Juvenile (P18) and adolescent (P50) rats were trained on the Morris water maze for 3 consecutive days and then tested either recently (24 hours after training) or remotely (3 weeks after training). The labeling of c-Fos was used as a marker

for neuronal activation in the hippocampus to assess the contribution of this brain region in the expression of the recent and remote memories. The juvenile and adolescent rats that underwent the probe test 24 hours after being trained spent about the same amount of time in the target quadrant, while the juveniles that were tested remotely spent significantly less time in the target quadrant compared to the other groups. The adolescent rats that were tested remotely spent significantly more time in the target quadrant showing the best memory. Additionally, c-Fos activation was significantly higher in the CA3 region of the hippocampus of the adolescent rats that were tested remotely compared to the other groups. These findings suggest that the acquisition and retention of spatial memories in rats vary relative to the degree of neural development, and that the processes involved in memory consolidation become more pronounced as the rat ages.

Title: Differential consolidation of explicit and implicit memories under general anesthesia

Authors: *G. CHÁVEZ MARCHETTA[1,2], I. BALDERAS[2], C. J. RODRIGUEZ-ORTIZ[2], J. L. MCGAUGH[3], F. BERMUDEZ-RATTONI[2];

Abstract: Controversy exists whether memory formation can or cannot occur during anesthesia. In this work, we tested if different types of memory could be consolidated under general anesthesia. Pentobarbital was injected i.p. at a post-acquisition phase in rats in order to affect consolidation of different tasks; Morris water maze, Cued water maze, Object recognition, Conditioned taste aversion and Neophobic attenuation; each one related to different memory systems. We found that general anesthesia has different effects on memory consolidation; while implicit memory is consolidated, explicit memory is not. General anesthesia induced by

pentobarbital disrupted consolidation of Morris water maze, taste and object recognition memory and the extinction of conditioned taste aversion. However, memory consolidation for conditioned taste aversion and the cued Morris water maze was intact. These data indicate that pentobarbital disrupts the consolidation of explicit, but not implicit memories.

Title: Increased task demand during a spatial memory retention test recruits the anterior cingulate cortex

Authors: J. CARR, N. M. FOURNIER, *H. LEHMANN;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Spatial memory is believed to become increasingly dependent on the anterior cingulate cortex (ACC) over a protracted period. For instance, damaging the ACC in rats weeks after learning causes retrograde amnesia in the Morris Water Task, but the same damage just a few days after learning does not impair memory. Similarly, immediate early gene (IEG) expression in the ACC is greater for remote than recent spatial memories. These findings have been taken as evidence supporting systems consolidation, a process in which cortical structures, in this case the ACC, come to store memories that were initially dependent on the hippocampus. The recruitment of the ACC, however, can also be explained by an increase in cognitive demand when processing remote memories. This account does not imply a time-dependent storage progression, but a recruitment of the ACC because remote memories are more difficult to process. The current study tested this latter hypothesis by manipulating retention difficulty during a spatial memory test and assessing IEG expression in the ACC. Rats were trained in the hidden platform version of the Morris water task in a room rich in extra maze cues. The rats were then either tested for retention three days later in the same room with the same cue configuration

(Recent condition), three days later in the same room with prominent cues removed (Altered condition), or 30 days later in the same room with the same cue configuration (Remote condition). The intent with the cue removal in the Altered condition was to increase retention difficulty at time point that would have yet recruited the ACC because of systems consolidation. One hour after testing, the rats were euthanized, their brains sectioned, labelled for c-Fos, and quantified for c-Fos expression in the ACC using unbiased stereology. All three groups showed retention of the platform location during the test, but the performance was strongest in the Recent group. We also found, just like in other studies, that c-Fos expression in the ACC was significantly higher for the rats in the Remote condition than the Recent condition. Expression of c-Fos, however, was also significantly greater in the rats from the Altered condition than the Recent condition. Expression of c-Fos did not significantly differ between the Altered and Remote conditions. Thus, increasing cognitive demands and processing by reducing the number of cues available for retrieval during a recent memory test recruited the ACC similar to the extent of what is observed during remote memory testing. These findings do not preclude the involvement of the ACC in systems consolidation, but they provide evidence-based support for an alternative explanation.

Title: Single bout of resistance exercise improves hippocampal memory consolidation

Authors: *J. C. SOARES[1], J. FERNANDES[2], L. G. Z. BALIEGO[2], R. M. ARIDA[2];
[1]Psychobiology Dept., [2]Physiol. Dept., Univ. Federal de São Paulo, Sao Paulo, Brazil

Abstract: Over the past decade, several studies have indicated that chronic resistance exercise (i.e., strength training, weight lifting, etc.) is beneficial for brain health and cognitive function. Human findings have demonstrated that regular resistance exercise can counteract the age-

related decline in cognitive function, ameliorate signs of Parkinson's disease, decrease anxiety and alleviate depressive symptoms. Over the last years, there has been a growing interest in the effects of exercise on changes in cognition after a single bout of acute resistance exercise. The idea that a single bout of resistance exercise can activate the molecular machinery needed for memory consolidation remains to be explored. Therefore, the purpose of the present study was to examine the effects of a single bout of resistance exercise applied immediately after the training of contextual fear conditioning on the long-term memory and on the expression of IGF-1 and synaptic proteins in the hippocampus. Methods: Male Wistar were familiarized with climbing a ladder (1.1 X 0.18 m, 2-cm grid, 80° incline) without load for three days and randomly assigned into Sham and resistance exercise groups. The resistance exercise group were submitted to a maximal carrying capacity test and 72 hours later subjected to a single bout of resistance exercise applied immediately after the fear conditioning training. Subsequently, animals were tested for contextual (24h) and tone (48h) fear memory. Another group of animals was submitted to a single bout of resistance exercise and 24 hours later were euthanized and the hippocampus were dissected to western blot and ELISA analysis of expression of IGF-1 and synaptic proteins (synapsin I, synaptophysin and PSD-95), respectively. Results: Exercised rats improved contextual ($p<0.05$) but not tone fear memory. Hippocampal IGF-1 expression was not altered by RE. However, the levels of synapsin I, synaptophysin and PSD-95 increased significantly in the hippocampus of resistance exercise group ($p<0.05$). Conclusion: Our results suggest that a single bout of resistance exercise applied immediately after the contextual fear conditioning training can improve hippocampal memory consolidation probably through activation of synaptic machinery.

Title: Functional inactivation of hippocampus during memory consolidation of mixed choice task applied through the first learning trials is sufficient to suppress the use of hippocampal strategy for the subsequent trials

Authors: A. SERGEEVA[1], K. UZHCA[2], L. URPA[1], B. GROSS[1], *G. R. POE[3];
[1]Univ. of Michigan, Ann Arbor, MI; [2]New York Univ., New York, NY; [3]Dept Anesthesiol., Univ. Michigan, Ann Arbor, MI

Abstract: It has been widely accepted that hippocampal-based learning is the preferred learning strategy for the spatial food reward task in rats. Moreover, multiple factors have been associated with shifting the learning strategy toward alternative, non-hippocampal learning. However, no current research has explored how quickly animals restore use of the most efficient (hippocampal) strategy after withdrawal of hippocampus-suppressing treatment. To address this question, we trained animals on a mixed-choice food reward task using an eight-box octagonal maze. Long Evans rats were trained to search for food rewards hidden in constant positions relative to room cues. After each trial, the maze was randomly rotated, and the rat's starting position was changed randomly to reveal the contribution of different memory systems. Animals failing to use a hippocampal strategy remained able to find food every lap, but could only reduce the number of errors to 2 per lap. "Hippocampal learners" could reach 1 or fewer errors per lap after multiple sessions. Each group of rats was subjected to one of four treatments temporarily inhibiting hippocampal learning: (1) 2 hours of sleep deprivation, or (2) isoflurane anesthesia; (3) intrahippocampal norepinephrine infusion, or (4) optogenetic stimulation of the locus coeruleus during sleep. The treatment was applied following each training session during the offline consolidation period for the first three sessions. Post-treatment, animals were trained on the same task for the next 6 days/training sessions. The control group was subjected to the same procedures, but were allowed sleep ad libitum during periods when the experimental group was treated. All treatments induced suppression of the hippocampal strategy, not only during sessions following the treatment, but also for the next six days of training. The number of errors in the four groups was significantly higher than the control group. This suggests that treated animals did not shift back to the preferred/hippocampal strategy. To exclude permanent damage of the hippocampal memory system caused by treatment, animals injected with norepinephrine and optogenetically stimulated were re-trained on the same task in a different environment and maze. All rats were able to use the hippocampal strategy in a new environment and reached less than 1 error per lap by the end of the training, showing that treatment did not cause irreversible changes. Our findings indicate that functional inactivation of the hippocampus subsequently impairs cognitive flexibility. Dramatic changes in the environment of the task were required to restore the ability to update and optimize learning strategies.

Title: The amnesia induced by post-reactivation anisomycin-impaired reconsolidation of object location memory causes the brain to reengage the acquisition mechanisms of when there was no prior knowledge of that memory

Authors: *J. J. ZHANG, K. NADER;
Psychology, McGill Univ., Montreal, QC, Canada

Abstract: Experimental amnesia can be brought about by either impairing memory storage or memory retrieval. The traditional paradigm called recovery from amnesia cannot differentiate between whether the impairment is due to a storage or retrieval impairment. We previously developed a novel second learning paradigm that dissociates between the two (Hardt, Wang & Nader, 2009). This task depends on the finding that the first but not subsequent time animals acquire a memory, its acquisition is blocked by NMDAR-antagonist (2R)-amino-5-phosphonovaleric acid (AP5). To date, reconsolidation has been shown to occur in a variety of behavioural tasks including fear conditioning, contextual fear conditioning, incentive learning, to name a few. In contrast, few studies have explored reconsolidation of hippocampal-dependent spatial memory tasks such as object location. To this end, we identified the elements of the task required for reactivation of object location memory using four different open field contexts similar to the training context: with the bedding removed, with the objects removed, with objects removed and with different bedding, and with objects removed and with no bedding. Preliminary results revealed that reactivating the training memory with an open field with no objects, or no bedding and no objects, led to a reconsolidation effect. By establishing the elements required to induce reconsolidation we can then ask if reconsolidation blockade engaged first or second learning mechanisms by blocking reconsolidation of first learning memory, then testing for the susceptibility of second learning acquisition to AP5. In the next experiment, we induced reconsolidation of first learning object location memory, then trained the same animals with a second learning of object location paradigm. By blocking reconsolidation with bilateral infusions of anisomycin into the dHC, acquisition of second learning was AP5-sensitive. That is, second learning reverted to the AP5-sensitivity characteristically shown by first learning, not second learning acquisition. This suggests that blocking reconsolidation caused the second learning event to be treated as if it was the first time the object location information was acquired. Similar results have previously been attained with infusions of PKMζ-inhibitor ZIP after consolidation of first learning. We feel this task should be used more broadly to differentiate between storage or retrieval impairments.

Title: The endocannabinoid system mediates stress-induced amnesia

Authors: *A. BUSQUETS-GARCIA[1,2], M. GOMIS-GONZÁLEZ[2], R. SRIVASTAVA[3], L. CUTANDO[2], A. ORTEGA-ALVARO[2], S. RUEHLE[3], F. REMMERS[3], L. BELLOCHIO[1], L. BINDILA[3], G. MARSICANO[1], B. LUTZ[3], R. MALDONADO[2], A. OZAITA[2];

Abstract: Memory consolidation is a labile process under the direct influence of emotional experiences. However, little is known about the underlying mechanisms. The endocannabinoid system plays an important role in the modulation of both emotion and memory, but the integration of these functions in the memory consolidation has not yet been addressed. This study investigates the involvement of cannabinoid type-1 (CB1) receptors in stress-induced amnesia for a non-emotional memory. Using a model for declarative memory in mice, the novel object-recognition test, we found that stress and the arousal state of the animal determine the consolidation outcome in this memory. Such a memory trace was obliterated under physical or psychological acute stress conditions. These amnesic effects of stress were not observed after local or systemic injection of the CB1 receptor antagonist rimonabant, and after the administration of the peripherally acting CB1 receptor antagonist AM6545 or genetic

inactivation of the CB1 receptor gen. According to these behavioral data, the c-Fos activation in different brain regions induced after shock was also blocked by the CB1 receptor antagonism. Using several cell type-specific conditional CB1 receptor knockout mouse lines, we found that CB1 receptors in dopamine β-hydroxylase (dbh) expressing adrenergic/noradrenergic cells are necessary and sufficient for the stress-induced amnesia, whereas CB1 receptors in other cell populations were not involved in this response. Notably, the removal of the adrenal glands prevented the amnesic-like effect of stress. In addition, the pharmacological modulation of adrenergic/noradrenergic system showed that both alpha- and beta-adrenergic receptors are involved in this stress-induced amnesia.In summary, central and peripheral adrenergic/noradrenergic transmission determine the consolidation of non-emotional memories, and this function is under the direct control of CB1 receptors expressed in dbh-positive cells. The elucidation of this mechanism opens novel therapeutic approaches for the treatment of memory- and stress-related disorders using drugs acting on peripheral CB1 cannabinoid receptors.

Title: Selective erasure of neural engrams of nicotine-associated memories to prevent nicotine craving and relapse

Authors: ***Y. XUE**[1], J. DENG[2,1], Y. CHEN[2,1], S. SUN[2,1], L. ZHANG[1], L. ZHANG[1], L. LU[2,1]; [1]Natl. Inst. on Drug Dependence, Peking Univ., Beijing, China; [2]Inst. of Mental Health/Peking Univ. Sixth Hosp. and Key Lab. of Mental Hlth., Beijing, China

Abstract: Background: Memories for substance abuse can be decreased by pharmacological interference after conditioned stimulus-induced memory reactivation (CS-MR). However, the procedure has limitations for “real world” relapse prevention, since the disruptive effect of the procedure is selective to the reactivated cues and does not generalize to other cues that have not been reactivated. In the present study, we investigated whether pharmacological interference after unconditioned stimulus-induced memory reactivation (US-MR) erases all nicotine-associated memory traces. Methods: In animal studies, rats were trained for pavlovian nicotine-associated memory with conditioned place preferences (CPP) and instrumental nicotine-associated memory with self-administration model. Memory was reactivated by exposure to previous nicotine-associated cues (as CS-MR) or a low dose of nicotine (as US-MR). In human study, smokers were trained for the association between pictures on the computer screen and smoking tobaccos. Memory reactivation was induced by smoking tobacco. Results: We found that cerebral ventricular microinjections of inhibitors of protein synthesis immediately after but not 9 h after CS-MR or US-MR disrupted subsequent recall of nicotine CPP memory. We also confirmed the phenomenon in instrumental nicotine-associated memory (nicotine self-administration). Subsequently, we found systemic administration of propranolol, an antagonist of adrenergic β-receptor, immediately after US-MR disrupted subsequent recall of nicotine CPP memory or nicotine self-administration memory. Furthermore, when rats were trained for two types of nicotine-associated memories (i.e. CPP memory and self-administration memory), systemic administration of propranolol immediately after US-MR disrupted subsequent recall of both of them, while propranolol administration immediately after CS-MR only disrupted subsequent recall of the memory reactivated previously. Lastly, after smokers learned the association between smoking tobaccos and two associated cues, oral administration of propranolol one hour before US-MR also decreased all the smoking-associated memories, including new learned cue memories and existing cue memories in real world. Conclusions: Our findings indicate that pharmacological interferences after US-MR lead to erasure of all nicotine-associated memory traces, and the US-MR-targeting inhibition may be a new strategy for the treatment of nicotine relapse.

Title: Histidine decarboxylase (HDC) and histaminergic receptors gene expression (H1, H2 and H3) acts distinctly along the timeline in the medial prefrontal cortex, dorsal hippocampus and amygdala after an aversive experience

Authors: *L. CANTO DE SOUZA[1], R. MATTIOLI[2];
[1]Univ. De Sao Paulo - FFCLRP/USP, Ribeirão Preto -, Brazil; [2]Univ. Federal de São Carlos, São Carlos, Brazil

Abstract: Histamine acts as a modulatory neurotransmitter in the mammalian brain and there is evidence that it can modulate memory in different types of behavioral tasks. Here we investigated the HDC (histidine decarboxylase) and histaminergic receptors (H1, H2 and H3) gene expression in medial prefrontal cortex (mPFC), dorsal hippocampus and amygdala of male mice subjected to step-down inhibitory avoidance. The animals were assigned into 4 groups (n=4-5): control (naïve mice that did not experienced the aversive stimulus); 9 h post-training (mice that had their brains removed nine hours after training); 24 h post-training (mice that had their brains removed twenty four hours after training); 2 h post-test (mice that had their brains removed two hours after test). In mPFC we found an increase of HDC gene expression 24 h post-training and 2 h post-test; H2 gene expression increased 24 h post-training and 2 h post-test. In dorsal hippocampus HDC gene expression decreased 9 h post-training; 24 h post-training H2 and H3 gene expression increased; 2 h post-test H1 gene expression increased. Further, in amygdala, HDC gene expression increased 9 and 24 h after training; 9 h post-training H2 and H3 gene expression decreased and remained low after 24 h post-training and 2 h post-test; 2 h post-test H1 gene expression increased. We suggest that histamine acts distinctly along the timeline in the mPFC, dorsal hippocampus and amygdala after an aversive experience; dorsal hippocampus's H2 and H3 receptors and mPFC's H2 receptors might be involved in the aversive memory consolidation; dorsal hippocampus and amygdala's H1 receptor and mPFC's H2 receptors might be involved in emotional memory reconsolidation.

Title: A sex difference in the bidirectional effects of the CB1 antagonist/inverse agonist rimonabant on consolidation of cocaine-associated memory in mice

Authors: *S.-J. HU[1], H.-A. CHANG[2];
[2]Psychology, [1]Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Cannabinoid CB1 receptors are implicated in various forms of learning and memory, including cocaine-associated memory. Our previous study showed that systemic or intra-medial prefrontal cortex administration of the CB1 receptor antagonist/inverse agonist rimonabant impaired the consolidation of conditioned place preference (CPP) induced by a high dose (20 or 40 mg/kg) of cocaine, while facilitated that induced by a low dose (2.5, 5, or 10 mg/kg) in the male wild-type mice. These results suggest that rimonabant bidirectionally modulates the consolidation of cocaine-induced CPP memory. The current study aimed to investigate the receptor and sex hormone mechanisms underlying the bidirectional effects of rimonabant on cocaine-induced CPP. We first examined whether the CB1 receptor mediated rimonabant's effects by using the CB1 knockout mice and found that rimonabant did not facilitate memory consolidation of a low-dose (10 mg/kg) cocaine-induced CPP in both genders of the CB1 knockout mice. Likewise, rimonabant did not enhance the low-dose cocaine-induced CPP in the female wild-type mice. To test whether the sex hormone estrogen was involved, we tested rimonabant's effects on the low-dose cocaine-induced CPP in the vehicle-treated vs. estrogen-treated ovariectomized (OVX) female wild-type mice and found two interesting results. First, the estrogen replacement in the OVX mice per se enhanced the low-dose cocaine-induced CPP memory. Second, rimonabant facilitated cocaine-induced CPP memory in the OVX mice supplied with vehicle (sesame oil), while impaired the same memory in the OVX mice replaced with estrogen. Finally, rimonabant's effects on a high-dose (40 mg/kg) cocaine-induced CPP in both genders of the CB1 knockout mice as well as in the sham-control vs. OVX female wild-type mice are currently under investigation. Taken together, our results first indicate that the facilitating effect of rimonabant on the low-dose cocaine-induced CPP in the male wild-type mice is indeed mediated by the CB1 receptor. Second, estrogen is involved in the sex difference in the rimonabant's modulatory effects on cocaine-associated memory.

Title: The naturally-occurring compound Garcinia indica impairs the reconsolidation of a cocaine-associated memory

Authors: *M. S. MONSEY, H. SANCHEZ, J. R. TAYLOR;
Mol. Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Sustained abstinence from cocaine use is frequently compromised by exposure to environmental stimuli that have previously been strongly associated with drug taking. Such cues trigger drug-associated memories, leading to craving and potential relapse. Our work has demonstrated that manipulating cocaine-cue memories by destabilizing them through interfering with the reconsolidation process is one potential therapeutic tool to prolong abstinence. For manipulations of established memories to be clinically useful, however, it would be optimal to identify a compound that can be administered systemically and that is natural with minimal side effects. We chose to assess the use of the naturally-occurring compound, garcinol, to manipulate an established cocaine-cue memory as it has previously been shown to block the reconsolidation of auditory Pavlovian fear memories in rats when given systemically (Maddox et al., 2013). Here, rats received 12 d of cocaine self-administration training during which time an active lever press resulted in a 1mg/kg i.v. infusion of cocaine while concurrently a cue light and tone were presented for 10 s. Next rats underwent lever extinction for 8 d, where lever pressing did not result in cocaine infusion or cue presentation. The following day, rats underwent memory reactivation in a novel context where the cues were briefly presented. Thirty minutes after reactivation rats received either a 10 mg/kg i.p. injection of garcinol or vehicle. Twenty-four hours after the reactivation session, rats were returned to the original chamber for a cue-induced reinstatement test where each active lever press resulted in a 10 s cue presentation. We found that post-reactivation garcinol is capable of impairing the reconsolidation of a cocaine-associated cue memory. These effects were also specific to a directly reactivated cue. Using non-reactivated controls we also show that the ability of systemic garcinol to effectively impair the reconsolidation of a cocaine-associated memory is predicated on active memory recall during the reactivation session; that is, in the absence of memory retrieval, garcinol has no effect on the retention of the memory. Additionally, we found that the effect of garcinol on reconsolidation is

temporally constrained; when rats are given systemic garcinol 6 h after reactivation there is no effect on retrieval. Therefore, systemic garcinol within a narrow window following memory retrieval can significantly impair reconsolidation. In sum, we show that systemic garcinol can block the reconsolidation of a cocaine-cue memory in a manner that is specific to the reactivated memory only and that is temporally constrained.

Title: Age-related decline of spatial discrimination performance based on difficulty may reflect pattern separation deficits

Authors: ***S. A. JOHNSON**[1], L. S. GAYNOR[1], P. K. SACKS[1], S. M. TURNER[1], W. M. YODER[1], B. K. ORMEROD[1], A. P. MAURER[1,2], J. L. BIZON[1], S. N. BURKE[1,3]; [1]Dept. of Neurosci., Univ. of Florida, Gainesville, FL; [2]Biomed. Engin., Gainesville, FL; [3]Inst. on Aging, Gainesville, FL

Abstract: Cross-species evidence suggests that perceptual discrimination deficits are a core feature of age-related cognitive decline. In particular, individual aged rats impaired in spatial memory show correlated deficits in odor discrimination learning (LaSarge et al 2007 Neurobiol Aging 28:928). The goal of this study was to determine whether aging is associated with impairment of dentate gyrus (DG)-dependent perceptual discrimination ability in rats cross-characterized for spatial memory. Young (6-8 m) and aged (24-26 m) male Fischer 344 x Brown Norway rats were first trained on a spatial reference memory version of the water maze task (Bizon et al 2009 Neurobiol Aging 30:646). Relative to young, aged rats showed impaired spatial memory across probe tests [$p<0.04$]. Rats were then trained to perform a DG-dependent delayed-match-to-sample spatial discrimination task (Gilbert et al 2001 Hippocampus 11:626). In the task, rats learn to displace a target object covering a baited food well, and must recall the

location of this well based on peripheral cues when subsequently presented with two identical objects: one in the target location and one in a distractor location. Rats were initially trained to perform an easy version of the task, in which the distance between target and distractor objects was 80-95 cm. Young and aged rats learned this task within the same number of trials [p=0.21]. To assess spatial discrimination ability, rats were then tested on easy, intermediate, and difficult discrimination problems, in which the distances between target and distractor were 90, 48, or 15 cm, respectively. Young rats performed well above chance on both easy and intermediate problems [p's<0.001]. In contrast, aged rats performed above chance on easy [p0.24]. To further assess whether aging affects integration of spatial discrimination and memory functions, rats were trained to criterion and tested on intermediate problems with a delay of 1, 2 or 5 min imposed between cueing of the target location and choice between target and distractor locations. Recall of the target location was moderated by both delay duration [$F(5,70)=3.51$, $p<0.001$] and age [$F(1,14)=5.07$, $p<0.04$]. Considered together, these data suggest that age-related perceptual discrimination deficits may contribute to broader memory impairment. Furthermore, loss of spatial discrimination ability as a function of task difficulty is consistent with the interpretation that DG function is compromised by aging, and could reflect an underlying deficit in pattern separation computations performed by this region.

Title: Nonlinear oscillations of the hippocampus

Authors: *A. P. MAURER[1], S. N. BURKE[1], A. SHEREMET[2];
[1]Evelyn F. McKnight Brain Inst., [2]Engin. Sch. of Sustainable Infrastructure & Envrn., Univ. of Florida, Gainesville, FL

Abstract: Over 75 years of research have been dedicated to examining hippocampal oscillations in regards to their neurobehavioral correlates and mechanisms of generation (Jung and Kornmüller, 1938). The theta rhythm, which is 4-12 Hz fluctuation in the local field potential (LFP) prominent during movement and REM sleep (Vanderwolf, 1969), is perhaps one of the best described oscillations. Although early studies discussed theta as a nonlinear process (Leung, 1982), linear decompositions are often used to quantify the neurophysiological rhythms of the brain. Nonlinear measures, however, may be better suited for analyzing the dynamical processes in the nervous system (Aru et al., 2014). Therefore, in order to advance a fundamental understanding of the oscillations in the hippocampus, the current study utilized higher-order spectral analyses of the LFP data collected from the dorsal and intermediate regions of the hippocampus as rats traversed a circular track for food reward. A bispectral analysis was used to quantify the nonlinearities of theta, such as skew, asymmetry and the harmonics as a function of running velocity in both the dorsal and intermediate hippocampus. Moreover, the slope of the power spectral density was determined in both areas of the longitudinal axis. In the dorsal region, as movement velocity increased, the LFP became increasingly nonlinear showing higher skew, asymmetry and modulation of variance. Moreover, the bispectral analysis identified multiple harmonics of theta that developed as a function of running speed reaching a fifth harmonic at the fastest velocities. Finally, the power spectral properties of the LFP moved from pink- towards white-noise at faster running speeds. The emergence of nonlinear properties of the theta rhythm was also observed in the intermediate portion of the hippocampus, but the effect was attenuated. Together these data suggest that hippocampal LFP follows nonlinear dynamics that may reflect a dissipative system, which loses energy along the long axis.

Title: Reductions in GABA(B) receptor signaling contribute to age-related impairments in behavioral flexibility

Authors: *S. BEAS[1], J. A. MCQUAIL[1], B. SETLOW[2], J. BIZON[1];
[1]Neurosci., [2]Psychiatry, Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: Behavioral flexibility involves the adaption of behavior in response to changing environmental demands, and this prefrontal cortex (PFC)-dependent executive function is critical for navigating complex environments. Loss of behavioral flexibility is associated with a number of neuropsychiatric diseases, and has been linked to inhibitory signaling dysfunction. Behavioral flexibility also significantly declines with age but the neurobiological causes of such decline are poorly understood. Previous work from our lab indicates that GABAergic signaling via GABA(B) receptors becomes dysregulated in the aged PFC. The current study combined molecular and pharmacological methods to determine if such age-related GABAergic signaling alterations contribute to impaired behavioral flexibility. Young adult (6 mo) and aged (24 mo) rats were tested on an attentional set-shifting task that assesses behavioral flexibility in which they were required to discriminate between two response levers to earn food rewards. Upon learning an initial response rule to criterion (e.g., visual cue = correct choice), the response rule was "shifted", such that the rat had to ignore the initial rule and respond according to a different rule (e.g., left lever = correct choice). Young and aged rats acquired the initial discrimination comparably, but aged rats were impaired relative to young on the set-shift. Notably, there was considerable variability among aged rats' performance, such that some performed within the range of young whereas others fell outside this range. Western blotting was then performed on homogenates prepared from micro-dissected medial PFC (mPFC) to determine expression of GABA(B)R1a and GABA(B)R1b subunits. Consistent with our previous work, expression of both subunits was significantly reduced in aged compared to young mPFC. Among aged rats, lower expression of both subunits was strongly associated with worse set shifting performance. These data suggest that age-related loss of mPFC GABA(B)R-mediated inhibition may contribute to impaired behavioral flexibility. To test this hypothesis, subsequent experiments determined whether the GABA(B)R agonist baclofen could improve behavioral flexibility in aged rats. Baclofen administered either systemically (2.5 mg/kg) or directly into the mPFC (0.5 nmol) in aged rats significantly enhanced performance compared to vehicle controls. Together, these data suggest that attenuated GABA(B)R signaling in mPFC contributes to age-related deficits in behavioral flexibility, and that GABA(B)Rs may represent a therapeutic target for remediating such deficits.

Title: Age-related impairments in object-place associations signify a decline in systems-level neural communication

Authors: *J. E. REASOR[1], A. R. HERNANDEZ[1], S. M. TURNER[1], S. E. BATHLE[1], S. A. JOHNSON[1], A. P. MAURER[1,2], S. N. BURKE[1];
[1]Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Biomed. Engin., Gainesville, FL

Abstract: No single neurobiological deficit can account for the wide spectrum of cognitive changes observed in old age. In fact, most adaptive behaviors are supported by networks distributed across multiple brain regions, which renders the identification of a locus of dysfunction untenable. For example, episodic memory, which requires the integration of sensory stimuli with spatial locations, exhibits significant declines with senescence and relies on interactions between medial temporal lobe and neocortical structures. Therefore, understanding how different brain regions interact to support cognition is critical for uncovering the neurobiological mechanisms of age-associated cognitive decline. The neural circuit that supports memory includes the hippocampus (HPC) and the perirhinal cortex (PER). The HPC is critically involved in spatial reference memory (Morris et al., 1982), while the PER is necessary for object recognition (Winters et al., 2005). While both of these areas exhibit age-associated dysfunction (Rosenzweig and Barnes, 2003; Burke et al., 2010), deficits arising from the PER or HPC are often not correlated within individuals (Burke et al., 2010). Thus, it is unknown how aging impacts behaviors that require PER-HPC interactions. The goal of the current experiment was to determine the effect of aging on a task that requires communication between the HPC and PER. Young (4-6 months, n = 9) and aged (24-26 months, n = 14) rats were cross-characterized on a spatial reference memory version of the hippocampal-dependent water maze task and a PER-HPC inter-region dependent object-place paired association task (OPPA; Jo and Lee, 2010). Although aged rats did not exhibit a deficit in the spatial learning index or path length measures of water maze performance, ($F [1, 19] = 0.59$, $p = 0.45$), they were significantly impaired in

acquiring object-place associations relative to young ($F [1, 43] = 4.94$, $p < 0.05$). As this specific cohort of aged rats was unimpaired in spatial reference memory, these results demonstrate that deficits in the formation of object-place associations do not solely arise from generalized impairment of the hippocampus. Furthermore, these data support an emerging hypothesis that behaviors supported by functional connectivity across memory networks are particularly vulnerable to aging, as local dysfunction may propagate leading to global communication deficits across the memory circuit.

Title: NR2A-containing NMDARs in the PFC are required for working memory and predict age-related cognitive decline

Authors: *J. A. MCQUAIL[1], B. S. BEAS[1], K. L. SIMPSON[1], K. B. KELLY[2], C. J. FRAZIER[2], B. SETLOW[3], J. L. BIZON[1];
[1]Dept. of Neurosci., [2]Dept. of Pharmacodynamics, [3]Dept. of Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: NMDA receptor (NMDAR)-dependent persistent firing of pyramidal neurons in the prefrontal cortex (PFC) is a likely neurophysiological correlate of working memory. NMDARs are tetrameric complexes comprised of obligate NR1 subunits that associate with NR2A or NR2B subunits to form a ligand gated ion channel. The subunit composition of the NMDAR complex confers unique channel properties and also determines retention at the synaptic zone versus diffusion to extrasynaptic sites. However, the contribution of specific subtypes of NMDARs to working memory and their changes with age are not well understood. To address these questions, the present study combined behavioral analysis of a delayed response (DR)

working memory task that is dependent upon an intact medial PFC (mPFC, the rodent homologue of dorsolateral PFC) and sensitive to aging, with behavioral pharmacological and molecular approaches in young adult (6 months) and aged (22-24 months) Fischer 344 rats. Experiment 1 evaluated behavioral consequences of acute intra-mPFC administration of NMDAR antagonists to young adult rats during DR task performance. Selective antagonists of NR2B-containing NMDARs, ifenprodil and Ro-25 6981, had no effect on DR task accuracy. In contrast, the NR2A-preferring antagonist NVP-AAM077 significantly impaired accuracy relative to vehicle. Experiment 2 used Western blotting methods to measure NMDAR subunit levels in mPFC homogenates prepared from a separate cohort of young adult and aged rats previously characterized on the DR task. NR1, NR2A and NR2B subunit expression was lower in aged compared to young rats, and NR2A protein expression was positively correlated with DR accuracy in aged rats. Apart from marginal reductions in AMPA receptor subunit levels, there were no other age-related changes in synaptic, spinous, or dendritic proteins. These experiments demonstrate that blockade of NR2A-NMDARs within the mPFC significantly impairs performance on a rodent working memory task. Moreover, attenuated expression of mPFC NMDARs coincides with onset of age-related working memory deficits and loss of NR2A subunit reliably predicts severity of working memory impairment. Jointly, these studies support a vital role for NR2A-NMDARs in working memory, possibly due to preferential localization at synaptic sites, and further suggest that their dysfunction may be a causal factor in working memory impairments that are prevalent among older individuals. Ongoing work will determine if positive modulation of synaptic NMDARs restores working memory in aged rats and evaluate age-related changes to NMDAR subunit:protein interactions.

Title: An open-source software suite for collecting and analyzing spontaneous object recognition data

Authors: *N. TOPPER[1], R. NDUM[1], A. R. HERNANDEZ[1], S. A. JOHNSON[1], J. REASOR[1], J.-M. MIZELL[1], S. TURNER[1], A. P. MAURER[1,2], S. N. BURKE[1,3];

Abstract: Behavioral neuroscience often necessitates tracking an animal as they move through an environment and quantifying exploration-related parameters. A common example is the spontaneous object recognition task in which the time a rat spends exploring an object is monitored (Ennanceur and Delacour, 1988). While there are several commercial options available for quantifying task parameters, purchasing software and multiple licenses may be cost-prohibitive for large-scale projects or budget-conscious laboratories. Moreover, without an open-source algorithm, end users are restricted to the structure of the original programming. Therefore, we have developed a two-part software suite that integrates with a web camera for data collection, organization and quantification. The first part of the code, dubbed "Collector", can load and process previously recorded data, or be integrated with a "live recording" for online tracking. Collector then tracks animal position, determines distance from user specified locations of interest (e.g., an area containing an object), and extracts threshold crossings. These variables are used in the second aspect of the software suite, "Minion", which provides an initial automated scoring of the behavioral data that can be refined by the user. For certain behavioral tests, such as spontaneous object recognition, exploration times are often scored when a rodent's nose is within a specified distance from an object. When complete autonomy is provided to tracking algorithms, there are often false positives in which the rat was in proximity, but not engaged with the object. Therefore, Minion provides a platform that allows user interaction and verification of exploration epochs provided by the algorithm. Exploration times can be calculated with the precision of the video framerate. Importantly, this scoring suite also offers the capability to automatically rename, and shuffle datasets, facilitating blind scoring (relative to serial analysis of video data which may have temporal cues to experimental conditions). Finally, the output of the algorithm, containing latency, exploration time, and length of each epoch of exploration, is readily converted to a comma-separated values file for import into Microsoft Excel and other downstream applications. In addition to spontaneous object recognition, this software suite can be used for animal tracking across a wide variety of behavioral paradigms. These include exploration or foraging in open arenas, tracking on land-based mazes (e.g. radial-arm, Barnes, and elevated-plus mazes), the Morris water maze, and monitoring of freezing behavior in fear conditioning paradigms.

Title: Object-place paired associations require interactions between prefrontal and perirhinal cortices

Authors: *A. R. HERNANDEZ[1], J. E. REASOR[1], S. M. TURNER[1], S. E. BARTHLE[1], S. A. JOHNSON[1], J. L. BIZON[1], A. P. MAURER[1,2], S. N. BURKE[1];
[1]Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Biomed. Engin., Gainesville, FL

Abstract: The networks that support episodic memory are distributed across the brain. Specifically, the ability to link a sensory stimulus with a spatial location, which is a cornerstone of episodic memory, requires communication between the medial temporal lobe and prefrontal cortex. In line with this idea, lesion studies have demonstrated that successful performance on the Object-Place Paired Association (OPPA) task requires the perirhinal cortex (PER), medial prefrontal cortex (mPFC) and hippocampus (HPC; Lee and Solivan, 2008; Jo and Lee, 2010a). This task tests an animal's ability to use their current spatial location to determine which of two objects is associated with a reward. While it is known that OPPA performance requires functional communication between the HPC and PER (Jo & Lee, 2010 J Neurosci 20:9850), it is unknown whether the mPFC acts in concert with these structures or functions independently to establish relevant goal representations. Importantly, mPFC activity has been shown to facilitate communication between PER and entorhinal cortices, which could promote the transfer of information between HPC and neocortex (Paz et al. 2007). To determine the role of PER-mPFC communication in forming object-place associations, young adult male Fischer 344 rats were trained on the OPPA task prior to receiving reversible disconnection lesions. After reaching criterion performance, rats were implanted with 4 cannulae bilaterally targeting the PER and mPFC. Following recovery and re-establishment of criterion performance, rats were tested 30 min after intra-cerebral infusions of the GABAA agonist muscimol or vehicle. Rats received, in a randomized sequence: 1) bilateral PER infusions, 2) bilateral mPFC infusions, 3) ipsilateral PER

and mPFC infusions, or 4) contralateral PER and mPFC infusions. Functional disconnection of PER-mPFC with contralateral muscimol infusions significantly impaired task performance, relative to vehicle infusions ($p<0.05$). Importantly, ipsilateral inactivation of PER and mPFC did not impair performance, such that rats performed at criterion levels ($p=0.57$). These results indicate that functional connectivity between the PER and mPFC is critical to the formation and referencing of object-location conjunctions. Together these data support the hypothesis that interactions between mPFC and rhinal cortices modulate HPC- PER functional connectivity. Thus, deficits in the OPPA task that occur in old age (see Reasor et al. 2015 SfN Abstract) may be better attributed to network dysfunction, rather than impairments within a single brain region.

Title: Subregional and behaviorally-relevant transcriptional changes related to GABA and glutamate signaling in the aged rodent prefrontal cortex

Authors: *C. M. HERNANDEZ, III[1], J. A. MCQUAIL[1], B. S. BEAS[1], B. SETLOW[2], J. L. BIZON[1];
[1]Neurosci., [2]Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: The rodent medial prefrontal cortex (mPFC) is considered the homologue to primate dorsolateral PFC and includes the prelimbic (PL) and infralimbic (IL) subregions. These subregions differ in their anatomical connections and functional contributions to a number of PFC-mediated behaviors. The normal aging process is associated with a decline in PFC-mediated executive functions such as working memory and behavioral flexibility, and previous work from

our laboratory indicates that dysregulated excitatory and inhibitory signaling within mPFC contributes to this decline. The goal of this study was to use targeted, low-density PCR arrays to extend these prior findings, and specifically to identify subregional and behaviorally-relevant age-related alterations in gene expression related to GABA and glutamate signaling. Young (6 mo) and aged (24 mo) F344 rats were first trained on mPFC-dependent set-shifting and delayed-response tasks that assess behavioral flexibility and working memory, respectively. Tissue punches (1 mm) from PL and IL were collected 2 weeks later for analysis of gene expression. There were surprisingly few differences in basal gene expression between the PL and IL subregions, and only a few robust changes were observed as a function of chronological age. Interestingly, however, several classes of genes were significantly upregulated in aged rats that performed comparably to young on the set-shifting and working memory tasks. These genes included subunits of ionotropic glutamate receptors, enzymes important for GABA/Glu synthesis, and excitatory and inhibitory amino acid transporters. Notably, the vast majority of these expression changes were only evident in the PL subregion. Together, these data indicate that gene transcription related to excitatory/inhibitory signaling can become markedly altered in the aged PFC, and, that excitatory/inhibitory signaling alterations in the PL subregion may be particularly relevant for executive function in aging.

Title: Chronic variable stress recapitulates age-related changes to glutamate and GABA receptors in the PFC

Authors: M. M. BRUNER[1], J. A. MCQUAIL[1], I. M. BACKES[2], R. R. CLIFTON[2], B. SETLOW[3], D. A. SCHEUER[2], *J. L. BIZON[1];
[1]Neurosci., [2]Physiol. and Functional Genomics, [3]Psychiatry, Univ. of Florida Col. of Med., Gainesville, FL

Abstract: Normal aging is associated with impaired cognition, including executive functions supported by the prefrontal cortex (PFC). Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis also accompanies the aging process and a long-standing hypothesis in the cognitive aging field suggests that the cumulative effects of stress and concomitant glucocorticoid exposure over the lifespan precipitate neural changes that mediate the emergence of cognitive deficits. Our prior work strongly implicates altered glutamatergic and GABAergic signaling in age-related impairment of cognitive functions supported by the PFC. As this brain region is enriched in glucocorticoid receptors, the present study was designed to test the hypothesis that chronic, unpredictable stress alters expression of glutamate and GABA receptor subunits in a manner that mirrors the effects of advanced age. Young adult rats were exposed to a 14-day chronic variable stress (CVS) paradigm (an unpredictable schedule of stressors including insulin-induced hypoglycemia, 60 min restraint, 7 min swim in 16°C water, and predator urine) and brain tissue was collected on Day 15. Western blot analysis was used to measure protein levels of ionotropic glutamate receptor (NMDAR and AMPAR) and GABA(B)R subunits in the PFC of CVS rats and unstressed (UNS) controls (n=6-8/group). While NMDA receptor subunit expression (NR2A, NR2B) was not affected by stress, the AMPAR GluR2 subunit was significantly reduced in the CVS group (-29% vs UNS; $p<0.05$). In addition, CVS recapitulated a marked reduction in PFC GABA(B)R expression that is a consistent feature of aging. Expression of both GABA(B)R1a (-49% vs UNS; $p<0.05$) and GABA(B)R1b (-44% vs UNS; $p<0.05$) was significantly reduced in the CVS condition. This reduction in GABA(B)R subunits was not accompanied by a change in the expression of VGAT, a marker of GABAergic synapses. The finding of reduced AMPAR subunit expression, but preserved NMDAR subunit expression, supports morphological findings that CVS reduces stubby spine (AMPAR-enriched) density in the PFC but not thin spines (NMDAR-enriched). Furthermore, this study provides novel evidence that GABA(B)Rs in the PFC are a key player in the pathophysiology of stress-induced alterations to PFC function. Collectively, these data suggest substantial overlap in the molecular mechanisms through which psychogenic stress and aging impair PFC neural activity required for higher-order cognition.

Title: Cholinergic modulation of spatial discrimination performance in young and aged rats

Authors: L. S. GAYNOR[1], S. J. JOHNSON[1], P. K. SACKS[1], A. P. MAURER[1,2], J. L. BIZON[1], *S. N. BURKE[1,3];
[1]Neurosci., Univ. of Florida, Gainesville, FL; [2]Biomed. Engin., Gainesville, FL; [3]Inst. on Aging, Gainesville, FL

Abstract: Hippocampal-dependent mnemonic function is modulated by the neurotransmitter acetylcholine (ACh; Hasselmo 2006 Curr Opin Neurobiol 16:710; Parent and Baxter 2004 Learn Mem 11:9). It has specifically been proposed that elevated ACh levels during waking behavior and exposure to novelty serve to balance excitation and inhibition within the hippocampus, reducing interference to support perceptual discrimination function and memory consolidation. By consequence, ACh could play a significant role in regulating hippocampal-dependent computations, such as pattern separation and completion, which support perceptual discrimination. The goal of this study was to determine whether increasing ACh availability with the acetylcholinesterase inhibitor donepezil would alleviate age-related deficits in hippocampal-dependent spatial discrimination. Furthermore, we investigated whether ACh neurotransmission via alpha-7 subunit-containing nicotinic ACh receptors (nAChRs) is required for spatial discrimination performance. Young adult (6-8 m) and aged (26-28 m) male Fischer 344 x Brown Norway hybrid rats were trained to perform a delayed-match-to-sample spatial discrimination task (Gilbert et al 2001 Hippocampus 11:626; Johnson et al 2015 Society for Neuroscience abstract) and were tested to assess baseline discrimination ability. All rats were then tested following systemic injections of the cholinergic agonist donepezil (vehicle, 1 mg/kg, 3 mg/kg) and the alpha-7 containing nAChR antagonist methyllycaconitine (MLA; vehicle, 0.1 mg/kg, 0.5 mg/kg) using a within-subjects random blocks design. Drugs were injected intraperitoneally 40 min prior to testing on easy, intermediate, and difficult spatial discrimination problems. Donepezil improved spatial discrimination performance across both easy and intermediate problems in aged rats [$p<0.05$], but did not enhance performance beyond baseline in young rats [$p=0.37$]. In contrast, blockade of alpha-7 containing nAChRs with MLA impaired young rats' spatial discrimination ability. Considered together, these data implicate ACh neurotransmission in mediating hippocampal computations that support perceptual discrimination function across

the lifespan. Furthermore, these results suggest that increasing ACh levels through systemic treatment with donepezil is a viable therapeutic intervention for alleviating age-related cognitive decline.

Title: Aging alters excitatory and inhibitory modulation of GABAergic interneurons in layer 2/3 of the rodent medial prefrontal cortex

Authors: *K. B. KELLY[1], J. A. MCQUAIL[2], C. M. HERNANDEZ[2], J. L. BIZON[2], C. J. FRAZIER[1,2];
[1]Dept. of Pharmacodynamics, [2]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Recent animal studies suggest that age-related impairments in working memory are likely to be associated with increased inhibition of cortical pyramidal neurons in the medial prefrontal cortex. In the current study, we sought to extend our understanding of this phenomenon by more directly evaluating how aging alters the physiology and functional modulation of cortical GABAergic interneurons. Towards that end, we performed whole-cell patch clamp recordings from GABAergic interneurons in Layer 2/3 of the medial prefrontal cortex using slices extracted from both aged (20 month) and young adult (4 month) F344 rats. With respect to excitatory signaling, we found that interneurons, unlike pyramidal neurons, experience a loss of spontaneous excitatory input in age, and that the amount of current carried by NMDA receptors during an evoked EPSC is also reduced. Recent data further indicate that synaptic NMDA current in cortical interneurons in young animals is carried by combination of NR2A and NR2B containing receptors, and ongoing studies are expected to reveal whether NR2A or NR2B current is more severely impacted by age. With respect to inhibitory signaling, our results indicate that aging leads to a loss of tonic GABAergic inhibition experienced by

cortical interneurons, and that this change is likely associated with a functional increase in neuronal gain. These results also differ from, and likely compliment, prior observations made in pyramidal neurons. Future studies will attempt to evaluate whether specific subpopulations of cortical interneurons are particularly susceptible to tonic inhibition in young animals. Overall, our data reveal several clear and novel age related changes in the physiology and functional modulation of cortical interneurons, and provide additional mechanistic insight on how aging ultimately alters excitability in cortical networks that subserve executive function.

Title: A low-cost, open-source gait tracker for rodents

Authors: *R. NDUM[1], N. C. TOPPER[1], A. R. HERNANDEZ[1], S. N. BURKE[1,2], A. P. MAURER[1,3];
[1]Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Inst. on Aging, Gainesville, FL; [3]Biomed. Engin., Gainesville, FL

Abstract: Animal models of cerebellar disorders, Parkinson's disease, motor degeneration, arthritis and nerve regeneration often necessitate quantification of specific gait parameters in order to evaluate the efficacy of potential therapeutic interventions. Unfortunately, equipment for monitoring gait parameters is often cost-prohibitive and may reduce ethological validity if walking is restricted to a treadmill apparatus. Moreover, gait measurements that rely on this type of forced walking can be difficult to implement in rats. The current poster presents an open-source gait tracker capable of being used for rats and mice during natural movement as well as an algorithm capable of recording and quantifying gait variability, cadence and other parameters related to motor performance. Similar to other commercially available products, the present gait

maze operates on frustrated-total internal reflection trapping ultraviolet light within the acrylic until another medium (e.g., a paw) comes in contact with the floor. In other words, paw presses become illuminated proportional to the pressure of placement. The light is then recorded on a modified GoPro camera from Back-Bone Gear Inc. Specifically, the UV filter was removed, and the stock lens replaced with one of a variable focal length, in order to provide a low cost platform for recording at 120 framerates per second. Furthermore, an angled mirror is used to simultaneously record a profile view of the animal, allowing for the measurement of additional performance parameters, such as angle of spinal flexion and plantigrady. This implementation of a gait tracker can be assembled for less than $1500. Moreover, it does not rely on an enclosure for the subject, as is the case in commercially available products. Thus, this gait tracker is highly versatile and can readily be integrated with neurophysiological recordings, deep-brain stimulation, or other behavioral testing apparati to monitor gait in the context of a dual motor-cognitive task. Finally, providing initial open-source software, the intention of the current project is to make gait tracking readily available to laboratories at extremely low cost in order to accelerate collaboration, development and discovery.

Title: The effects of sleep deprivation on spatial representations in young and aged adult mice during the object-place recognition task

Authors: *R. K. YUAN, I. A. MUZZIO;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sleep is thought to play a key role in memory consolidation, due to findings showing that neuronal ensembles activated during navigation are reactivated during sleep, and that sleep deprivation causes deficits in several hippocampus-dependent tasks. Moreover, previous

literature has shown that both cognition and sleep undergo several age-related changes. Here, we examined changes in sleep characteristics and cellular activity in young and aged adult C57bl/6 mice that were sleep-deprived after training in a hippocampus dependent object-place recognition task. On day 1, animals were habituated to a novel environment in which they subsequently explored an array of 3 objects placed in the environment, over the course of 3 consecutive training sessions. Immediately after the last training session, animals were sleep deprived for 5 hours using an automated sleep deprivation system consisting of a cylindrical enclosure with a continuously rotating bar. The following day, animals were reintroduced to the environment for a single test session in which one object was displaced. We found that aged animals and young sleep-deprived animals showed a reduced preference for the displaced object compared to young controls. Similar to previous findings in rats, young control mice displayed high place field stability from the third training session to the displaced object test session. However, aged animals and young sleep-deprived animals remapped strongly between the training session and the test session, suggesting that the animals perceived the context as novel. Additionally, we examined patterns of REM and NREM sleep following sleep deprivation and found that young sleep-deprived animals exhibited increased NREM sleep relative to controls, while aged animals showed increases in both REM and NREM. Our preliminary findings suggest that animals may need to maintain a stable representation of the context in order to perform the object-place recognition task, and that both sleep deprivation and age result in decreased place field stability in the long-term corresponding with impaired performance. Furthermore, sleep deprivation may have a differential effect on subsequent REM and NREM sleep in young and aged adult mice.

Title: Post-translational modifications of the NMDA receptor GluN2B subunit in the frontal cortex of old mice are related to spatial learning and cognitive flexibility

Authors: ***K. R. MAGNUSSON**, D. R. ZAMZOW, V. ELIAS, V. ACOSTA, E. ESCOBEDO; Dept Biomed Sci, Coll Vet Med. & Linus Pauling Inst., Oregon State Univ., Corvallis, OR

Abstract: The N-methyl-D-aspartate receptor (NMDAR) is particularly vulnerable to the effects of aging. The GluN2B subunit of the NMDAR, compared to other NMDAR subunits, suffers the greatest losses of expression in the aging brain, especially in the frontal cortex. One protein from the NMDAR complex, the scaffolding protein PSD-95, has an increased interaction with GluN2B in crude synaptosomes of the aged frontal cortex, which correlates with poorer learning. In this study we explored some of the mechanisms that may promote differences in the NMDAR complex in the frontal cortex of aged animals. Two ages of mice, 3 and 24 months, were behaviorally tested in the Morris water maze. The old mice were divided into two categories (good and poor learners), based on reference memory performance of young in place trials (threshold = mean + 2SD). The frontal cortex from each mouse was subjected to differential centrifugation, followed by solubilization in Triton X-100. Proteins from Triton insoluble membranes (synaptic membranes), Triton soluble membranes (extrasynaptic membranes), and intracellular membranes/cytosol were examined by Western blot. Although old mice designated as good learners performed worse than young, the old mice assessed as poor learners were significantly worse than both the young and good old in place learning. The old good learners showed impairments in reversal trials. Both old groups showed declines in GluN2B expression in the synaptic membranes of frontal cortex from young, with no change in PSD-95 expression. Levels of 115 kDa GluN2B cleavage product were found with greater intensity on Triton soluble membranes and GluN2B phosphotyrosine 1472 was increased in the synaptic membranes from frontal cortex of the old good learners, as compared to young. GluN2B phosphotyrosine 1336 was reduced and Fyn was increased in the old poor learners. These results suggest that better spatial learning in older individuals may negatively impact cognitive flexibility. The previously reported negative relationship of the PSD-95:GluN2B ratio in crude synaptosomes to memory may, in part, be due to good learners having more cleaved GluN2B in the extrasynaptic membrane than poorer learners. This may have been influenced by alterations in phosphorylation during aging.

Title: Social memory of old-age mice and the effects of juvenile interactions

Authors: *A. S. ALMEIDA, A. R. P. CAIXETA, G. S. PEREIRA;
Inst. De Ciências Biológicas- Univ. Federal De Minas Gerais, Belo Horizonte, Brazil

Abstract: Introduction: Intuitively, we all know that aged people are usually very close to younger individuals. In fact, studies have showing that social stimulus can promote engagement in persons with dementia. Furthermore, social isolation accelerates, while social stimulus prevents the memory impairments observed in animal models for Alzheimer's disease. Here we tested the hypothesis that housing old-age mice with a juvenile mouse will decrease the cognitive impairments caused by natural aging and social isolation. Methods: Adult (2 months old) and old-aged (18 months old) male C57/BL6 mice and Swiss juvenile mice (21 days old) were used. Animals were maintained in 3 different housing conditions during one week: Adult mice housed with other adult mice (AAH), aged mice housed with other aged mice (OOH) and one aged mouse housed with one juvenile mouse (OJH). On the eighth day the animals were submitted to the social recognition paradigm to test social short- and long-term memories, S-STM and S-LTM, respectively. The social recognition index was analyzed by one-way ANOVA followed by the Bonferroni test. Results: S-STM was preserved in AAH (0.33±0.03) and OOH (0.36±0.04) groups, but impaired in OJH animals (0.54±0.05). Similar results were observed for S-LTM [AAH (0.37±0.01), OOH (0.36±0.02), OJH (0.63±0.06)]. Conclusion: Social memory was not impaired in old-age mice and the juvenile stimulus impaired their social memory, which was the opposite of what we predicted. We intend to evaluate other types of memories and also to verify if long-periods of co-housing old-age and juvenile mice would present a positive effect on cognition. Abstract: Over 80% of women will experience pregnancy and childbirth, and it is well known that both the brain and behavior are altered with pregnancy. Studies have found that rats that have more than one litter (multiparous) exhibit better reference and working memory and less hippocampal neurodegeneration with age (Kinsley et at, 1999; Pawluski et al, 2005; Gatewood et al, 2005); however, humans exhibit a decline in verbal recall memory that lasts from pregnancy through 3 months postpartum (Glynn, 2012). Studies involving the effects of pregnancy and reproductive experience on learning in mice are lacking. Based on the previous rat literature, we hypothesized that multiparous female mice would exhibit enhanced memory on a hippocampal dependent contextual fear memory task. To analyze this, we employed both multiparous and virgin (nulliparous) females from the BXD mouse panel (n=10 strains/grp), a genetic reference panel in which the resulting lines are descended from crosses between C57BL/6J and DBA/2J and are 99.5% isogenic yet genetically diverse. We found that reproductive experience significantly affected contextual fear memory in middle aged (12-20 mo) female BXD mice. Specifically, middle-aged multiparous BXD mice had significantly worse contextual fear memory compared to their nulliparous counterparts (paired two-tailed t-test: p=0.002). These results suggest that reproductive experience in middle-aged BXD mice negatively affects hippocampal function. Follow up studies using the BXD reference panel, which have been densely phenotyped and provide an excellent resource to study both genetic and phenotypic variation across a population in traits, will enable dissection of genetic mechanisms on cognitive functions and other phenotypic traits related to human mental health, including depression and anxiety. Identification of novel gene variants and/or unexpected related health traits that compound or mitigate the memory decline following childbirth is of major significance for biomarker development and personalized therapeutics.

Title: Nest building and circadian rhythm activity is impaired in APOE4 mice compared to C57 mice

Authors: *K. BOGGS[1], K. A. PEDEMONTE[1], C. L. C. NEELY[1], S. A. STAVROU[1], S. N. HOWELL[1], L. BOZZELLI[2], J. M. FLINN[1];
[1]George Mason Univ., Fairfax, VA; [2]Interdisciplinary Program in Neurosci., Georgetown Univ., Washington, DC

Abstract: Nest building by mice is an innate behavior that provides the animal with shelter and temperature regulation. Because nest building is instinctive for mice, it is often used to assess animal welfare. The ability of mice to build nests is influenced by several factors including temperature and illness, and changes in nesting suggest an alteration to the environment or the animal itself (Gaskill et al., 2013). Hess et al. suggest that nest building is additionally influenced by the biological relevance of the nesting material. Previous research on nest building in C57 mice has reported significant nest building results using pressed cotton squares (Deacon, 2006). However, attempts by our lab have been made using cotton squares with Alzheimer's (AD) mouse models generated on a C57 background, with variable results. Many AD patients have deficits in activities of daily living (ADL), including activities such as bathing, dressing, and feeding, and nest building serves as a measure of ADL in mice. It is essential to establish an appropriate nesting material in genetically modified mice before conducting an experiment, to ensure that nesting behavior is a result of the animal model rather than the material provided. Thus, 4 different nesting materials were tested in C57 (n=10) and APOE4 mice (n=11), older than 9 months. The nesting materials included iso-BLOX cotton squares (Harlan 6060), Diamond Twists (Harlan 7979C.CS), Soft Cob bedding (Harlan 7987C), and shredded paper. To assess nest building, animals were individually housed for 2 days with each of the 4 nesting materials, for 4 nesting trials per animal. Results indicate that shredded paper is more reliable than the other 3 nesting materials ($p<0.01$), followed by Soft Cob bedding, which was significantly better than the other 2 nesting materials ($p<0.05$). There was no significant difference between iso-BLOX cotton squares and Diamond Twists. Additionally, there was a main effect of genotype, with the E4s performing worse ($p<0.01$). Another aspect of daily living is circadian rhythm (CR) activity, which is measured in mice by observing wheel running activity. In a 5-day CR assay, C57s consistently initiated activity at 19:00 hours, while E4s demonstrated a delay in activity onset by 6 hours for 2 of the testing days ($p<0.05$). C57s had longer bouts and more counts/bout, suggesting that E4s had more random circadian rhythm activity. A day-by-day repeated-measures ANOVA indicated a day*genotype interaction ($p=0.05$) for number of bouts/day. While number of bouts for E4s were shorter in duration and of fewer counts, bouts/day were significantly higher ($p<0.05$), demonstrating a significant main effect of genotype.

Title: Disparate brain lipid profiles in mouse models of IGF-1 deficiency

Authors: *S. LOGAN[1], J. E. SANDERS[1], N. M. ASHPOLE[1], R. S. BRUSH[2], R. E. ANDERSON[2], W. E. SONNTAG[1];
[1]Reynolds Oklahoma Ctr. on Aging/Geriatric Med., [2]Opthalmology, Univ. of Oklahoma HSC, Oklahoma City, OK

Abstract: Insulin-like growth factor-1 (IGF-1) deficiency with age is associated with impairments in learning and memory. Nevertheless, different models of IGF-1 deficiency (e.g. the growth hormone receptor (GHR) and IGF-1 knockout) appear to have diverse effects on cognitive function. Previous studies indicate that growth hormone (GH) can regulate hepatic lipid biosynthesis but the effects on cognitive function are unknown. Lipids have been shown to mediate critical aspects of neuronal function. Changes in the lipid milieu in brain have been reported in aging and age-related neurodegenerative diseases. In this study, we performed a comparative analysis of the brain lipid profile in two models of IGF-1 deficiency. Our hypothesis is that models of systemic GH/IGF-1 deficiency have unique effects on brain lipid profiles and cognitive function. We induced knockdown of 1) the hepatic growth hormone receptor (GHR) and 2) hepatic IGF-1 using liver-specific AAV8-TBG-Cre (L-Cre) or -GFP (L-GFP). Mice, either growth hormone receptor floxed (GHRf/f) or IGF-1f/f, were retro-orbitally injected with AAV8 at 2-3 months of age. Mice were assessed behaviorally at different timepoints post-injection using the radial arm water maze (RAWM) for spatial memory. Following behavioral testing, tissues were harvested and brain regions were analyzed for lipid profiles. GHRf/f-L-Cre mice (6m post knockdown) showed deficiency in the reversal task in behavioral analysis indicating a deficit in memory compared to -L-GFP controls. IGF-1f/f-L-Cre animals (3m and 1y post knockdown) showed no behavioral differences compared to -L-GFP controls. In both animal models Cre-injected animals showed ~60% reduction in circulating IGF-1 levels compared to GFP controls. GHRf/f-L-Cre mice showed significant changes in hippocampal phospholipids compared to GHRf/f-L-GFP. MUFA synthesis (c18:1) was increased in the

hippocampus as well as in the serum of the GHRf/f-L-Cre mice compared to -GFP controls. IGF-1f/f-L-Cre mice, with comparable circulating IGF-1 levels to the GHRf/f-L-Cre mice, showed no significant changes in hippocampal phospholipids profiles or fatty acid synthesis. While there may be a compensatory mechanism in the brain of IGF-1f/f-L-Cre mice regulating fatty acid synthesis, the lipid changes in the GHRf/f-L-Cre mice suggest an effect of growth hormone in fatty acid/lipid regulation, which is correlated with deficiency in cognition. By understanding the specific role of these lipids in brain function and its regulation by IGF-1, we expect to develop metabolic targets of therapeutic potential to avert or delay age-related cognitive impairment.

Title: Early life IGF-1 deficiency results in age-related cognitive impairment

Authors: E. L. HODGES[1], N. M. ASHPOLE[2], *W. E. SONNTAG[2];
[1]Oklahoma Ctr. for Neurosci., [2]Dept. of Geriatric Med., Univ. of Oklahoma HSC, Oklahoma City, OK

Abstract: Previous studies indicate that the decline in circulating IGF-1 with age contributes to cognitive dysfunction. Nevertheless, studies have reported differential cognitive outcomes of young animals deficient in hepatic IGF-1. To address these disparate effects, we developed mouse models in which a deficiency of circulating IGF-1 can be initiated at different stages of the lifespan. Here, we report the behavioral results of a comprehensive study on the time-dependent effects of IGF-1 deficiency on lifespan and behavior in C57BL/6 mice. Cognitive assessment was performed on male mice with either a hepatic specific knockout of IGF-1 (induced at p15) by crossing $Igf^{f/f}$ mice with albumin-Cre or $Igf^{f/f}$ mice injected with a hepatic specific AAV-Cre (AAV8-TBG-Cre) or AAV8-TBG-eGFP at 5 or 15 months of age. In each group, hepatic IGF-1 knockdown reduced serum IGF-1 levels by at least 50% compared to controls. Using the Barnes maze to assess spatial learning and memory, we find that male mice deficient in circulating IGF-1 beginning at p15 and tested at 26 months of age are cognitively

impaired when compared to non-deficient litter-mate controls. During probe trials, performed 24 hours after the last day of after acquisition, animals with early onset IGF-1 deficiency (p15) were only able to find the platform 17% of the time compared to 58% in their litter-mate controls. Additionally, these animals visited the target location less frequently than control groups. These deficiencies were not observed when circulating IGF-1 was reduced at 5 or 15 months of age. Our results provide compelling evidence that the age of onset of IGF-1 deficiency has an important influence on the development of cognitive dysfunction in C57BL/6 mice.

Title: A novel slow (1-3 Hz) oscillatory cell type in the lateral septum

Authors: *J. R. HINMAN, J. R. CLIMER, G. W. CHAPMAN, M. E. HASSELMO;
Ctr. for Memory and Brain, Boston Univ., Boston, MA

Abstract: A multitude of oscillatory patterns are present in the brain ranging in cycle duration from hours to seconds to milliseconds. Varying constellations of channels endow individual neurons with the capability to oscillate at these various frequencies. We performed multiple single unit recordings in awake behaving rats in both the medial septum (MS) and the adjacent lateral septum (LS), which is distinct from its medial neighbor based on the neurochemical composition of its constituent neurons and its afferent and efferent projections. The oscillatory properties of neurons in the two regions were compared. A novel oscillatory cell type was identified in LS with a frequency ranging from 1 to 3 Hz. Unlike classically described delta frequency activity, the slow rhythmic firing of these LS neurons does not occur during slow wave sleep. In fact, the oscillatory activity is most robust during locomotor behavior during which the oscillation frequency increases as a function of running speed, similar to the manner in which theta rhythmic neurons in MS have oscillation frequencies that increase as a function of running speed. Slow rhythmic LS neurons are not simply firing on an interval of multiple theta

cycles, as is observed in neurons that fire on alternate theta cycles. There is actually a lack of any relationship between slow rhythmic LS and theta rhythmic MS neurons. Cross-correlations between simultaneously recorded slow rhythmic LS neurons and theta rhythmic MS neurons revealed no relationship between the two oscillatory cell types and slow rhythmic cells have no theta phase preference. Despite the lack of temporal coordination between the two oscillatory cell types, both slow rhythmic LS neurons and theta rhythmic MS neurons have strong temporal interactions amongst themselves. Both oscillatory cell types maintain a variety of phase relationships with other oscillatory cells of the same frequency. Overall, slow rhythmic LS neurons behave similarly to theta rhythmic MS neurons, albeit at a slower frequency, and may play a role in updating or synchronizing downstream supramammillary nucleus circuits.

Title: Medial septal infusion of a serotonin 1A receptor agonist anxiolytic reduces theta frequency in the medial entorhinal cortex

Authors: *C. MONAGHAN[1,2,3], G. CHAPMAN, IV[1,3], M. HASSELMO[1,3];
[1]Dept. of Psychological and Brain Sci., [2]Grad. Program for Neurosci., [3]Ctr. for Systems Neurosci., Boston Univ., Boston, MA

Abstract: Theta rhythm is a prominent 6-10 Hz oscillation that can be found in the local field potential (LFP) and rhythmicity of single unit firing throughout many areas of the rodent brain, including the medial septum (MS), hippocampus, and medial entorhinal cortex (MEC). This rhythm can be disrupted through interfering with normal activity within the MS with lesions (Mitchell et al., 1982) or pharmacological inactivation (Mizumori et al., 1990). Temporarily inactivating the MS pharmacologically also disrupts the spatially periodic firing of grid cells

recorded in the MEC (Brandon et al., 2011; Koenig et al., 2011). Anxiolytics provide a method of investigating mechanisms underlying grid cell firing and their associated circuit, as anxiolytics have been shown to reduce the frequency of theta rhythm recorded in the hippocampus (McNaughton et al., 1986; Coop & McNaughton, 1991; Wells et al., 2013) and the mEC (Monaghan et al., 2014, Soc. Neurosci. Abstr.). While multiple types of anxiolytic drugs reduce the y-intercept, and not the slope, of the relationship between theta frequency and running speed when given systemically, it is not known if effects are exerted through actions on the MS. Here we report the effects of MS infusions of the serotonin 1A receptor agonist 8-OH-DPAT and the benzodiazepine diazepam on LFP activity and firing properties of single units recorded in the MEC. We found that MS infusions of 8-OH-DPAT, but not diazepam, reduced the y-intercept of theta frequency across running speeds, suggesting that benzodiazepines decrease theta frequency when given systemically via actions in a different brain region. This result lends support to the prediction made by John et al. (2014) that benzodiazepine action in the septo-hippocampal circuit is not sufficient to produce significant effects on theta frequency, which can perhaps be extended to the septo-entorhinal circuit as well.

Title: *In vivo* rebound spike characteristics of medial entorhinal cortex cells

Authors: *Y. TSUNO[1,2], G. CHAPMAN[2], M. E. HASSELMO[2];
[1]Psychology, [2]Ctr. for Memory and Brain, Dept. of Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Medial entorhinal cortex is an anatomical gateway between neocortex and hippocampus, and plays a critical role in spatial learning and memory. The medial entorhinal cortex contains a variety of spatially modulated cells, including grid cells. Grid cells have

attracted interest because of their highly-organized hexagonal response pattern indicating an allocentric representation of the outside world. On the other hand, medial entorhinal cortex layer II stellate cells predominantly interact via inhibitory feedback, and it is possible that hyperpolarizing input affects the probability of subsequent spikes due to rebound potentials and rebound spikes. Our laboratory recently proposed a model incorporating rebound spikes to generate grid cell activity. To examine the characteristics of rebound spikes *in vivo*, patch clamp recording was performed from medial entorhinal cortex cells in ketamine and xylazine anesthetized mice. We injected brief hyperpolarizing current at various phases of the oscillation superimposed with sinusoidal oscillation, and found that hyperpolarizing current stimulation at specific phases of sinusoidal oscillation increased the probability of subsequent spikes at the peak of the oscillation in some cells. Also, the effect of the hyperpolarizing input to subsequent spikes is larger in the cells that had larger sag amplitude, indicating a relationship between sag potential and rebound spikes. In addition, larger and longer hyperpolarizing current square pulse stimulation could result in larger probability of eliciting rebound spikes. We did not observe a relationship between amplitude or duration of hyperpolarizing current square pulse stimulation and the temporal delay for rebound spikes relative to the end of hyperpolarizing current stimulation. These results suggest that rebound spikes exist *in vivo* and may play a critical role for emerging grid cell activity in medial entorhinal cortex cells.

Title: Optogenetic silencing of septal cholinergic cells, memory and hippocampal theta

Authors: *J. R. CLIMER[1,2], M. E. HASSELMO[1];
[1]Dept. of Psychological and Brain Sci., [2]Grad. Program for Neurosci., Boston Univ., Boston, MA

Abstract: Acetylcholine plays an important role in memory. Specifically, administration of the cholinergic antagonist scopolamine has been shown to disrupt the ability to encode new memories (Ghoneim and Mewaldt, 1975; Petersen, 1977). Prominent theta and gamma oscillations can be found in the medial temporal lobe (Bragin et al., 1995; Buzsáki, 2002, 2006; Colgin et al., 2009; Belluscio et al., 2012). Theta modulates the power of gamma oscillations, and this theta-gamma coupling has been proposed to play a role in the routing of hippocampal inputs (Colgin et al., 2009; Schomburg et al., 2014). Furthermore, experiments in our laboratory have shown altered theta-gamma coupling in entorhinal cortex following scopolamine (Newman et al., 2013). Modeling work in our laboratory has suggested how differential modulation of inputs, and thus encoding and retrieval, by theta phase and acetylcholine could be useful for stable memory formation (Hasselmo and Wyble, 1997; Hasselmo et al., 2002). Here, we leverage the temporal and anatomical specificity of optogenetics to explore this hypothesis. Using archaerhodopsin expressed in ChAT positive neurons, we can silence medial septal cholinergic neurons, reducing cholinergic tone selectively in the hippocampal circuit. We use the hippocampally-dependent delayed non-match to position task to investigate the role of acetylcholine in hippocampal memory. This task allows us to repeatably separate encoding and retrieval, and thus we can examine the effect of cholinergic silencing during the different phases of the trial, testing whether septal acetylcholine is required for encoding on the seconds to minutes timescale. Additionally, we have performed recordings using silicon probes with sites spanning layers of hippocampal region CA1 during running. Using current source density and phase-amplitude coupling, we have examined the effects of cholinergic silencing on anatomically sourced hippocampal inputs. Together, these results will provide insights into the role that acetylcholine plays in shaping hippocampal physiology, and the relationship between this physiology and memory processing.

Title: Task-relevant dynamics of neural network activity in mouse prefrontal cortex

Authors: *H.-A. TSENG, X. HAN;
Boston Univ., Boston, MA

Abstract: Decision making process involves prefrontal area to integrate the sensory information, and to convert it to proper decisions based on learnt rules. While primate prefrontal cortex (PFC) has been well characterized for its crucial role in decision making process, mouse PFC is much less understood. As an attractive animal model with increasingly available genetic and molecular tools, mice provide a unique system to link understandings across molecular, genetic, neural network and behavioral levels. To understand how mouse PFC neurons process sensory information during decision making, we characterized PFC activities in freely moving mice performing an auditory discrimination task. In this task, mice were trained to initiate the presentation of one of three auditory cues, and to obtain reward at specific locations according to the cue features. We recorded single neuron activities and local field potentials (LFPs) using tetrodes bundles positioned at four sublocations within PFC, while mice are performing the task. We discovered that PFC neurons exhibit task relevant activities, with distinct neuron populations increasing activities at discrete phases of the behavioral task. Further examination shows that the spike activities could be modulated by the information relevant to the stage of the task where they have highest spike activities. Beside the spike activity, the beta oscillation of LFP is also modulated by the task progress and exhibits two peaks. One right before mice initiated the task, and the other always towards the end of the task. While the timing of the first peak is consistent across the trials, the timing of the second peak is positively correlated with the trial duration. Overall, our results showed that both spike and LFP are modulated by the task progress, and the spike activity could carry the curial information relevant to the task.

Title: Cholinergic modulation of cortico-cortical interaction

Authors: N. JAMES[1], H. GRITTON[1], N. KOPELL[2], *X. HAN[1];
[1]Biomed. Engin., [2]Mathematics, Boston Univ., Boston, MA

Abstract: Cortical projecting cholinergic neurons modulate neural circuit interactions over a wide range of spatiotemporal scales, from transient influence on information processing within local brain regions to long term impacts on synaptic plasticity and general arousal across multiple brain areas. Over the years, *in vitro* slice physiology experiments have established a comprehensive understanding of the biophysical mechanisms underlying acetylcholine action on various cell types and local circuit interactions. In addition, *in vivo* pharmacological experiments, via systemic or intracranial infusion of cholinergic agonists or antagonists, have established a direct link between cholinergic activation and attentional processing, sensory detection and plasticity. However, detailed neural circuit mechanisms underlying acetylcholine actions across large neural networks during information processing is less well understood. To examine the functional role of acetylcholine on coordinating cortical-cortical interactions, we performed simultaneous recordings in the auditory cortex and the prefrontal cortex in awake head fixed mice, when mice were presented with auditory stimuli. We discovered that auditory stimuli could effectively elicit responses in the prefrontal cortex during passive listening state, and the responses seen in prefrontal cortex are modulated by muscarinic receptor activation within the auditory cortex. Together our results suggest that acetylcholine can gate information flow from the auditory cortex to the prefrontal cortex selectively via muscarinic receptor mechanisms.

Title: Alpha coherence between frontal and auditory cortex during extinction learning in mice

Authors: *N. JAMES, H. GRITTON, Z. YAO, N. KOPELL, X. HAN;
Boston Univ., Boston, MA

Abstract: Cortical synchrony--a hallmark of executive functioning--is theorized to contribute to communication between networks during cognition. In particular, selective attention and cognitive flexibility--the ability to update task rules when conditions change--are two notable deficits often characterized in individuals with impaired executive function. To understand the functional role of neural synchrony in selective attention and cognitive flexibility, we recorded from auditory (AC) and frontal cortex (FC) while mice performed an extinction learning task. Prior to recording, animals were trained to lick for a small water reward that had been paired with two distinct tones separated by 1.5 octaves. Once the associations were well learned, recordings were made from animals when the reward was withdrawn from one of the two tones while the other was maintained. We observed that frontal neurons show enhanced sensitive to the extinguished tone during extinction learning. In addition, we found that neural synchrony between AC and FC is enhanced broadly during cue processing but that alpha (8-13 Hz) power and coherence is selectively enhanced only for the extinguished tone, and only as mice learned to suppress licking. Taken together, these results suggest that increased coherence between sensory and association regions is an inherent property of auditory discrimination and that alpha oscillations may underlie the processes necessary for cognitive flexibility.

Title: Representations of novel and familiar object-place associations differ during slow and fast gamma rhythms in the hippocampus of freely behaving rats

Authors: *C. ZHENG[1], K. W. BIERI[2], L. L. COLGIN[3];
[1]Univ. of Texas At Austin, Austin, TX; [2]Inst. for Neurosci., [3]Ctr. for Learning and Memory, The Univ. of Texas at Austin, AUSTIN, TX

Abstract: Hippocampal gamma rhythms are thought to play a role in memory operations by coordinating the activity of neurons that code related information. Increasing evidence suggests that gamma rhythms split into distinct slow (~25-55 Hz) and fast (~60-100 Hz) gamma subtypes, yet the significance of these different subtypes with regard to memory remains unclear. In this study, we investigated how slow and fast gamma rhythms relate to memory encoding of novel object-place associations and memory retrieval of familiar object-place associations. Place cell spikes and local field potentials were recorded in hippocampal subfields CA1 and CA3 for 6 rats and CA1 for 1 additional rat. Recordings were collected during three different novelty conditions: a novel object placed in a familiar location, a familiar object placed in a new location, and a novel object placed in a new location. The strongest and most consistent behavioral and physiological effects were observed when a novel object was placed in a new location; results from this condition are described below. Fast gamma power in CA1 and CA3, and CA3-CA1 fast gamma phase synchrony, significantly increased during exploration of novel object-place associations compared to familiar object-place associations. On the other hand, CA3-CA1 slow gamma phase synchrony was significantly higher during exploration of familiar object-place associations. Also, hippocampal place cell spikes were more strongly phase-locked to fast gamma during exploration of novel object-place associations than during exploration of familiar object-place associations. Such effects were not observed for slow gamma phase-locking

of place cell spikes. Moreover, CA1 place cells with fields close to novel objects in new locations exhibited significantly higher firing rates during fast gamma epochs than during slow gamma epochs. These results suggest that novelty signals induce fast gamma coordination of hippocampal subfields and corresponding enhancement of place cell firing during encoding of novel object-place associations.

Title: Hippocampal place cells exhibit distinct spatial coding modes in mice

Authors: *B. J. GEREKE[1], D. T. JONES[2], L. L. COLGIN[2];
[1]Inst. for Neurosci., [2]Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Previous work in rats has demonstrated that 'prospective' and 'retrospective' coding modes exist in grid cells (de Almeida et al. 2012) and place cells (Muller and Kubie 1989, Battaglia et al. 2004, Bieri et al. 2014). In this context, prospective and retrospective modes are defined as times when the majority of a place cell's spikes occur prior to (prospective), or shortly after (retrospective), the animal passes through its place field. In CA1 place cells, retrospective modes have been proposed to support the encoding of recent information, driven by persistent firing in medial entorhinal cortex (MEC). On the other hand, prospective modes are thought to reflect a CA3-dependent memory retrieval of representations of upcoming locations. Consistent with this idea, Bieri et al. (2014) showed that CA1 slow gamma rhythms, thought to reflect inputs from CA3, are more prominent during prospective coding, whereas CA1 fast gamma rhythms, thought to reflect inputs from MEC, are more prominent during retrospective coding. These results are intriguing, but a causal dependence of coding modes on anatomically segregated inputs has not yet been demonstrated. Mice offer the genetic tractability to investigate this question, and thus it is important to determine whether such coding modes are also found in

mice. Here, we demonstrate that CA1 place cells indeed display distinct prospective and retrospective coding modes in mice. As in rats, these modes occurred more frequently than predicted from a distribution of randomly shuffled displacements of place cell spikes. Also, as in rats, pairs of cells were more likely to participate in the same coding mode if they were active at approximately the same time, suggesting that coding modes are coordinated at the population level. Moreover, an increased probability of retrospective events was observed during the first passes through a field in a recording session, consistent with the experience-dependent, backward expansion of place fields shown in rats (Mehta et al. 1997). With these results in place, an investigation of the causal dependence of coding modes on anatomically segregated inputs is now possible.

Title: CA3 slow gamma power is driving CA1 theta phase in rat hippocampus

Authors: *H. JIANG[1], A. BAHRAMISHARIF[2], M. VAN GERVEN[1], K. W. BIERI[3], L. L. COLGIN[3], O. JENSEN[1];
[1]Ctr. for Cognitive Neuroimaging, Donders Inst., Nijmegen, Netherlands; [2]Dept. of Psychiatry, Academic Med. Ctr., Amsterdam, Netherlands; [3]Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: It is well established that theta and gamma oscillations interact in the rat hippocampus. One example is the coupling between theta phase and gamma power in the CA1. This theta-gamma cross-frequency coupling (CFC) might facilitate the transient coordination of local networks on short time scales and integrate the processing between more distant networks. However, it is unclear whether the phase of the theta oscillations drives the gamma activity or whether the gamma activity drives the phase of the theta oscillations. We here apply spectral Granger causality and a novel measure termed cross-frequency directionality (CFD) to

investigate the directional interaction between the hippocampal subregions CA1 and CA3. This CFD measure is based on the phase-slope index (PSI) between the phase of slower oscillations and the power envelope of faster oscillations. The data were recorded from freely exploring rats. Granger analysis revealed that CA3 drives CA1 in the theta and gamma band. Further, the gamma power in CA3 was strongly coupled to the theta phase in CA1. Importantly, the CFD measure demonstrated that CA3 gamma power was driving CA1 theta phase. We conclude that the information flow in rat hippocampus is coordinated by an interaction between theta phase and gamma power. The finding that CA3 gamma power drives CA1 theta phase challenges theories suggesting that hippocampal theta activity coordinates neuronal processing reflected in the gamma band. Rather, it seems as if 'bursts' of gamma band activity in CA3 can phase adjust the recorded theta oscillations in CA1.

Title: Chemogenetic activation of hippocampal area CA2 neurons increases gamma oscillations in hippocampus and prefrontal cortex

Authors: *G. M. ALEXANDER[1], L. Y. BROWN[2], S. FARRIS[1], C. B. PANTAZIS[3], D. J. LUSTBERG[1], B. GLOSS[1], N. W. PLUMMER[1], P. JENSEN[1], S. M. DUDEK[1];
[1]Neurobio. Lab., Natl. Inst. of Envrn. Hlth. Sci., Research Triangle Park, NC; [2]Curriculum in Neurobio., Univ. of North Carolina, Chapel Hill, NC; [3]Grad. Sch. of Biomed. Sci., Rutgers Univ., Piscataway, NJ

Abstract: Gamma oscillations (30-120Hz) occur widely throughout the hippocampal formation where they are believed to play a critical role in the encoding and retrieval of declarative memories by coordinating the activation of local neuronal populations into transient cell assemblies. Gamma oscillations have warranted considerable attention in schizophrenia because individuals diagnosed with the disease display abnormalities in this frequency band during a variety of perceptual and cognitive tasks. Although relatively understudied, the CA2 field of the hippocampus is becoming increasingly recognized as a socio-cognitive hub for processing memories containing socially relevant information. Because impairments in social cognition are

a common symptom associated with schizophrenia, and because CA2 is unique within the hippocampus in its susceptibility to loss of interneurons in schizophrenia, abnormal gamma activity in CA2 emerges as a candidate mechanism for linking the known cellular and network pathologies with the socio-cognitive impairments observed in individuals with schizophrenia. To address the relationship between CA2 neuronal activity and gamma oscillations in hippocampus and prefrontal cortex, we infused adeno-associated viruses coding for a cre-dependent excitatory DREADD (Designer Receptors Exclusively Activated by Designer Drugs) into hippocampi of mice that express cre recombinase selectively in CA2 pyramidal cells under the control of the *Amigo2* promoter. We then implanted electrode arrays to monitor activity of hippocampal and prefrontal cortical neurons before and following administration of the DREADD ligand, Clozapine-N-oxide (CNO), while animals freely behaved in an open field. We found that CNO increased firing of CA2 pyramidal neurons and dose-dependently increased power of local field potentials in the gamma frequency range in both and hippocampus and prefrontal cortex. At the level of the healthy brain, these findings demonstrate that activation of CA2 neurons is sufficient to induce gamma oscillations not only within the hippocampus, but also in the PFC, suggesting that the CA2 circuitry may play into distributed neural networks beyond its primary target, CA1. In the diseased brain, these findings support the idea that the loss of interneurons from CA2 may underlie, at least in part, the abnormal gamma oscillations observed in schizophrenic patients and provide a mechanistic link to the socio-cognitive impairments observed in patients with schizophrenia.

Title: Pattern separation of spiketrains by individual granule cells of the dentate gyrus

Authors: *A. MADAR[1], L. A. EWELL[2], M. V. JONES[1];
[1]Neurosci., Univ. of Wisconsin-Madison, Madison, WI; [2]Neurobio., UCSD, San Diego, CA

Abstract: Pattern separation is the process thought to minimize the overlap between patterns of neuronal activity representing similar episodic memories. Theoretical work has suggested that the dentate gyrus (DG) performs this role (O'Reilly; Myers; Aimone) but experimental evidence is incomplete (Leutgeb; Neunuebel; Deng; Ramirez). One of the main limitations has been the difficulty to simultaneously measure DG inputs and outputs *in vivo*, in order to compare the similarity of patterns before and after DG processing. To rigorously assess pattern separation, we have thus developed an electrophysiological assay in the mouse brain slice, which constitutes an accessible platform to stimulate DG afferents and record its output at the same time. Although most studies have considered pattern separation as populations of neurons separating spatial patterns, it is possible that individual neurons of the DG can separate temporal patterns. To test this hypothesis, we generated 12 sets of Poisson impulse trains (~10 Hz), each set consisting of 5 trains with a fixed correlation between each other (0.25 to 1, for 5ms bins). These sets of input patterns were then delivered to the DG, in horizontal slices (400 μm), by focally stimulating the lateral perforant path, while performing whole-cell current-clamp recordings from DG granule cells (GC) (100 stimulus sets for 26 GC). Using Pearson's correlation coefficients as a similarity measure between spiketrains, we found that GC output spiketrains are significantly less correlated with each other than are their driving inputs. Importantly, the decorrelation is higher for very similar inputs than for already dissimilar inputs, consistent with the hypothesized role of pattern separation in memory. Similar results were found using the SPIKE-metric (Kreuz), a bin-less similarity measure based on spike timing. We attempted to rule out whether this form of pattern separation could merely be due to noisy neuronal processing. Shuffling of spikes in original output spiketrains, as well as simulation of output spiketrains based on the mean spike reliability and jitter measured in the original dataset, resulted in outputs significantly more separated but less reliable than the real outputs. This suggests that temporal pattern separation in single GC cannot be explained by trivial random processes, but rather likely involves dedicated biophysical mechanisms. References: Aimone et al. Title: Study of the interval timing with administration of NMDA antagonist in rats

Authors: *S. SAKATA[1], A. UJITA[2], M. HATTORI[3];
[1]Hiroshima Univ., Hiroshima, Japan; [2]Behavioral Sci., Hiroshima Univ., Higashi-Hiroshima, Japan; [3]Inst. of Biomed. & Hlth. Sci., Hiroshima Univ., Hiroshima, Japan

Abstract: Timing behavior is very important to survival and goal reaching in all animals. It is known that animals have some special timing ability of intervals. However, neural mechanisms of time perception are still unknown. The purpose of this study is to investigate the effects of NMDA antagonist on timing behavior. Firstly, using six male rats of Wistar strain, approximately 3 month-old at the beginning of the experiment, we examined psychological expectation of the interval timing in laboratory experimental settings with the peak-interval (PI) procedure. Interval-timing refers to time estimation in the second-to-minutes range. In the PI procedure, rats were trained on a fixed interval schedule to press lever for food after a specified interval (30 seconds in this experiment) as signaled by a certain stimulus. The rats received reinforcement only for desirable response. Though with some individual variations, the distribution of the lever press responses eventually showed an apparent peak in the vicinity of 30 seconds. Secondly, after 30 sessions of trainings, NMDA antagonist was administered directly into the septum region of the brain via microinjection. As a result, the peak time shifted rightward and lever press responses increased. This result of this study suggests that the comparison between the rats administered with NMDA antagonist, NMDA agonist, dopamine agonist and antagonist may clarify neural mechanisms of the interval timing.

Title: Theta sequence generation by excitatory-inhibitory interactions in CA1 networks

Authors: *A. CHADWICK, M. VAN ROSSUM, M. NOLAN;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The activity of cells in the rodent hippocampus is strongly modulated by both the location of the animal in an environment and the ongoing theta oscillation. Place cells, but not interneurons, show a strong spatial modulation of their firing rates, while both place cells and some interneurons exhibit phase precession, a phenomenon whereby they spike at a faster frequency than the LFP theta oscillation, causing their spikes to shift to an earlier phase of this rhythm on each successive cycle. Both the mechanisms and functions of phase precession remain largely unclear. We tested whether a minimal model based on the circuit architecture of CA1 and its input from the medial septum accounts for phase precession in place cells and interneurons. In this model place cells and interneurons are reciprocally connected. Interneurons receive pacemaker input from the medial septum, which entrains theta oscillations in the circuit. In simulations of a single place cell and interneuron, we found that phase precession in both cells emerges naturally. When the animal is outside of the place field, the interneuron is fully entrained to the pacemaker theta oscillation and the place cell is rhythmically inhibited, resulting in subthreshold theta oscillations. When the animal enters the place field, the place cell begins to spike, which perturbs the interneuron and causes a transient increase in frequency of the coupled pair of cells. In large scale network simulations, robust phase precession and theta sequences were observed, provided certain constraints on place field mapping and the sparsity of the spatial code were met. In generating phase precession from rate coded place cell inputs, the model we propose suggests that the CA1 circuit flexibly transforms slow rate coded inputs which vary over behavioural timescales into a temporal population code at the timescale of a single theta cycle. The network maintains a short term memory of its inputs, and faithfully preserves their temporal ordering at a much faster timescale suitable for neural processing. Such a network can equally process non-spatial inputs, and can explain why the hippocampus is crucial for the memory of temporal order and transitive relations in general.

Title: Bi-directional optogenetic modulation of prefrontal parvalbumin neuron activity in spatial working memory

Authors: *C. K. YOUNG, M. CARLÉN;
Karolinska Institutet, Stockholm, Sweden

Abstract: Normal brain function requires the coordination of activities from key structures in the brain through oscillation and synchrony. Various implementations of a spatial working memory paradigm in rodents have demonstrated robust coherent activity between the hippocampus and the medial prefrontal cortex at theta (4-12 Hz) frequencies prior to decision making. Parvalbumin (PV+) neurons in the cortex are crucial in coordinating global and local synchrony through feedforward and feedback inhibition. Particularly, putative PV+ interneurons in the prefrontal cortex exhibit spiking entrainment at theta frequencies themselves, as well as entraining local pyramidal neurons during periods of high hippocampo-prefrontal theta coherence through increasing the strength of their inhibitory inputs to pyramidal neurons. In this study, we sought to bi-directionally modulate prefrontal PV+ neuron excitability, hence controlling the level of rhythmic theta entrainment from the hippocampus and ultimately, to enhance or decrease spatial working memory performance. We record caudal hippocampal and medial prefrontal multiunit and local field potential activities from behaving PV-Cre mice injected with either SSFOs (hChR2(C128S/D156A)) or Jaws (Halo57(K200R/W214F)) to increase or decrease PV+ neuron excitability, respectively. The mice were trained to perform a delayed non-matching-to-sample task on an automated figure-of-eight maze. Unilateral optical stimulation was applied during the "choice" phase of the task, namely in the central arm of the maze before committing to right or

left arm visits. We are able to identify a subset of putative PV+ neurons that increased or decreased their spiking activities consistent with the type of opsin activated, and the related changes in spiking activities of putative principle neurons in validation experiments. During the task, optical stimulation to increase or decrease PV+ neuron activities resulted in expected changes in individual neuronal firing rates in the local circuitry (i.e. increase/decrease putative PV+ and pyramidal neuronal firing rates). We are currently investigating changes in theta-entrainment of prefrontal ensembles by optogenetic modulation and effects of optogenetic modulation when applied to other (i.e. delay and consummatory) periods of the task.

Title: The role of the nucleus reuniens of thalamus in synchronization of oscillations of the prefrontal cortex and hippocampus in urethane anesthetized rats

Authors: *B. KOCSIS, F. PETTERSSON SVENSSON, A. T. ROY;
Harvard Med. Sch., Boston, MA

Abstract: Recent anatomical studies suggest that while hippocampus (HC) directly projects to prefrontal cortex (PFC) the return projection is indirect, through the nucleus reuniens of the thalamus (nRe). This study provides novel electrophysiological evidence that neuronal transmission from the PFC-to-HC is predominated by a 3-4 Hz signal and is mediated via the nRE, in contrast to the HC-to-PFC drive which is strongest at theta frequency and is mediated by direct projection. Local field potentials (LFP) were simultaneously recorded in the HC, PFC and nRe of 17 rats under urethane anesthesia during short episodes of electrical stimulation (0.1 ms square waves at 100Hz, 10 s duraction) of the nucleus reticularis pontis oralis (RPO). Stimulation intensity was systematically varied, spanning a range from threshold to maximum, identified as intensities where low-frequency theta rhythm appears in the HC and where its frequency no longer increases. The LFP segments were extracted and subjected to FFT to obtain power density spectra. Peak frequencies were identified in the HC and PFC respectively, and the power at these two frequencies was calculated for all three signals. Spectra were normalized

across experiments. Pearson's correlations of peak power at both frequencies were calculated between the PFC and HC. Partial PFC-HC correlations were then calculated in which the influence of the nRE was removed. Stimulation of the RPO generated theta (4-9 Hz) oscillations in the HC and a 3-4 Hz LFP rhythm in the PFC. Both rhythms were often present in the spontaneous LFPs, as well. The frequency of both rhythms showed linear relationships with RPO stimulus intensity. Theta frequency was never an integer multiple of the PFC rhythm. Peak powers also changed in a stimulus-dependent manner. The power of theta rhythm, detectable in all three signals, showed direct correlation with stimulation intensity in the HC and PFC but not in the nRE. Similarly, 3-4 Hz was also detectable in the HC and nRe during RPO stimulation but its power negatively correlated with stimulus intensity in all 3 structures. Thus, the 3-4 Hz signal followed the opposite trend of what was observed the theta signal, suggesting a possible negative coupling between the two rhythms. Furthermore, we found significant correlation between theta power in HC and PFC (0.441) which only slightly decreased after partialization with the theta signal in the nRe (0.357; 19% decrease). In contrast, HC-PFC correlation at the peak of the 3-4 Hz rhythm showed a 97% decrease (from 0.506 to 0.016) after partialization with nRe LFP, suggesting that PFC-HC correlation at 3-4 Hz but not at theta frequency is largely mediated by the nRE.

Title: A variable oscillator underlies the measurement of time intervals in the medial prefrontal cortex during classical eyeblink conditioning in rabbits

Authors: C. R. CARO-MARTÍN, R. LEAL-CAMPANARIO, R. SÁNCHEZ-CAMPUSANO, J. M. DELGADO-GARCÍA, *A. GRUART;
Pablo de Olavide Univ., Seville, Spain

Abstract: We were interested in determining whether rostro-medial prefrontal cortex (rmPFC) neurons participate in the determination of conditioned stimulus-unconditioned stimulus (CS-US) time intervals during classical eyeblink conditioning. Rabbits were classically conditioned with a delay paradigm consisting of a tone (600 Hz, 90 dB) as CS. The CS started 150, 350, 600, 1100, or 2100 ms before and co-terminated with an air puff (100 ms, 3 kg/cm2) directed to the cornea as US. Eyelid movements were recorded with the magnetic search-coil technique and with the EMG activity of the orbicularis oculi muscle. Unitary recordings of pyramidal neurons were carried out following procedures described elsewhere (Leal-Campanario et al., J. Neurosci., 33: 4378, 2013). For unitary analysis we developed a customized spike sorting algorithm that estimates the number of neuronal spikes distributed across time according to up to twenty-two physiological parameters characterizing each action potential. Reflex, spontaneous, and conditioned eyelid responses presented a dominant oscillatory frequency of about 10 Hz. In its turn, the firing rate of each recorded neuron presented a single peak of activity with a frequency dependent on the CS-US interval (i.e., about 12 Hz for 250 ms, about 6 Hz for 500 ms, andabout 3 Hz for 1000 ms). Interestingly, rmPFC neurons presented their dominant firing peaks at 3 preferred times evenly distributed with respect to CS start, also depending on the CS-US interval (only for intervals of 250, 500, and 1000 ms). No significant neural responses were recorded at very short (50 ms) or large (2000 ms) CS-US intervals. In accordance with the present results, we can conclude that rmPFC neurons do not encode the oscillatory (or kinematic) properties characterizing eyelid responses in behaving rabbits (Gruart et al., J. Neurophysiol., 83: 836, 2000), but are probably involved in the determination of CS-US intervals of an intermediate range (250-1000 ms). We proposed that this variable oscillator underlies the generation of working memories in rabbits, in a way probably different to neural mechanisms underlying working memories in primates.

Title: Prelimbic cortex infusion of SSRI fluoxetine reduces the effects of emotional distracters on interval timing

Authors: *A. R. MATTHEWS, M. BUHUSI, C. V. BUHUSI;
Dept. of Psychology, Utah State Univ., Logan, UT

Abstract: Emotional distracters impair cognitive function. Emotional processing is dysregulated in affective disorders such as depression, phobias, schizophrenia, and post-traumatic stress disorder. Among the processes impaired by emotional distracters, and whose dysregulation is documented in affective disorders, is the ability to time in the seconds-to-minutes range, i.e., interval timing (Buhusi and Meck 2005, Nat Rev Neurosci 6:755-65). Presentation of task-irrelevant distracters during a timing task results in a delay in responding suggesting a failure to maintain subjective time in working memory, possibly due to attentional and working memory resources being diverted away from timing, as proposed by the Relative Time-Sharing model (Buhusi and Meck 2009, Philos Trans R Soc B 364:1875-85). Here we investigated the role of the prelimbic cortex in the detrimental effect of anxiety-inducing task-irrelevant distracters on timekeeping, using local infusions of serotonin reuptake inhibitor (SSRI) antidepressant fluoxetine, in procedures previously developed in our lab (Matthews et al. 2012, Frontiers in Integrative Neuroscience 6(111): 1-12). Because in previous research we found that chronic administration of fluoxetine decrease the disruptive effect of emotional events on timekeeping (Christensen et al. 2013, Neuroscience Meeting Planner, Program No. 856), we hypothesized that fluoxetine acts in the prelimbic cortex to reduce the effects of anxiety-inducing distracters on interval timing. Similar to results reported by Matthews et al. 2012 for antidepressant nomifensine, and to previously reported effects of chronic fluoxetine, prelimbic cortex infusions of fluoxetine revealed a dissociation between the effects on interval timing and time sharing (resource allocation), and between neutral and anxiety-inducing distracters. Fluoxetine was effective in a dose-dependent manner only during trials with anxiety-inducing distracters, but not when the distracters were neutral, or in trials without distracters. Results are discussed in relation to the brain circuits involved in the Relative Time-Sharing of resources, and the pharmacological management of affective disorders.

Title: Latent variable modeling of hippocampal replay

Authors: *E. ACKERMANN, C. KEMERE;
Electric and Computer Engin., Rice Univ., Houston, TX

Abstract: Neuronal firing patterns are often preserved and repeated in a time-compressed manner (so-called replay or neural reactivation), but it remains challenging to (i) identify and (ii) quantitatively assess these events from extracellularly recorded neural data. Much is still unknown about replay, and the ability to reliably detect replay events is of critical importance in order to further analyze the nature of, and functional role of replay in learning and memory. Moreover, a statistical understanding of replay events is still lacking. For example, what percentage of the bursts of neural activity during sharp wave-ripple complexes (SPW-R) in the hippocampus are considered replay events? And what do those sequences represent that are not classified as replay? Most current approaches to detect replay rely on either template matching, or on decoding-based sequence identification, followed by an ad hoc scoring step. Unfortunately these approaches lack a principled framework, making it difficult to extend these approaches to more complicated environments. Furthermore, the lack of a principled framework makes a comparison between different approaches---and the interpretation of results---difficult. Here I show how latent variable models---and hidden Markov models (HMMs) in particular---can be used to identify and quantify putative sequences of reactivation in a principled manner. Using HMMs to detect replay events shows comparable performance to existing approaches (in terms of detection accuracy), but there are a number of key advantages. First, the principled framework makes it straightforward to extend replay detection to arbitrarily complex environments, given enough training data. Second, in contrast to template matching approaches, HMMs allow us to identify replay events that did not explicitly form part of the training data, such as shortcut or exploratory sequences. Third, since the HMM is a generative statistical model, we can use it in a simulation context to answer several interesting questions, such as how many different environments might be needed to lead to the level of variability that we typically observe in neural activity during SPW-Rs. Finally, HMMs allow us to detect replay in regions of the brain where behavioral correlates might not be available---the model parameters including the sequential structure in the data are all learnt directly from the neural data itself. This novel approach to studying replay, along with several extensions such as the use of semi hidden Markov models (where state durations are modeled explicitly), is expected to lead to a deeper understanding of replay and its functional significance in learning and memory.

Title: Cortical stroke alters temporal processing of cortico-hippocampal circuits

Authors: *J. W. HE, Y. NISHIJIMA, Y. AKAMATSU, J. LIU;
Dept of Neurosurg., UC San Francisco/SFVAMC, San Francisco, CA

Abstract: Stroke is the major cause of adult disability in the United States. More than half of the stroke survivors experience cognitive impairment in later life. However, the neural mechanism of the post-stroke cognitive impairment is poorly understood. Previously we have shown that experimental stroke via the distal occlusion of the middle cerebral artery (dMCAO) induced persistent electrophysiological changes in the hippocampus and impairment in performing the Barnes Maze test, a hippocampal-dependent cognitive test, suggesting that the hippocampal activity and function is significantly altered after cortical stroke. The aim of our current study was to determine in what aspect the communication between the hippocampus and cortex is affected after stroke. Multichannel extracellular electrophysiology recording was conducted in urethane-anesthetized rats housed in either standard or enriched environment (EE) for one month, beginning one week after either stroke or sham surgery. Our results showed that chronic experimental stroke increased theta phase-shift between the CA1 oriens layer and the nearby parietal cortex (network phase-shift) in the contralateral (intact) hemisphere, and EE attenuated the network phase-shift. At the single-unit level, cross-correlation analyses confirmed that the theta-phase modulation of cortical neurons was altered after stroke, which could be restored by EE. Both regression analysis and simulation data suggested that the network phase-shift altered the spike timing property of cortical units after stroke. Thus, these results suggest that stroke disrupts cortico-hippocampal communication by increasing theta phase-shift and changing the time-varying phase modulation in cortical units, while cognitive enhancement via enrichment attenuates these changes. Our data provide the mechanistic insight in the neural mechanism underlying post-stroke cognitive impairment.

Title: Synaptic-functional and behavioral states characterizing intrinsic and extrinsic hippocampal circuits during operant conditioning in rats

Authors: *R. SANCHEZ-CAMPUSANO[1], I. FERNÁNDEZ-LAMO[2], A. GRUART[2], J. DELGADO-GARCÍA[2];
[1]Biophysic and Med. Physic Center. Univ. de Oriente, Santiago de Cuba, Cuba; [2]Pablo de Olavide Univ., Seville, Spain

Abstract: It is generally assumed that associative learning is able to evoke more-or-less stable changes in synaptic strengths in selected cortical and subcortical sites. It has also been shown during classical eyeblink conditioning (Gruart et al., Cereb. Cortex, in press, PMID: 24654258, 2014) that these changes depend on the specific and timed activation of multiple hippocampal and other cortical synaptic contacts, evoking a precise map of synaptic-timing states. However, a still-open question is whether synapses included in the intrinsic hippocampal circuit, and those involved in its main inputs (perforant pathway) and outputs (subiculum, prefrontal cortex, and thalamic reuniens nucleus), present similar changing rates in synaptic strength and configure a coherent map of functional states, when the tools of an operant conditioning task are used to modify well-defined behaviors (going to the lever, at the lever, lever pressing, going to the feeder, eating, resting, exploring, grooming) of the animals. Here, we have recorded activity-dependent changes in synaptic strength --namely, the slope of the chronically evoked field postsynaptic potentials (fPSPs), in different intrinsic and extrinsic hippocampal synapses (n = 12) during the acquisition and storage of operant conditioning tasks in alert behaving rats. Rats were trained using a fixed-ratio (1:1) schedule. Furthermore, we have developed an analytical approach of state functions to characterize the learning process and the underlying synaptic changes. We characterize qualitatively and quantitatively two types of evolution patterns for all the synapses: 1) the synaptic-timing changes during each behavior, and (2) the timing-behavioral changes of each synapse. Preliminary results indicate that the acquisition of an operant conditioning task is a multisynaptic process in which the contribution of each identified synapse

is different in strength, and takes place at different moments across the learning process. In addition, the precise functional states of the selected synapses during a given behavior changes in accordance with the learning state, determined by values reached in the learning curve (first two sessions, maximum rate of change, and asymptotic values). In conclusion, the precise and timed activation of multiple synaptic contacts during operant conditioning of behaving rats evokes a well-defined dynamic map of functional states characterizing the acquisition of new motor and cognitive skills and the underlying synaptic plasticity.

Title: The role of the dorsomedial striatum in spatial working memory

Authors: *H. AKHLAGHPOUR, J. WISKERKE, J. CHOI, J. AU, I. B. WITTEN;
Princeton Univ., Princeton, NJ

Abstract: A comprehensive explanation of how working memory is achieved by the brain will most likely involve the interaction of several cortical and sub-cortical brain regions. The striatum is one of the brain regions implicated in working memory, but its precise role remains unclear. We aim to clarify the role of the striatum by recording from striatal neurons of rats while they perform a delayed non-match to sample task. Extracellular recordings from a total 115 units in the dorsomedial striatum of 9 rats revealed that neurons exhibited sequential peaks in firing rates tiling the duration of the trial. Maximum firing rates were biased towards the beginning of the delay period. Roughly 60% of the recorded neurons transiently encoded the sample stimulus at some point in the trial. For most neurons, information about the sample stimulus reached its maximum around the onset of the delay period. Surprisingly, the times of maximum mutual information with the sample stimulus did not correlate with the peak firing rate times. Our findings suggest that the dorso-medial striatum may have a more crucial role at the start of the delay period, which is consistent with theories that suggest that the striatum is responsible for gating information to working memory networks.

Title: Ventral striatum represents rewards before the orbitofrontal cortex in the Restaurant Row task

Authors: ***Y. A. BRETON**, B. J. SCHMIDT, A. D. REDISH;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: We used the Restaurant Row task to investigate the timing of representations of the flavor-based decision in populations of orbitofrontal cortex (OFC) and ventral striatal (VS) cells. In this task, rats made stay/skip decisions at each of 4 zones in daily, hour-long sessions. Rats ran clockwise around a loop with 4 spokes, at the end of which a feeder provided 2 food pellets of unique flavor (cherry, banana, plain, and chocolate) after a cued delay that lasted 1-30s, randomly offered on each encounter with the zone. Zones were only activated in sequence. As rats entered each zone, a sequence of tones counted down the delay until a reward was delivered or the rat exited, proceeding to the next zone. OFC and VS cells have been proposed to contribute differently to flavor-based decision-making, but the timing of their representations in a foraging task is not known. To determine the timing of representations of flavor offers in our spatially-driven operant task, we recorded from OFC and VS cells using a 24-tetrode assembly. We then used Bayesian decoding methods to infer the probability of representation of the currently-offered flavor, the previously-offered flavor, the next flavor, the flavor presented on the opposite side of the maze, and non-specific activity. The Bayesian algorithm was trained from firing in the first 3s following reward delivery (for each flavor) or firing at all other times (for non-specific activity), in 125ms bins. The test set consisted of firing in the first 5s of zone entry, in 125ms bins. We performed this Bayesian decoding algorithm separately for OFC and reward-responsive VS cells. We then isolated the time course of representations of each goal type (current, next, previous, or opposite) for each choice (stay, skip) in each structure. When

rats decided to wait through the delay until rewarded, representation of the current zone in both OFC and VS increased over the first 5s of zone entry compared to previous, next, and current zones. Two-way ANOVAs showed significant time bin x goal interactions in both structures. Post-hoc tests of decoding to current goal contrasted with the three other goal types showed significant increases for both structures at later time points. To assess the temporal relationship of the increase in current zone representations between the VS and OFC, the decoded probability of representing the current zone was re-aligned to its value when the rat entered the zone for each structure. This analysis revealed that the ventral striatum provided representations of the currently offered flavor before the OFC. The first time point at which VS reliably represented the current goal preceded the OFC.

Title: Systemic injection of clonidine, α2-adrenergic receptor agonist, differentiates prospective spatial representation between options in hippocampal neural ensemble activity

Authors: ***S. AMEMIYA**, A. D. REDISH;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Decisiveness is an important aspect of choice behavior. In human studies, clonidine, an inhibitory α2-adrenergic receptor agonist, increases decisiveness by suppressing mental planning of future actions in decision making. In rats, mental planning of future actions has been observed to occur during “vicarious trial-and-error” (VTE) re-orienting behaviors at choice points, as reflected in hippocampal place cell sweeps of representation ahead of the animal during these re-orientation behaviors. Systemic clonidine suppresses VTE. In order to test whether the neural planning events were similarly affected by systemic clonidine, we examined the influence of clonidine on neural activity in the hippocampal CA1 region from rats running a decision-making task. Rats ran a modified Hebb-Williams maze, consisting of a changeable

central path, a final decision point, and rewarded return rails leading to the start of the loop. On each lap, only one side or the other was rewarded. Three reward-contingencies were used: turn left, turn right, or alternate for reward. During the analyzed probe trials, the rewarded rule changed approximately halfway through the session. On a subset of trials, clonidine (30 μg/kg) or vehicle was delivered IP 30 min before the run. Hippocampal representations were assessed by applying a one-step Bayesian spatial decoding algorithm to the recorded neural ensemble activity. Consistent with previous studies, clonidine suppressed, but did not eliminate, the occurrence of VTE-like events. Since mental planning is reflected in spatial representation of future paths in hippocampus, we compared spatial decoding probability between the chosen path and the unchosen path at the choice point. Under vehicle, spatial representations showed an increased representation of the chosen path during Non-VTE laps, while spatial representations showed alternating representations of the two options during VTE laps. Clonidine hastened the differentiation of spatial representations of the chosen path from the unchosen path before rats' reaching the final choice point during non-VTE laps, and suppressed the spatial representation of the unchosen path during VTE laps. Our findings further connect hippocampal representations of options with the decision process and suggest a relationship between the behavioral decisiveness seen under clonidine and limited exploration of plans. The fact that animals only explored one option under clonidine (which they then chose) even when performing vicarious trial and error behaviors suggests that the limited hippocampal search process may help drive behavioral outcomes.

Title: Sequential activity during theta and sharp wave ripples supports flexible decision making

Authors: *A. E. PAPALE[1], M. C. ZIELINSKI[2], L. M. FRANK[4], S. P. JADHAV[3], A. D. REDISH[5];
[1]Neurosci., Grad. Program in Neurosci., Minneapolis, MN; [2]Grad. Program in Neurosci., [3]Neuroscience, Psychology & Volen Ctr. for Complex Systems, Brandeis Univ., Waltham, MA; [4]Ctr. for Integrative Neurosci., UCSF, San Francisco, CA; [5]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Two mechanisms have been proposed as hallmarks of planning in the hippocampus. Sharp wave ripple (SWR) sequences and theta sequence sweeps are both serial representations of paths in an environment. Theta sequence sweeps have a (5-12Hz) theta local field potential signature and occur during movement and attentive pausing, while SWR sequences co-occur with sharp wave ripples (150-250Hz) which are most prevalent during immobility and reward consumption. While both types of activity are well suited to guide decision-making, the relationship between them remains poorly understood. We therefore examined the timing and content of these events in the context of CA1 recordings taken from animals performing a T-maze spatial adjusting delay-discounting task Consistent with previous results, flexible decision making at a choice point of the maze was accompanied by a behavior known as vicarious trial and error (VTE) in which the rat tends to pause and look back and forth before proceeding. During VTE, we confirmed previous findings that decoded representations during theta sequence sweeps were more forward of the rat (Johnson & Redish 2007), consistent with a role in searching through future outcomes. In contrast, SWRs occurred during pauses while rats are waiting at food-delivery sites. As the rat prepared to start on the next lap, SWR sequences began to represent future positions ahead of the rat, consistent with previous findings (Singer et. al., 2013; Pfeiffer & Foster 2013). Interestingly, VTE and SWR event frequency was anti-correlated, both within-session and across-session. In both cases, as the rate of SWR events increases, the occurrence of VTE decreases. Within session, these changes occurred during strategy transitions. Across-session, these changes occur in parallel with learning, with VTE and theta sequences more prevalent early and SWR sequences more prevalent later. Finally, in order to test for a causal relationship between SWR occurrence and VTE behavior, we examined data from a working memory alternation task (Jadhav et al 2012). As demonstrated in the companion poster, VTE increased dramatically in rats in which awake SWRs were disrupted. These findings suggest that theta sequence sweeps and SWR sequences serve complementary functions. Disruption of SWR may result in compensatory increases in search through future outcomes when confronted with a choice, and may leave rats temporarily stuck in earlier stages of learning accompanied by VTE.

Title: Functional coupling between ventral striatum and orbitofrontal cortex in rats running a decision task

Authors: *J. J. STOTT[1], A. D. REDISH[2];
[1]Grad. Program in Neurosci., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Both orbitofrontal cortex (OFC) and ventral striatum (vStr), are engaged during reward-based decision-making tasks. Recent work has shown differences in timing between OFC and vStr activity, but few studies have looked at synchronous activity in these structures, which could provide clues to their respective contributions to the decision-making process. We analyzed local field potential (LFP) signals from simultaneous OFC and vStr recordings in rats performing an economic decision-making task, the Spatial Adjusting-Delay Discounting task. Rats ran along a T-maze track, making binary choices on each lap between a larger, delayed reward, and a smaller, immediate reward. Delay to the larger reward was titrated based on the rat's decisions. On a fraction of laps, rats showed prominent pause and look behavior at the choice point, termed "Vicarious Trial and Error" (VTE). This pause and look behavior was more frequent early in the session, and gradually decreased as rats' transitioned to a fixed 'left-right' alternation strategy later in the session, when the value of both sides was roughly equal. Power spectral density analyses showed a prominent peak at 50 Hz (γ50) for OFC and peaks at both 50 Hz (γ50) and 80 Hz (γ80) for vStr. In both OFC and vStr, γ50 power increased dramatically during reward delivery, while γ80 power dropped precipitously, as has been reported previously for vStr, showing a strong task-dependent difference in these two frequency bands. We found parallel results for the coherence between OFC and vStr LFP signals after reward delivery (increasing for γ50, and decreasing transiently for γ80). We applied two measures of directional connectivity to our data set. Looking at the maximum crosscorrelation between γ-filtered LFPs, we found that LFP gamma oscillations in vStr consistently led those in OFC. Likewise, using Granger Causality (GC) analysis, we found that time-domain GC was greater in the vStr to OFC direction than in the OFC to vStr direction, indicating that vStr more strongly influences OFC, at least on this decision-making task. Spectrally, this influence was strongest at gamma frequencies (40-70 Hz). Interestingly, GC values in the vStr to OFC direction were greater during deliberative VTE events, as compared to non-VTE passes through the choice point, but this was

not the case for GC values measuring OFC influence on vStr. Taken together, these data suggest that vStr strongly influences the OFC in the gamma range, and that vStr more strongly influences OFC during deliberative decision-making modes.

Title: Rats titrate to different adjusted delays on parallel foraging and decision-making (delay-discounting) tasks

Authors: E. C. CARTER[1], D. W. STEPHENS[1], *A. D. REDISH[2];
[1]Ecology, Evolution and Behavior, Univ. of Minnesota, St., Paul, MN; [2]Dept. Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Behavior depends on consequences that differ through time (intertemporal choice). Several theories have been proposed to explain how organisms balance temporally proximate and more distal consequences. One dominant view is that the value of a future reward is discounted by the delay until its receipt. In contrast, many models from foraging theory predict that organisms have evolved to maximize the overall rate of reward, and thus, opportunity cost drives the preference for immediacy. To compare these hypotheses, we measured the behavior of rats on two tasks with identical reward rates and physical demand: one used to assess delay discounting (DD: choice between a larger-later or a smaller-sooner reward) and one based on foraging (PATCH: choice between investing time at a source of food or moving on). In both tasks, rats ran through a 95cm x 114cm maze with 18cm high LEGO walls forming a square with a central track. Food-delivery sites were placed at the NW and NE corners of the square; one-way doors forced the rats to enter from the top and to leave by the side paths. In DD, the rats ran through the central track to turn left or right. One direction provided 6 pellets after a delay D, while the other direction resulted in 2 pellets after 1s. Choosing the larger-later side increased D by 1s, while choosing the smaller-sooner side decreased D by 1s. In PATCH, one side was

blocked off so the rat ran a single loop. On arriving at the reward, the rat received 2 pellets after 1s. If the rat then stayed for a delay (D-1)s, the rat received 4 pellets. The delay was adjusted as on the DD task with staying equivalent to choosing the larger-later reward. To vary travel between choices, we also ran versions of the tasks for which 3 switchbacks had been added to the return paths. Despite the similarities between the the two tasks, rats titrated D to very different delays (DD: M = 6s, IQR = [3s, 8s]; PATCH: M = 29s, IQR = [26s, 32s]). Adding switchbacks to the return paths increased each titration target (DD: M = 10s, IQR = [6s, 12s]; PATCH: M = 32s, IQR = [29s, 34s]), but there was no evidence of an interaction between task and path length. No models of intertemporal choice simultaneously fit behavior on both tasks, including hyperbolic and exponential delay discounting, long-term and short-term rate maximization, and the recently developed TIMERR and heuristic models. Although each model explained behavior in a single task reasonably well, none explained the pattern of behavior seen in both tasks. This indicates that these tasks may access different decision processes. We suggest that rats (and other animals) may be averse to leaving a cued reward, perhaps because of valuation driven by preference for endowed rewards.

Title: Disrupting awake sharp-wave ripples increases vicarious trial and error behavior

Authors: ***M. C. ZIELINSKI**[1], A. E. PAPALE[3], A. D. REDISH[4], L. M. FRANK[5], S. P. JADHAV[2];

Abstract: The hippocampal circuit shows sequential activity of place cells representing paths in an environment during two distinct activity patterns, sharp-wave ripples (SWRs, 150-250 Hz) and theta oscillations (5-12 Hz). SWR-associated forward and reverse replay during pauses in behavior has been shown to represent prospective, retrospective and remote trajectory information (Diba & Buzsáki, 2007; Karlsson & Frank, 2009). In comparison, theta sequences are seen during motion and attention, particularly during most mobile behaviors. Theta sequences represent upcoming paths serially at choice points in maze tasks coinciding with vicarious trial and error (VTE) behaviors, during which animals pause and look back and forth (Johnson & Redish, 2007). Current evidence suggests a role for both of these hippocampal mechanisms in planning and decision-making, but their specific roles and the relationship between them are unclear. Here, we show that disruption of awake SWRs during a working memory task leads to increased VTE behavior, demonstrating a causal link between these two phenomena. We examined VTE behavior in rats learning a W-track spatial alternation task. Awake SWRs on the track were disrupted, without altering place cell activity, using real-time detection coupled to electrical stimulation in the ventral hippocampal commissure. We have previously shown that disrupting SWRs impairs memory-guided decision-making on this task (Jadhav et al., 2012). Control animals received similar closed loop feedback stimulation, but with a delay of 150-200ms to leave SWR activity intact. VTE behavior was quantified during outbound trajectories (trials from the center of the W-track outward) that require spatial working memory. We found that SWR disruption animals showed a significantly higher incidence of VTE compared to control animals. Further, SWR disruption animals showed significantly higher VTE in both correct and error trials, and throughout the entire learning period following the first day of acquisition. Loss of SWRs thus led to a compensatory increase in VTE behavior as animals attempted to learn the task. In agreement, we found SWRs and VTE to be anti-correlated in a spatial adjusting delay-discounting task (demonstrated in the companion poster). SWRs and theta sequences during VTE may therefore represent complementary hippocampal mechanisms for planning and deliberation associated with memory-guided decision-making.

Title: Anterior cingulate cortex-hippocampal interactions during goal-driven behaviors

Authors: *J. Y. YU[1], A. LOBACK[2], I. GROSSRUBATCHER[1], D. LIU[1], L. M. FRANK[1]; [1]UCSF, San Francisco, CA; [2]Princeton Univ., Princeton, NJ

Abstract: The brain has the remarkable ability to quickly adjust behavioral choices when faced with unanticipated changes in the world. This ability requires interactions among multiple brain systems, including the hippocampus and the prefrontal cortex (PFC). While neural correlates of planning and decision making have been identified in both the PFC and the hippocampus separately, it is unclear how these brain areas interact to support adaptive behavior. We examined these interactions in rats performing a novel spatial foraging task where changing reward location contingencies require the animals to dynamically adjust spatial trajectory choices. The task was designed to engage the hippocampus and the anterior cingulate cortex (ACC), a part of the PFC critical for adaptive decision making, and inactivation of ACC was sufficient to disrupt trajectory choices without altering motivation. We then recorded from multiple single neurons in both the ACC and the hippocampus of awake, behaving rats to examine the interactions between these structures. We found that network ensemble patterns in the ACC preceding trajectory decisions are dynamic and reflect the operative reward contingency and location. We also found strong modulation in the activity of a large population of ACC neurons coincident with hippocampal sharp-wave ripples (SWR), events during which the hippocampus can reactivate sequences of place cells reflecting possible future trajectories. Furthermore, the pattern of ACC modulation during hippocampal SWRs was also related to the current reward location and contingency. These findings indicate that temporally precise interactions occur between the ACC and the hippocampus at the time of SWRs and that these interactions reflect behaviorally relevant information including location and reward contingency. This mode of cortical-hippocampal interaction could provide a mechanism where information about future trajectory options from the hippocampus is combined with information about reward contingencies to influence adaptive decisions.

Title: Spatially periodic firing in grid cells requires local inhibition through parvalbumin interneurons

Authors: *Q. CAO, C. MIAO, E. I. MOSER, M.-B. MOSER;
Kavli Inst. For Systems Neuroscience, CNC, NTNU, Trondheim, Norway

Abstract: Grid cells in the medial entorhinal cortex (MEC) are an essential component of the brain's representation of local space. The maxtrix-like hexagonal firing pattern of grid cells is thought to reflect attractor network mechanisms but the exact implementation remains elusive. A common property of attractor networks is the presence of strong recurrent connections between cells with similar functional properties. In most attractor network models, such connections are excitatory. However, in layer II of the MEC, where most grid cells are located, the most abundant cell type - the stellate cells - is connected exclusively via inhibitory interneurons (Couey et al., 2013). Recent attractor network models have shown that grid patterns can be generated in network where grid cells are connected only by all-or-none inhibitory interneurons, if the network receives steady excitatory input from an external source such as the hippocampus (Couey et al., 2013)(Bonnevie et al., 2013). One prediction of these models is a disruption of the grid pattern if the inhibitory connections between the stellate cells are silenced. We tested this prediction by reducing activity specifically and locally in parvalbumin-expressing interneurons (PV) in the MEC, the main type of inhibitory cell in this area. We used PV-Cre transgenic mice and injected Cre-dependent adenoassociated virus (AAV) expressing the pharmacologically selective designer Gi-protein-coupled muscarinic receptor hM4D (Armbruster et al., 2007). The AAV was injected into MEC. At the same time tetrodes were implanted in the injection area. Three weeks after viral infection, the activity of grid cells was collected while the animal ran freely in a 1 m box both before and after injection of clozapine-N-oxide (CNO, a specific ligand of hM4D). CNO injection caused a clear disruption of the grid pattern. The hexagonal periodicity

was reduced, and firing was dispersed across most of the recording environment. There was no systematic change in firing rate. We are currently testing the effects on border cells and head direction cells, which may possible depend less on the inhibitory connections of the stellate-cell network. The disruption of the grid pattern points to a role for PV-expressing interneurons in the formation of grid patterns in principal cells in the MEC.

Title: Local deformations in the entorhinal grid cell pattern

Authors: ***M. HAGGLUND**, M.-B. MOSER, E. I. MOSER;
Kavli Institute, CNC, Trondheim, Norway

Abstract: Grid cells are spatially modulated cells that fire in a hexagonal pattern when an animal moves across the environment. Recent studies have demonstrated that, as animals get familiar with an environment, the grid pattern undergoes a rotation and deformation that can fully be accounted for by shear forces along the boundaries of the environment. In large environments, these changes may be local, responding to forces from different boundaries, but the mechanisms underlying these variations are poorly understood. In this study we investigated the interaction between grid cells and the geometry of the environment as animals foraged in differently sized and shaped environments. We applied a sliding window autocorrelation across the recording environment. Grid features were determined locally and related to each other and to the walls and corners of the environment. The autocorrelograms of multiple cells in each position of the map were averaged to gain better resolution and stability. Animals displayed variability in their grid structure throughout the environment. In large recording boxes, the grid was often fragmented so that the grid took on distinct characteristics in different parts of the environment. Typically, the grid had one or more basins where it displayed almost no deviation from

hexagonality. In these locations, the grid tended to align with the wall, with almost no rotational offset, or the axis aligned with the diagonal of the box at 45 degrees. In the rest of the environment, ellipses could be fit to the inner hexagon of the grid pattern. The tilt of these ellipses was not aligned with the axes of the box. Taken together, these findings corroborate the model established earlier that the grid first aligns to the box, but it extends this model by showing how the grid might still retain its default structure in parts of the environment.

Title: Retrosplenial-parahippocampal projections in the rat are present and adult-like before eye-opening

Authors: ***J. SUGAR**, M. P. WITTER;
Kavli Inst. for Systems Neurosci. and Ctr. for Neuronal Computation, Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: Retrosplenial cortex (RSC) is important for a variety of cognitive tasks, particularly within the field of spatial learning and memory. The presence of head-direction cells in rat RSC provides strong support for the notion that RSC plays a role in spatial cognition. Head-direction cells, and other spatially modulated cells are also found in the hippocampal-parahippocampal region (HF-PHR), suggesting a functional relationship. In the adult rat, RSC is connected with pre- and parasubiculum, medial entorhinal cortex, postrhinal cortex and subiculum, areas known to be part of a circuit important for spatial information processing. We have recently shown that sparse connections within the HF-PHR are present at birth, reaching adult-like features before eye-opening and before the first spatially modulated neurons appear at postnatal day (P)15 (Langston et al. 2010 Science 328:1576; O'Reilly et al. 2012 SFN Abstr.702.02). In this study, we aimed to investigate whether RSC connections to PHR develop in parallel with development of HF-PHR connections or in parallel with development of spatially modulated cells in HF-PHR.

To examine development of RSC - PHR connectivity, rats aged P0-P26 were injected with anterograde tracers into RSC. Investigations of anterogradely labeled axons revealed that sparse connections were present at P0. Injections in all parts of RSC, across all postnatal ages, resulted in comparable topology of labeled fibers. During the first week, the connectivity developed gradually and reached adult like densities around P10. We therefore conclude that the topology of RSC - PHR projections is present at birth, while the density of the projections is fully developed during the second postnatal week. Thus, RSC - PHR connections develop in parallel with connections within HF-PHR.

Title: Topography of place maps along the CA3-to-CA2 axis of the hippocampus

Authors: *L. LU, K. M. IGARASHI, M. P. WITTER, E. I. MOSER, M.-B. MOSER;
Kavli Inst. For Systems Neurosci. and Ctr. For Neural Computation, NTNU, Trondheim, Norway

Abstract: The intrinsic structure of the hippocampus exhibits considerable diversity along the transverse axis, not only between but also within subfields. In CA3, cell morphology and connectivity change gradually from the proximal end (near the dentate gyrus) to the distal end (near CA2), with CA2 appearing in some respects as an extension of CA3 and in others as a distinct subfield with its own gene expression and connectivity patterns. We asked whether the heterogeneity of the CA3-CA2 axis is reflected in how space is mapped onto place cells in these subfields. We observed a transition from cells with small and sharp place fields in proximal CA3 to cells with large and dispersed fields in the most distal CA3 and CA2. The shift was

accompanied by a progressive loss in the ability of place cells to distinguish different configurations of the same spatial environment. The gradual loss of this ability along the CA3-CA2 axis matches several gradients in intrinsic connectivity, such as the increase in recurrent excitatory connections and the parallel decrease in mossy-fiber inputs from granule cells in the dentate gyrus. There was also a reduction along the CA3-CA2 axis in the extent to which place cells formed uncorrelated representations in different places, and in their ability to maintain stable spatial firing over time, but the transition was non-linear, with the sharpest drop within the distal CA3, 200 - 250 μm from the CA2 border. The changes mirror gradients in gene expression and extrinsic connectivity, such as inputs from the supramammillary nucleus, which partly override the cytoarchitectonic CA2-CA3 boundary and extend into distal tip of CA3. The results point to the CA3-CA2 axis as a functionally graded system with powerful pattern separation at the proximal end, near the dentate gyrus, and stronger pattern completion at the distal end, in and near CA2.

Title: Temporal spike coordination in the prefrontal-thalamo-hippocampal circuit during trajectory decisions

Authors: *H. T. ITO, E. I. MOSER, M.-B. MOSER;
NTNU, TRONDHEIM, Norway

Abstract: Phase synchrony of cortical oscillations is considered as a key mechanism for changing signal flow between regions (Singer, 1999). The connection from area CA1 of the hippocampus to the medial prefrontal cortex (mPFC) is an example of a circuit in which functional connectivity is thought to be modulated by cortical oscillations depending on

behavioral demands. Temporal spike coordination of mPFC neurons relative to theta oscillations in CA1 local field potentials (LFPs) is enhanced when animals run down on the central stem of a T-maze, before they reach the choice point where they have to select one of two routes (Jones and Wilson, 2005; Benchenane et al., 2010). This increase of temporal spike coordination is considered a reflection of enhanced signal flow from CA1 to mPFC. We here report that mPFC and CA1 are theta-coupled also in the reverse direction but with the midline thalamic nucleus reuniens (NR) as a link. In NR neurons, which project to both mPFC and CA1, spikes were found to exhibit enhanced phase-locking to theta oscillations in CA1 LFPs on the central stem, before the decision point, on a T-maze continuous alternation task. Phase-locking was weaker in other regions of the maze. There was also enhanced theta phase coherence between CA1 and NR LFPs on the stem. Our findings point to temporal spike coordination in NR as a potential mechanism for controlling signal flow from mPFC to CA1. This functional connection is essential for CA1 neurons to represent future action plans derived from mPFC (Ito et al., 2015). Thus, by reciprocally coupling mPFC and CA1 cells, theta-frequency spike coordination may enable trajectory decisions during spatial navigation. We are currently exploring the role of the supramammillary nucleus (SUM) as a potential source of behavior-dependent modulation of theta oscillations in the mPFC-NR-CA1 circuit. SUM gives rise to inputs to mPFC, NR and CA2 of the hippocampus, which in turn projects to CA1. We found that many neurons in SUM exhibited rhythmic firing at theta frequency in behaving animals. Some of these neurons increased rhythmic activity on the central stem of the maze, pointing to a key role for SUM in behavior-dependent modulation of theta rhythms in the mPFC-NR-CA1 circuit.

Title: Commisural connections of the medial entorhinal cortex in rodents

Authors: *K. ZHENG, Ø. W. SIMONSEN, M. P. WITTER;
Kavli Inst/Cnc, NTNU, Trondheim, Norway

Abstract: The rodent medial entorhinal cortex (MEC) contains a variety of spatially modulated neurons, including grid cells, head direction cells, border cells and speed cells. Grid cells are mostly prominent in layer II, as are stellate cells, suggesting that the stellate cell is the candidate grid cell. We have previously reported that stellate cells are locally connected through fast spiking interneurons. The MEC on both sides of the brain are strongly interconnected and these reciprocal connections are topologically organized. *In vivo* recordings have shown that grid cell firing properties are remarkably stable in both hemispheres, pointing to a unified spatial representation in both hemispheres (Stensola et al 2012, Nature 492, 72). Here we studied the commissural connections between the left and right MEC, postulating that these underly this unified spatial representation. We used anterograde and retrograde tracing in mice (n = 13) and corroborated that the main origin of the commissural projection is from neurons in layer III, although a low number of layer II cells contribute as well. The commissural fibers terminate in layers I/II. Using confocal microscopy, we established that commissural fibers target stellate cells and interneurons within layer II. Using an optogenetic approach, we performed multi-cell patch recordings in layer II neurons while optically stimulating commissural inputs which expressed the ChR2 channel. Our results support and extend the anatomical observations and indicate that commissural input might be integrated into the local grid cell network.

Title: Optogenetic characterization of stellate cells in medial entorhinal cortex layer II

Authors: D. C. ROWLAND[1], E. R. SKYTØEN[1], R. NAIR[1], C. G. KENTROS[1], *E. I. MOSER[2], M.-B. MOSER[1];
[1]NTNU Kavli Inst. Systems Neurosci, Trondheim, Norway; [2]Kavli Inst. Systems Neurosci, Trondheim, Norway

Abstract: Layer II of the medial entorhinal cortex (MECII) contains two principal cell types: pyramidal cells and stellate cells. Accumulating evidence suggests that these two cell types have distinct physiological properties and projection patterns. Reelin-expressing stellate cells provide the main excitatory input to the dentate gyrus, CA3 and CA2 region of the hippocampus. The pyramidal cell population forms tight clusters intermingled among stellate cells, earning them the name “island cells”. Pyramidal cells differ from stellate cells in that they express calbindin but not reelin, receive strong cholinergic input, and do not project directly to principal cells in the hippocampus but rather to interneurons in CA1. Together, these observations hint at a fundamental functional difference between the two populations. The currently available data lead to mixed conclusions. Some studies suggest that stellate cells make up a large percentage of grid cell population while others suggest that stellate cells are almost never grid cells. We previously used a tta-based transgenic mouse line to drive expression of arch, an optogentic silencer, in stellate cells (Rowland et al., SfN 2014). Delivering short pulses of light, we found that grid cells and border cells were silenced robustly, indicating that the stellate cell population included grid cells and border cells. However, the relatively low firing rate of the neurons precluded an exact determination of the latency of the response and therefore left the possibility that the cells were secondarily silenced. Here, we introduce new methods for stimulation-based identification of stellate cells. First, we crossed the same transgenic mouse line to a line that expresses reachr, a red-shifted channelrhosopsin variant. Second, we made an AAV virus that expresses Chief, another chanelrhodopsin variant, exclusively in cells that express the tta. The specificity of the latter method can be further improved by injecting the virus directly into the dentate/hilar region and retrogradely infecting sparse populations of reelin-expressing stellate cells. Functional characterization of the cells that express the channelrhodopsin variants is ongoing.

Title: Entorhinal speed cells project to the hippocampus

Authors: *J. YE[1], S.-J. ZHANG[1,2], E. KROPFF[1,3], M.-B. MOSER[1], E. MOSER[1];
[1]Ctr. for Neural Computation, Kavli Inst. For Systems Neuroscience, NTNU, Trondheim, Norway; [2]Tsinghua-Peking Ctr. for Life Sciences, IDG-McGovern Inst. for Brain Res., Sch. of Life Sciences, Tsinghua Univ., Peking, China; [3]Leloir Institute, IIBBA - CONICET, Buenos Aires, Argentina

Abstract: Hippocampal place cells receive input from multiple functionally specialized spatial cell types in the medial entorhinal cortex (MEC), including grid cells, head direction cells and border cells, with grid cells as the main contributor (Zhang et al., 2013). These cell types are sufficient to map instantaneous position but for activity to be translated from one group of active cells to another, in a way that reflects the animal's movement in the external environment, the cells must have access to information about the current speed and direction of the animal. Recent work has shown that running speed is represented in the firing rate of a ubiqutous population of cells with linear and context-invariant responses to running speed (Kropff et al., SfN 2014). Such ´speed cells´ were identified in both MEC and hippocampus, albeit with slightly different temporal dynamics. In the present study, we asked if hippocampal cells receive speed information from speed cells in the MEC. We used a combined optogenetic-electrophysiological strategy to determine whether hippocampal projection neurons in MEC include speed cells. Retrogradely transportable recombinant adeno-associated virus expressing Flag-tagged channelrhodopsin-2 (ChR2) was injected in the dorsal hippocampus. Virally transduced and optogenetically tagged cells were identified in MEC as cells that fired at fixed minimal latencies of 9-10 ms in response to local flashes of 473-nm blue laser light. Speed cells were identified as cells with a Pearson product-moment correlation between instantaneous firing rate and running speed that exceeded the 99thpercentile of a shuffled distribution of spike times. The population of MEC neurons with short and reliable response times included speed cells, indicating that these cells project directly to the hippocampus. More than 50% of the hippocampus-projecting speed cells had interneuron-like firing properties (narrow waveforms and high firing rates). The population of responsive cells also included neurons with longer response times (up to 30 ms, mostly putative interneurons), suggesting that additional speed cells were stimulated synaptically. The long tail of the latency distribution for speed cells contrasts with the distributions for grid cells, border cells and head direction cells, which were sharp and unimodal, with peaks at 9-10 ms. Taken together, the observations point to entorhinal speed cells as a key component of the MEC input to the place cells in the hippocampus.

Title: Clonal architecture of the network supporting spatial representation in the medial entorhinal cortex

Authors: *F. DONATO, R. I. JACOBSEN, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) contains the basic elements of the brain's representation of space, most notably the grid cells, which fire at the vertices of a periodic hexagonal array that covers the entire available environment. Attractor network mechanisms, relying on selective connections among neurons tuned to specific spatial features, have been proposed to account for the emergence of the grid pattern. Since the coordinated maturation of clonally related cells produces preferential connectivity between functionally similar neurons (a feature of the attractor network) in other cortical areas, we took a developmental approach to study MEC microcircuits. By systematic labeling of dividing cells during neurogenesis, or targeted in-utero infection of post-mitotic neuroblasts, we primed cohorts of neurons born in specific time windows for further manipulation, in order to determine their connectivity and function in the adult. We found that stellate cells were anatomically distributed in a dorso-ventral gradient reflecting their neurogenesis, with early born cells located in the dorsal pole of the MEC, and later born cells at progressively more ventral positions. In stark contrast, pyramidal neurons did not show any developmental topography. Despite anatomical overlap between consecutive waves of neurogenesis, clonally related cohorts of stellates cells exhibited stereotyped distributions along the dorso-ventral axis, which were conserved between different animals, thereby recapitulating the spatial organization of grid modules. These data raise the possibility that the temporal organization of stellate cell-neurogenesis might a) set the schedule for the coordinated maturation of clonally related cells into functionally distinct subpopulations; b) determine selective connectivity for the formation of independent microcircuits and hence c) lay the basis for the presence of functionally segregated subnetworks underlying the modular organization of grid cells.

Title: Speed cells in the medial entorhinal cortex

Authors: *E. KROPFF CAUSA[1,2], J. E. CARMICHAEL[3,2], E. I. MOSER[2], M.-B. MOSER[2]; [1]Leloir Inst. - IIBBA - CONICET, Buenos Aires, Argentina; [2]Kavli Inst. For Systems Neurosci. and Ctr. For Neural Computation, NTNU, Trondheim, Norway; [3]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Grid cells in the medial entorhinal cortex (MEC) and surrounding parahippocampal areas are unique in their spatial code (Hafting et al, 2005). Unlike other place-modulated neurons, their population firing pattern not only repeats periodically within a given environment, but also seems to apply equally to all explored environments (Fyhn et al, 2007), reflecting the uniformity of space despite the unevenness of contextual details. This property makes grid cells ideal candidates for a path integration-based representation of space (McNaughton et al, 2006). In such a scheme, running speed is integrated across short time windows to obtain the instantaneous displacement of the animal,which in conjunction with head direction input is used to update the representation of the animal´s position. Any path integration mechanism thus requires running speed as a major input.However, while speed has been reported to correlate marginally with entorhinal theta frequency (Jeewajee et al, 2008) and firing rate of grid cells (Sargolini et al, 2006; Wills et al, 2012), the existence and nature of a reliable and locally available speed signal has remained unclear. We found that running speed is represented in the firing rate of a ubiquitous but functionally dedicated population of MEC neurons (~15%) with low levels of overlap with other MEC populations, such as grid, head direction and border cells. Speed cells are characterized by a positive, linear response to running speed, with a great variability in slope and y-intercept. This response is context-invariant, so that running speed can be decoded from speed cell activity even across rooms or in darkness without loss of accuracy. Speed cells and grid cells share a similar prospective bias of around 50 to 80 ms. In both cell types, prospective activity is highly modulated by theta rhythm, suggesting that path integration could take place on a theta cycle basis (Navratilova et al, 2012). In the hippocampus, speed cells were also identified in a smaller proportion (~10%) and with a higher overlap with the place cell population. These cells, however, had a retrospective behavior, while place cells had no temporal bias, a combination that seems to be incompatible with path integration. Taken together, these

observations point to MEC speed cells as a key component of the dynamic representation of self-location.

Title: Hippocampal remapping after partial inactivation of the medial entorhinal cortex

Authors: *C. MIAO, Q. CAO, H. T. ITO, H. YAMAHACHI, M. P. WITTER, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neuroscience, CNC, NTNU, Trondheim, Norway

Abstract: Hippocampal place cells undergo remapping when the environment is changed (Muller and Kubie, 1987; Colgin et al., 2008). The mechanism of hippocampal remapping remains elusive but spatially modulated cells in the medial entorhinal cortex (MEC) have been identified as a likely contributor. Using pharmacogenetic and optogenetic approaches, we tested the contribution of MEC cells by examining in mice whether partial inactivation in MEC shifts hippocampal activity to a different subset of place cells with different receptive fields. Local infusions of AAV virus were used to express the pharmacologically selective designer Gi-

protein-coupled muscarinic receptor hM4D (Armbruster et al., 2007) or the light-responsive microbial proton pump archaerhodopsin (ArchT) (Han et al., 2011) in the MEC, and place cells were later recorded in the CA3 of the hippocampus after application of the inert ligand clozapine-N-oxide (CNO; in hM4D-expressing mice) or light at an appropriate wavelength (in ArchT-expressing mice). CNO and light both caused partial inactivation in MEC. hM4D and ArchT were expressed across widespread regions of MEC, covering most of its dorsolateral and mediolateral extent, but the inactivation caused only minimal changes in the spatial firing pattern of place cells in CA3. However, while spatial firing was maintained, the distribution of firing locations was altered following even quite restricted silencing in the dorsal parts of MEC. Partial MEC inactivation caused substantial changes in hippocampal spatial representation at the neural ensemble level, reminiscent of the global remapping that occurs in place cells when animals move from one environment to another. The results point to MEC input as an element of the mechanism for remapping in place cells.

Title: Grid synchronization in merged space

Authors: *T. WERNLE, M. MØRREAUNET, E. I. MOSER, M.-B. MOSER;
Kavli Institute/CNC The Fac. of Medicine, NTNU, Trondheim, Norway

Abstract: Natural environments are compartmentalized and likely represented by multiple local maps stitched together at salient landmarks (Derdikman et al., 2009). The mechanisms for generating coherence between discrete grid maps have not yet been established. To search for these mechanisms, we trained rats in two rectangular compartments A and B (each 1x2m) separated by a wall. Once two distinct maps were established we removed the wall, allowing the rat to explore the merged open square box (2x2m). Exploration in the large environment was not accompanied by de novo grid formation. Instead, the grid matrices were similar to either one or both of the rectangular maps A and B. In order to reveal the contribution of the initial representations to the global grid pattern in the entire environment we performed several analyses. First, we assessed local similarity between maps using a sliding-box correlation

approach. This approach was tested on a large artificial dataset of rate maps in order to determine optimal bin size for different grid scales and expected range of correlation values for all possible solutions. Subsequent analysis of real data showed that the open field grid pattern was rarely a simple extension of one map but rather a complex fusion of the A and B maps. Fusions could be achieved globally by phase shifting the A and B maps relative to each other or locally by merging the maps at the transition in the center of the box. The type of response was specific to grid modules and global and local fusions could occur simultaneously. Fusion responses required successive visits to the merged environment. In ongoing analyses we are testing the change in local periodicity across the entire environment and we are comparing real field locations to expected field locations of extended A and B maps. The data suggest so far that distinct grid maps for large environments get synchronized both globally and locally, that the effects depend on experience, and that the type of response depends on grid scale.

Title: Body and world-centered coordinate transformations in the parietal-hippocampal network

Authors: *A. A. WILBER[1,2], I. SKELIN[1,2], B. L. MCNAUGHTON[1,2];
[1]Univ. of California, Irvine, Irvine, CA; [2]Canadian Ctr. for Behavioral Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: A preponderance of evidence suggests that the internal map of the environment is represented in world-centered (allocentric) coordinates; however, movements and perception of the environment are in body-centered (egocentric) coordinates. Therefore, to navigate in space, it is essential to translate between egocentric and allocentric coordinates. Cell activity in the parietal cortex and hippocampus suggests a parietal to hippocampal circuit for transforming landmark representations from egocentric to allocentric coordinates (Wilber et al., 2014),

consistent with theoretical modeling work (McNaughton et al., 1995). A more recent computational modeling predicts two conjunctive representations that are utilized for bi-directional coordinate transformation (Byrne et al., 2007). We described one of these conjunctive representations in parietal cortex for translating from egocentric to allocentric coordinates previously (body centered x head direction). In addition, the computational model predicts a second conjunctive cell type for allocentric to egocentric translation: allocentric landmark direction x head direction. Therefore, we set out to look for evidence that the parietal-hippocampal network also participates in allocentric to egocentric transformation. To do this we recorded single cells in the parietal cortex and hippocampus while rats performed a random spatial sequence task with 32 reward locations arranged around the perimeter of a platform. Each reward location was marked as active with a blinking light, which acted as a landmark. Using lights as "landmarks" allowed for good coverage of landmark directions and headings. As we and Deshmukh and Knierim (2013) previously reported, cells in the hippocampus encode the allocentric direction x distance of landmarks. We also found cells in the parietal cortex that exhibit the properties predicted for allocentric to egocentric transformation, cells that signaled a specific combination of allocentric landmark location and head direction. From such cells the body-centered location of a landmark could be "read out." Interestingly, we previously reported parietal cortex cells which specifically signal body centered landmark direction. Thus, we have extended our previous findings describing a parietal cortex-hippocampal circuit for transforming landmarks from egocentric to allocentric coordinates. We now show that this circuit is part of a larger network that is also capable of translating from world- to body-centered coordinates.

Title: A methodological pipeline for serial-section imaging and tissue realignment for whole-brain functional connectomics

Authors: *B. J. CLARK[1,2], L. MESINA[2], A. A. WILBER[3,2], A. DEMECHA[2], C. E. L. STARK[3], B. L. MCNAUGHTON[3,2];
[1]The Univ. of New Mexico, Albuquerque, NM; [2]Univ. of Lethbridge, Lethbridge, AB, Canada; [3]Univ. of California, Irvine, Irvine, CA

Abstract: Understanding the neurobiological basis of cognition and behavior, and disruptions to these processes following brain injury and disease, requires a large scale assessment of information exchange amongst populations of neurons, as well as knowledge of their patterns of connectivity. We present an approach that allows for a large-scale investigation of brain connectivity. Animals received unilateral microinjections of retrograde tracers (FluoroGold or cholera toxin-B Alexa Fluor 594) in dorsal cortex and were sacrificed 2 weeks after microinfusion (for details see Wilber et al 2015 Frontiers in Neural Circuits). Serial-section images of whole-mounted brains were acquired during vibratome sectioning in the coronal plane. Tissue sections were then collected and immunohistochemistry was conducted to label neuronal cell bodies and immediate early gene product. Subsequent wide-field fluorescent scans of whole tissue sections were acquired using NanoZoomer whole-slide scanning microscopy (NanoZoomer Digital Pathology RS, Hamamatsu Photonics), which is capable of automatically capturing wide-field multispectral fluorescent images over entire brain sections at high resolution. A custom software platform was developed in Matlab which utilized the open-source software platforms ANTs (http://picsl.upenn.edu/software/ants/), which is a diffeomorphic, vector-field based registration software, the open-source image processing toolkit, Fiji (http://fiji.sc/Fiji), and the neuronal segmentation software, FARSIGHT (www.farsight-toolkit.org). This platform will accommodate an automated analysis pipeline in which neuronal boundaries are automatically identified through segmentation and the x- y- position in each image is co-registered with corresponding serial images acquired during vibratome sectioning. This tool will allow for the representation of whole brain data in 3-D, and the development of methods for rapid segmentation and detection of tracer. We will address the informatics problem of dealing with data from a large number of serial sections and extend this method for detection of multiple immediate early gene products (i.e., measures of functional activation of discrete neuronal populations at single-neuron resolution). This work will lend itself uniquely to analyze both structure and function across entire brains, and will form the basis of a large-scale understanding of the effectiveness of treatments for brain injury and disease.

Title: Low and high frequency electrical perforant pathway stimulation as conditioned stimuli for active avoidance learning: A combined fMRI and electrophysiological study

Authors: *S. RIEMANN, F. ANGENSTEIN;
Funktionales Neuroimaging, DZNE, Magdeburg, Germany

Abstract: Direct electrical stimulation of the right perforant pathway (PP) was used as conditioned stimulus to learn an active avoidance task in a shuttle box. To monitor learning related changes in dentate gyrus and whole brain activity, electrophysiological recordings and functional magnetic resonance imaging (fMRI) were combined. In naïve, medetomidine sedated rats the right PP was electrically stimulated and the resultant activity in the granular cell layer of the dentate gyrus was recorded by measuring extracellular field potentials. Simultaneously changes in whole brain activity were determined by measuring blood oxygen level dependent (BOLD) signal intensities. Two different stimulation protocols (20 consecutive trains, train duration 8 s with an inter-train interval of 52 s) were used for electric stimulation of the PP. One train consisted of 8 bursts of 20 pulses each at 100 Hz repetition rate, i.e., 200 ms burst duration, inter-burst interval 800 ms, thus 1 burst per second (100Hz protocol) or continuous 5 pulses per second (inter-pulse interval 200 ms) for 8s (5Hz protocol). The same protocols were then used as conditioned stimulus for an active avoidance task during the following three days (1 hour of 60 trials per day). PP activation preceded a foot shock, thus by jumping over a hurdle after PP stimulation the rat could avoid a foot shock. This means that the initially meaningless PP stimulation became behaviorally relevant during shuttle box training. One day after the last training session, i.e., day 4, the initial combined electrophysiological fMRI measurement was repeated. Rats performed better in shuttle box learning with the 100Hz than with the continuous 5Hz protocol but both groups learned the task. In naïve rats the 100Hz protocol caused a significant BOLD signal in the hippocampus and in the enthorinal cortex whereas the 5Hz protocol led to a BOLD-signal more restricted to the site of stimulation. In trained rats significant BOLD responses were observed in target regions of the hippocampus, such as the septum, nucleus accumbens, and anterior cingulate cortex/medial prefrontal cortex regions during 100Hz but not during 5Hz stimulation protocol. Without additional training the BOLD response pattern remained similar at day 13 when the measurement was repeated. Both groups remembered the task when tested one day later (day 14).

Title: From default to adjusted. How BOLD fMRI responses relate to neuronal activity in the rat hippocampus during repetitive stimulations

Authors: *F. ANGENSTEIN, C. HELBING, S. RIEMANN;
Deutsches Zentrum Für Neurodegenerative Erkrankungen (DZNE), Magdeburg, Germany

Abstract: During repetitive electrical stimulations of the right perforant pathway concurrent measurements of field potentials in the dentate gyrus and blood oxygen levels dependent (BOLD) signal intensities in the hippocampus were performed to disentangle the role of incoming activity (defined by the applied electrical pulses) and outgoing activity (i.e., spiking activity of the principal neurons measured as population spike) for the formation of a BOLD response. The stimulation pattern were modified that A) the same amount of incoming pulses generate different number of population spike, B) different amount of incoming pulses generate the same number of population spikes and C) increasing number of incoming pulses caused concurrent increases in the number of population spikes. Most of the used stimulation protocols caused variable BOLD responses during repetitive stimulations. Generally, the first stimulation train caused a substantial BOLD response that was followed by an ongoing elevated BOLD signal intensity, which in turn obscured a putative BOLD response to the second train. Thereafter BOLD responses recovered during the following 2 trains and then declined continuously during all succeeding trains, however with a different rate. Based on this general BOLD time series, the response during the first train was considered as response of the naïve dentate gyrus/hippocampus to the stimulus, whereas the responses to the following 3 trains were considered to reflect a reorganization of intrahippocampal circuitry to the incoming stimulations and the responses to the following trains were considered as an adaptation of intrahippocampal circuitry to these repetitive stimulations. Although the stimulation parameters varied considerably, the BOLD response to the first stimulation train was almost identical for 7 out of 10 stimulation protocols, thus in the naïve hippocampus the BOLD response does not relate to electrophysiological parameters of neuronal activity; it rather reflects a default BOLD response to a complex stimulus. However, after reorganization of intrahippocampal circuitry the BOLD

response relates either to the incoming or outgoing activity. Based on these results we present first conservative conclusions about altered neuronal activations that can be drawn from measured BOLD responses in the hippocampus.

Title: Understanding emotion in the brain: Comparing categorical and dimensional models of emotion using multivariate pattern analysis

Authors: *J. C. FOO[1], K. SAKAI[2];
[1]Univ. of Tokyo, Tokyo, Japan; [2]Tamagawa Univ., Tokyo, Japan

Abstract: The study of emotion has given rise to two main views about how to model affect: categorical and dimensional. The first view classifies emotions into discreet categories (i.e. anger, surprise, happiness, etc.) based in motivational systems while the other view suggests that emotions are dimensional and can be decomposed into factors such as valence, arousal and control. This study aims to examine the how emotions are represented in the brain using multivariate pattern analysis (MVPA), a variation of functional magnetic resonance imaging (fMRI). Subjects were scanned while they watched emotional videos and rated the emotional experience elicited by the videos both categorically and dimensionally. Behaviorally, subjects were able to rate the emotions they experienced using both categorical and dimensional scales, supporting the idea that both types of emotion can be consciously represented. fMRI analyses using the general linear model revealed parametric effects of emotional dimensions in the ventromedial prefrontal cortex (valence) and intraparietal sulcus (arousal). MVPA analysis found greater than chance level decoding accuracy of both categorical and dimensional emotions,

suggesting that that both types are intrinsically represented in the brain. Meanwhile, results obtained by using a sliding-window MVPA searchlight suggest that differences may exist in the course of how categorical and the various dimensional emotions arise in the brain. Interestingly, average decoding accuracy across subjects for categorical emotions and the valence dimension increased as videos progressed, while accuracy for the control dimension increased until reaching a peak just after the mid-point of videos, followed by a subsequent decrease. For the arousal dimension, accuracy was constantly high. The accuracy increases in categorical emotion and valence may reflect accumulation processes, while the control result suggests the exertion of control during the occurrence of emotional events in videos. Results of the sliding-window searchlight also suggest that regions involved in creating the emotional experience change dynamically throughout the course of emotional development. Together, these results emphasize the fluidity and complexity of emotions, urging us to take a comprehensive view incorporating both models.

Title: Control of attentional gain modulation by affective valence

Authors: ***X. ZHANG**, Z. SAFIULLAH, S. JAPEE, L. G. UNGERLEIDER;
Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: The normalization model of attention proposes that attention can affect performance by contrast or response gain changes, depending on the stimulus size and the relative size of the attention field. Here, the attention field was manipulated by affective valence, positive faces versus negative faces, while the stimulus size was fixed in a spatial cueing task. Emotional faces served as a cue to attract spatial attention, followed by a pair of gratings. Subjects performed an orientation discrimination task on one of two gratings; for each of five contrasts (the contrasts of both gratings were identical on any given trial and covaried across trials in random order). A response-cue at stimuli offset indicated the target location, yielding valid cue (the emotional face matched response-cue) and invalid cue (mismatched) conditions. Comparing performance accuracy (*d'*) for valid and invalid trials revealed the spatial cueing effect for each contrast. The

measured psychometric function for each affective valence (positive and negative) and each trial condition (valid and invalid) was fit with the standard Naka-Rushton equation. Two parameters d'_{max} (asymptotic performance at high contrast levels) and c_{50} (the contrast yielding half maximum performance) determined response gain and contrast gain, respectively. We observed a change in the spatial cueing effect consonant with a change in contrast gain for positive faces and a change in response gain for negative faces. Significantly, individual differences in self-reported emotional strength of positive and negative faces correlated with contrast and response gain changes, respectively. An ongoing functional magnetic resonance imaging experiment confirmed that subjects' attention fields were wider for positive faces than that for negative faces. Together, these findings suggest that emotional attention shapes perception by means of the normalization framework.

Title: Valence-general attentional resource for emotional information revealed by activation of the ventral part of the anterior cingulate cortex

Authors: *T. MINAMOTO[1], M. OSAKA[2], N. OSAKA[3];
[1]Natl. Inst. of Information and Communicatio, Suita, Japan; [2]Human Sci., Osaka Univ., Suita, Japan; [3]Psychology, Kyoto Univ., Kyoto, Japan

Abstract: The ventral part of the anterior cingulate cortex (vACC) is shown to activate under emotional conflict raised by the emotional Stroop task. Taking advantage of the nature of the vACC, the present study examined characteristic of attentional resource for emotional information. Specifically, we tested whether attentional resource is organized in a valence-based manner (i.e., separate attentional resource for negative and positive valence) or valence-general (i.e., common attentional resource regardless of emotional-valence). Combining the emotional working memory (WM) task with the emotional Stroop task, we measured activation of the

vACC with fMRI. Participants were randomly assigned to the negative WM task group or positive WM task group (n = 16 in each group). In the task, participants were instructed to memorize a photograph with emotional content (high intensity or low intensity), which was followed by the emotional Stroop task. In the Stroop task, participants judged a color of a emotional word stimulus whose valence was either negative or positive. If attentional resource for emotional information is arranged in a valence-based manner, activation of the vACC would be smaller when emotional valence of the memory item (especially high emotion) and Stroop stimulus was congruent due to competition for the resource while such pattern would not be observed when valence of the two stimuli was incongruent. On the other hand, if the attentional resource is arranged in the valence-general, activation of the vACC would be smaller when high emotional WM load is given in comparison to the load regardless of the emotional valence. The result was in line with the latter hypothesis; therefore, attentional resource for emotional information may be arranged in valence-general manner.

Abstract: When we spend time with a partner in romantic relation, we often feel excitement and healing. Previous functional magnetic resonance imaging study showed the neural activity in the medial insula, anterior cingulate cortex, and striatum, which were known to be involved in the dopaminergic system, related to the romantic love. In the present study, we tested the hypothesis that dopaminergic system was activated when viewing portraits of romantic partner by using positron emission tomography (PET) with [^{11}C]raclopride, a dopamine D_2/D_3 receptor antagonist. We recruited ten normal volunteers who had a romantic partner. During PET scan,

they passively viewed portraits of their romantic partners and, as a control, of friends of same sex for whom they had neutral feelings during the PET scan. The presentation of visual stimulus was started at 15 minutes before administration of [^{11}C]raclopride, and lasted for 30 minutes. The results showed statistically significant activation of dopaminergic system in the medial orbitofrontal cortex (mOFC) and the medial prefrontal cortex (mPFC), when viewing portraits of romantic partner compared with those of friends, the former has been strongly implicated in a variety of rewarding experiences, including that beauty and love. A positive correlation was found in the mOFC between excitement level and dopaminergic activation only for the romantic partner not for friends. Thus, these results suggested that attachment to romantic partner might be represented as dopaminergic activity in the reward system. In the future, it is necessary to investigate whether attachment to romantic partner affects on mental or behavioral performance in such as the mentally exhausted situation.

Title: Investigating the effect of goal-directed eye movements during extinction on amygdala activity and long-term expression of fear memory

Authors: *L. D. DE VOOGD[1,2], J. W. KANEN[1], K. ROELOFS[1,3], G. FERNÁNDEZ[1,2], E. J. HERMANS[1,2];
[1]Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands; [2]Dept. for Cognitive Neuroscience, Radboudumc, Nijmegen, Netherlands; [3]Behavioural Sci. Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Eye movement desensitization and reprocessing (EMDR) is seen as a promising treatment option for fear-related psychiatric diseases such as post-traumatic stress disorder (PTSD). Indeed, experimental studies have shown that performing goal-directed eye movements following recall of autobiographical episodic memories can reduce the vividness and

emotionality of these memories. However, the effect of goal-directed eye movements on retention of fear memory has not been tested directly, and critically, the mechanisms by which eye movements may affect mnemonic processes remain poorly understood. Previous research suggests that performing tasks involving endogenous attention suppresses neural activity in the default mode network (DMN), a large-scale brain network which includes the ventromedial prefrontal cortex (vmPFC) and medial temporal lobe regions such as the amygdala and hippocampus. These regions are also critically implicated in fear and safety learning. We therefore hypothesized that deployment of endogenous attention during goal-directed eye movements suppresses activity in these regions and might thereby affect fear retention. To address this hypothesis, twenty-four healthy volunteers were tested in a Pavlovian fear conditioning paradigm, the most widely used experimental laboratory model of fear and safety learning, which is used in both animal and human research. Participants came to the lab on three consecutive days for an acquisition, an extinction, and a recall phase. During fear acquisition, two stimuli (CS+) were associated with a mild electrical shock, while two other stimuli (CS-) were never reinforced. During extinction, one CS+ and one CS- was always followed by a block of goal-directed eye movements. Blood Oxygenation Level-Dependent functional MRI data, pupil dilation, and skin conductance responses were recorded throughout all phases of the experiment. Preliminary results show that during eye movement blocks, there is suppression in the amygdala, hippocampus, and vmPFC relative to baseline compared to the fixation blocks. Further analyses will focus on whether this temporary suppression of brain regions supporting fear acquisition and extinction may affect retention of fear memories.

Title: Dynamic shifts in large-scale brain network balance in response to acute stress

Authors: *C. B. YOUNG[1,2,3], G. RAZ[5], D. EVERAERD[2,3], C. F. BECKMANN[2,4], I. TENDOLKAR[2,3,6], T. HENDLER[7], G. FERNANDEZ[2,4], E. J. HERMANS[2,4];

Essen, Essen, Germany; [7]Departments of Physiol. and Pharmacol. and Psychiatry, Tel Aviv Univ., Tel Aviv, Israel

Abstract: The acute response to stress can be beneficial, such as during imminent threat, but also detrimental, for example when individuals are unable to regulate responses to minor stressors. Stressors trigger a cascade of neurochemical changes which are thought to result in alterations in coordinated activity across large-scale brain networks. However, how stress affects the dynamic interactions within and between such networks remains poorly understood. One recent theory states that as individuals exhibit a stress response, cohesion within the salience network (SN) increases, while the executive control network (ECN) is suppressed. To test this hypothesis, we used functional MRI and a mild stress induction paradigm (exposure to emotionally arousing cinematographic material), and examined how functional connectivity within and between the SN and ECN changes as participants react to this stressor. A 10 min movie fragment was first divided into a low-arousal and a high-arousal period based on subjective arousal ratings provided by a sample of 17 male participants. A separate sample of 120 male participants passively viewed the movie clip during an fMRI scan and heart rate data were simultaneously collected. Consistent with arousal ratings, heart rate was significantly higher during the high-arousal period in comparison to the low-arousal period of the movie, confirming the efficacy of the stress induction. To specifically address the question of how network interactions evolve over time when exposed to a stressor, we calculated heart rate and measured brain network cohesion in a dynamic manner within both movie periods. As predicted, we found that across time and within both periods, increased heart rate was accompanied by increased SN cohesion. Critically, during the high-arousal period only, the correlation between SN and ECN cohesion decreased as heart rate increased. Thus, exposure to acute stress disrupts coupling between the SN and ECN as individuals exhibit increasing physiological arousal. This finding demonstrates that acute stress is associated with a shift in brain function at the level of balance between large-scale networks. Such a global brain state change may explain shifts in cognitive functioning during acute stress and play an important role in the development and maintenance of stress-related mental disorders.

Title: Altered resting state functional connectivity in the medial temporal lobe subsystem of the default mode network in posttraumatic stress disorder

Authors: *D. R. MILLER[1,3], S. M. HAYES[4,2,3], J. P. HAYES[5,2,4], J. M. SPIELBERG[4,2], G. LAFLECHE[3,2], M. VERFAELLIE[3,2];
[1]Anat. and Neurobio., [2]Psychiatry, Boston Univ. Sch. of Med., Boston, MA; [3]Memory Disorders Res. Ctr., [4]Neuroimaging Res. for Veterans Ctr., [5]Natl. Ctr. for PTSD, VA Boston Healthcare Syst., Boston, MA

Abstract: Posttraumatic stress disorder (PTSD) is a psychiatric disorder that develops after exposure to life-threatening events and is characterized by debilitating re-experiencing, avoidance, and hyperarousal symptoms. Recent work has provided evidence for disrupted connectivity in intrinsic networks in PTSD, particularly the default mode network (DMN). In addition to two midline core hubs, the DMN consists of two functionally and anatomically distinct subsystems, a medial temporal lobe (MTL) system and a dorsal medial prefrontal cortex (dMPFC) system. The goal of this study was to examine the status of these subsystems in PTSD. PTSD is associated with impaired contextual fear extinction learning, and such learning depends on the ventral MPFC (vMPFC) and hippocampus, two regions that are part of the MTL subsystem of the DMN. Thus, we hypothesized that PTSD may differentially affect the MTL subsystem. Sixty-nine Operation Enduring Freedom/Operation Iraqi Freedom (OEF/OIF) veterans with PTSD and 44 OEF/OIF veterans without PTSD underwent two resting state fMRI scans with their eyes open. We assessed group differences in functional connectivity using a core hub (posterior cingulate cortex; PCC) as well as a node in each DMN subsystem (vMPFC and dMPFC) as seed regions. Results showed that individuals with PTSD had decreased functional connectivity between the PCC and the MTL subsystem, specifically the hippocampus and vMPFC. Groups did not differ in functional connectivity between the PCC and dMPFC subsystem. Connectivity between the PCC and hippocampus was negatively associated with total PTSD symptom severity and avoidance symptomatology. Using seed regions from the MTL and dMPFC subsystems, we found significantly reduced anti-correlation between the vMPFC node of the MTL subsystem and the dorsal anterior cingulate cortex in the PTSD group. There were no group differences in the dMPFC subsystem. These findings suggest that aberrant functional

connectivity within the DMN is restricted to the MTL subsystem in PTSD and may act as a mechanism by which contextual fear extinction processes are disrupted.

Title: Negatively connoted music increases brain activity in the prefrontal cortex: a nirs study

Authors: S. CROWEL, Z. MESSER, J. ADAY, C. BRATONIA, *M. ZIAT;
Psychology, Northern Michigan Univ., Marquette, MI

Abstract: In this study we examined changes in cortical hemodynamic activity using Near-Infrared Spectroscopy (NIRS) while participants were watching thirty second neutral video clips associated with a auditory music stimulus that can trigger a : 1) neutral, 2)positive (pleasant), or 3) negative (unpleasant) emotion. The main goal was to assess whether the three different conditions reflected changes of oxygenated (Hbo) and, deoxygenated (Hbr) in the prefrontal cortex while the videos were presented to participants. A NIRS probe (8 sources and 9 detectors) was attached to the front of the head using an elastic headband. The participants were also asked to rate the valence after each video on a scale from -2 to 2. NIRS data indicated an increase in HbO and HbR above baseline levels for the unpleasant condition as opposed to the pleasant and neutral conditions which showed decrease in HbO below baseline levels and no significant changes in HbR. These results suggest that when an unpleasant auditory stimulus is paired with a neutral video, the prefrontal cortex showed increased levels of HbO as well as HbR. These findings were also corroborated by the behavioral data, as the unpleasant condition was rated negatively (-1.33) when paired with a neutral video and was significantly different ($p < 0.01$) from the average rating for neutral and pleasant conditions that were rated +0.5 and +0.67 respectively.

Title: A multivariate analysis of brain networks involved in facial gaze and emotion processing

Authors: *M. ZIAEI[1], W. VON HIPPEL[1], J. HENRY[1], N. EBNER[2], H. BURIANOVÁ[3]; [1]Univ. of Queensland, Brisbane, Australia; [2]Univ. of Florida, Gainesville, FL; [3]Ctr. for Advanced Imaging, Brisbane, Australia

Abstract: Eye gaze direction plays a fundamental role in social interaction in that it influences the perception of facial features and particularly the processing of facial emotion expressions. Yet, the neural mechanisms that underlie the integration of gaze and emotional cues in faces are not well understood. Given the complexity of the involved higher cognitive processes, it is reasonable to assume that large-scale brain networks are recruited, rather than discrete brain regions. The objective of this study was to delineate the brain networks that subserve the processing of emotional expressions with direct and averted gaze. Twenty healthy adults participated in a functional magnetic resonance imaging experiment in which they were asked to identify the emotional expressions of happy, angry, or neutral faces, displayed with direct or averted gaze. The results showed that the functional networks engaged during the identification of angry faces were different depending on the gaze, whereas the same functional network was recruited for direct and averted happy faces. Angry averted gaze recruited a network that comprised bilateral amygdala, striatal nucleus, and superior temporal gyrus, whereas angry direct gaze recruited bilateral insula and anterior cingulate gyrus, the critical nodes of the salience network. Our findings provide novel insights into the impact of eye gaze on processing of angry emotional expressions, and the results have broader implication for understanding the underlying neural mechanisms of social-cognitive functions involved in the processing cues from the faces in healthy and clinical populations.

Title: Differences in resting-state functional connectivity 24-hours after delay and trace fear conditioning

Authors: *L. HOPKINS[1], D. H. SCHULTZ[2], F. J. HELMSTETTER[1];
[1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Rutgers Univ., Newark, NJ

Abstract: Resting-state functional connectivity (RSFC) measures synchronous activity between brain areas when participants are not engaged in a task. RSFC can be used to investigate connectivity profiles after learning when memory is being consolidated. Here we explored differences in functional connectivity at rest after a delay (DFC) or trace (TFC) fear conditioning task. In each procedure a neutral visual stimulus signaled the occurrence of shock. In the DFC group the CS and UCS overlap and co-terminate while in TFC the CS and UCS are separated by a blank period of time called the trace interval. It is well established that DFC and TFC rely on different brain areas during acquisition. The amygdala is involved in both but TFC engages additional structures including the hippocampus and medial prefrontal cortex (mPFC). As stable long term memory forms after training, some brain areas are engaged time-dependently while others are always required. Most work on RSFC and memory is restricted to the period immediately after learning. Here subjects trained with DFC or TFC underwent an 8-minute resting state scan both immediately after conditioning and 24-hours later. After parcellation into multiple ROIs we compared RSFC between groups at the 24-hour time-point. We also compared RSFC within each group across time. Across groups, increased RSFC was apparent in the TFC group relative to the DFC group in two ROI pairs 24-hours later. RSFC was enhanced between the temporal pole and insula as well as between the posterior cingulate (PCC) and cerebellum. Across time, DFC subjects had enhanced RSFC between one ROI pair of temporal lobe structures 24-hours later whereas TFC subjects had enhanced RSFC between two ROI pairs involving temporal, frontal, and parietal structures 24-hours later. The enhanced connectivity between more widespread brain areas involved in emotional processing, complex cognition, and memory in the TFC group 24-hours post-conditioning may reflect the additional changes at the systems level required for the long-term consolidation of a more complex fear memory. These results indicate that RSFC can be used to identify more long-term brain changes that may reflect the memory consolidation process and that may be unique to specific forms of learning.

Title: Imaging of social cognition in low-functioning autism

Authors: *A. G. MCKECHANIE[1,2], T. J. MOORHEAD[1], C. THORBURN[2], N. ROBERTS[1], E. C. JOHNSTONE[1], D. G. C. OWENS[1], A. C. STANFIELD[2];

Abstract: Background: A major objective of autism spectrum disorders (ASD) research has been to delineate the affected neural systems. Functional magnetic resonance imaging (fMRI) of the brain has played a key role in this research, but its application has been limited to affected individuals with preserved or superior intellectual functioning due to difficulties in obtaining informed consent, tolerability of the scanner environment and the lack of suitable fMRI tasks for individuals with intellectual impairment. Objective: The objective of this study was to demonstrate that it is feasible to reliably use a fMRI task in individuals with intellectual impairment ± co-morbid autism spectrum disorder (ASD) in a task of implicit emotion processing, and to explore the neural correlates of emotion processing in individuals with comorbid intellectual impairment and autism spectrum disorder. Methods: We conducted an fMRI study using an implicit facial emotion processing task. Diagnosis of ASD was confirmed using the Autism Diagnostic Observation Schedule (ADOS). Prior to undergoing the scan, participants were able to practice the task on a laptop and also to practice on a mock scanner (where there were no time pressures). Results: All participants (N=18) successfully completed the functional task, thus demonstrating that fMRI techniques are possible to use in those with impaired intellect ± comorbid autism spectrum disorder. When examining the differential neural response to the fearful faces with the response to the neutral faces, there were a number of brain regions which showed significantly greater activation in the non-ASD group, compared to the ASD group. These were in similar areas as described in the broader ASD literature. In contrast, there were no regions of increased activation in the ASD group. Conclusions: In this study we

have demonstrated that it is possible to undertake fMRI studies in individuals with intellectual impairment, who were previously considered unable to participate in such studies. We have mirrored findings of decreased cerebral function in brain regions previously linked with emotional processing deficits in non-intellectually impaired individuals with ASD.

Title: The effects of early adversity on emotional appraisal: implications for amygdala-mPFC circuit development

Authors: *M. R. VANTIEGHEM[1], L. GABARD-DURNAM[1], J. FLANNERY[2], B. GOFF[3], D. GEE[4], K. HUMPHREYS[5], E. TELZER[6], C. CALDERA[3], T. HARE[7], N. TOTTENHAM[1]; [1]Columbia Univ., New York, NY; [2]Univ. of Oregon, Eugene, OR; [3]Univ. of California Los Angeles, Los Angeles, CA; [4]Weill Cornell Med. Sch., New York, NY; [5]Tulane Univ. Sch. of Med., New Orleans, LA; [6]Univ. of Illinois at Urbana-Champaign, Champaign, IL; [7]Univ. of Zurich, Zurich, Switzerland

Abstract: Previous research suggests that early adverse caregiving alters the developmental trajectory of amygdala-prefrontal circuitry, resulting in heightened emotional reactivity and adult-like fear learning. This research has focused primarily on the function of this circuit when processing facial expressions of clear valance, such as those of fear and happiness. However, adult studies have shown that facial expressions with ambiguous affect (i.e., surprised) can elucidate trait-like emotional biases that are associated with amygdala-mPFC circuitry. Further, typically developing children show a negative bias to surprise faces that declines with age. The current study examined the effects of early adversity on emotional appraisals of surprised faces in a sample of previously institutionalized (PI) youth and comparisons between the ages of 6-14 (N=167, mean age=9.8, M=65). Participants viewed a standardized set of surprised, happy, and

angry faces and rated whether each face “felt good or felt bad” as quickly as possible. Resting-state fMRI scans were acquired for a subset of participants to examine the functional integrity of amygdala-mPFC circuitry. PI youth showed more positive (i.e. adult-like) appraisal of surprised faces relative to comparisons ($p<0.05$). Preliminary findings suggest that stronger (i.e. more mature) amygdala-mPFC connectivity was associated with more positive appraisal of surprised faces across both groups ($p<0.05$). Although PI youth showed elevated levels of social anxiety at the group level, those individuals with more positive appraisals showed lower levels of social anxiety ($p<0.01$). These findings suggest that more positive appraisal of ambiguous emotional cues may reflect an ontogenetic adaptation following early adversity.

Title: Resting state conectivity of the amygdala after the exposure to a stressful video

Authors: *D. VÁZQUEZ CARRILLO[1], J. MARTÍNEZ-SOTO[2], S. ALCAUTER[1], E. PASAYE[1], L. GONZALES-SANTOS[1], F. A. BARRIOS[1];
[1]Inst. de Neurobiología, Univ. Nacional Autónoma De México (UNAM), Queretaro, Mexico; [2]Univ. de Guanajuato, Guanajuato, Mexico

Abstract: Introduction: Everyday we are exposed to a variety of stressful conditions. Since stress has a negative impact in emotional and physical health, the study of stress response and its functional basis in human brain is of great interest for the neuroscience and health-care community. Amygdala has long been implicated as a main responsible in the triggering of brain's response to stressful conditions [Veer, *et. al.*2011]. The aim of this study is to characterize the change in amigdalae's resting state functional connectivityafter been exposed to a stressful event. MethodologyResting state fMRI and high resolution T1 images were acquired in 32 healthy male participants (mean age: 36.18 and sd= 12.46), before (basal) and after (stress) being exposed to a stressful video [extracted from Faces of Death #4]. Stress was quantified with the Stress and

Activation Adjectives Checklist (Martínez-Soto, *et. al.*2012). The left and right amygdalae were segmented on the T1 images for each individual using FSL's FIRST. After standard preprocessing (no smoothing, no global signal regression), functional connectivity maps were obtained using each amygdala as seed. Paired t-tests were performed to identify significant changes in connectivity between the basal and stress states. Results: Subjects weresignificantly morestressedafter watching the video ($t(32)=-3.65$, $p<0.01$). Decreased functional connectivity($p<0.05$, uncorrected)was evident in regionsinvolved in cognitiveprocessingand effortful regulation of affect, such as superior frontal gyrus, middle frontal gyrus, PCC, and precuneus(Figure).Increased connectivity ($p<0.05$, uncorrected)was evident in occipitalandinferior temporalcortices, as well as in pre-and post-central sulci. Functional connectivity changes seem to be more dramaticfor the left amygdala(Figure). Conclusion: Subjects were significantlymore stressed after watching the video. Amygdala's functional connectivity showed significant changes with frontal and posterior brain regions, relevant for both emotional and cognitive processing.Betterunderstanding of brain stress responsemay play a crucial role in improving

Title: Temporal dynamics of fear learning and generalization in the human brain

Authors: *S. NASR[1], E. A. BOEKE[2], S. N. DECROSS[2], R. P. F. WOLTHUSEN[2], R. B. H. TOOTELL[2], M. R. MILAD[2], D. J. HOLT[2];
[1]Martinos Ctr. For Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA; [2]Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Functional MRI studies have shown that an extensive network of regions, including the amygdala, hippocampus, insula, anterior cingulate cortex, and caudate nucleus, show conditioned fear responses in humans. However, it remains unclear which of these regions contributes to the acquisition versus the expression of conditioned fear. To examine this question, we conducted an fMRI study in which 37 healthy humans underwent a Pavlovian fear conditioning and generalization procedure. Skin conductance responses (SCR) and fMRI data were collected simultaneously throughout the experiment. During the conditioning phase, a face stimulus was intermittently paired (CS+) or not (CS-) with a mild electrical shock delivered to the fingers. During the subsequent generalization phase, 5 generalization stimuli (m1-m5, individualized based on each subject's discrimination threshold) and the CS+ and CS-, were presented. Four time intervals during conditioning and two time intervals during generalization (two trials per interval) were examined. An anatomical region-of-interest fMRI analysis was conducted. Fear generalization was defined as a response to the generalization stimulus that was most similar to the CS+ (m1) that was significantly greater than the response to the CS-. Based on the SCRs, the subjects acquired differential conditioned fear responses and showed fear generalization. In the fMRI data, during fear conditioning, ANOVAs revealed a significant stimulus type by time interaction for the anterior insula, caudate nucleus and hippocampus, due to a progressive increase in differentiation in the BOLD responses to the CS+ vs. CS- as learning occurred (CS+ > CS- in the anterior insula and caudate nucleus; CS- > CS+ in the hippocampus). The anterior insula, and to a lesser extent the anterior cingulate cortex, also showed significant generalization of fear responses, that was sustained over time. In summary, we found that the anterior insula is involved in both the acquisition and expression (as manifested by fear generalization) of conditioned fear responses in humans, suggesting that interoceptive processing is critically involved in both learning and retrieval of fear signals in humans. Moreover, the caudate nucleus and hippocampus showed evidence for a role in the acquisition of fear and safety signals, respectively, but not in generalization. Thus, these two regions may be primarily involved in communicating learned fear and safety signals to other structures, such as the prefrontal cortex.

Title: Dissociable Neural correlates of positive and negative emotions during human sound processing

Authors: *N. OKAMOTO[1,2], M. HARUNO[2];
[1]Fac. of Integrated Human Studies, Kyoto Univ., Kyoto Univ., Kyoto-Shi/Kyoto-Fu, Japan;
[2]CiNet NICT, Suita-shi/Osaka-fu, Japan

Abstract: What kind of mechanism in the brain yields positive or negative emotion while we process sounds? Although there are some studies investigating how brain activity changes depending on genres and likability of music, few studies have contrasted positive and negative emotions by comparing positive and negative sounds. Here, we investigate how the positive and negative emotions arise by conducting a functional magnetic resonance imaging experiment of sound evaluation. Participants (n=26) were instructed to bring their own favorite music, and we prepared nine different noise sounds ranging from machine noise to mosquito flying sound. Participants were exposed to three different blocks (i.e, music, noise, and nothing: order was randomized), each of which lasted for 30s. Each kind of block appeared 13 times in a session and the total time of the session was 20min, and all participants experienced two sessions. Participants were asked to evaluate each block by five different grades (Most comfortable, A little comfortable, Neutral, A little uncomfortable, Most uncomfortable) by pressing a button. We also measured heartbeat, breathing, pulse wave, and skin conductance of each participant during MR scanning. Functional image processing were carried out using the Statistical Parametric Mapping software (SPM12, London) on a MATLAB (The MathWorks, MA) platform, and we also conducted a correlation analysis of beta values obtained from the first level analysis of SPM with each participant's average evaluation in each condition. We found significant increase of activity during the favorite music block in comparison with the noise block in the nucleus accumbens (NAcc), anterior cingulate cortex (ACC), and auditory cortex ($p<.001$, unc.). On the other hand, we found significant increase of activity during the noise block increased in the amygdala, hippocampus, and dorsolateral prefrontal cortex (DLPFC) ($p<.001$, unc.). In addition, beta values in NAcc and ACC were correlated with each subject's average evaluation during the music condition, and the beta values in the amygdala and auditory cortex were correlated with each subject's average evaluation during the noise condition. Interestingly, we also found that

noise activity in the amygdala was weaker in the second session, while the one in DLPFC was higher in the second session, indicating some opposite contributions of these two regions. These results indicate that different regions in the brain are involved in the generation of positive and negative emotions during human sound processing. It is an important future research topic to clarify what network mechanism is the key to the generation of subjective sensations.

Title: Neural specificity in processing visual and auditory socially-relevant information as revealed by fMRI

Authors: ***J. WHITEHEAD**[1,3,4], J. L. ARMONY[2,3,4];
[1]Integrated Program in Neurosci., [2]Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [4]BRAMS Laboratory, Ctr. for Res. on Brain, Music and Language, Montreal, QC, Canada

Abstract: Social communication in a natural setting relies on input from various sensory modalities. Some emotion-sensitive brain regions, such as the amygdala, can respond to relevant information conveyed in different modalities (e.g., auditory and visual) using a variety of channels (e.g., face and body expressions, speech and music). Yet, it remains largely unknown whether these very different types of stimuli are processed by the same neural populations, or whether the observed responses, as seen with techniques such as functional magnetic resonance imaging (fMRI), reflect the engagement of independent yet overlapping uni-modal, category-specific neurons. To directly address this question, we employed an fMRI adaptation paradigm in a series of experiments designed to measure neural responses to social communicative signals as a function of their sensory modality (visual vs. auditory), affective value (neutral vs. fear) and category (music vs. speech; faces vs. body expressions). We used a fast (TR=529ms), high-resolution (8 mm3 isotropic) multiband sequence to maximize temporal and spatial specificity of the observed responses, as well as statistical power. Initial results confirmed modality- and category-specific adaptation effects in cortical regions, which could not be explained solely in

terms of category differences along basic physical properties. Our findings for music, a powerful emotionally arousing stimulus with no obvious survival or evolutionary relevance, are particularly interesting as they can provide new empirical evidence that can inform the ongoing debate about the nature of the neural representation of such type of stimulus class.

Title: A meta-analytic review of the role of ventromedial prefrontal cortex and amygdala in emotion regulation

Authors: *S.-J. TSAI[1], C.-S. R. LI[2];
[1]Med., Natl. Yang-Ming Univ., Kaohsiung City, Taiwan; [2]Psychiatry and Neurobio., Yale Univ., New Haven, CT

Abstract: Background: The ventromedial prefrontal cortex (vmPFC) has long been implicated in regulating fear response. Recent literature points to differential responses of subregions of the vmPFC to positive and negative affect (Myers-Schulz B et al, 2012 Mol Psychiatry). Therefore, a detailed examination is needed to understand how the vmPFC interacts with amygdala under various emotional contexts. **Methods:** Human fMRI studies are searched on PubMed with keywords of [(ventral medial prefrontal cortex, ventromedial prefrontal cortex, OR vmPFC) AND (amygdala)]. Studies are included if performed on healthy subjects with significant same- or opposite- direction of activities reported for both the vmPFC and amygdala. Emotional contexts in these studies are further categorized as passive (e.g., viewing pictures of facial expressions) and participating (e.g., emotional control and appraisal; cost-effect/moral judgments), with subcategories of emotions (e.g., happy, sad, angry, and fear) specified. We performed neuroanatomical meta-analysis of activity patterns by activation likelihood estimation (ALE) (Eickhoff SB et al, 2009 Hum Brain Mapp). **Results:** The vmPFC and amygdala co-

activate to passive happy, angry and sad emotion induction, but not fear, which evoked increased amygdala and decreased vmPFC activity. An opposing pattern of vmPFC and amygdala activity is shown under emotional control and reappraisal. vmPFC activations in association with amygdala activity changes are mapped to functionally distinct subregions in general agreement to the account of perigenual vmPFC response to positive emotion. Elevated activity of perigenual vmPFC and amygdala were also noted when subjects participate in ethical decisions or risk-seeking behaviors. **Conclusions:** These preliminary results echo recent proposal of separate functional subregions of the vmPFC, and suggest the need of more research on the role of vmPFC subregions in emotional regulation and decision making.

Title: The effect of dynamic facial expressions on subsequent emotional information processing: an fMRI study

Authors: *S. KIM, H. YOON, S. KIM;
Korea Univ., Seoul, Korea, Republic of

Abstract: Responses to emotional information are known to be modulated by regulatory efforts. However, little is known as to how the contextual information influences experiential and neural correlates of emotional information processing, especially when the context is emotionally conflicted with the valence of ongoing emotional information. We wanted to examine in what way preceding dynamic facial expressions of emotions modulate neural to subsequent unpleasant information. Twenty-three healthy adults participated in this functional neuroimaging study (12 women, mean age = 22.83, SD = 2.26). Inside the brain scanner, participants were presented with a series of negative and neutral pictures and their task was to rate the level of emotional arousal elicited by each picture. Each trial of the task started with the presentation of one of the dynamic facial expression that lasted for 2 s: happy, neutral, and angry expression. Then, a crosshair

fixation appeared for about 2 s with jittered durations, followed by either negative or neutral pictures for 6 s. Then, participants rated the level of emotional arousal on a Likert scale ranging from 1 to 4 for 3 s. Brain images were acquired by a 3T Siemens scanner located at Korea University Brain Imaging Center and analyzed using SPM8. Regions of interest (ROIs) were functionally defined as spheres with 6mm radius centered at the peaks of activation clusters identified from the overall contrast of negative versus neutral pictures. A one-way ANOVA on percent signal changes of each ROI was conducted with a factor of facial expressions. The cuneus showed the main effect of facial expression with a linearly increasing activity trend from positive to negative face conditions. Correlation analysis revealed that the activation level of cuneus was negatively correlated with that of amygdala when the picture was preceded by positive face. We also found significant negative correlation of cuneus activations with vlPFC activations in the happy face condition. These results indicate that the emotional context which is inconsistent with subsequent emotional information gives rise to conflicting situation that causes attenuated cognitive processing of information. This might make the emotional response greater but allow one to attempt to resolve the conflict

Title: Working memory load enhanced interpersonal reconnection

Authors: ***K. SAKAKI**[1], T. NOZAWA[1], R. YOKOYAMA[2], Y. SASAKI[1], R. KAWASHIMA[1]; [1]Tohoku Univ. (IDAC), Aoba-Ku Sendai-Shi Miyagi-Ken, Japan; [2]Kobe Univ., Chuo-Ku, Kobe-Shi, Hyogo-Ken, Japan

Abstract: Some previous studies showed that response for social exclusion had individual difference. One is the antisocial response such as withdrawal or aggressive behavior. The other is the prosocial response such as trying to make new friendships. This phenomenon is called “interpersonal reconnection”. Our previous fMRI study revealed that people who had lower reconnection tendency (RT) showed higher insula activity, which is known to relate to negative emotions, during imaging social situation after exclusion. We hypothesized that working memory load, which is known to distract emotion, could suppress the insula activity and negative emotions and promote reconnection. This study was approved by the Ethics Committee of

Tohoku University Graduate School of Medicine. Written consent was obtained from all subjects. Two runs of fMRI scans were conducted on 18 university students. Each run contained two tasks: a Cyberball task (CB) and a Reconnection evaluation task with working memory load (RETWM). CB is a virtual ball-tossing task. We set up 2 conditions: an Inclusion condition (I) that is a control condition in which the probability of receiving a ball was set to 0.5, and an Exclusion condition (E) in which the probability was set to 0.1. A trial of RETWM consisted of 4 phases. In the first phase, 2 figures were presented randomly on 2 corners of the screen. In the second phase, subjects imagined presented situation as clearly as possible, and rated their desire to participate in the third phase. In the last phase, subjects answered the location of a specified figure. In the control condition of RETWM, the answer was visible throughout the 4 phases. The trial was repeated 8 times per session. We conducted 4 sessions for each subject, corresponding to the 2 by 2 task design of E or I and Memory (M) or Control (C). We defined the RT for each subject as the [EC - IC] and the promotion effect of WM load on reconnection (WM-effect) as the [(EM - EC) - (IM - IC)] in the averages of the attractiveness-corrected ratings. Behavioral result suggested that the promotion effect of WM load may be effective only for people who have low RT. SPM analysis showed that (1) right dorsolateral prefrontal cortex (DLPFC) was more activated getting a working memory load on thinking about social situation after exclusion; and (2) the activation of primary visual cortex was negatively correlated with WM-effect. It is known that the DLPFC is related to emotion regulation, and vividness of mental imagery was correlated with activation in the primary visual cortex. Our results suggested that WM load (1) promoted emotion regulation; and (2) inhibited vivid imaging, leading to promotion of reconnection.

Title: Distinct contributions of acoustic parameters in the recognition of emotional prosody

Authors: *D. BENIS, J. PERON, T. OTT, S. FRÜHHOLZ, D. GRANDJEAN;
Neurosci. of Emotion and Affective Dynamics Lab., Univ. of Geneva, Geneve, Switzerland

Abstract: Emotional prosody is defined as modifications in segmental and supra-segmental speech parameters during an emotional episode (Grandjean, Banziger, & Scherer, 2006). Relevant acoustic parameters for emotional prosody recognition include fundamental frequency (f0), tempo, amplitude, and repartition of spectral power across frequency bands. While emotional prosody recognition have been shown to correlate with perceived modulations of these acoustic features (Schirmer and Kotz, 2006; Sauter et al., 2010), the distinct contribution of acoustic cues to emotion recognition performance remains unclear. Furthermore, while emotional prosody has been shown to involve the basal ganglia network (Frühholz et al., 2014), distinct contributions of acoustic cues on basal ganglia activity during emotional prosody decoding remains to be investigated. The aim of the present study was then to investigate the influence of two acoustic features (namely f0 and amplitude) on emotional prosody recognition performances and on basal ganglia BOLD activity. To this end, we analyzed behavioral performances and BOLD responses in the basal ganglia of 22 healthy participants, while they performed an emotional vocal stimulus evaluation task (Péron, Grandjean, et al., 2010). In this experiment, three types of emotional prosodic stimuli were presented: 1. Original vocal stimuli; 2. F0 flattened stimuli and 3. Energy flattened stimuli. Participants were then instructed to judge the emotional content of each stimulus using a set of visual analog scales (one scale for each emotion presented: happiness, neutral, anger, disgust, fear) as well as the arousal level resulting from stimulus presentation. We observed a global accuracy decrease on emotional scales as well as a decrease in arousal reports during classification of emotional f0 flattened stimuli compared to native stimuli. These effects were significantly more important for anger compared to happiness stimuli, and resulted in an increase of classifications on the non-target neutral scale. Interestingly, such behavioral effects were not observed for energy flattened emotional stimuli. F0 flattening was also associated with modulations of BOLD activity in the basal ganglia system during emotional prosody decoding, Taken together, these results seem to confirm the importance of the fundamental frequency in emotional prosody recognition and suggest that acoustic cues are used differentially according to the valence of the prosodic stimulus processed, through differential activations of the basal ganglia system.

Title: Behavioral and ERP responses to emotionally evocative images among high and low trait anger college age men

Authors: K. ROSS[1], D. ADDLEMAN[2], A. EARLY[1], C. REYES[1], S. BAKER[1], H. O'HORA[1], R. E. PHINNEY[2], W. M. STRUTHERS[2], H. WHITNEY[3], *N. THOM[4,1];
[1]Applied Hlth. Sci., [2]Psychology, [3]Physics, [4]Wheaton Col., Wheaton, IL

Abstract: Little is known about how specific traits, such as trait anger, alter emotional processing. Gaining a better understanding of how traits alter emotional processing could improve clinical care. Therefore, we tested the effect of trait anger on behavioral and EEG responses to a variety of emotionally evocative scenes. Men ages 18-22 with either normal levels of self-reported trait anger (STAXI = 18.4 +/- 5.4; n=16) or high levels of trait anger (STAXI = 28.2 +/- 2.2; n=11) were recruited to examine the effects of emotionally evocative scenes previously shown to elicit anger, fear, and joy (Harmon-Jones, 2006 & 2007; Mikels, 2005)). During picture viewing, event-related potentials (EPN and LPP) and arousal, valence, and anger intensity were measured. Mixed-model ANOVA with follow-up contrasts were used to detect differences between/within dependent variables. The main novel finding is that men who reported high levels of trait anger also reported higher levels of anger intensity when viewing fear-inducing pictures ($p=.007$). As expected, all men reported greater arousal when viewing evocative pictures ($p < 0.001$). Follow-up analysis revealed higher arousal ratings ($p<0.05$) for joyful, fearful, and anger scenes compared to neutral scenes. In addition, all men viewed the anger and fearful pictures as unpleasant and the joyful pictures as pleasant ($p < 0.001$). Follow-up comparisons indicated that all pictures types were rated differently from each other on valence (all ps < 0.001). Among men with normal trait anger, EPN amplitudes were greatest for joy and fearful images (ps < 0.03) and all emotionally evocative pictures showed greater amplitude compared to neutral images ($p = 0.04$). For the LPP, mean amplitude was not different between anger, fear, and joy images (all ps > 0.05), but LPP amplitude across all emotion types was elevated when compared to neutral pictures ($p = 0.008$). ERP amplitudes have only been analyzed for men with low trait anger; analysis of high trait anger men and the comparison between the two groups is forthcoming. These findings present novel results examining how trait anger affects behavioral and neuro-electric responses to emotionally evocative picture stimuli. Because men with high trait anger became more angry in response to fearful or threatening images, these results are consistent with the elicitation hypothesis (Deffenbacher et al., 1996; Quinn et al., 2014) which suggests that high trait anger elicits anger more frequently and due to a

broader range of stimuli. Future studies should more robustly examine how trait anger triggers response to various emotionally laden stimuli, such as sadness or sorrow.

Title: Neural mechanisms of communication via facial expression

Authors: *S. V. SHEPHERD, W. A. FREIWALD;
The Rockefeller Univ., New York, NY

Abstract: Human communication abilities are unique, but build upon a common foundation we share with our primate kin. Primates live in complex social groups with which they must coordinate their behavior, exchanging signals comprising postures, movements, and vocalizations. Scientists have made progress in understanding how facial signals are decoded in primate brains, but know almost nothing about how these signals are produced. We recorded brain activity in monkeys seeing and responding to communicative signals in an MRI scanner. Stimuli were made from video recordings of six monkeys producing a variety of facial expressions. Stimulus videos were simultaneously recorded from multiple angles; a half-silvered mirror was used when recording direct gaze to facilitate naturalistic eye contact. Two 11-second clips were gathered from each monkey, synchronously from three viewpoints. Phase scrambled versions of each video were used as low-level visual controls, and were generated by randomly rotating each Fourier component a consistent amount across each frame. To reduce habituation, we limited exposure to each video. Long (13 second) gaps were placed between videos. Within

each run, only one video per subject was shown. Within each session, each video (i.e. subject, event, perspective and scramble) was shown exactly once. Monkeys produced an affiliative gesture, called a 'lipsmack', in response to brief video of subject-directed monkey expressions. Facial movements were recorded by MR-safe video camera and later analyzed both digitally and by manually scoring behavior while blind to stimulus condition. IRON-fMRI imaging was used to track changes in cerebral blood volume associated with neural activity. By comparing both perceived and produced facial behavior to these simultaneously-recorded brain images, we identified key regions involved in processing social interactions and translating perceived signals into appropriate expressive responses. We find that perception of social stimuli activated the extended face patch system, and that production of the macaque 'lipsmack' signal correlated with activation of facial motor regions. Finally, we examine functional correlations between perceptual and motor face patches to determine candidate pathways by which these socially-driven facial expression may arise.

Title: Early social experience influences cortical gray matter integrity in chimpanzees (Pan troglodytes): A sourced-based morphometry analysis

Authors: *K. R. DAVIDEK[1], W. D. HOPKINS[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: Although recent work has indicated the influence of early social experiences on behavioral and cognitive development in chimpanzees (Pan troglodytes), much less is known regarding their impact on overall cortical development. Here, we used source-based morphometry (SBM) to quantify differences in structural gray matter connectivity in 92 adult chimpanzees matched on age, sex and scanner magnet who were either mother-reared (MR) or human-reared (HR). The original SBM analysis identified 28 independent component regions. Multiple analyses of variance revealed that MR and HR chimpanzees differed in eight component regions which included the cerebellum, dorsal prefrontal cortex, anterior cingulate, superior and middle temporal gyri, and the precentral inferior gyrus. For all but two components, MR chimpanzees had significantly higher weighted component scores compared to HR

individuals. Our results demonstrate the long-lasting impacts of early social experience on cortical gray matter development and morphology in regions critical for emotional and cognitive processes.

Title: Electroencephalographic correlation during visual, maternal and erotic stimulation in mothers at different stages of postpartum

Authors: *M. PÉREZ-HERNÁNDEZ[1], R. M. HIDALGO-AGUIRRE[2], M. HERNÁNDEZ-GONZÁLEZ[2], C. AMEZCUA[2], M. A. GUEVARA[2];
[1]Correlación Electroencefalográfica y Conducta, [2]Neurofisiología de la Conducta Reproductiva, Inst. De Neurociencias, Guadalajara, Mexico

Abstract: The postpartum period is a critical reproductive state in which women present several hormonal, neural, behavioral and emotional changes. The hormonal changes underlying the onset of lactation, have been associated with the persistent inhibition of ovaric cycle, which, mainly in primiparous mothers, are associated with a diminished libido and less interest for those stimuli not related to the newborn. The aim of this study was characterize the prefrontal-parietal electroencephalographic correlation (rEEG) of primiparous mothers at different stages of postpartum during visual, maternal and erotic stimulation. In this study participated primiparous nursing mothers that were divided in three groups postpartum (PPT): Nursing 1 (N1, 1.5 to 3 PPT months), Nursing 2 (N2, 4 to 5.5 PPT months) and Nursing 3 (N3, 6.5 to 8 PPT months). A fourth group conformed by no mothers (NM) was considered as a control group. The EEG was recorded on prefrontal and parietal areas during observation of the maternal and erotic videos. The mothers of the N1 group showed a lower rEEG intrafrontal left (F1-F3) as well as a lower intrahemispheric prefrontal-parietal rEEG (F3-P3, F4-P4) only during the observation of erotic stimuli. Groups N2 and N3 showed changes during the observation of both stimuli; when they watched the erotic video showed a lower rEEG intrahemispheric prefrontal-parietal left (F3-P3) and when they watched the maternal video showed a lower rEEG interhemispheric prefrontal (F3-F4) and intrahemispheric prefrontal left rEEG (F1-F3). This data suggests that the degree of coupling among prefrontal and prefrontal-parietal cortices changes in relation to different stages

of postpartum. These results provide information about the brain functional changes experienced by the nursing mothers through the postpartum, associated to the processing of maternal and sexually relevant stimulus.

Title: Evoked neural harmonics during naturalistic viewing: dissociable effects of perceptual quality and hedonic content

Authors: ***V. MISKOVIC**, K. KUNTZELMAN, N. HANSEN, N. FLETCHER; Psychology, Binghamton Univ., Binghamton, NY

Abstract: Population-level neuronal responses in early visual cortex can be driven by the periodic presentation (ON/OFF flicker or counter-phase modulation) of a stimulus at a fixed frequency. This type of periodic stimulus delivery elicits large-scale oscillatory field potentials (known as steady state visual evoked potentials or SSVEPs) with multiple frequency components. In addition to the neuronal responses that match the input frequency of the driving stimulus (frequency following or 1F evoked potentials), there are also robust responses at the second harmonic (frequency doubling or 2F components). Frequency following and frequency doubling neuronal responses appear to reflect the contributions of distinct types of cells in the visual cortex with different functional roles. Preliminary evidence employing simple visual cues suggests that frequency following responses provide a high fidelity representation of the sensory qualities of the stimulus (contrast, luminance, coherence) while frequency doubling neurons exhibit substantial modulation by attention (responses are amplified for features with high behavioral relevance). We tested this hypothesis concerning the differential roles of frequency following and frequency doubling visual responses by recording SSVEPs to naturalistic scenes flickered ON/OFF at 12 Hz. We systematically varied two factors: (1) the coherence of the images (perceptually distorted to perceptually intact) and (2) their affective salience (neutral or highly aversive). Our findings provide additional support for the suggestion that the frequency following and frequency doubling SSVEPs have distinct functional roles in the human visual system. The amplitude of the 1F visual evoked potential was modulated in a linear fashion, with

the lowest amplitudes for the most distorted and highest amplitudes for the most intact images, regardless of hedonic content. By contrast 2F SSVEP responses were modulated according to hedonic salience - aversive scenes evoked larger amplitudes compared to neutral scenes, consistent with prior evidence from other imaging modalities. The visual system seems to balance two competing demands - providing high fidelity sensory representations of its environment and selectively enhancing the representation of salient features therein - via temporal segregation of its responses.

Title: Emotional music and voices: a magnetoencephalography study

Authors: ***K. LOGIE-HAGEN**[1,2], S. RIGOULOT[3,2], J. L. ARMONY[3,2], P. JOLICOEUR[4,2,5]; [1]McGill, Montreal, QC, Canada; [2]Intl. Lab. for Brain, Music, and Sound Res. (BRAMS), Montreal, QC, Canada; [3]Dept. of Psychiatry, Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [4]Dept. of Psychology, Univ. de Montréal, Montreal, QC, Canada; [5]Ctr. de Recherche en Neuropsychologie et Cognition (CERNEC), Montreal, QC, Canada

Abstract: Music is similar to the human voice in its auditory complexity and both can serve different functions, such as convey emotional information. However, the specificities of neural networks involved in the processing of music and voice are currently widely debated. As such, we used magnetoencephalography (MEG) to investigate the similarities and differences in how humans process emotional music and voices. Participants (N=21) listened to human vocalizations, as well as short (1.5 sec) musical excerpts played with saxophone, piano, or violin. Prior to the study the auditory stimuli were rated as sad, happy, fearful or neutral. Source localization (dSPM) revealed significant differences in spatial and temporal activation patterns between vocalizations and music, particularly within the temporal lobes, consistent with previous fMRI results. Specifically, vocalizations elicited stronger activation in both hemispheres during the magnetic equivalent of the P50, compared to music. Vocalizations also resulted in slightly

more temporal/frontal lobe activation in later components (200 ms onwards). In turn, musical excerpts evoked significantly stronger responses during the magnetic equivalent of the N100, especially in the right temporal lobe. These differences between music and human vocalizations were mainly driven by piano. In contrast, violin elicited similar patterns in magnetic signal to those of vocalizations, which is likely due to the similarity of violin to the human voice in their frequency. In terms of emotion, the largest differences were observed between happy and sad stimuli. By using emotionally complex auditory stimuli across various domains, results from this MEG study can provide valuable insights into how music and human voices are processed in the brain. Our study is also useful as a means to assess the strengths and limitations of the MEG approach in cognitive affective research.

Title: Altruism effects on event-related potentials following violent video game play

Authors: *R. D. FARERO[1], J. J. FOWLER[1], J. HOST[1], K. BRALEY[1], C. PHIEL[2], M. A. KISLEY[3], D. S. ALBECK[1];
[1]Univ. of Colorado Denver Dept. of Psychology, Denver, CO; [2]Univ. of Colorado Denver Dept. of Integrative Biol., Denver, CO; [3]Univ. of Colorado, Colorado Springs Dept. of Psychology, Colorado Springs, CO

Abstract: Previous research has shown that playing violent video games alters a person's behavior and physiology. In the present study electrical signals from the brain were recorded by electroencephalography (EEG) in order to capture the neural response to emotionally charged visual images before and after playing a violent video game. Participants were shown a total of 360 images; with 24 violent, 24 positive and 312 emotionally neutral images, as rated by previous similar studies. Level of altruism was collected through a self-report survey. EEG responses to violent images were isolated, filtered and averaged. Preliminary results indicate that an individual's altruism level is correlated to within subject change in average amplitude of

visually-evoked responses to violent images r= 0.689, n= 13, p<.01. The within subject change was calculated by subtracting individual's average amplitude of visually-evoked responses before playing a violent video game by the average amplitude after playing a violent video game. A greater visually-evoked EEG response implies the brain is allocating more cortical activation to the stimulus, thus a greater level of attention when viewing the images. This increase may suggest that playing the violent video game sensitized the brain of higher altruistic individuals toward violent images. Additionally, the lower altruistic individuals had less cortical activation after playing the video game suggesting desensitization towards the violent images after playing a violent video game. The oxytocin receptor genotype in these participants is also currently being studied.

Abstract: Emotionally charged images evoke greater electrophysiological responses in the brain than neutral images, as measured by scalp electroencephalography. In this study we are using event-related potential (ERP) methodology to study how playing a violent video game affects the neural response to different types of images. Participants were shown a total of 360 images; 24 violent, 24 positive and 312 emotionally neutral, as rated in previous studies. Preliminary data has found that participants who committed the greatest number of violent acts during 15 minutes of video game play exhibited a significantly stronger ERP than those who committed the fewest number of violent acts in the game. ERP responses were quantified by the average amplitude of

the late positive potential (LPP) elicited by image presentation. Measurements were taken at the PZ zone, with the ERP in for the violent images being statistically significant, low vs. high violence ($t(11) = 3.28$, $p < .05$). Oxytocin receptor genotype in these participants is also currently being studied.

Title: Emergent cortical dynamics during aesthetic experiences

Authors: *K. KONTSON[1,2], M. MEGJHANI[2], J. BRANTLEY[2], J. G. CRUZ-GARZA[2], S. NAKAGOME[2], D. ROBLETO[3], M. WHITE[3], E. CIVILLICO[1], J. CONTRERAS-VIDAL[2]; [1]U.S. Food and Drug Admin., Silver Spring, MD; [2]Dept. of Electrical and Computer Engin., Univ. of Houston, Houston, TX; [3]Menil Collection, Houston, TX

Abstract: In this work, the brain response to conceptual art was studied through electroencephalography (EEG) to characterize the neural basis of aesthetic judgments and experiences. To ensure recording of neural dynamics during natural cognition, participants were not constrained to a laboratory environment as in previous studies, but were moving and thinking freely as they viewed an exhibit by artist Dario Robleto at the Menil Collection in Houston, TX. The brain activity of a diverse group of 127 participants was recorded using two dry-electrode mobile EEG headsets (actiCAP Xpress - Brain Products, Germany; StarStim - Neuroelectrics, Spain) and one gel-based wireless, mobile EEG headset (actiCAP - Brain Products, Germany). Data were segmented according to each piece in the exhibit and grouped into three classes describing the complexity of the pieces viewed based on the calculated perceptual features (gradient, luminance, texture, and composite features) of the art pieces. Features in the time, frequency, and wavelet domain were extracted from the EEG data and used as inputs to machine learning tools to classify different patterns of brain activity associated with viewing artworks of varying complexity. The maximum classification accuracy obtained was 55% ± 1.03%, which was determined to be statistically greater than chance level at 33% (paired sample t-test, $p <$

0.01). To understand the neural networks engaged during aesthetic perception and judgment, a functional analysis of dynamic brain activity was performed in participants using the reference gel-based system. Results revealed a significant increase in connection strength between several predefined regions of interest while participants viewed one of the complex pieces of art deemed by participants to be the most aesthetically pleasing compared to viewing a blank wall. Viewing an art piece with complex perceptual features resulted in early recruitment of posterior visual areas followed by focal activations of frontal areas. Differences in the strength of connections while viewing a complex piece of art were also observed for participants of different ages and gender. The results of this work may shed light on how aesthetic experiences engage the brain to stimulate creativity, and could lead to development of innovative neurotechnologies intended to restore or enhance aesthetic reactions in neurologically-impaired persons while allowing to study the brain 'in action and context'. Title: Personality traits predict insular activation during anticipation of affective pictures: an fMRI

Authors: ***K. MAKITA**[1], N. KANAYAMA[1], T. UYAMA[1], G. OKADA[1], T. SASAOKA[1], M. MACHIZAWA[1], K. ONODA[2], S. YAMAWAKI[1];
[1]Hiroshima Univ., Hiroshima, Japan; [2]Shimane Univ., Izumo-shi, Japan

Abstract: Anxiety is an important mechanism for generating adaptive behavior as it guides appropriate responses to undesirable events; however, an excessive anxiety becomes problem. Previous findings suggest that the score of "Harm Avoidance (HA)" measured by Temperament and Character Inventory (TCI), an inventory for personality traits, assesses individual's tendencies who has passive avoidance for incoming undesirable events or pessimistic anxiety for one's future. Studies have suggested that a person with high HA score has a risk factor for

development of depression and anxiety disorders (Cloninger et al., 2006). However, neural bases of personality traits pertaining risk factor of depression remains unclear. This study was undertaken to determine the neural locus of brain activity correlated with HA scores during anticipation of pictures which induce emotional feelings. 16 healthy subjects were participated in this study (21~26 years, 8 men). Before scanning in MRI, subjects completed TCI questionnaire, then were subjected to a cued reaction time task in MRI. In the task, a warning tone was presented on each of a series of trials and followed by an emotional picture. The pictures were selected from the International Affective Picture System (IAPS) (Lang et al., 2008). Two types of warning tones (High: 4000Hz, Low: 500Hz) were created. High tone served as a certain cue for a subsequent negative picture (negative anticipation); Low tone was followed by a positive picture (positive anticipation). After the picture presentation, subjects were required to respond their feelings by button press. As a result, subjects' scored 37~61 in HA (mean=50.9, SD=±5.59). These HA scores were entered into the whole brain regression analysis, and we found that subjects' HA scores significantly predicted the degree of activation in a network of brain regions including left insula during anticipation of negative compared to positive pictures. Subjects who have higher tendency of HA showed relatively higher activation in the left insula during negative anticipation compared to positive anticipation. Based on previous study that reports increased insula's activation when one direct one's attention on something unknown (Grinband et al., 2006), our results suggest that a person who has higher anxiety (higher HA scores) tend to respond to incoming unpleasant events more sensitively compared with the others (lower HA scores). In terms of an adaptive behavior, as is important to anticipate and prepare for the events which can happen in the future, a person with higher anxiety are prone to evaluate future negative events excessively, thereby inducing a risk to have depressive mood.

Title: Increased dorsomedial prefrontal cortex and precuneus activation precede correct emotion identification

Authors: *M. A. ORLOFF, M. C. COFFMAN, A. TRUBANOVA, M. RULOFF, S. W. WHITE, D. GRACANIN, I. KIM, M. A. BELL, S. M. LACONTE, J. A. RICHEY; Virginia Tech., Blacksburg, VA

Abstract: Background: There are six basic emotions that are inborn and recognized across virtually all cultures. Many individuals with mental disorders such as schizophrenia, ADHD, and ASD demonstrate difficulties identifying certain emotions nonverbally, via facial expression. We sought to identify which brain regions are responsible for the emotion misidentification in a healthy adult sample to inform problems that could be occurring in clinical populations. Objectives: Utilize fMRI to characterize brain regions that are differentially activated immediately prior to correct or incorrect emotion identification. Hypothesis: We predicted that the fusiform gyrus (FG) would show decreased activation prior to incorrectly identified faces, as compared to correctly identified faces due to its role in face processing. Methods: Male participants (N=20, mean age=23.4, mean FSIQ=110) were recruited from the community. During fMRI, participants viewed slow-motion videos of faces morphing from neutral to one of the six basic emotions (happiness, sadness, fear, disgust, surprise, and anger). Participants were instructed to indicate once they recognized the displayed emotion and then asked to choose which of the emotions was shown. Each subject completed 30 trials, with an average of five faces displaying each emotion. Preprocessing was accomplished using SPM8. Onset times and durations of events were used to model a signal response containing a regressor for each response type (correct and incorrect), which was convolved with a double-gamma function to model the hemodynamic response of the 2 seconds prior to the button press, indicating recognition. Results: There was increased activation in both the dorsomedial prefrontal cortex (dmPFC) and the precuneus in the two seconds immediately preceding correct identification ($p<0.01$, FDR corrected). Contrary to our initial hypothesis, no significant activity was observed in the FG. Conclusions: Our findings demonstrate that increased activation in the dmPFC and the precuneus immediately precedes accurate, but not inaccurate judgments of other's emotions. Consistent with this finding, Ochsner et al. (2004) found that both the medial prefrontal cortex and the precuneus were active in judgments of both self and others across all basic emotions. Lack of between-group activation differences in the FG suggest that emotion identification accuracy was not due to difficulties with facial processing.

Title: Beyond eyeballing: modelling event-related pupil responses with canonical response functions

Authors: *C. W. KORN[1], D. R. BACH[1,2];
[1]Univ. of Zurich, Zurich, Switzerland; [2]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Pupil responses have recently received renewed interest as they may allow inferring psychological and neural variables of information processing in emotional and motivational processes. Previous studies analyzed baseline-corrected averages, or directly regressed variables of interest on pupil size. Up to now, a unified and principled analysis approach for pupil responses is lacking. This is surprising given the established use of biophysical models for analyzing neuroimaging and psychophysiological data, for example in the framework of general linear convolution models (GLM). Here, we establish such a GLM approach for event-related pupil responses. To derive the biophysical properties of pupil responses, we presented participants (n = 23) with five different luminance levels for 5 s each (120 trials). Dilations and constrictions differed in shape, showing that pupil time series are not simply the output of a linear time invariant (LTI) filter. Still, the system could be approximated by combining two LTI filters. One filter takes the luminance time series as continuous input, incorporating the dilation response and a non-linear relation between luminance and steady-state pupil size. A second filter models the difference between dilation and constriction by taking a brief unit input for each positive luminance change. We derived canonical impulse response functions (CRFs) from our data and analytically approximated them with gamma functions. A GLM based on the two CRFs explained 60.1% of the variance in our data (SD across participants = 13.3). Crucially, this GLM explained more variance than a baseline model which only took steady-state pupil size into account (47.7%, SD = 11.2). The results were robust for different filter settings and CRF approximations. Notably, the model makes the counter-intuitive prediction that constrictions dominate the responses to brief flashes of both light and darkness. This was confirmed in an independent group of participants (n = 14) with luminance changes of 200 ms. Here, our GLM explained 43.6% of the variance (SD = 11.9) while the baseline model explained a negligible variance proportion (0.3%, SD = 0.2). Based on luminance-evoked pupil changes, we have characterized the biophysical properties of event-related pupil responses in a GLM approach. The same biophysics should apply to cognitive influences on pupil size and we will apply the model to cognitive tasks. Analyses routines will be available in the PsPM toolbox (pspm.sourceforge.net). Our parsimonious mathematical description of pupil responses will be

helpful for refining their relation to behavioral and brain indices of emotional and motivational processes.

Title: Exploring the origins of learned salience: valuable, risky, novel, and aversive

Authors: W. GRIGGS, A. GHAZIZADEH, *O. HIKOSAKA;
Lab. Sensorimotor Res., Natl. Eye Inst., NIH, Bethesda, MD

Abstract: An object is considered salient if it attracts attention/gaze more strongly compared to its surrounding. While the role of physical features in bottom-up salience has been studied extensively, systematic examination of causal origins of nonphysical salience has been lacking. Here we examined various factors that may change an object's salience through experience (learned salience). Random computer-generated fractals with no prior life experience were used to create object histories from scratch. We monitored eye movements of macaque monkeys (n=4) while they freely viewed objects that differed only by a single experiential factor, namely: value, risk, novelty or aversiveness. Objects were differentially trained on these factors for >5 days prior to testing in free viewing. We measured salience by the ability of the object to attract and maintain gaze during free viewing in the absence of any behavioral outcome. For value contrast, sets of 5 random fractals were associated with increasing amount of juice reward (0%, 25%, 50%, 75%, 100% of max juice). For risk contrast, sets of 5 random fractals had the same mean juice reward but increasing variance around the mean (0%, 25%, 50%, 75%, 100% of max variance). Analysis of gaze in free viewing showed a monotonic increase in attraction and maintenance of gaze as a function of object value. Risk free viewing also caused longer viewing times, but in contrast with value, risky objects did not necessarily attract more saccades. Third, free viewing of novel vs. familiar fractals showed higher attraction and retention of gaze to novel objects, with decreasing effect as the novelty wore off. Finally, objects with aversive but non arousing outcomes (time-out or aversive tastants) showed weaker gaze bias compared to neutral objects. On the other hand, objects associated with an arousing and aversive outcome (airpuff) showed increased gaze bias. Therefore, for aversive objects, arousal or threat seems a better predictor of salience than negative valence. Our results suggest that, while the final outcome for

all these experiential dimensions may look the same (i.e. gaze bias), the underlying mechanisms are diverse. Such multiple mechanisms for learned salience may cooperate or compete to bias attention and gaze.

Title: Noradrenergic mechanisms of arousal-biased competition in memory

Authors: *D. CLEWETT[1], M. SAKAKI[2], S. NIELSEN[1], G. PETZINGER[1], M. MATHER[1]; [1]USC, Los Angeles, CA; [2]Univ. of Reading, Reading, United Kingdom

Abstract: Selection is at the core of efficient cognitive processing. According to the Arousal-Biased Competition (ABC) model, arousal amplifies the stakes of on-going selection processes, leading to “winner-take-more” and “loser-take-less” effects in perception and memory. Thus, arousal helps optimize memory of important information when it matters most. To explain how this process occurs in the brain, we recently proposed the Glutamate Amplifies Noradrenergic Effects (GANE) model, which posits that arousal-induced norepinephrine (NE) release biases the competition for limited mental and metabolic resources in favor of prioritized (e.g., goal-relevant) information. According to GANE, an activity-dependent increase in local norepinephrine leads to the activation of β-adrenoreceptors and, as a result, the selective enhancement and consolidation of a high priority trace. The goal of this human pharmacological study was to test GANE theory using a double-blind, placebo-controlled, randomized design in which 26 healthy younger adults were administered 40mg of propranolol, a β-adrenoreceptor blocker, or 40mg of vitamin E placebo. After pill administration, participants completed an emotional oddball task in which they were asked to prioritize a neutral object appearing just before an emotional or neutral black-framed image within a sequence of 7 individually presented neutral objects. To assess ABC memory effects, we examined the interactions between arousal, priority and drug condition in corrected recognition memory for oddball-1 (high priority) and oddball+1 (low priority) objects. Task-induced increases in salivary alpha-amylase were also measured to determine how global increases in noradrenergic system activity were associated

with arousal-related modulation of priority effects in memory. Under placebo, emotional relative to neutral oddballs impaired mean recognition memory for lower priority oddball+1 objects but had no effect on memory of high priority oddball-1 objects. This anterograde amnesic effect of arousal was blocked by propranolol. Individuals who recalled more high priority objects preceding an emotional versus neutral oddball image also showed greater task-induced increases in salivary alpha-amylase, indicating that individual differences in NE release induced by the oddball task may be critical for the arousal-induced memory enhancement of high priority oddball-1 objects. Together these findings suggest that norepinephrine mediates the selective influence of emotional arousal on short-term memory.

Title: Tasteful packaging: How health and ethical messaging can affect the consumer experience

Authors: *M. M. NIEDZIELA, A. JORDAN, H. STONE, M. ROSAZZA;
HCD Res., Flemington, NJ

Abstract: Ethical buzz words like “organic”, “sustainable”, and “non-GMO” have become increasingly popular for consumer products. Consumer demand for such products is rising rapidly. Health and environmentally conscious consumers are driving sales of products yet it is unknown how much of an impact such claims have on consumer perception. Using a combination of psycho-physiological measures, traditional quantitative questionnaires and conjoint analysis, we aimed to understand the consumer’s experience when exposed to these claims. QUANTITATIVE: Subjects (n=302) were exposed to 12 images of yogurt packaging with varying claims combinations including control (plain package), environmental (“organic”, “sustainable”, “non-GMO”) and dietary (“low fat”, “low calorie”) and were then given a questionnaire to assess perceived taste, brand perception, and cost perception of the stimuli as well as general health and environmental implications on grocery purchases. PSYCHO-PHYSIOLOGICAL: Subjects (n=18) were exposed to 12 images of yogurt packaging with varying claims combinations including a control (plain package), environmental (“organic”, “sustainable”, “non-GMO”) and dietary (“low fat”, “low calorie”) for 8 seconds each while

being measured for HR, GSR, and fEMG. Visual attention was also measured using eye tracking. Subjects were then asked to answer a questionnaire. RESULTS/CONCLUSION: Psycho-physiological data showed that claims helped sustain arousal and engagement with products, but can also have a negative effect on pleasantness and cognitive attention. Environmental and health claims also had an effect on perceived taste and amount consumers were willing to pay for the product with significant differences between males and females and among different age groups. The results of this study provide much needed insight into the importance of consumer package communications for health and environmental issues.

Title: Functional interaction between amygdala and orbitofrontal cortex during the processing of emotionally salient auditory stimuli depends on the emotional valence of the stimuli

Authors: Z. CHEN[1,2], H. LIN[1,2], L. PARKKONEN[2], J. WEI[3], J. DONG[3], Y. MA[3], *S. CARLSON[1,2];
[1]Univ. of Helsinki, Helsinki, Finland; [2]Aalto Univ. Sch. of Sci., Espoo, Finland; [3]Kunming Inst. of Zoology, Chinese Acad. of Sci., Kunming, China

Abstract: It is well known that amygdala is anatomically connected reciprocally with orbitofrontal cortex (OFC) in human and nonhuman primates (Cavada et al., 2000). The functional connection between these areas is considered to relate to regulation of emotions and impulsive behaviour (Rolls, 2004). Here, we studied whether the strength of this functional connection reflects the processing of the emotional content embedded in naturalistic stimuli. We recorded intracranial local field potentials bilaterally in the amygdala (basolateral nuclei) and

caudal OFC in three Rhesus monkeys while they listened to audio clips (duration 0.95-1.5 s) of recordings of monkey vocalizations that were categorized according to their social context and judgements of human listeners as neutral (coo), threatening (bark), fearful (scream) and happy (warble) monkey calls. We examined the oscillatory synchronization between the amygdala and OFC by using a cluster-based permutation test. The beta-band (15-25 Hz) coherence between the left amygdala and left OFC differed significantly between the monkey calls with different emotional valence; the coherence was stronger to the monkey calls with salient emotional content than to the neutral monkey call, being strongest to the fearful call, and stronger to the threatening and fearful calls than to the happy call. However, the beta coherence between the right amygdala and right OFC in the same conditions was inconsistent in the three monkeys. Our results suggest that the processing of emotionally salient, naturalistic auditory stimuli in the amygdala-OFC axis contributes to the emotion-associated behaviour. References: 1. Title: Song preference measured by behaviors depends on song similarity in female zebra finch

Authors: *R. TABATA, K. HOTTA, K. OKA;
Grad. Sch. of Sci. and Technology, Keio Un, Yokohama, Japan

Abstract: Male zebra finches (Taeniopygia guttata) court females to sing songs. Male songs have two different types: directed and undirected songs. Directed song is the just directed to the female for courtship, in contrast undirected song is sung alone without female birds. Male's song is different in individual, while females distinguish directed songs, and select the male bird with high preference as her mate. Therefore, male song is one of the important cues for mate-choice and pair bonding in female zebra finches. Females display preference for particular song: conspecific songs over heterospecific songs, familiar songs of the father over unfamiliar conspecific songs, and mate's directed songs over mate's undirected songs. However, how directed song preference of female is related to behaviors is still unknown, and female's song

preference to several directed songs has not been evaluated yet. The purpose of this study is to quantify the directed song preferences of female over several directed songs based on song similarity. Previous studies have estimated the mating preferences of females by choice-chamber experiments. To evaluate the directed song preferences of female in detail, we recorded female behaviors and extracted following six indexes: spatial proximity, hop on perches, tail-quivering or body shakes, production of calls, bill-wipes, and peck keys. These indexes were analyzed by principal component analysis (PCA) in individual subject. Song similarity to mate's directed song is calculated by Sound Analysis Pro (SAP) software. Songs used in this experiment are 15s duration and contain several motifs, so song similarity is estimated as the average of each motif similarity calculated each period of song called motif. The first to third principal components are more than 85% proportion of variance in almost subjects, so three dimensions reduction is appropriate. Euclidean distance to mate's directed song was calculated from the first to third principal components, and we examined the relationship between song similarity and mate's directed song. As a result, song similarity and behaviors show correlation in all females experimented (N=8). This result demonstrates that female tend to perform preference-related behaviors, if song similarity between mate's directed songs and other's directed song is high score. This result indicates that song preference to other's directed song measured by female's behavior depends on song similarity to mate's directed song. There is a possibility to evaluate directed song preference in individual female by behavioral analysis.

Title: The influence of social skill training on the ability of emotional face recognition

Authors: I. B. F. GREBOT[1], *W. C. DE SOUZA[2], A. M. M. NOZIMA[1], J. S. R. AGUIAR[1], G. F. S. FERREIRA[3];
[1]Inst. of Psychology, Univ. of Brasília, Brasília, Brazil; [2]Univ. Brasilia, Brasilia-DF, Brazil; [3]Dept. of Psychology, Ctr. universitário IESB, Brasília, Brazil

Abstract: The ability to identify facial expressions of emotion has undisputable evolutionary implications and has been linked to social skills. Similarly, the practice of clinical psychology demands the development of certain social skills, albeit in a specific context. Thus, it could be

expected that individuals within the supervised training stage of the regular psychology undergraduate course would have developed these abilities. The objective of this research was to evaluate possible correlations between the identification of the six basic facial expressions and the undergraduate course stage. This research consisted of a sample of 163 participants, 82.8% female, divided into two groups ("novice" and "veteran"), based on the stage of the undergraduate course. The experimental task consisted on the presentation of a series of facial expression stimuli, divided into static and dynamic. The results show that there was no significant difference in the ability of facial expression identification, between the experimental groups. As suggested by other research in this field, the ability to identify facial expressions demands specific training.

Title: Motion and emotion: depression reduces psychomotor performance and alters affective movements in caregiving interactions

Authors: *K. S. YOUNG[1,2], C. E. PARSONS[2,3], A. STEIN[2], M. KRINGELBACH[2,3]; [1]UCLA, Los Angeles, CA; [2]Psychiatry, Univ. of Oxford, Oxford, United Kingdom; [3]Aarhus Univ., Aarhus, Denmark

Abstract: Background: Impaired social functioning is a well-established feature of depression. Evidence to date suggests that disrupted processing of emotional cues may constitute part of this impairment. Beyond processing of emotional cues, fluent social interactions require that people physically move in synchronized, contingent ways. Disruptions to physical movements are a

diagnostic feature of depression (psychomotor disturbance) but have not previously been assessed in the context of social functioning. Here we investigated the impact of psychomotor disturbance in depression on physical responsive behavior in both an experimental and observational setting. Methods: In Experiment 1, we examined motor disturbance in depression in response to salient emotional sounds, using a laboratory-based effortful motor task. In Experiment 2, we explored whether psychomotor disturbance was apparent in real-life social interactions. Using mother-infant interactions as a model affective social situation, we compared physical behaviors of mothers with and without postnatal depression (PND). Results: We found impairments in precise, controlled psychomotor performance in adults with depression relative to healthy adults (Experiment 1). Despite this disruption, all adults showed enhanced performance following exposure to highly salient emotional cues (infant cries). Examining real-life interactions, we found differences in physical movements, namely reduced affective touching, in mothers with PND responding to their infants, compared to healthy mothers (Experiment 2). Conclusions: Together, these findings suggest that psychomotor disturbance may be an important feature of depression that can impair social functioning. Future work investigating whether improvements in physical movement in depression could have a positive impact on social interactions would be of much interest.

Title: Conditioned place preference successfully established in typically developing children

Authors: *B. L. THOMPSON[1,2], L. HILLER[2], S. TAKATA[2];
[1]Cell and Neurobio., Univ. of Southern California, Los Angeles, CA; [2]Div. of Occup. Sci. and Occup. Therapy, USC, Los Angeles, CA

Abstract: Affective processing, known to influence attention, motivation and emotional regulation is poorly understood in young children, especially for those with neurodevelopmental disorders characterized by language impairments. New strategies and tools that probe more

complex internal responses, such as feelings, drives, and motivations independent from language, become necessary for populations of children with language delays and other language impairments, and even typically developing children. In this study we faithfully adapted a well-established animal paradigm used for affective processing, conditioned place preference (CPP) for use in typically developing children between the ages of 30-55 months. To our knowledge, this was the first attempt at establishing the use of CPP in children. The current study addressed whether young children could learn a conditioned place preference. The paradigm utilized straightforward Pavlovian conditioning methods in a custom-built child friendly arena to assess whether a preference had been conditioned. Children displayed a robust CPP, with an average 2.4 fold increase in time spent in the preferred room. Importantly, associative learning as assessed with conditioned place preference was not correlated with scores on the Mullen Scales of Early Learning, indicating that CPP can be used with children with a wide range of cognitive skills. Moreover, this technique could also useful for populations with language impairments or delays, as performance in this task does not depend upon expressive language. As such, the utility of this task is seen to reach far beyond the typical pediatric population, and can be a useful probe for understanding motivation and associative learning in children with neurodevelopmental disorders. We note that there are numerous studies employing animal models to study human disorders, but the reverse - adaptation of well-regarded rodent models in studies to further understand human behavior- is the exception. Translational studies like this are necessary for understanding the biological underpinnings of human behavior and disorders. The use of well-conserved, behavioral probes that have clearly defined structure-function relationships in animals provides a unique opportunity to establish similar neurobiological relationships in children.

Title: Developmental changes in the perception of voluntary and involuntary emotional vocalizations

Authors: *S. H. CHEN, S. KRISHNAN, S. EVANS, S. GULDNER, A. A. GOMES, N. KHAMOSIA, S. SCOTT;
Inst. of Cognitive Neurosci., London, United Kingdom

Abstract: How does age affect the perception of emotion? Laughter and crying are fundamental to the human experience and are produced and heard right from infancy to adulthood. While laughter and crying can be helpless or involuntary, voluntary versions can be deliberately used in social situations. Involuntary laughter is perceived as more contagious than voluntary laughter. Laughter that humans perceive as involuntarily produced elicits greater activity over auditory regions such as the Heschl's gyrus and STG. However, laughter perceived as voluntarily produced elicits greater activity in the anteromedial prefrontal cortex, an area associated with making social inferences (McGettigan et al., 2013). Both temporal and prefrontal regions show protracted changes in grey matter density over development (Gogtay et al., 2004), yet the behavioural consequences of such change on development are unclear. In this study, we investigate the perception of emotional vocalizations across age. In a large-scale study conducted in the Science Museum, London, we tested 1,847 visitors. Participants were played vocalizations varying in voluntariness (involuntary/voluntary) and emotion (laughter/crying); they rated emotional sounds on 5-point Likert scales for their perceived authenticity ('How real do you think the emotion is?') and their contagiousness ('How much do you want to join in?'). Only data from 1,723 participants (1,010 females) who passed our catch-trials criterion was further analysed. The final age-distribution was: 3-9-years, N = 318; 10-17 years, N = 346; 18-23 years, N = 362; 24-29 years, N = 259; 30-59 years, N = 399; 60-76 years, N = 39. Preliminary analyses showed that the developmental trajectories for perception of voluntary and involuntary expressions differed: with age, the difference between authenticity ratings increased (laughter: $R2 = 0.108$, $p < 0.001$; crying: $R2 = 0.161$, $p < 0.001$). The same was true of the contagion ratings (laughter: $R2 = 0.097$, $p < 0.001$; crying: $R2 = 0.053$, $p < 0.001$). Our results suggest a shaping of the response to voluntary sounds over the lifespan, rather than to involuntary sounds. This indicates an important, but differential, role for social factors and experience in learning about the perception of emotional vocalizations.

Title: Compounds found in energy drinks can differentially affect depression in adolescent and adult male rats

Authors: *K. H. CHAUHAN[1], S. L. PEREZ[2], K. URIBE[3], D. WOO[1], U. AKPARA[1], M. EVELYN[1], S. SINGH[1], M. MURITALA[1], S. AYO[1], F. JACQUES[1], S. SOYEMI[1], A. COLE[1], P. DUVALSAINT[1], D. PETERS[3], A. ELZANIE[1], D. HARRIS[1], S. MARACHERIL[1], M. A. GUZMAN[1], A. ALEXANDER –STREET[2], K. Y. SALAS-RAMIREZ[1];
[1]Dept of Physiology, Pharmacology, and Neurosci., Sophie Davis Sch. of Biomed. Education, CCNY, New York, NY; [2]Biol., Lehman College, CUNY, Bronx, NY; [3]Biol., City College, CUNY, New York, NY

Abstract: In the United States, nearly 75% of children under the age of 18 consume caffeine, not just in coffee, soda and tea, but also in energy drinks like Red Bull and Monster, which also contain taurine. Energy drinks claim to improve mood, cognition and motor performance. More recently, energy drinks have been shown to decrease the subjective effects of impairment and increase binge drinking. Few animal studies directly compare the behavioral effects of caffeine and taurine in adolescents and adult subjects. The objective of this study was to determine the individual and combined effects of caffeine and taurine on locomotion, anxiety and depression, in adolescent and adult male rats. 32 adolescent and 32 adult male subjects were randomly divided into four groups (1) caffeine (20mg/kg/day; ip), (2) taurine (100mg/kg/day; ip), (3) caffeine & taurine (as a cocktail/day; ip) or (4) saline (ip/day). Treatment was initiated on PND 33 in adolescent males and PND 68 in adult males. One week after treatment began; consecutive behavioral assessments to assess anxiety (elevated plus maze), locomotion (open field) and depression (forced swim) were performed while the males continued to be exposed to these compounds. The energy drink compounds did not affect locomotion or anxiety on either adolescent or adult male rats. However, two-way ANOVAs revealed a main effect of treatment ($p < 0.002$) as well as age ($p < 0.0001$), showing that both adolescent and adult males have reduced immobile time in the forced swim test. Males treated with caffeine and the cocktail containing caffeine and taurine spent significantly less immobile time, while taurine alone had no effects, after three weeks of exposure. These data highlight the antidepressant properties of

caffeine, alone and when it is combined with taurine. In general, adult males spent significantly more immobile time than adolescent males demonstrating that adolescent male display less depressive behavior. Taken together, these data suggest that active compounds found in energy drinks can have differential effects on emotional regulation, dependent on the developmental time of exposure, which in turn can impact behavioral outcomes related to psychopathologies and possibly cognitive function.

Title: Correlational EEG study between love, attachment, and the mirror neuron system

Authors: *E. SHAKOOR, J. E. FISHBEIN, M. PALOMINO, J. A. PINEDA;
UCSD, San Diego, CA

Abstract: When we are in love or attached to our partners, we experience a greater understanding and connection with them; these feelings may be linked to the idea that humans mirror the actions and behaviors of other humans. Hence, topics related to love and attachment have been increasingly explored within this context. One definition of love is the longing to commit to another that emerges from our desire to expand our sense of self to include the person with whom we love. A natural question, then, is whether there is a link between love, attachment, and the human mirror neuron system? We hypothesized that women in a romantic relationship experience increased mirror neuron activity reflected by mu rhythm suppression evident in EEG when they encounter positive and negative stimuli related to their partners as opposed to controls. We studied females in 6 to 18 month long heterosexual romantic relationships and recorded EEG and EKG as they read positive compliments directed to them by their partners, and as they watched videos of their partners receiving a staged slap to the face. The participants' mu rhythm suppressions were compared to those observed when responding to three controls under the same conditions. In order to evaluate and compare the love and

attachment levels of our participants, we administered two surveys_The Love Attitudes Scale, and The Attachment Style and Close Relationships Scale. The former measures six kinds of love: passionate, playful, friendship, practical, intense, and selfless. The latter assesses secure, anxious, and avoidant attachment. Results indicate that love and attachment scales correlate differently with respect to the duration of the romantic relationships. Passionate and friendly love, the two most relevant to the early phases of a relationship, correlate positively with the duration of the relationship, while avoidant and anxious attachment styles correlate negatively. We predict that these participants will show increased mirror neuron activity, as indexed by increased mu suppression when they receive compliments from their partners or when they view aversive stimuli being inflicted on their partners compared to controls. Examining the relationship between love, attachment, and the mirror neuron system in heterosexual couples adds to the known functionality of the mirror neuron system, and furthermore offers a vital link between feelings of romantic love and mu rhythm suppression_one that has yet to be established.

Title: Theta oscillations in human approach-avoidance conflict relate to threat memories

Authors: *S. KHEMKA[1,2], G. BARNES[3], R. J. DOLAN[3], D. R. BACH[2];
[2]Dept. of Psychiatry, Psychotherapy and Psychosomatics, [1]Univ. of Zurich, Zurich, Switzerland;
[3]Wellcome Trust Ctr. for Neuroimaging, London, United Kingdom

Abstract: Simultaneous presence of appealing and aversive aspects of a situation results in approach-avoidance conflict (AAC). Rodent models based on AAC are commonly used to study anxiety-like behaviour (e.g. elevated plus maze, open field, operant conflict). In these test beds, ventral hippocampus but not dorsal hippocampus or amygdala is involved in controlling anxiety-like behaviour. Further, hippocampal local field potential shows increase in theta power and theta frequency compared to familiar environments. A recent functional neuroimaging and lesion study in humans has demonstrated a similar role for the anterior hippocampus, the analogue to the ventral hippocampus in rodents. Using magnetoencephalography (MEG), we have previously also suggested increased hippocampal theta power in human AAC. Here, we seek to relate

human hippocampal theta oscillation specific task aspects and behaviours. We developed a virtual AAC computer game based on rodent operant conflict tests. As an approach incentive, a monetary token was presented in each trial that participants could collect by making a response. Presence of a sleeping "predator" with three different wake up probability served as an avoidance motivation. The predator could wake up and catch the participant, leading to loss of tokens. Theta power from the hippocampus was estimated using linearly constrained minimum variance beamformers. Extending previous findings, our results suggests that induced theta activity (1-4 Hz)in medial temporal lobe is higher during high threat compared to low threat in medial temporal lobe within 1 sec of token appearance, i. e. during the actual conflict. Before the token appeared, i. e. during presentation of the predator context alone, no difference between threat levels was observed. Also, potential loss did not impact on theta power. Further analyses suggest that theta power does not relate to expected outcome or to specific behaviours. We also observe that theta activity after token appearance at low threat level is lower than a pre-trial baseline. To summarize, our results suggest that theta power increases with (learned) threat level but not with the explicitly signaled threat magnitude. This could suggest that it is related to retrieval of fear memories during conflict.

Title: Insular lesion and attenuated sensitivity to the emotions of others

Authors: ***Y. TERASAWA**[1], Y. KUROSAKI[3], Y. IBATA[4], Y. MORIGUCHI[5], S. UMEDA[2]; [1]Psychology, Keio Univ., Kanagawa, Japan; [2]Dept. of Psychology, Keio Univ., Tokyo, Japan; [3]Dept. of Communication Disorders, Hlth. Sci. Univ. of Hokkaido, Sapporo, Japan; [4]Nasu Red Cross Hospital,, Ohtawara, Japan; [5]Dept. of Psychophysiology, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: The insular cortex has been considered to be the neural base of visceral sensation for many years. Previous studies in psychology and cognitive neuroscience have accumulated

evidence indicating that interoception is an essential factor in the subjective feeling of emotion. Recent neuroimaging studies have demonstrated that anterior insular cortex activation is associated with accessing interoceptive information and underpinning the subjective experience of emotional state. Only a small number of studies have focused on the influence of insular damage on emotion processing and interoceptive awareness. Moreover, disparate hypotheses have been proposed for the alteration of emotion processing by insular lesions. Some studies show that insular lesions yield an inability for understanding and representing disgust exclusively, but other studies suggest that such lesions modulate arousal and valence judgments for both positive and negative emotions. In this study, we examined the alteration in emotion recognition in three right insular-damaged cases with well-preserved higher cognitive function. Participants performed an experimental task using morphed photos that ranged between neutral and emotional facial expressions (i.e., anger, sadness, disgust, and happiness). Recognition rates of particular emotions were calculated to measure emotional sensitivity. Also, they performed heartbeat perception task for measuring interoceptive accuracy. Their interoceptive accuracy was remarkably low and the cases identified emotions that have high arousal level (e.g., anger) as less aroused emotions (e.g., sadness). The current results show that insular lesions lead to attenuated emotional sensitivity across emotions, rather than category-specific impairments such as to disgust. Our findings support the hypothesis that the insular cortex modulates recognition of emotional saliency and mediates interoceptive and emotional awareness.

Title: Electrophysiological correlates of subliminal affective face priming

Authors: *M. TANAKA[1,2], T. MAEKAWA[1], K. OGATA[1], N. TAKAMIYA[1,3], E. YAMADA[4], S. TOBIMATSU[1];

of Physical Therapy, Prefectural Univ. of Hiroshima, Hiroshima, Japan; [4]Saiseikai Kanagawa-ken Hosp., Kanagawa, Japan

Abstract: Purpose: Behaviorally, “affective priming effect” refers to the phenomenon that presentation of affective prime stimuli shifts subsequent affective evaluation to the target stimuli. However, neural correlates of “subliminal” affective face priming effects are largely unknown. Here, we studied neural activities accompanied with subliminal affective face priming effect using high-density ERPs. Methods: Nine healthy volunteers (6 males, mean age 24.1±2.0 y.o.) seated in front of a 20 inch monitor in a silent darken room. Stimulus sequences consisted of two types of 17 ms-subliminal prime faces (i.e. fearful or scrambled faces) followed by a backward mask (SOA 300 ms) and three types of 800 ms-target faces (i.e. neutral, emotionally ambiguous, or fearful faces). Prime and target face stimuli were presented in a random order with 864 trials (144 trials × 2 prime faces × 3 target faces). Subjects were instructed to judge the expression of target faces as neutral or fearful by button-pressing. Response time (RT) and emotional judgment for target faces were recorded. Continuous EEG was recorded by a 128 channels EEG system while subjects performed the task. ERPs were obtained by averaging the response for each target face separately. According to previous reports, N170 and N250r (“r” means “repetition”) in the occipito-temporal area were analyzed. Latency and peak amplitude for each component of ERP was compared by a three-way repeated measures ANOVA (2 types of prime stimuli × 3 types of target stimuli × hemispheres). Results: All subjects accomplished the experiment. Behaviorally, there were no significant differences in RT and emotional judgment for both priming conditions. Regarding ERPs, ANOVA revealed that N170 to the ambiguous target face followed by fearful prime faces was significantly larger than that of scrambled prime faces. N250r to ambiguous target face followed by fearful prime faces was significantly smaller than that of the scrambled prime faces. Conclusions: Although there have been some reports that the N250r is getting larger for repetitions of the same image or familiar face, the N250r to ambiguous faces was reduced by subliminal fearful face priming in this study. This finding is consistent with the phenomenon that the cortical activity for primed stimuli was smaller than that for unprimed stimuli (i.e. “repetition suppression”). Thus, it is concluded that N250r may be sensitive to subliminal affective priming.

Title: Decoding of emotional states during watching movies using multimodal neurophysiological signals

Authors: ***J. CHOI**, J. CHOI, K. KIM;
Yonsei Univ., Wonju, Korea, Republic of

Abstract: Emotional status is reflected in the physiological signals on central and autonomic nervous systems (CNS and ANS). The purpose of this study is to investigate whether different emotional states can be decoded from multimodal neurophysiological signals. In particular, we tried to decode a subject's emotional response to affective movies from single-trial electroencephalograms (EEGs) and several signals reflecting the behavior of ANS. Fifteen healthy university students participated in the experiment. Thirty-two affective movie clips reflecting four types of different emotional states were selected from based on the valence-arousal model (high/low valence and high/low arousal). Right after watching every single movie clip, the subjects rated their emotional response to the movie in valence, arousal, dominance, and like/dislike levels. Multichannel EEGs, skin temperature, Galvanic skin response (GSR), and photoplethysmogram (PPG) were recorded during the tasks. The spectral, temporal and spatial characteristics of EEGs showing significant differences among different emotional states were determined to construct feature vectors for pattern classification. The time and frequency domain features of the physiological signals were selected so that they reflect the characteristics of the ANS, and the measures showing significant differences among the emotional states were selected as additional feature vectors. A support vector machine (SVM) with Gaussian radial basis function (RBF) kernel was adopted as a pattern classifier along with principal component analysis (PCA) for dimensionality reduction. The classification accuracy was calculated by ten-fold cross-validation. When only the EEGs were used, the classification accuracies were as high as as 96.58% and 98.07, for the decoding of valence and arousal levels, respectively. It was still as accurate as 90.62 and 90.02% for the case of using only the ANS physiological signals. By using multimodal decoding strategy, i.e., using both the CNS and ANS signals, the classification accuracies were 97.29% and 98.47% for valence and arousal, respectively. Our results demonstrate that the different emotional states to the affective movies can be decoded with high accuracy from multimodal neurophysiological signals.

Title: Neural responses to emotion: an event-related potentials study

Authors: *E. ZHANG;
Univ. of Shanghai For Sci. & Technol., Shanghai, China

Abstract: Human emotion can be elicited by static visual stimuli (e.g. pictures), meanwhile emotional movie as stimulus is emerging in the psychophysiological study of emotion. The present study aims to explore brain activity through electroencephalogram (EEG) recording, during which different affective movies are presented to subjects. Subjects (12 male, 20-21 years old) performed a passive viewing task, using 49 non-auditory affective movie clips from the Emotional Movie Database (EMDB) as stimulus. Film clips of EMDB were estimated to elicit five emotional states (horror, erotic, social negative, social positive and neutral) in the affective space. The amplitude and the latency of event-related potentials (ERPs) component for each emotion were calculated. For the early components of ERPs, P1, N1 and P2 were located at 100 ms, 120 ms and 180 ms, respectively, under each emotional state. The N1 amplitude was stimulus-locked. For the slow components of ERPs, the P300 wave was detected at parietal and occipital lobes. In addition, erotic emotion stimuli elicited the maximal amplitude of P300. One robust negative slow wave, the N450 component, was found in the frontal lobe during 250-450ms after movie onset, and the amplitude of it was emotion-sensitive. The motivated brain area following different emotional stimulus was identified using low-resolution electromagnetic tomography (LORETA). The present results show that different amplitude of stimulus-locked components found in ERPs, such as N1, P300 and N450, may be related to the distinct pattern of neural activity and neural circuit of each emotion stimulus.

Title: Time course and localization of brain activity in humor comprehension: an ERP/sLORETA study

Authors: *M. SHIBATA[1], Y. TERASAWA[1], T. OSUMI[2], K. MASUI[1,3], A. SATO[1], S. UMEDA[1];
[1]Keio Univ., Tokyo, Japan; [2]Dept. of Human Sci., Hiroshima Shudo Univ., Hiroshima, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Humor comprehension is a complex process that requires the detection and resolution of the incongruity, eliciting a positive feeling of mirth or reward. Although a number of imaging studies have investigated the incongruity-detection and resolution process, it is difficult to functionally and anatomically dissociate these processes. In this study, we conducted the event-related potentials (ERP) experiment using the same materials in our previous fMRI study (Shibata et al., 2014). We also conducted source localization analysis using standardized low resolution brain electromagnetic tomography analysis (sLORETA) to examine the time course and localization of brain activity in incongruity detection and resolution stages (Pascual-Marqui, 2002). Eighteen participants were instructed to read funny or unfunny scenarios and to judge whether the target sentence is funny or not. Results showed that within the P200 time window, critical words in the funny condition elicited larger P200 amplitudes than those in the unfunny condition in the central electrode sites. Within the P600 time window, critical words in the funny condition elicited larger P600 amplitudes than those in the unfunny condition in the central and parietal electrode sites. The sLORETA analysis on the P200 ERPs revealed a stronger activation for funny condition relative to unfunny condition in the superior frontal gyrus (SFG) and medial prefrontal cortex (mPFC). The sLORETA analysis on the P600 ERPs revealed a stronger activation for funny condition relative to unfunny condition in the middle temporal gyrus (MTG) and inferior parietal lobule (IPL). These ERP results were almost consistent with those of our fMRI study. Taken together, the results of sLORETA analysis and connectivity analysis in our previous fMRI study suggest that the incongruity - detection process activates the SFG and mPFC during the 200-250 ms post-stimulus onset interval, whereas incongruity-resolution process generates activation at the right MTG and IPL during the 580-620 ms post-stimulus onset interval. These results also suggest that the comprehension of humor and literal language already differed during earlier phases of processing, and followed by a P600 component reflecting incongruity-resolution process.

Title: Network interactions during affective picture processing: An ECOG study

Authors: ***A. TRONGNETRPUNYA**[1], F. BARTSCH[1], J. CIBULA[2], A. KEIL[3], M. DING[4]; [2]Dept. of Neurol., [3]Dept. of Psychology, [4]J. Crayton Pruitt Family Dept. of Biomed. Engin., [1]Univ. of Florida, Gainesville, FL

Abstract: Human EEG and fMRI studies have shown that motivationally salient stimuli activate a distributed brain network. What remains not well-understood is how elements of the network interact with one another during affective processing. FMRI's poor temporal resolution and EEG's inability to access deep brain structures limit their utility to address this question. In this study we recorded electrocorticogram (ECOG) from patients undergoing evaluation for surgical therapy to treat intractable epilepsy. The subjects were asked to passively view 20 pleasant (erotica, romantic courtship, sport scenes), 20 neutral/calm (household scenes, people), and 20 unpleasant (mutilation, human violence, attacking animals) stimuli from the International Affective Picture System (IAPS) in random order. Each picture was presented for 1000ms with inter-trial intervals varied from 6000 to 9000ms. A time-frequency analysis of high gamma activity revealed a time period of interest (300 ms to 600 ms). Granger causality was then evaluated in this time period between electrodes in the medial temporal lobe (MTL) and in the posterior lateral temporal lobe (PLTL). It was found that (1) inter-areal communication is bidirectional, (2) it takes place mainly in the theta band, and (3) the strength of interaction, especially MTL->PLTL, is modulated by picture valence. Results were corroborated by analyses of cross-area phase-amplitude-coupling between theta and high gamma. Together, these findings provide initial evidence that emotional perception relies on a wide-spread network of structures communicating through distinct patterns of oscillatory activity.

Title: N170 Differences on emotion recognition between deaf/ hard of hearing and normally hearing individuals

Authors: *C. C. MORALES[1], A. V. GONZALEZ[2], E. M. DUBON[2], J. P. ABARA[2], S.-M. KANG[2];
[2]Psychology, [1]California State Univ. Northridge, Los Angeles, CA

Abstract: The N170 event-related component is associated with early-face sensitivity (Botzel et al.,1995). A study investigating facial processing found that both deaf and non-deaf individuals showed a faster N170 latency with misaligned faces than with aligned faces (Mitchell, Letourneau, & Maslin, 2013). Another study conducted by Utama et al. (2009) found that N170 amplitude was related to intensity levels of facial emotion among healthy subjects. Thus in order to further investigate the relationship between N170 and emotion recognition, this study explored differences in N170 amplitudes of emotion recognition between normally hearing participants and deaf/ hard of hearing individuals. Participants were given an emotion recognition task that contained a whole-face and half-face condition. Participants were instructed to identify the emotions presented on a computer screen, while the even-related brain potentials on the four locations of the head (FZ, CZ, PZ, and Oz) were recorded. A total of 42 images of happy, anger, disgust, surprised, sad, and neutral emotions from the NimStim Face Stimulus Set (Tottenham et al., 2002) were presented for each condition. A mixed ANOVA found a main significant difference between condition, $F(1,13) = 17.93$, $p < .001$, with half-face condition (M=-3.74, SD=1.77) having a higher N170 amplitude than the whole-face condition (M=-1.74, SD=1.86) . At PZ for the half face condition there was a higher N170 amplitude for the deaf group (M=-5.24, SD=1.94) than in the control group (M=-3.24, SD=3.03). At PZ for the whole face condition, there was a higher N170 amplitude for the control group (M=-2.57, SD=2.63) than in the deaf group (M=-.46, SD=.52). These results indicate that the deaf group allocated more neuronal resources in the half-face condition, while this pattern is reversed in the whole-face condition. There was a significant interaction for condition and group for N170 latency $F(1,13) = 6.45$, $p = .025$, with whole-face condition for control (M=136.52, SD=22.72) having a higher N170 latency than the whole face condition for deaf (M=-127.17, SD=27.83) . There was a

higher N170 latency for the half-face condition for the deaf group (M=151.06, SD=19.66) than in the control group in the half-face condition (M=129.78 SD=16.02). These results indicate that for the deaf group the N170 was elicited faster when recognizing emotions when viewing all facial features, whereas the control group had a faster N170 latency for the half-face condition.

Title: Self-other differences in mu event-related desynchronization correlate with self-reported perspective-taking

Authors: *T. DEPAOLA, D. J. BARBERA, C. WOODRUFF;
Northern Arizona Univ., Flagstaff, AZ

Abstract: Simulation theories offer an account of empathic perspective-taking by assuming that one understands another's feelings by simulating the other's emotions. While simulation offers an efficient means of adopting the perspective of another, it also poses a problem to be solved. If the emotions one feels can come both from one's own emotional state as well as the emotional state of others, how does the brain determine which emotions belong to the self and which to the other? Building on previous studies using blocked designs, the current study utilized event-related desynchronization (ERD) to analyze the time course of electroencephalographic (EEG) mu rhythm desynchronization and to determine whether correlations between blocked mu suppression and perspective-taking replicate with ERD and perspective-taking. Participants viewed videos clips of their own and others' faces forming one of four emotional expressions. ERD's were computed for 1.5s epochs following stimulus onset. Initial analyses revealed significant self-other differences in ERD between 340-960ms for central and frontal electrodes ($p < .05$ for C4, Fc4, and F4), replicating blocked mu suppression data. Furthermore, a negative association was found between self-reported perspective-taking ($r = -.341$) and mu ERD in electrode FC3 and a positive association was found between perspective-taking and self-other ($r = .371$) ERD difference scores. The self-other ERD differences as well as their correlations with

perspective-taking replicate previous research and extend it by revealing the time course of these differences and correlations.

Title: Effects of parasympathetic activation on neural responses during emotional reactivity and regulation in adolescents

Authors: D. G. GHAHREMANI[1], D. VRANEK[1], A. HOLOVATYK[1], A. DEAN[1], *E. D. LONDON[2];
[1]Psychiatry & Biobehavioral Sci., [2]Dept. of Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: Parasympathetic tone is an important contributor to homeostatic balance and likely has significant influence on the flexibility of cortico-limbic networks involved in regulation of emotion and arousal. Adolescence is a neurodevelopmental period in which cortico-limbic circuitry has not yet reached maturation, likely resulting in greater difficulty with regulation of emotions. We sought to determine how a brief intervention for increasing parasympathetic tone via controlled breathing impacts adolescent emotion reactivity and regulation. Twenty-one adolescents (13-18 years old) underwent two fMRI scanning sessions in which resting state scans were acquired before and after they performed a reappraisal-based emotion regulation task, which involved proximal/distal perspective taking while viewing images containing neutral or negatively arousing content (IAPS pictures). Prior to each scan session, participants engaged in either a controlled breathing exercise known to increase parasympathetic activation or a control condition in which they were guided through a relaxation exercise that involved normal breathing. Parasympathetic tone was measured using heart rate variability during rest in supine position before and after breathing or relaxation. Controlled breathing increased heart rate variability (an indication of greater parasympathetic tone), reduced fMRI activation to emotional images in occipital and posterior parietal areas, and increased activation in dorsolateral prefrontal and striatal regions. These preliminary results suggest that enhancement of parasympathetic

activation results in greater fronto-striatal recruitment during emotional arousal. Given the role of fronto-striatal networks in self-regulation, activation in such networks may reflect greater capacity for self-regulation resulting from increased parasympathetic tone.

Title: Measuring engagement in movie trailers using behavioral and neural responses

Authors: *D. KANG[1], J. KIM[1], D.-P. JANG[2], Y. CHO[3], S.-P. KIM[1];
[1]Human and Systems Engin., UNIST, Ulsan, Korea, Republic of; [2]Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of; [3]Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: A movie trailer is a commercial advertisement that aims at attracting audiences and encouraging them to see the movie afterward. So the movie industry strives to create a better movie trailer that delivers key information and mood of a movie. However, methods to evaluate the effectiveness of trailers have been little changed from a traditional way such as self-reports. Self-report has been criticized in terms of its credibility since participants has limitations on describing their implicit mental states objectively. Neurocinematics has emerged to probe affective and cognitive states of audiences by analyzing neural responses to movie. However, in most neurocinematics studies, self-report was still used to validate the credibility of neurophysiological results. In this neurocinematics study, we addressed this issue by employing a psychophysical task to assess neural responses without relying on subjective reports. We adopted a dual-task framework where participants watched movie trailers as a primary task while they also had to react promptly to a tactile stimulus as a secondary task. We measured a secondary task reaction time (STRT) and brain activity to assess how deeply participants were engaged in trailers. We hypothesized that the more participants were engaged in trailers, the slower STRT would be. A neural engagement index was developed as temporal changes in differences between frontal alpha (7~10Hz) and beta (12~14 Hz) power values of electroencephalography (EEG). After watching each movie trailer, participants reported their

anticipation, fun, attentiveness and preferential rank scores. With the three different measurements, - STRT, neural engagement index and self-reports - we evaluated eight different movie trailers from various genres. As a result, we found a significant correlation between STRT and neural engagement index. On the other hand, there was no significant correlation between self-reports and STRT, or self-reports and neural engagement index. These results may suggest a novel way of evaluating neural data for neurocinematics, highlighting that the credibility of neural engagement index should be assessed using a more objective method instead of using traditional self-reports.

Title: The parietal cortex and the fearful face recognition

Authors: ***K. ZHAO**[1,2], W. ZHOU[3], Y. LI[4], T. YU[5], L. WANG[2,6];
[1]Chinese Acad. of Sci., Beijing, China; [2]Key Lab. of Mental Health, Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [3]Tsinghua Univ. Yuquan Hosp., Beijing, China; [4]Beijing Haidian Hosp., Beijing, China; [5]Xuanwu Hospital, Capital Med. Univ., Beijing, China; [6]CAS Ctr. for Excellence in Brain Sci., Shanghai, China

Abstract: Fearful faces would convey signals of potential threat and recognizing such facial expressions with precision in conspecifics is evolutionarily advantageous. The predominant view in this field was that the amygdala plays a significant role in the recognition of such faces. In contrast, some studies did not duplicate this finding, which raises a possibility that the achievement of this function may originally come from other cortical areas projecting to the amygdala. Lesion studies have demonstrated that the damage of the parietal region, particularly to the right side, can affect the processing of fearful faces. However, it remains unclear in human how neural activities in the parietal cortex respond to such faces. Neural oscillations,

prominently evident in the local field potentials (LFPs) recorded in many brain areas, serve as a potentially temporal reference. In this study, we employed a modified Brief Affect Recognition Test paradigm. During this task, a flashing face from one of four categories (fearful, surprising, happy or neutral) occurred after a fixed fixation period and epileptic patients with implanted electrodes were instructed to report its category. Intracranial recordings (ECoG or SEEG) were simultaneously performed during the task running. The behavioral results showed that both fearful and surprising expression were easily misrecognized as seen in our previous studies. Meanwhile, clear-cut results showed a significantly increased high-gamma (80-200 Hz) power in the inferior parietal area and the supramarginal gyrus only for fearful faces before a judgment. This specificity was not found for surprise, happy, or neural face identification. In contrast, the recording from the amygdala did not show such categorizing function. These findings suggest that the parietal cortex, especially in the supramarginal gyrus other than the amygdala, play vital roles in recognizing fearful face.

Title: Contralateral attention-related attenuation of occipitotemporal electrocortical activity by backward masked snakes & guns

Authors: I. BEUNTELLO[1], W. RIZER[1], *J. M. CARLSON[2];
[1]Northern Michigan Univ., Marquette, MI; [2]Psychology, Northern Michigan Uniersity, Marquette, MI

Abstract: Signals of environmental threat capture observers' attention. Fearful facial expressions enhance the amplitude of the face sensitive N170 event-related potential at occipitotemporal electrode sites in the hemisphere contralateral to their presentation. However, non-face visual threats, such as snakes and guns, also capture spatial attention; although it is unclear how visual cortical processing is affected by these threat types. To address this knowledge gap we ran a dot-probe task to measure spatial attention elicited by backward masked threat stimuli including snakes, spiders, knives, and guns while reaction time and electroencephalogram data were collected (N = 14). Electroencephalogram data were segmented and time-locked to the onset of the backward masked threat stimulus. The behavioral results

suggest that backward masked threats capture spatial attention, F (1, 13) = 11.18, p = 0.005. Reaction times were faster for threat-congruent (M = 320.15 ms) compared to threat-incongruent (M = 325.84 ms) targets. The event-related potential data indicated a hemisphere × visual field interaction on the N1 at occipitotemporal electrode sites (F (1, 11) = 9.80, p = 0.01) where amplitudes where attenuated in the hemisphere contralateral to the threat stimulus. Thus, non-face threats capture attention by attenuating early contralateral occipitotemporal electrocortical activity.

Title: Heart rate variability in dogs: Toward a valid behavioral model of empathy in companion animals

Authors: *J. MANOR, M. BOTTEN, W. CHU, E. P. WIERTELAK;
Psychology, Macalester Col., Saint Paul, MN

Abstract: Domestic dogs have a unique and close relationship with humans. Dogs seem to show sensitivity and empathy towards the emotional states of humans (e.g., Custance & Mayer, 2012), but it has been difficult to distinguish empathetic behavior from curiosity or seeking self-comfort. This study aimed to measure a physiological marker of empathy in domestic dogs through heart rate variability (HRV) monitoring and behavior analysis. Heart rate variability (HRV) is the beat-to-beat variation in heart rate (HR). HRV represents a measure of autonomic nervous system functioning and inhibitory control. In children, HRV measures have been used to link high autonomic regulation with more positive and intense emotionality as well as higher ratings of sympathy toward others (Eisenberg et al., 1996). In the present study, testing was done by recording HRV and behavioral responses in 16 dogs in four experimental conditions: owner is crying, owner is laughing, stranger is crying, and stranger is laughing. The results indicate that there was no significant difference between the owner and stranger in any condition, but that crying elicits significantly more person-oriented/empathetic behaviors than laughing or talking. There was also a significant negative correlation between the number of person-oriented behaviors exhibited and HRV in the stranger crying condition. Interestingly, only for dogs with high baseline HRV, there was also a strong negative correlation between HRV and person

oriented behaviors during the owner crying condition. This physiological change in HRV that occurs with increased behavioral response to a distressed individual suggests that dogs are experiencing the distress of the individual and responding in an empathetic manner.

Title: Changes in autonomic arousal elicited by human amygdala stimulation are parameter-dependent

Authors: *J. T. WILLIE[1], C. S. INMAN[1], D. I. BASS[1], R. E. GROSS[1], S. HAMANN[2]; [1]Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA; [2]Psychology, Emory Univ., Atlanta, GA

Abstract: The amygdala, located within the medial temporal lobe, regulates emotional responses, motivation, and memory. However, few contemporary studies have used direct electrical stimulation of the amygdala in humans to examine stimulation-elicited physiological and emotional changes, and the nature of such effects remains unclear. To determine the effects of amygdala stimulation on acute autonomic physiology, we utilized epilepsy patients undergoing intracranial EEG monitoring in which depth electrodes were implanted surgically from a lateral temporal approach into unilateral or bilateral amygdala. Subjects underwent either sham or acute monopolar electrical stimulation at various parameters in electrode contacts located in either amygdala or within the lateral temporal cortex. Stimulation was applied at either 50 Hz (pulse width of 300 μsec) or 130 Hz (pulse width of 90 μsec), while amplitudes were increased from lower (4 ≤ mV) to higher (>4 mV, 12 mV maximum) amplitudes in a stepwise fashion, with subjects blinded to stimulation condition. Varying pulse widths for each frequency were chosen to balance the charge density delivered across frequencies. Skin conductance responses (SCR), respiratory rate, heart rate, and electromyographic Hoffman-reflex amplitudes, and video images were recorded. At stimulation amplitudes well below patients' subjective awareness of stimulation, and without eliciting any seizures, we found that increasing linear, dose-responsive stimulation effects, with higher-amplitude amygdala stimulation (but not lateral control or sham stimulation) eliciting rapid and significant heart rate deceleration and increasing

skin-conductance. This pattern of results parallels stimulation findings with animals and is consistent with orienting/defensive physiological responses observed with aversive visual stimuli. Notably, all the described physiological effects were observed below thresholds in which patients reported being conscious of stimulation or changes in mood. Such changes occurred only at higher stimulation amplitudes. In a subsequent experiment, ongoing emotional responses to emotional videos were also not interrupted by amygdala stimulation. More intense stimulation may be required to elicit subjective emotional responses such as fear that have been reported previously. In summary, these findings suggest that acute amygdala stimulation in humans is safe and can reliably elicit changes in emotion physiology without significantly affecting subjective emotional experience providing a useful paradigm for investigation of amygdala-mediated modulatory effects.

Title: The effects of RMTg lesions on the response of nigral dopamine neurons to footshock and habenula stimulation: an electrophysiological study in anesthetized rats

Authors: *P. D. SHEPARD, H. L. PALACOROLLA, P. L. BROWN, D. B. BRADY, R. P. MCMAHON, G. I. ELMER;
Dept. of Psychiatry/MPRC, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: GABA neurons in the rostromedial tegmental area (RMTg) are an important source of inhibitory input to dopamine (DA) neurons within the substantia nigra (SN). Dense innervation of the RMTg by glutamatergic efferents from the lateral habenula (LHb) provide the hodological substrate for a feedforward inhibitory pathway that underlies the transient inhibition in DA cell firing elicited by aversive stimuli ranging from the loss of an expected reward to peripheral nociceptive stimulation. Here, we sought to determine (i) the degree of confluence in the response of individual SN DA neurons to footshock and habenular activation and (ii) whether excitotoxic lesions of the RMTg altered this response pattern. Extracellular single unit recordings

were obtained from DA neurons in the SN of sham (n= 40 cells) or RMTg lesioned rats (n= 34 cells). 7-14 days prior to the recordings, rats received a midline injection (110 nl) of ibotenic acid (400 mM) or saline. The number of NeuN and amphetamine-induced cFos positive neurons in RMTg lesioned rats was reduced by 87% and 92%, respectively. Spontaneous activity was recorded for several minutes prior to applying brief biphasic constant current pulses pseudorandomly at 0.5 Hz to the ipsilateral LHb (1 mA, 100 usec) or contralateral footpad (5-7 mA, 1 ms). Neuronal responses were categorized as: inhibition (I), excitation (E), inhibition followed by excitation (I/E), excitation followed by inhibition (E/I) or no change (N/C). The majority of cells recorded in sham-treated rats showed a biphasic I/E response to LHb stimulation (36/40). The response to footshock was more heterogeneous but comprised predominantly of cells exhibiting either an I/E (n = 14) or I (n=19) response. RMTg-lesioned rats showed significantly greater variability in their response to LHb stimulation with 50% of the cells characterized by an initial excitation (n=6), NC (n=9) or an indeterminate response (n=2). The increased heterogeneity was accompanied by a disproportionate reduction in the number of I/E cells in lesioned animals (11/34). Comparable changes were observed in the response to footshock including a significant reduction in the proportion of cells characterized by an I/E response (6/34) and a corresponding increase in the NC category. Notably the proportion of cells exhibiting a monotonic inhibitory response to footshock was not altered by RMTg lesions (14 vs12). These data suggest that activation of the RMTg by aversive stimulation has a biphasic effect on SN DA neurons that reflects both the direct and indirect influence of the RMTg.

Title: Spatial working memory compared in pigeons and humans

Authors: J. E. WOLF[1], J. F. MAGNOTTI[2], J. O. TAYLOR[1], R. LEE[1], *K. J. LEISING[1]; [1]Dept. of Psychology, 298920, Texas Christian Univ., Fort Worth, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: Change detection procedures are commonly used to assess the capacity (number of objects) of working memory. Previous comparisons of working memory between human and

non-human animals have focused on object-based ("what") working memory, but this is only one aspect of memory. In our study, we trained pigeons and humans to complete a spatial ("where") change detection task. In this task, subjects selected (peck/touch) the item that changed location across a brief delay. Both pigeons and humans performed above chance at selecting the one changed item among the 2, 3, or 4 items in the sample and test displays, as well as across delays of 0, 100, or 1000 ms. From these data we computed spatial working memory capacities for number of locations. We also tested both species with trials in which a visual mask was inserted into the delay following the sample display. The data from pigeons and humans indicate that the mask was most disruptive on trials with a short delay (e.g., 100 ms), and on trials with greater numbers of items (e.g., 3 and 4). These results are the first to compare spatial working memory in pigeons and humans in a change detection task, and indicate the use of iconic memory at delays of 100 ms or less and working memory at longer delays in both species.

Title: A comparison of c-fos expression in avian hippocampus after relational task and associative task

Authors: *O. F. LAZAREVA[1], M. J. ACERBO[2], M. STACHO[3], O. GÜNTÜRKÜN[3], A. GERTSBERG[1], J. RICK[1], K. PANFIL[1], J. FEUCHT[1];
[1]Drake Univ., Des Moines, IA; [2]Psychology, Iowa State Univ., Ames, IA; [3]Biopsychologie, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Recently, Lazareva, Kandray, and Acerbo (2015) showed that hippocampal lesion in pigeons selectively impairs relational behavior in a transitive inference task. Here, we have explored the involvement of hippocampus in another traditional relational task, transposition. Unlike transitive inference task, transposition task does not require manipulating relational information; instead, animals are simply trained to learn the physical relation between the stimuli (e.g., larger or smaller) and use the same relation when presented with novel pairs of stimuli. We trained pigeons to discriminate two pairs of circles of different sizes, S1-S2 and S3-S4 (where numbers indicate a constant increase in circle size from S1 to S4). Some pigeons were trained to

always select a smaller (or a larger) circle in each pair (relational group). The other pigeons were trained to select a smaller circle in one pair and a larger circle in another pair (associative group); in other words, these pigeons had to memorize each stimulus instead of relying on their relationship. After all birds has reached criterion, they were tested with two novel pairs, S2-S8 and S2-S3. Behavioral results indicated that relational group indeed learned to always select a smaller (or a larger) circle, while associative group learned to select previously reinforced circle and avoid previously nonreinforced circle. Next, we analyzed c-fos expression in four hippocampal areas: dorsomedial ventral (DMv) area similar to mammalian CA1; dorsalmedial dorsal (DMd) area similar to CA3; and, dorsolateral ventral (DLd) and dorsolateral dorsal (DLd) areas similar to entorhinal cortex. We found significantly higher levels of c-fos expression in relational group than in associative group for all four areas, although the difference was most pronounced in DLv. These results suggest that hippocampus may be involved in relational tasks that are based on a physical relationship and that do not explicitly require encoding or manipulating relationships between different training stimuli.

Title: Blockade of GABA and glutamate receptors in nucleus subpretectalis/interstitio-pretecto-subpretectalis impairs figure-ground discrimination in pigeons

Authors: *M. J. ACERBO[1], O. F. LAZAREVA[2], S. ATTERBERG[2], H. MOSES[2];
[1]Psychology, Iowa State Univ., Ames, IA; [2]Psychology, Drake Univ., Des Moines, IA

Abstract: Figure-ground segregation is a fundamental visual ability that allows an organism to separate an object from its background. Our earlier research has shown that nucleus rotundus (Rt), a thalamic nucleus processing visual information in pigeons, together with its inhibitory complex, nucleus subpretectalis/interstitio-pretecto-subpretectalis (SP/IPS), is critically involved in figure-ground discrimination (Acerbo et al., 2012; Scully et al., 2014). Here, we further investigated the role of SP/IPS by conducting bilateral micro-injections of GABAergic receptor antagonist and agonist (bicuculline and muscimol, respectively) and glutamate receptor antagonist (CNQX) after the pigeons mastered figure-ground discrimination task. We used two

doses of each drug (bicuculline: 0.1mM and 0.05mM; muscimol: 4.4mM and 8.8mM; CNQX: 2.15mM and 4.6mM), and alternated drug injections with baseline (ACSF) to eliminate potential carryover effects. The order of injections was randomized across birds, and figure trials and background trials were analyzed separately for each drug and dose. We found that all drugs produced a dose-dependent impairment in figure-ground performance. Low doses of bicuculline and CNQX impaired figure accuracy but had no effect on background accuracy; in contrast, high doses of both drugs impaired background accuracy while recovering figure accuracy to near-baseline levels. Finally, muscimol produced an equivalent, dose-dependent impairment on both figure and background trials. Together, these results further confirm our earlier hypothesis that inhibitory projections from SP/IPS to Rt modulate figure-ground discrimination, and suggest that figure-ground discrimination requires a precise balance between excitatory and inhibitory inputs.

Title: Mechanosensory specialization of duck trigeminal ganglia neurons occurs before hatching

Authors: *E. R. SCHNEIDER[1], E. O. ANDERSON[1], M. MASTROTTO[1,2], W. LAURSEN[1,2], E. O. GRACHEVA[1,2], S. N. BAGRIANTSEV[1];
[1]Cell. & Mol. Physiol., [2]Yale Program in Cell. Neuroscience, Neurodegeneration and Repair, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Organisms evolve varied prey detection strategies depending on ecological niche, and these adaptations can provide a rich source of information for sensory biology. For instance, tactile-foraging waterfowl depend on their acutely touch-sensitive bill to feed in murky water. The glabrous skin covering the bills of these birds is densely populated with mechanoreceptors tuned to detect transient touch and vibration (Berkhoudt et al, 1980, Netherlands J. Zoology 30:1). We have shown that dissociated neurons of trigeminal ganglia (TG) innervating the bill in tactile-foraging waterfowl are optimized to detect mechanical stimuli, with a majority of neurons expressing the mechanotransducer Piezo2 in tactile-specialized vs. non-specialized species. In

the domestic duck, the majority of TG neurons have fine-tuned their ability to detect mechanical stimuli by lowering response threshold and increasing gain (Schneider et al, 2014, PNAS, 111:14941). During development, neurons from duck TG show increased sensitivity to mechanical stimuli as early as four days prior to hatching, compared to embryonic TG neurons from chicken, a bird without tactile specialization, at a comparable developmental stage (duck current at 6 μm stimulation = 2.3 ± 0.4 nA, mean ± s.e.m., n=40; chicken, 0.6 ± 0.2 nA, n = 18, $p < 0.005$, Kruskal-Wallis test). The majority of embryonic duck TG neurons responded to mechanical stimulation (66.7%) whereas only 17.8% of chicken neurons were mechanosensitive (n = 60 duck; 102 chicken). This is consistent with our histological observations that the majority embryonic ducks contain Piezo2 mRNA (69.3%) compared to only 34.9% of embryonic chicken TG neurons. We have previously shown the adult duck TG has significantly fewer neurons containing mRNA for thermosensors TRPV1 and TRPM8 compared to duck dorsal root ganglia (DRG), and TG of non-specialized species. Prevalence of these markers in embryonic duck TG did not significantly differ from adult TG. These observations suggest that the specialization of duck embryonic TG neurons to mechanosensation occurs prior to hatching, consistent with ducks precocial ability to forage soon after hatching, and dependence on the sense of touch for foraging behavior.

Title: Pretecto-hypothalamic circuit is essential for prey perception and feeding behavior in zebrafish

Authors: *A. MUTO, K. KAWAKAMI;
Natl. Inst. of Genet., Mishima, Shizuoka, Japan

Abstract: One of the important tasks for vision is to discriminate objects into categories such as food and non-food based on their visual features. In lower vertebrates, the initial step of visual recognition of possible prey, or a small object, starts in the retina. The major target of the retinal projections, the optic tectum of the midbrain has a role in computation of object size and also serves as visuotopic map to locate the prey. Although one component of the premotor circuits for prey capture is shown to be reticulospinal neurons in the nucleus of the medial longitudinal fascicle (nMLF), it is not known whether visual information about the prey directly goes to only this premotor pathway to exert prey catching behavior, or there is another pathways in which visual information converges to an dedicated neuronal module, or a small subset of prey detecting neurons during visuomotor integration for feeding control. Here we show that genetic identification of pretecto-hypothalamic circuit that is essential in prey detection in zebrafish larvae. Subpopulation of the pretectal neurons were activated in the presence of prey. Laser-ablation of these pretectal neurons specifically abolished prey capture behavior. Furthermore, pretectal neurons projected to the inferior lobe of the hypothalamus (ILH), the feeding center in fish, which also showed neuronal activity correlated to the pretectal activity in the presence of prey. Together, these results suggest that the pretecto-hypothalamic circuit serves as a prey detector at the interface of the sensory and motor systems and possibly convert visual perception of food to feeding behavior in zebrafish. The neuronal module dedicated to cognition of prey may provide a place for modification of feeding behavior by internal states and past feeding experience.

Title: Oscillatory movement correlates with sensory noise in active electrosense

Authors: *C. CHEN[1], I. D. NEVELN[1], M. A. MACIVER[2];
[1]Biomed. Engin., [2]Biomed. Engin. and Mechanical Engin., Northwestern Univ., Evanston, IL

Abstract: Spatiotemporal dynamics of different sensory systems often demand specific motor repertoire, which is referred as active sensing. A particular type of weakly electric fish (E.

virescens), will oscillate its body back and forth (a.k.a. whole-body oscillation) to gather information when tracking a movable object using electrosense. However, when using vision, this extra oscillatory movement disappears. From an information theoretic perspective, whole-body oscillation can be considered as a behavioral response to help compensate for the lower contrast and weak signals associated with electrosense. This is confirmed by experimentally showing that the whole-body oscillation amplitude increases with lower signal-to-noise ratio (SNR), which is achieved by electronically jamming the fish (shown to deteriorate electrosense) during controlled tracking experiments. Therefore, it is reasonable to believe that the whole-body oscillation might belong to a specific motor repertoire which is controlled by electrosensory feedback such that its amplitude varies with different ratios of signal to noise within electrosense. To better understand and quantify this and other similar active sensing motor patterns, we have been applying control and information theory. We simulated a mobile sensor tracking a linearly moving object with varying levels of noise. Using a control strategy that distributes sensory measurements proportionate to the expected information density, the resulting sensor trajectory has similarities to whole body movement patterns of the fish using electrosense. The simulated sensor moves in an oscillatory manner alongside the object while also tracking the object movements. Moreover, this pattern diminishes after increasing the SNR in simulation, which resembles fish's behavior when using vision - a sensory modality that has less measurement noise in clear water and daylight conditions.

Title: Non-periodic responses to sinusoidal electric stimulation in ampullary electroreceptors of glass catfish

Authors: *Y. ADACHI[1], K. TATENO[2];
[1]Dept. of Life Sci. and Systems Engin., [2]Dept. of Human Intelligence Syst., Kyushu Inst. of Technol., Kitakyushu, Japan

Abstract: One-dimensional return map analysis was applied to reveal nonlinear response to sinusoidal electric stimulation in ampullary electroreceptors of transparent glass catfish (Kryptopterus bicirrhis/minor). External electric stimulation modulates spontaneous afferent nerve impulses via ampullary electroreceptors. The electroreceptors are sensitive to the sinusoidal electric stimulation around 10 Hz. One-dimensional return maps were constructed from afferent nerve impulses. Glass catfish (5-7cm long) were placed on an experimental chamber, which filled with aerated water of 23 °C ± 2. The fish were anesthetized by 125mg/l of MS-222. The stimulation electrodes were placed in front of and behind the fish. The sinusoidal electric current was passed between a pair of the stimulation electrodes. Stimulation frequency was 1, 2, 4, 8, 10, 20, 40, 80, and 100 Hz. The glass microelectrode was set in an ampullary canal. Spontaneous nerve impulses showed regular beating with little fluctuation. In the one-dimensional return map, all points clustered around a fixed point. Interpulse intervals of nerve impulses were modulated by the sinusoidal electric stimulation in the frequency range between 2 and 40 Hz. Interpulse intervals of the nerve impulses were shorten by the depolarization and prolonged by the hyperpolarization. The one-dimensional return map of the nerve impulses were classified into 2 types: four segments arrayed to an L shape or a triangular-shaped ring. The L shape maps were caused by a burst of nerve impulses. Although the burst of nerve impulses were induced repeatedly, interpulse intervals in the burst of nerve impulses were not exactly the same as the previous intervals. Those one-dimensional return maps did not form a cluster at a fixed point, but four line segments. For the triangular return map, the density of intervals of nerve impulses moderately varied. The triangular map did not have a stable fixed point, and interpulse intervals were non-periodic. The latency of first impulses in each stimulation phase were also collected. The latency of first impulses were not fixed. Those results indicate that the sinusoidal electric stimulation induced non-periodic responses of the nerve impulses. The frequency range of the non-periodic responses is consistent with those of avoidance behavior of glass catfish. We conclude that non-periodic responses of electroreceptors may trigger the avoidance behavior of glass catfish.

Title: The role of SK channels in optimizing neural processing and behavioural perception of natural stimuli in the electronsensory system

Authors: *C. HUANG[1], M. J. CHACRON[1,2];
[1]Dept. of Physiol., [2]Dept. of Physics, McGill Univ., Montreal, QC, Canada

Abstract: The understanding of how neural circuits perform key computations underlies the fundamental knowledge of how cellular machinery leads to neural network activity, which in turn determines perception/behavioral responses. Several studies have shown that neural coding strategies in many sensory systems are adapted to the natural scene statistics to efficiently encode sensory stimuli as well as to maximize redundancy reduction in spatiotemporal correlations. Despite this, the molecular and/or neural network mechanisms underlying such optimal adaptation are poorly understood in general. Here we investigated how small conductance calcium-activated potassium (SK) channels contribute to optimizing neural coding and perception of natural second-order envelopes, which are found ubiquitously across sensory systems and carry important spatiotemporal information necessary for perception. In order to do so, we used the electrosensory system of the gymnotiform weakly-electric fish *Apteronotus leptorhynchus* as a model for its unique advantages for *in vivo* awake-behaving experiments. We recorded from sensory pyramidal neurons in the electrosensory lateral line lobe (ELL) in response to naturalistic envelope stimuli and demonstrated that these neurons are optimally tuned to encode information over a continuous range of envelope frequencies. To better understand this adaptation process, we built a simple phenomenological model that included SK channels. Computational simulations of this model predicted that the strength of SK currents were essential in determining whether tuning was optimal to the natural scene statistics. We tested our modelling predictions by both pharmacologically inactivating and over-activating SK channels in pyramidal neurons and demonstrated that the changes in levels of SK channel activation led to predictable changes in neural tuning and behavioural perception to natural stimuli. Our results therefore show for the first time a novel function of SK channels in that they provide a cellular mechanism which gives rise to optimal neural responses and behavioural perception to natural stimuli in a vertebrate model system. The strong homology between SK channels and the weakly-electric fish to their mammalian counterparts suggest that it is very likely that our results will be generally applicable across systems and species.

Title: An optimal neural encoding model predicts anti-correlated spike-trains in the p-type afferents of a weakly electric fish

Authors: E. C. JOHNSON, D. L. JONES, *R. RATNAM;
Coordinated Sci. Lab., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: P-type afferents of weakly electric fish are the primary sensory neurons of the electrosensory system. Objects in the immediate environment of the fish modulate the self-generated Electric Organ Discharge (EOD) and are encoded as modulations in the instantaneous firing rate of P-type afferents. The spike trains of these afferents exhibit strongly anti-correlated interspike intervals (ISIs) which are presumed to facilitate optimal detection of weak signals generated by small prey. From a computational perspective, spike-timing models with dynamic thresholds have been shown to generate spike-trains with strong anti-correlations. Recently, we proposed a deterministic, optimal, energy-constrained neural encoder, with a dynamic threshold that functions as an built-in decoder. We show that the dynamic threshold (decoder) reconstructs the EOD modulations from the spike-train. The reconstruction is compared with the EOD modulations to feed back an internal copy of the coding error to the encoder (spike generator). The encoder generates spike-trains with optimally timed spikes so as to minimize decoding error subject to a constraint on the rate at which spikes are fired. Here, we extend the deterministic model to stochastic spike-trains. A stochastic spike-firing rule is introduced to create jitter in the predicted spike-times. The optimally encoded spike-times were compared with experimentally determined spike-times from P-type afferents. As with the deterministic optimal coder, the spike-times for the stochastic encoder and the P-type afferent were in close agreement with one another. Of interest here is that spike-trains from the optimal coder demonstrate ISI correlations and ISI return-plots which are very close to the experimental data. Further, anti-correlations are known to stabilize firing-rate (or spike-count) over multiple time-scales. Thus, maintaining a stable firing rate is a natural outcome of the energy (spike-rate) constraint implicitly built into the optimal coder. We conclude that anti-correlated ISIs are a signature for optimal encoding in the electrosensory system.

Title: Dopaminergic modulation of pre-pulse inhibition in larval zebrafish

Authors: *J. P. BARRIOS[1], S. ANJEWIERDEN[2], J. NEWTON[2], S. LUKS-MORGAN[1], R. DHINGRA[1], A. D. DOUGLASS[1];
[1]Neurobio. and Anat., [2]Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: Prepulse inhibition of the startle response (PPI) has been the primary experimental measure of sensorimotor gating in both clinical patients and animal models for decades. This simple reflex modulation is known to be deficient in patients with a range of psychiatric disorders including schizophrenia, obsessive-compulsive disorder and Tourette's syndrome. Treatment of clinical patients and work in animal models has revealed that this behavior is dependent on the neuromodulator dopamine (DA). PPI and PPI deficits are intriguing clinical observations and they raise equally intriguing basic questions about the nature of fast reflex modulation by DA. Interestingly, this behavior is conserved in zebrafish and present in larval fish as early as 5 days post fertilization. We have shown that audiomotor PPI can be evoked and monitored in 6-8 day old zebrafish in a head-fixed context. Subthreshold prepulses given 200, 400 and 800ms before the startling pulse prevented c-bend startle responses in over 30% of trials. The percentage of trials showing inhibition of startle behavior was positively correlated with inter-stimulus interval such that the 800ms delay produced significantly more startle inhibition than the 200ms delay. Interestingly, trials that lack the stereotypical c-bend often show a distinct motor behavior characterized by a long latency to initiation, low angular velocity and low total tail bend angle. These observations constitute the basis for studying the inhibition of the startle reflex by DA in a whole-brain context, taking advantage of the transparency and small size of the larval zebrafish brain. This head-fixed preparation allows us to use whole-brain two-photon calcium imaging and spatially targeted optogenetics to study the circuit mechanisms driving this fast modulation of the acoustic startle reflex. We are currently using this preparation to identify the DA neurons responsible for PPI in these animals focusing in particular on a population of TH2-expressing cells in the hypothalamus. We will use whole-brain calcium imaging to

determine how DA transforms the c-bend startle behavior into a routine swim. These experiments will provide a comprehensive map of the circuits that underlie PPI and allow us to define the mechanisms by which endogenous dopaminergic neurons shape the behavior.

Title: Neurotoxicity of inorganic mercury in white seabream (Diplodus sargus) - morphofunctional brain alterations and behavioural shifts following waterborne exposure and post-exposure periods

Authors: S. PUGA[1], P. PEREIRA[1,2,3], F. PINTO-RIBEIRO[1], J. RAIMUNDO[3], O. ARAÚJO[3], M. PACHECO[2], *A. A. ALMEIDA[4];

Brasília, 1449-006, Lisbon, Portugal; [4]Univ. Minho, Braga, Portugal

Abstract: The metal mercury (Hg) is extremely neurotoxic to humans and wildlife. In aquatic environments, Hg is present in organic (mainly methylmercury - MeHg) and inorganic (iHg) forms. Both Hg species can be bioaccumulated and biomagnified in fish, inducing toxic effects. In fact, high levels of Hg were recorded in fish brain, along with neurodegenerative damage, disturbances on sensory processing, and behavioural changes. Nevertheless, it remains to be clarified which Hg species (iHg versus MeHg) is mainly accumulated in the fish's brain, as well as the contribution of different uptake routes (water versus diet). In this study, we evaluated the swimming performance of the white seabream (D. sargus), and identified alterations in brain morphology together with Hg accumulation in brain and eyes. Initially, fishes were exposed to realistic levels of iHg in water (2 µg L-1) during 7 (E7) and 14 days (E14). After that, fish were allowed to recover for 28 days (PE28). At E7, exposed fish exhibited a significant decrease of

the first swimming distance, as well as a lower time for refuge. In parallel, exposed fish also presented lower total cell number in the optic tectum, cerebellum and hippocampus, together with high levels of Hg in brain and eyes. At PE28, previously exposed fish still swam a smaller distance in the first run, exhibited a lower resistance against the water flow (measured as time to immobility), and presented lower total cell number in the optic tectum. Accordingly, Hg levels in eyes and brain did not decrease during the recovery period. Realistic levels of waterborne iHg can alter fish swimming performance, and trigger total cell number loss in several brain areas responsible for endocrine regulation, sensory and motor-related systems, fine movement and equilibrium/posture without a rapid reversibility. Such impairments could have repercussions in the organism's fitness and survival, leading to increased vulnerability to predation with significant implications for food chain transfer of Hg.

Title: Stimulus-evoked serotonin dynamics in a teleost sensory system

Authors: *H. FOTOWAT[1], E. HARVEY-GIRARD[1], R. CACHOPE[2], J. F. CHEER[3], R. KRAHE[4], L. MALER[1];
[1]Cell. and Mol. Med., Univ. of Ottawa, Ottawa, ON, Canada; [2]Systems Neurobio., CHDI, Los Angeles, CA; [3]Anat. and Neurobiology, Psychiatry, Univ. of Maryland, Baltimore, MD; [4]Biol., McGill Univ., Montréal, QC, Canada

Abstract: We used weakly electric fish, Apteronotus leptorhynchus, to study the temporal dynamics of serotonin release in a primary sensory area. These fish use a self-generated quasi-sinusoidal electric field for communicating with conspecifics. The electric organ discharge frequency (EODf) is individual- and sex-specific and thus the presence of a conspecific causes a net electric field with amplitude modulations at the difference frequency (Df). Electroreceptors

on the fish's skin respond to these modulations and project to pyramidal neurons in the electrosensory lateral line lobe (ELL). The ELL is comprised of four distinct topographic segments, with the lateral segment (LS) specialized for processing electrosensory inputs that arise during interactions with conspecifics. Pyramidal neurons within this segment receive a robust serotonergic innervation and the postsynaptic consequence of serotonin signaling is to increase their bursting probability. The natural time-course of serotonin release in the context of agonistic encounters, however, is unknown. To address this gap in our knowledge, we used Fast-Scan Cyclic Voltammetry to measure, with a temporal accuracy of 0.1 seconds, the dynamics of serotonin release in the ELL-LS. Sensory stimuli consisted of brief encounters with same- or opposite-sex conspecifics simulated via application of a weak electric field at various Dfs to the fish tank. Such stimuli evoked a serotonin-like signal in the ELL-LS. Remarkably, these stimuli were significantly more likely to evoke a serotonin-like response in male than in female fish. Males were also more likely to exhibit a behavioral response (fast increases in their EODf; chirps) in the context of agonistic encounters. Spontaneous serotonin-like release events occurred in some of the trials without electrosensory stimulation. The probability of spontaneous release was, however, significantly lower than release in trials with stimulation. The relation between the probability of release and the identity of the simulated conspecific, i.e. the Df value, was highly variable across, but consistent within individuals. This result underlines the impact of an individual fish's past experience on the probability of release. Interestingly, loud auditory stimuli failed to evoke a response in the ELL-LS suggesting sensory modality specificity. Our results provide previously unseen insight into the time-course of stimulus-evoked dynamics of serotonin-like signals (ongoing experiments are aimed at pharmacological verification of the serotonergic nature of the signals) in a primary sensory area and its possible involvement in shaping the responses of sensory neurons.

Title: Social isolation alters socially induced serotonergic fluctuations in the inferior colliculus

Authors: *S. M. KEESOM, L. M. HURLEY;
Biol., Indiana Univ., Bloomington, IN

Abstract: Appropriate behavior during a social encounter requires that an animal be attuned to the details of social context, and past social experience plays an important role in shaping sensory responses to social signals. Mechanisms that mediate the influences of social experience on sensory systems have been less explored. In the auditory system, serotonin is strategically situated for mediating effects of social experience on sensory processing for three reasons: 1) the serotonergic system itself is sensitive to social experience; 2) socially triggered serotonergic fluctuations reflect behavioral differences among social encounters; and 3) serotonin alters evoked responses of auditory neurons to natural vocalizations. In this study, we directly tested how past social experience affects the acute social serotonergic response in the inferior colliculus, a region involved in processing vocalizations. We used carbon fiber voltammetry to measure serotonin during social encounters of male mice (Mus musculus) that were previously group-housed or individually housed for four weeks. When paired with an intruder male, both group-housed and individually housed mice demonstrated similar elevations in serotonin. However, social isolation altered the trajectory of serotonergic responses over multiple social encounters in a subset of mice from which we obtained repeated measurements. In this subset, group-housed mice had increased serotonergic responses during a second social encounter, whereas individually housed mice had drastically diminished serotonergic responses during the second encounter. Social isolation also altered the relationship between the serotonergic response and social behavior. For group-housed mice, serotonin was positively related to social investigation. In contrast, there was no relationship between serotonin and social investigation for individually housed mice. Thus, social housing influences both the serotonergic system's response to social context over multiple encounters and how it reflects variations among encounters of the same context. These results suggest that prolonged social isolation disrupts the ability of the serotonergic system to convey information about immediate social context to an auditory region.

Title: Seeing with sound - auditory-visual information transfer in Egyptian fruit bats

Authors: *W. METZNER[1], C. SCHILLING[2], A. GRINNELL[1];
[1]Integrative Biol. and Physiol., UCLA, Los Angeles, CA; [2]Neurobio., Univ. Ulm, Ulm, Germany

Abstract: Echolocating bats are able to use echoes of emitted sounds as a substitute for vision. They can catch small flying insects at night with as much facility as a swallow or flycatcher can during the daytime. Their skill at using sound for orientation and food capture is considered one of the most spectacular adaptations of any sensory system, and has spawned a very active field of research. These bats act as if they can form a three-dimensional acoustic image of the world with the echoes returning from one sound emission equivalent to what one would see with a single strobe illumination. It is extremely difficult to imagine how they do this, or indeed to prove that they can. Is the mental image they get from echoes anything like the visual image one gets with vision, or is it an entirely acoustic experience that does not get translated into the kind of gestalt that we and other visually orienting animals are familiar with. We propose to ask this question first of bats that have good vision, but are still capable of accurate echolocation. This is the case for an old world fruit bat, Rousettus, which lives in caves or tombs and uses echolocation when flying in the dark, but also has good vision and uses vision when there is enough light. Specifically, we asked two questions: 1. Can Egyptian fruit bats acquire a mental image of an object using vision (or hearing) alone? 2. Once such a mental image has been formed, can it be transferred from one sensory modality (e.g., vision) to another (e.g., hearing - or the other way around)? Using positive conditioning, we trained the bats to first localize a rewarded object (an X) that was presented pseudorandomly at either the left or right side using either vision (group 1; 3 bats) or hearing (group 2; 3 bats) alone. After only a few weeks, all experimental bats were able to perform these tasks far above the 75% level. Subsequently, we used a forced-choice alternative training paradigm to have the bats discriminate between a rewarded object (the X) and an unrewarded object (a cross) using either vision (group 1) or hearing (group 2) alone. Again, all bats performed above the 75%-level after only a few weeks of training. Finally, we tested if the same bats could also discriminate the objects using the other sensory modality, i.e. hearing in group 1 and vision in group 2. We found that only after a few sessions (much sooner than in the initial discrimination tasks, i.e., vision in group 1 and hearing in group 2), the bats performed this task correctly. This suggests that the bats can indeed, and amazingly easily, transform a mental image that they obtained using one sensory modality (vision in group 1 and hearing in group 2) to another modality.

Title: Neural activity in the SC of a flying echolocating bat

Authors: ***N. B. KOTHARI**, M. J. WOHLGEMUTH, C. F. MOSS;
Johns Hopkins Univ., Baltimore, MD

Abstract: The superior colliculus (SC) is a laminated midbrain structure implicated in species-specific orienting behaviors. Previous recordings from the SC of head restrained and passively listening bats revealed two classes of cells: 1) neurons that encode 2D head-centric space (azimuth and elevation) around the bat and 2) 3D neurons that encode not only the azimuth and elevation but also range. Range is encoded by neurons that exhibit pulse-echo delay tuning. SC recordings from bats resting on a platform and tracking a moving target revealed vocal-premotor activity prior to each sonar vocalization. Here we present extracellular recording data from the SC of freely flying bats, and characterize sensory, sensori-motor and motor neural activity. We trained big brown bats to locate and land on a platform for a food reward. While the bat performed this task, single unit activity was recorded across the SC laminae using a telemetry system. Synchronized with neural recordings, high-speed audio and video recordings captured the bat's echolocation, head aim and flight behaviors. To reconstruct the timing of the echoes arriving at the bat's ears, we developed an echo model using the recorded sonar vocalizations, the bat's 3D head aim and position in space. Correlating echo timing information with neural activity we characterize neurons that respond to echoes from different objects along the bats flight trajectory. Correlating the neural activity with the sonar vocalizations we find sensory-motor and motor neurons in the intermediate and deeper layers of the bat SC. Recording simultaneous activity across the SC laminae allows us to observe the integration of information across these functional layers. Such integration of information is essential for spatial navigation, orientation and prey capture by echolocating bats.

Title: On holey ground: vibrissal touch aids the placement of safe footing during locomotion

Authors: *K. ARKLEY[1], B. T. O'CONNOR[1], R. A. GRANT[2], B. MITCHINSON[1], T. J. PRESCOTT[1];
[1]Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom; [2]Div. of Biol. and Conservation Ecology, Manchester Metropolitan Univ., Manchester, United Kingdom

Abstract: The earliest mammals were small, nocturnal creatures, capable of highly varied and adaptable motor behaviors. It can be argued that the first mammals, or their therapsid reptilian ancestors, evolved a specialization of the outer epidermal layers of the integument – hair – with a predominantly tactile function. As a result of the sensory advantages of these tactile hairs, the early mammals were able to occupy a variety of new habitats, evolving a more sophisticated motor repertoire than their reptilian ancestors and the insulating pelagic hair. It is known that the *vibrissae* (whiskers) play a significant role in the guidance of fast-paced locomotion by providing a 'look-ahead' to detect upcoming obstacles [Arkley et al., *Curr Bio*, 24(13), 1507-12], but here, we test the hypothesis that whisker movements are also employed by the rat to guide the placement of safe footfalls. Using high-speed videography, whisker tracking and a pedobarograph, we compare foot placement, and whisker and head movements of functionally-blind rats locomoting on both a flat and holey floor from top-down and side-on views, obtaining kinematics in both the rostrocaudal and dorsoventral dimensions. As previously found, animals locomoting along a flat floor adopted a pronounced 'look-ahead' strategy at higher locomotion speeds, with more exploratory whisking movements at slow travel. When travelling along a holey floor, rats successfully avoided placing their feet in holes 95% of the time, appearing to modify their vibrissal and locomotor behaviours in order to monitor the area directly in front of the snout, whilst sampling the contours of the ground in order to guide safe footfalls. This was achieved by maintaining a head parallel with the floor, allowing consistent whisker contact with the ground, and by adopting frequent periodic whisker movements. The position of the whiskers about the snout were also much more bilaterally asymmetric, suggesting the position of the whiskers are constantly updated to monitor the location of holes, analogous to rats exploring an object. Analysis of whisker and head kinematics from a side-on view confirms that some whiskers make direct contact with the floor at all times during locomotion on the holey floor, but deviate during fast-paced locomotion on the flat floor. It seems likely that the differences in whisking and locomotion on a holey and flat floor arise as a product of the same strategic goal – safe locomotion. In particular, our data suggest vibrissal input during locomotion on uneven

ground informs the animal of the most appropriate place to position the feet, as evidenced by the overlapping spatial area of the floor that both snout and forepaws cover.

Title: Sub-second structure in mouse behavior

Authors: *A. B. WILTSCHKO[1,3], M. J. JOHNSON[3,2], G. IURILLI[2], R. E. PETERSON[2], J. M. KATON[2], S. L. PASHKOVSKI[2], V. M. ABRAIRA[2], R. P. ADAMS[3], S. R. DATTA[2]; [2]Dept. of Neurobio., [1]Harvard Med. Sch., Boston, MA; [3]Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA

Abstract: Complex animal behaviors are believed to be built out of simpler modules, which can be flexibly linked in different sequences to encode a variety of actions. However, the systematic identification of these behavioral modules in mammals remains a significant challenge. Here we characterize how the three-dimensional (3D) poses exhibited by mice change over time during unrestrained behavior and observe that mouse pose dynamics are inherently divided into brief (circa. 400 millisecond) motifs of 3D motion. Computational modeling of these fast dynamics reveals that mouse behavior is composed from a set of reused modules, each a stereotyped

trajectory through pose space that is connected in time to other modules through predictable transitions. We observe that a striking behavioral response to a predator odor is implemented by simply changing transition probabilities between modules, while changing the physical shape of the experimental arena evokes new behavioral modules. The sub-second structure of behavior is also sensitive to changes in the genome and neural activity, enabling detection of subtle behavioral changes induced by heterozygous mutation of a gene or modest optogenetic stimulation. This work reveals that mouse body language _ like birdsong and natural language _ is built from identifiable components and is organized in a predictable fashion on sub-second timescales; deciphering this language establishes an objective framework for characterizing the influence of environmental cues, genes and neural activity on mouse behavior.

Title: Dopamine agonist SKF 38393 increase syntactic grooming chains in high-yawning rats

Authors: *J. EGUIBAR[1], C. CORTES[2], A. TRUJILLO[3];
[2]Inst. of Physiol., [3]Biol. Sch., [1]Benemerita Univ. Autonoma de Puebla, Puebla, Pue., Mexico

Abstract: High-yawning (HY) subline of Sprague-Dawley rats yawned spontaneously more than the low-yawning (LY) under different environmental conditions. HY rats also had more grooming bouts and time spent in grooming behavior after when exposed to a novel environment or after wetting the fur. Grooming increased after systemic injection of D1 agonists such as SKF 38393. The aim of this study is to analyze the effects of SKF 38393 on syntactic grooming chains (SGC) in both sublines. All subjects were maintained under standard conditions with a light-dark cycle 12/12, free access to rodent pellets and water. At 100 days old, male subjects were injected s.c. with 16 mg/Kg of SKF 38393 and observed by 30 min between 11:00 to 13:00

h. The SGC were recorded using video camera and analyzed off-line by a blind observer using The Observer XT software. Statistical analysis did using ANOVA followed by Tukey´s test. The results showed that SKF 38393 increased the number and duration of SGC in both sublines ($P<0.05$). The D1 agonist produced a longer duration on SGC and hence the number of ellipses did around the vibrissae and ear areas in each SGC in both sublines being higher in HY ($P<0.05$). Finally SKF 38393 also increased the probability to complete SGC being greater in HY subjects ($P<0.05$). In conclusion, HY rats increased the number, mean duration of grooming bouts as well as the number of movements in the SGC after SKF 38393 with greater perseverance on the movements and higher velocity suggesting that HY subline is more anxious or of a perseverance of cleaning movements a characteristic of obsessive-compulsive disorder. Title: Speed vs accuracy: nervous systems tradeoffs using robust control

Authors: *Y. NAKAHIRA[1], J. C. DOYLE[2];
[2]Control and Dynamical Systems, [1]Caltech, Pasadena, CA

Abstract: Existing literature suggests neural networks evolved to optimize performance tradeoffs under various constraints, such as conduction velocity, energy consumption, signal to noise ratio, length of wiring, etc. We use robust control to develop a unified theory that connects channel capacity (information transfer between cells) and signaling delay (via conduction velocity) with computational performance in sensorimotor control tasks, and the resulting tradeoffs are consistent with the observed extreme heterogeneity in axon diameters. Delays,

feedback, noise, and dynamics are essential to the theory and are poorly treated in more familiar information theory and statistical physics. We model the nervous system as a feedback controller that attempts to maintain the body in a desired physical state despite disturbances, and neural fibers as communication channels between sensors of bodily and environmental states, controllers, and actuators (e.g. muscles). We first derive explicit formulas for robust performance of the feedback system given dynamic instability, signaling delay, actuator saturation, and the capacity of communication channels, where the performance is defined as the deviation from the desired state. Assuming that axonal fibers are contained in a region with fixed volume there is a tradeoff between signaling capacity (proportional to number of axons) and speed (proportional to radius for myelinated or sqrt(radius) for unmyelinated axon). These tradeoffs can be directly plugged into the robust performance formulas to find optimal capacities and delays as a function of the control objectives. The results show that, at one extreme, optimal robustness is achieved with minimum delay at the expense of low capacity when the environment is poorly known and fast reaction is required. In the other extreme, optimal robustness is achieved with large delay and signaling capacity when the environment is well known and slower action is acceptable. These results are consistent with but formalize for the first time the standard intuitions regarding the extreme heterogeneity in axon sizes needed to tradeoff speed with resolution in sensorimotor tasks.

Title: Blood- and CSF-based biomarkers of Alzheimer’s disease, mild cognitive impairment and vascular dementia among Panamanians

Authors: *A. E. VILLARREAL[1], S. E. O'BRYANT[2], M. EDWARDS[3], S. GRAJALES[4], G. BRITTON[4];
[1]INDICASAT AIP, Panama, City of Panama, Panama; [2]Intrnl. Med., Inst. for Aging & Alzheimer's Dis. Research, Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [3]Univ. of North Texas, North Texas, TX; [4]Ctr. de Neurociencias y Unidad de Investigación Clínica, Inst. de Investigaciones Científicas y Servicios de Alta Tecnología (INDICASAT AIP), Panama, Panama

Abstract: The Latin American and Caribbean region is experiencing significant growth in the aging population. In Panama the geriatric population is gradually increasing as in the rest of the world. We are conducting a biomarker-based study to describe the demographic and biomarker profiles of Panamanians with Alzheimer's disease (AD), mild cognitive impairment (MCI) and vascular dementia (VaD) using a serum- and CSF-based biomarkers. Here we show the results of a cross-sectional analysis of aged individuals for blood-based (N=154) and CSF (N=51) biomarkers. The following measures were obtained: global cognition was measured with the Mini-Mental State Examination (MMSE), disease progression with the Global Deterioration Scale, and depression with the Geriatric Depression Scale 30-item version. Age, gender, education, ApoE ε4 allele frequency, diabetes diagnosis and obesity status were also analyzed. The blood-based biomarkers were measured using non-fasting serum samples and analyzed in duplicate via a multi-plex biomarker assay platform using ECL on the SECTOR Imager 2400A from Meso Scale Discovery. A biomarker profile was generated using random forest analyses. CSF biomarkers Aβ1-42, T-tau, and P-tau181 were analyzed using ELISA (enzyme-linked immunosorbent assay). For the blood-based biomarkers, preliminary results show that the profile for AD subjects was highly accurate, yielding an area under the receiver operating characteristic curve (AUC), sensitivity, and specificity of 0.94, 0.86 and 0.90, respectively. The diagnostic accuracy statistics did not change with the addition of age, gender, education and ApoE ε4 status. For the MCI and VaD groups, the accuracy was lower with AUC, sensitivity and specificity of 0.58, 0.30 and 0.71 (MCI) and 0.60, 0.80 and 0.25 (VaD), respectively. The expression of at least one copy of the APOEε4 allele differed among groups ($X2 = 17.7$, $p = 0.001$), with at least half of AD (57%) and MCI (50%) groups expressing one or two copies. For the CSF biomarkers, preliminary results show significant correlations between Aβ1-42, ($r = .323$, $p = 0.024$), T-tau ($r = .505$, $p = 0.000$), P-tau181 ($r = .409$ $p = 0.004$) and the MMSE. Other results show that levels of Aβ1-42 were significantly lower in AD patients vs. controls (mean [SD], 557 [246] pg/mL vs. 856 [305] pg/mL; $P = .001$). Levels of T-tau (mean [SD], 530 [253] pg/mL vs. 234 [95] pg/mL; $P<.001$) and P-tau181 were significantly higher in AD patients vs. controls (mean [SD], 88 [37] pg/mL vs. 44 [14] pg/mL; $P<.001$). This is the first study to assess both blood and CSF biomarkers for an elderly cohort of Panamanians and adds to a growing body of research on biomarkers of dementia among Hispanics.

Title: Development of boron-doped diamond microelectrodes for human use: pre-clinical animal trials

Authors: *E. N. NICOLAI[1], S. PAEK[1], P. H. MIN[1], J. R. TOMSHINE[2], M. P. MARSH[2], M. L. SETTELL[1], S.-Y. CHANG[1], K. E. BENNET[2], D. JANG[3], F. S. MANCIU[4], K. H. LEE[1]; [1]Dept. of Neurologic Surgery, [2]Div. of Engin., Mayo Clin., Rochester, MN; [3]Dept. of Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of; [4]Dept. of Physics, Univ. of Texas, El Paso, TX

Abstract: Introduction: Fast scan cyclic voltammetry (FSCV) is an electrochemical technique used to measure electroactive molecules. This technique has proven powerful in providing an understanding of the real-time action of neurotransmitters such as dopamine and adenosine *in vivo*. The ability to measure neurotransmitters in humans would provide valuable biomarkers for neurosurgical techniques such as deep brain stimulation (DBS). Carbon fiber microelectrodes (CFM) are the current standard for *in vivo* FSCV recordings; however, this technology is not suitable for human use, as CFMs are fragile and degrade over time. Here we describe the pre-clinical testing of a boron-doped diamond (BDD) microelectrode in animal models of DBS for the ultimate goal of use in human patients. Method: BDD microelectrodes were designed and produced in-house. The Mayo-developed WINCS Harmoni was used to produce an FSCV waveform scanned from -0.4 to 1.45 V and back at 400 V/s every 100 ms for all experiments. Sensitivity to dopamine was assessed in multiple rodents via medial forebrain bundle stimulation and FSCV recording in the caudate putamen. Stimulation-evoked signals were obtained before and after Nomifensine, a dopamine reuptake inhibitor, injection in order to verify recording of dopamine. Sensitivity to adenosine was assessed in multiple rodents, multiple swine, and a single non-human primate via mechanical stimulation of the caudate putamen and thalamus while recording FSCV in the same location. Signals obtained were assessed by the presence of oxidation current at the known oxidation potentials for adenosine, 1.4 and 1.0 V. Longevity *in vivo* of BDD microelectrodes was compared to that of CFMs by using the same electrode of each

type multiple times in multiple animal experiments. Results: The BDD microelectrodes demonstrated the ability to measure dopamine in rodents and adenosine-like signals in rodents, swine, and a non-human primate. Compared to CFMs used in the same series of rodent experiments, BDD microelectrodes appeared to have degraded at a slower rate and maintained clearer, more robust signal detection. Finally, multiple CFM tips broke during experiments, while all of the BDD microelectrodes remained intact. Conclusion: The ability of BDD microelectrodes to measure electrically stimulated dopamine release and mechanically stimulated adenosine-like release *in vivo* supports their efficacy for use in detecting biomarkers related to DBS. Importantly, these results support the sensitivity, longevity, and safety of BDD microelectrodes for use in future human studies.

Title: AB oligomers and AD

Authors: *J. KALININA[1], M. S. MICHENER[1], B. E. SMITH[1], E. PARKER[1], J. A. STONE[1], E. VAN MAANEN[2], G. WILCOCK[3], D. SMITH[3], D. WARDEN[3], C. L. MASTERS[4], Q.-X. LI[4], C. J. FOWLER[4,2], C. J. WINROW[1], M. J. SAVAGE[1];
[1]Late Discovery and AD, Merck & Co., West Point, PA; [2]LAP&P consultants, Leiden, Netherlands; [3]Oxford Univ., Oxford, United Kingdom; [4]Melborne Univ., Melborne, Australia

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative dementia. Merck's β-secretase therapy against AD is currently undergoing Phase 3 clinical trials and shows dramatic reductions in Aβ monomer levels. With the recent emergence of Aβ oligomers as the most toxic Aβ species in AD, our work has focused on deciphering the different roles of Aβ oligomers in AD: (1) by establishing a sensitive, robust and automated assay for their scarce (sub-pg/mL) detection in human CSF, and (2) demonstrating their use as a diagnostic, and a marker in evaluating drug/oligomer pharmacodynamics in preclinical/clinical models of APP processing. To achieve the former, we used Singulex' Erenna technology to develop Aβ oligomer-specific CSF assay that can reliably discriminate AD vs. controls (*J.Neurosci*. **2014**,

34(8):2884-97). In our recent work, we are developing a prototype oligomer assay using Quanterix Simoa technology, which will is hoped to improve throughput, fully automate the assay, and reduce sample volumes. Using the Singulex assay and working collaboratively with several academic institutions (University of Melbourne, Oxford University), we have also explored the correlation of CSF oligomers with cognitive decline in cross-sectional/longitudinal AD and Control cohorts (AIBL, OPTIMA). Finally, in our effort to identify Aβ oligomers as a pharmacodynamic biomarker in response to secretase inhibition, we used cisterna magna ported-rhesus preclinical model in a four-way crossover design. Treatment with secretase inhibitors (BACE, GSi or vehicle) resulted in a significant (5-fold) reduction in oligomers in rhesus CSF in a time-/dose-dependent fashion, enabling a revised model of rhesus CNS APP processing that includes a role for oligomers. Together, these findings highlight potential utility of Aβ oligomers as diagnostic and prognostic tools for human AD; and, importantly, as a novel marker of pharmacodynamic response to secretase inhibitor therapy. Future work is planned to measure oligomer levels in clinical trials' CSF samples of BACEi.

Title: Evaluating transcytosis of bivalent and monovalent transferrin receptor antibodies *in vitro*

Authors: *F. LIU, S.-H. TSCHANG, J. PEREIRA, J. CROY, J. LU, R. DEMATTOS, M. RACKE;
Eli Lilly & Co., Indianapolis, IN

Abstract: The blood brain barrier (BBB) restricts entry of antibodies to the CNS to a mere 0.1 - 0.2%. Transferrin receptor (TfR) antibodies have been explored as carriers to deliver therapeutic antibodies across the BBB via receptor mediated transcytosis (RMT). Previous studies demonstrated that binding mode influences RMT and therefore brain exposure and drug potency. In order to better understand the impact of antibody valence on the efficiency of RMT, we examined several TfR antibodies as either monovalent or bivalent constructs in *in vitro* BBB

models. We characterized both human hCMEC/D3 and murine bEND.3 brain endothelial cells (EC) grown in transwells to assure appropriate conditions to test RMT. Then we used a pulse/chase method to allow uptake of antibodies into the monolayer and analyzed their internalization and subsequent trafficking throughout the system. We evaluated anti-human TfR antibodies mAB128.1 and MEM189 in both monovalent and bivalent forms in the hCMEC/D3 cells. The monovalent versions of antibody were internalized by the cells at half the level of their bivalent counterparts. For both monovalent and bivalent mAB128.1, the percentage of the antibody in the basolateral chamber compared to what was taken up by cells, was similar. However, for the monovalent MEM189 this percentage was significantly higher than the bivalent form. This suggests more robust transport of monovalent MEM189 out of the EC once internalized. In contrast to the human antibodies, monovalent and bivalent constructs of anti-mouse TfR antibody Mab8D3 entered murine bEND.3 cells to similar levels. Like the monovalent MEM189, monovalent Mab8D3 shows a higher percentage of externalization than the bivalent antibody. Our data demonstrates the utility of two brain endothelial cell lines in testing the design and activity of TfR antibodies to enhance BBB penetration of large molecule therapeutics.

Title: Cocaine induced glucose and dopamine fluctuations simultaneously recorded at single striatal locations using fast-scan cyclic voltammetry

Authors: *S. SMITH[1,2], W. GARRISON[1], C. LEE[1], A. KOMSA[1], L. SOMBERS[1];
[2]Chem., [1]North Carolina State Univ., Raleigh, NC

Abstract: Cocaine, a drug that is commonly abused, elicits a well-characterized and robust dopamine release in the striatum. Even cues that predict cocaine availability elicit striatal dopamine release, and it is this chemical signaling that is thought to underlie cocaine's reinforcing effects. However, the metabolic effects of cocaine administration are unclear, as direct attempts to investigate this question have produced controversial results. In fact, it is unclear how glucose, a key metabolic marker, fluctuates on a second-by-second basis in normal brain function, despite the fact that it serves as the principal energy source of the brain. This work aims to simultaneously quantify dynamic fluctuations of glucose and dopamine at single recording sites in the rat striatum using glucose oxidase-modified carbon-fiber microelectrodes coupled with background-subtracted fast-scan cyclic voltammetry, under basal conditions and in response to cocaine administration. This approach provides chemical selectivity, revealing sub-second dynamics of both chemicals at a single recording site to directly demonstrate how robust striatal dopamine release mediates local metabolic processes. An understanding of this interaction promises to inform therapeutic strategies for treating drug addiction and related disorders.

Title: Label-free method for characterization of diprenorphine binding to active and inactive state u-opioid receptors using LC-MS/MS detection

Authors: *T. EESSALU[1], M. JOHNSON[2], L. MARTIN[2], K. BURRIS[3], V. BARTH[1], T. WIERNICKI[3];
[1]Tailored Therapeutics- Neurosci., [2]Neurosci. Disc. Res., [3]DCRT, Eli Lilly & Co, Indianapolis, IN

Abstract: We report a simple highly sensitive quantitative label-free method for detecting direct receptor-ligand binding interactions using LC-MS/MS detection. This label-free method was

used to determine biophysical properties (koff, Kd, Bmax) of the non-selective opioid receptor binding ligand diprenorphine to cell membranes overexpressing human μ-opioid receptors. The equilibrium binding constant (Kd), number of binding sites (Bmax) and ligand dissociation rate constant (Koff) were determined under buffer conditions that promote both G-protein receptor active stat (coupled) and inactive state (uncoupled). Using the label-free direct binding method we determined that the results agree to published data using the indirect radiolabel tracer method. In the presence of GDP and sodium chloride the μ-opioid receptors were uncoupled from G-proteins and we saw the expected shift of the receptor equilibrium to the inactive state by a 20 fold decrease in equilibrium binding affinity (Kd) while the total number of available binding sites (Bmax) remained unchanged. We also determined that when the dissociation binding profile for diprenorphine μ-opioid receptors was performed under uncoupled buffer conditions a biphasic curve was seen with both fast and slow components. However, when dissociation experiments were performed under coupled buffer conditions, a single slow dissociation rate was seen. This LC-MS direct binding assay greatly enhances the speed at which receptor ligand candidates can be biophysically characterized, when compared to radiolabeling prospective candidate ligand molecules. The direct LC-MS binding detection technique now makes it possible to assess receptor binding interactions for agonists (full, partial, inverse), antagonists (competitive or non-competitive), or allosteric (positive or negative) modulators.

Title: An ultrasensitive immunoassay detects soluble Aβ oligomers in Tg mice prior to memory loss

Authors: E. N. CLINE[1], K. L. VIOLA[1], M. G. ROLLINS[1], S. N. MOHAMMAD[1], L. R. ZIESKE[2], *W. L. KLEIN[1];
[1]Neurobio., Northwestern Univ., Evanston, IL; [2]Singulex, Inc., Alameda, CA

Abstract: Background: The recent success of a Phase 1b clinical trial (antibody aducanumab; Biogen Idec) substantiates the hypothesis that aggregated forms of Aβ have a key role in Alzheimer's disease (AD) pathogenesis. Because amyloid beta oligomers (AβOs) are widely regarded as the aggregated form of Aβ responsible for AD onset, the therapeutic efficacy of aducanumab may come from targeting AβOs rather than amyloid plaques. AβOs accumulate early in AD and experimentally cause memory dysfunction and the major cellular pathologies associated with AD (*e.g.*, tau abnormalities, synapse loss, oxidative damage, *etc.*). An important resource currently unavailable to clinicians and researchers is an ultrasensitive assay for detection of AβO species at AD-relevant concentrations. Such an assay would have potential application to early diagnosis and therapeutics. **Methods:** We have developed an *ultrasensitive AβO immunoassay* (lower limit of quantification: 0.10 pg/mL = 20 fM) utilizing the research use only Erenna® Immunoassay Platform (Singulex) and a *highly AβO-specific human monoclonal antibody* (ACU-193; Acumen). This antibody is unique compared to Aβ-targeting antibodies that have gone to clinical trials in that it has little to no affinity for monomers or fibrils.
Results: With this assay, we have detected 3-10 fmol AβOs per mg total protein in brain extracts of 5xFAD Tg mice at 3.5 months, *prior to the onset of memory loss*. This preliminary data was obtained from 6 Tg mice and 3 wt littermates. At 24 months of age, AβO levels in Tg mice are increased another 10-fold. **Conclusions:** This preliminary data provides further evidence for the early accumulation of AβOs in AD. Future applications of this immunoassay include: (1) AβO detection in human brain extracts and, potentially, concentrated CSF; and (2) when combined with HPLC-SEC, characterization of the size distribution of AβOs throughout AD progression. Detection of specific populations of AβOs will fill a gap in our knowledge of the native structure of species prevalent over the course of AD and may show greater diagnostic potential than detection of whole AβO populations.

Title: Anticonvulsant effects of non-selective nonsteroidal anti-inflammatory drug and cyclooxygenase-2 selective inhibitor in the zebrafish seizure model

Authors: *P. G. BARBALHO;
Univ. of Campinas, Campinas, Brazil

Abstract: Introduction: Epilepsy is a common neurological disorder characterized by recurrent spontaneous seizures. Cyclooxygenase-2 (COX-2) is an enzyme that converts arachidonic acid into prostaglandins and it has been suggested that this enzyme can play a role in epilepsy. The present study was carried out to investigate the effect of the non-selective NSAID and COX-2 selective inhibitor (indomethacin and SC-236, respectively) on seizure onset latency and number of seizure behavior in the zebrafish seizure model. **Methods:** zebrafish were maintained according to standard procedures. All experiments procedures were approved by the Ethic Animal Committee. Seven days post-fertilization (dpf) larvae were placed individually in a 24 well-plate containing 15mM PTZ for 20 minutes. During PTZ exposure, the latency of seizure onset (n=10) and number of seizures (n=5) were analyzed. Latency was considered when the animal was exposed to PTZ until it achieves stage 3 (loss of posture). Six dpf zebrafish larvae were incubated in 307μM indomethacin solution or 1μM SC-236 solution (0.1% DMSO) in petri dishes for 24 hours and after that, at 7dpf, they were exposed to 15mM PTZ as described above. Data are presented as mean values ± standard error of mean (SEM). Statistical analyses were performed by Mann-Whitney test with $p \leq 0.05$ for a significant difference between groups, using the GraphPad Prism. **Results:** Indomethacin and SC-236 increased latency to seizure onset (n=10; $p<0.001$ and $p=0.001$, respectively) and reduced the number of seizure behavior when compared to animal from SG (n=10; $p=0.004$ and $p=0.007$, respectively). The mean±SEM for the latency to seizure onset (give in minutes) was: SG 2.2±0.25; 307μM indomethacin+SG 5.2±0.27; 1μM SC-236 3.9±0.37. The mean±SEM of number of seizure obtained for each group was: SG 34.4±6.2; 307μM indomethacin+SG 9.4±1.5; 1μM SC-236 3.0±0.7. **Conclusion:** Indomethacin and SC-236 treatment prior to PTZ-induced seizure increased the latency to seizure onset and significantly decreased the number of seizures during PTZ exposure, showing that both treatments presented an anticonvulsant effect in this model. Our findings support evidence that zebrafish is a valuable model for further investigations of the main role of inflammation in seizure as well as it is a valuable model for anti-inflammatory screening of compounds that are potentially therapeutic for seizures suppression. Title: Multiplex immunoassay detection of neurodegenerative and cytokine biomarkers in cerebrospinal fluid

Authors: *A. J. SAPORITA, J. MISTRY, J. HWANG;
EMD Millipore, Saint Charles, MO

Abstract: Progressive neurodegenerative disorders such as Parkinson's disease (PD) and Alzheimer's Disease (AD) affect millions worldwide and are becoming more prevalent as our population ages. Monitoring protein biomarkers in cerebrospinal fluid (CSF) of patients with these neurological disorders may be highly beneficial to understanding disease progression. Whereas biomarkers of AD have been established, the identification of reliable protein biomarkers to aid in the diagnosis of PD and the characterization of PD progression has been elusive. To add further complexity, some biomarkers are general indicators of neurodegeneration but cannot be used to distinguish AD and PD. For example, many cytokines are general biomarkers of neuroinflammation associated with these neurological diseases. Simultaneous monitoring of several protein biomarkers, using a multiplexed panel, may further our understanding of disease progression. We have developed a multiplex immunoassay to eight protein biomarkers of neurological disease: alpha-synuclein, glial fibrillary acidic protein (GFAP), neuron-specific enolase (NSE), angiogenin, transglutaminase 2 (TGM2), prion protein, UCHL1, and DJ-1. Notably, several of these proteins have been linked to PD. This assay is compatible with analytes from the MILLIPLEX®MAP Human Cytokine Panel I, allowing for rapid customization to enable simultaneous detection of both the cytokines and the other neurological disease biomarkers. Using the customized 20-plex immunoassay, we measured the expression of these 8 neurological disease biomarkers and 12 cytokines in CSF from PD patients, AD patients, and healthy controls. Angiogenin and NSE showed increased expression in PD samples relative to controls, while GFAP, NSE, UCHL1 and prion protein were elevated in AD samples. Several cytokines were detectable in CSF, including IL-4, IL-5, and VEGF, which showed increases in both PD and AD samples compared to controls. Increases in IFN-gamma and TNF-alpha also reached statistical significance in the AD group compared to controls. Angiogenin was the only analyte in our assay to exhibit selective elevation in PD CSF but not AD CSF. This study demonstrates the value of using customizable multiplex technology to evaluate multiple biomarkers of neuroinflammation and neurodegeneration.

Title: Crossing the blood-cerebrospinal fluid barrier in the mouse choroid plexus with an engineered receptor/ligand system

Authors: *H. R. MENDEZ-GOMEZ[1,2], A. GALERA-PRAT[3,4], C. MEYERS[1,2], J. SINGH[1,2], W. CHEN[1,2], M. CARRION[3,4], N. MUZYCZKA[1,2];

Abstract: Crossing the blood-brain and the blood-cerebrospinal fluid barriers are one of the fundamental challenges in the development of new therapeutic molecules for brain disorders because they prevent entry of most drugs from the blood into the brain. However, some large molecules, like the protein transferrin, cross these barriers using a specific receptor that transports them into the brain. Mimicking nature, we engineered a receptor/ligand system to cross the brain barrier by combining the human transferrin receptor with the cohesin domain from Clostridium thermocellum, and we tested it in the choroid plexus of the mouse brain with a dockerin ligand. By expressing our receptor in choroidal ependymocytes, which are part of the blood-cerebrospinal fluid barrier, we found that our systemically administrated ligand was able to bind to the receptor and accumulate in ependymocytes, where some of the ligand was transported from the blood side to the brain side.

Title: Differentiation of analytes using multiple fast-scan cyclic voltammetry

Authors: *D. KIM[1], Y. OH[1], H. SHIN[1], C. PARK[1], K. E. BENNET[2], I. KIM[1], D. JANG[1], K. H. LEE[2];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Mayo Clin., Rochester, MN

Abstract: In this study, we present a new method that is similar to paired-pulse voltammetry (PPV) but uses multiple pulses to calculate the kinetic properties of neurochemicals. We call this technique multiple fast-scan cyclic voltammetry (MFSCV), in which multipulse (10 pulses per scan) cyclic voltammetry is done at various voltages. We used the conventional triangle waveform (from -0.4 volt to +1.0 volt and back down to -0.4 volt, at a scan rate of 1000 V/s) and a 10Hz repetition time for our experiments. For practical applications of MFSCV, it can be possible to change the scan waveform, scan rate, scan repetition time, and each scan interval. These successive cyclic voltammograms have a rapidly decreasing patternbecause the adsorption time is decreasing rapidly. This means that the amount of adsorbed chemicals has a lower saturation with higher scan repetition rates at the same concentration of the neurotransmitter. As a result, in this study we have derived a theoretically decreasing pattern of dopamine (DA) using MFSCV and produced background- subtracted voltammograms, in which their differences can be fitted in the exponential equation that has been expanded to all voltages for making a new type of pseudo color maps. These maps are composed of two features: the kinetic maps (K-maps) that show the specific kinetic characteristics of a particular analyte and the concentration maps (A-maps) for said analyte. Using this method, we can get the conventional information and the desorption-reduction related constant maps at the same time. Lastly, we applied the MFSCV method to the three other electroactive species groups: catecholamines, indolamines and ascorbic acid (AA). These three groups each have different the desorption-reduction related constant characteristic. This flow cell experiment showed the coincidence with our derived theoretical values, since MFSCV values are affected by the previous iteration of the redox amount and ratio at the carbon fiber microelectrode surface.

Title: Measurement of dopamine absolute concentration using multiple fast-scan cyclic voltammetry

Authors: *Y. OH[1], D. KIM[1], H. SHIN[1], C. PARK[1], K. E. BENNET[2], I. KIM[1], D. JANG[1], K. H. LEE[2];
[1]Hanyang Univ., Seoul, Korea, Republic of; [2]Mayo Clin., Rochester, MN

Abstract: Neurotransmitters are endogenous chemicals that transmit signals between neurons across a synapse. This neurochemical transmission is a significant biomarker for understanding neuro-functional mechanism in the brain along with electrophysiological signals. Many techniques have been proposed to measure neurotransmitter concentration in the brain. Fast-Scan Cyclic Voltammetry (FSCV) is one such method thatmeasures neurotransmitters by detecting fine current occurring in the brain by applying voltage through a carbon fiber microelectrode (CFM). This technique has been used experimentally to measure chemical fluctuation within milliseconds in mammals. Dopamine (DA) is one metabolite measureable using FSCV. Nonetheless, because the background signal in FSCV is relatively large and unstable, tonic concentration of DA cannot be separated from the background signal. However, Heine, et. al., recently suggested a fast-scan controlled-adsorption voltammetry (FSCAV) technique for quantifying tonic levels of dopamine in the brain. In this research, we propose an optimized FSCV technique based on adsorption, desorption reaction within minimized CFM double layer to extract the absolute value of DA. By minimizing background signal and maximizing DA response in FSCV, we could detect absolute DA signal without utilizing the background subtraction method. Then, we could estimate specific concentration of DA using the extracted characteristic value from basic buffer. Unlike FSCAV, we could measure the absolute value of DA with clear features of oxidation and reduction of DA in striatum of a rat brain with minimized background effect.

Title: Engineering an "armor-plated" horseradish peroxidase (HRP) for connectomic studies

Authors: *M. G. PAEZ SEGALA[1], R. FETTER[2], J. SIMPSON[3], L. LOOGER[4];
[1]Looger Lab., Janelia Farm, HHMI, Ashburn, VA; [2]Dr Richard Fetter, [3]Dr. Julie Simpson, [4]Dr. Loren Looger, Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: In 1810, Planche 1reported that a tincture of guaiacum developed a stronger color when a piece of fresh horseradish root was soaked in it. During the next two centuries, horseradish peroxidase (HRP), responsible for the color change in Planche's experiment, was discovered, characterized and subsequently used extensively as a staining agent in diverse applications. In recent years the labeling of neurons and subcellular structures with subsequent visualization at nanometer resolution using different electron microscopic imaging strategies, such as focused ion beam milling block-face scanning electron microscopy (FIB-SEM) and transmission EM (TEM) (c.f. 2,3)_ENREF_1 has become a major workhorse in anatomy. Sample preparation for these applications usually incorporates HRP-generated H2O2-catalyzed polymerization of diaminobenzidine (DAB), which is then made electron-dense by subsequent reaction with osmium tetroxide (OsO4). These DAB/osmium deposits are easily visualized by electron microscopy or X-ray tomography. When using large-volume samples a compromise must be found between sample preparation for excellent ultrastructural preservation and the ability of HRP to catalytically produce a robust DAB product. Generally with higher concentration and duration of glutaraldehyde fixation, HRP's ability to catalyze DAB polymerization may be weakened or eliminated due to inactivation of the enzyme. In this work we report the rational design and molecular engineering of HRP's surface-reactive amino acids to decrease the sensitivity to aldehyde fixation, with the goal to permit robust enzymatic activity and ultrastructural preservation for electron microscopy. "Killer applications" include targeted staining of genetically-specified neurons, glia, or organelles in brains prepared for ultra-high-quality EM reconstruction for connectomics. Title: Development of a surface plasmon resonance assay for characterization of small molecule binding kinetics and mechanism of binding to kynurenine 3-monooxygenase

Authors: *S. PODA[1,2], M. KOBAYASHI[2], R. NACHANE[2], V. MENON[1], A. S. GANDHI[1], D. P. BUDAC[1], G. LI[1], B. M. CAMPBELL[1], L. TAGMOSE[1];
[1]Neuroinflam. biology, Lundbeck USA, Paramus, NJ; [2]Structural Biol., ZoBio. BV, Leiden, Netherlands

Abstract: When developing lead compounds against a validated drug target, the traditional drug discovery paradigm has focused primarily on optimizing drug-target interactions via the measurement of IC_{50} or K_i. However, it is recognized that efficacy and selectivity may also be driven by drug-target kinetics and the mechanism of binding an overlooked dimension in the conventional structure-activity relationships. In particular, drug-target residence time, which is defined as the reciprocal of the dissociation rate constant, has been shown to be a promising early stage indicator of *in vivo* drug activity. Kynurenine 3-monooxygenase (KMO), a pivotal enzyme in the kynurenine pathway was implicated as a potential therapeutic target for treating neurodegenerative and psychiatry disorders. Recently, RapidFire LC/MS/MS was reported as a sensitive, label-free, and direct method for monitoring the conversion of kynurenine to 3-hydroxykynurenine catalyzed by KMO. Previously, KMO assays based on absorbance of NADPH or release of tritiated water were described. However, none of these methods are suitable for the determination of the binding kinetics of compounds to KMO. We describe here a surface plasmon resonance assay which delivers both kinetic and the mechanism of binding data, enabling a detailed characterization of compound interactions with the KMO enzyme in real time.

Title: Gamma amino-butyric-acid measurement by an electrochemiluminescence method in small samples with high sensitivity

Authors: *J. C. SALAZAR SANCHEZ, A. MORALES-VILLAGRAN;
Dept. de Biología Celular y Mol., Univ. De Guadalajara, Zapopan, Mexico

Abstract: Gamma amino-butyric-acid measurement by an electrochemiluminescence method in small samples with high sensitivity. J. C. Salazar Sánchez and A. Morales Villagrán Gamma amino-butyric-acid (GABA) is the main inhibitory neurotransmitter in the central nervous systems. Alteration in its concentration is associated with several neurological disorders like Epilepsy, Parkinson, Alzheimer and Huntington disease. It has an important role in intercellular communication both in central nervous system as well as in other tissues. A complete characterization of GABA in several physiological and pathological processes requires a reliable quantification of this compound. Several methods have been developed with the aim to quantify GABA based on the instrumentation available, sensitive required, and organ/tissue analyzed. Most of these methods mainly use HPLC coupled to fluorescence and electrochemical detection. These methods requires a minimal volume for each sample and the sensitivity range is in micromolar concentration, which in some cases they do not reach the desired sensitivity for specific samples. The alternative suggested here is based on the use of enzymatic reactors that produce electrochemiluminescence signal. This is obtained using the well know GABAse complex that produces Nicotinamide adenine dinucleotide reduced form (NADH) as well as glutamate (Glu) among others products. Additional enzymatic reactors to determine the NADH and Glu are coupled. These are NADH oxidase and Glutamate oxidase that generate hydrogen peroxide, which is quantified in an electrochemiluminscence way in the presence of luminol. The luminescence obtained was proportional to the GABA concentration, for NADH, the calibration curves had a polynomic behavior with a R^2 value ≥ 0.97 in a nanomolar range (3-1000). Using Glu measurement derived from GABA, the sensitivity obtained was in the nanomolar range (50-1000) with a linear R^2 value ≥ 0.95. These alternatives could be used to determine this neurotransmitter in small volume samples and the main advantage is that a big number of samples can be analyzed in a short time.

Title: Afferent-specific neurochemical profiling of multiple glutamatergic inputs to the nucleus accumbens by combined optogenetics and microdialysis application

Authors: *N. SUTO[1], A. MATZEU[1], A. LAQUE[1], M. W. BUCZYNSKI[1], S. AZUMA[2], T. KERR[1], D. WATRY[1], R. MARTIN-FARDON[1], L. H. PARSONS[1], F. WEISS[1], P. P. SANNA[1], T. C. JHOU[3];
[1]Dept. of Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA; [2]Eicom, San Diego, CA; [3]Med. Univ. of South Carolina, Charleston, SC

Abstract: Optogenetics is widely adopted in many branches of neuroscience. This rapidly evolving technology takes the advantage of light-gated receptors to manipulate genetically targeted biological systems with progressively increasing degree of cell-type and circuit level specificity. However, the neurochemical impacts of optogenetic manipulation largely remain uncharacterized and are only indirectly inferred by the effects of secondary pharmacological manipulation (antagonists) on electrophysiological and/or behavioral responses. In the present study, the neurochemical impacts of optogenetic stimulation of glutamatergic inputs to the nucleus accumbens (NAc) - neurochemical signal thought to encode reward-associated cues, and thus mediate reward-seeking (motivated) behaviors - were directly monitored by brain microdialysis in anesthetized rats. In NAc, the prototypical excitatory transmitter glutamate is known to trigger post-synaptic action potential in intrinsic neural population as well as pre-

synaptic release of diverse neurochemicals. Based on a previous report (Britt et al., 2012, Neuron, 76, 790-803), distinct glutamatergic afferents originating in the medial prefrontal cortex (mPFC), basolateral amygdala (BLA) or ventral hippocampus (vHipp) were examined in separate groups of rats. In all cases, afferent-specific optogenetic stimulation of distinct glutamatergic inputs and microdialysis sampling of extracellular neurochemicals were both conducted in the same brain region - either core or shell of NAc. Neurochemical contents of the dialysate samples were resolved by high performance liquid chromatography, and detected by a conventional electrochemical method (Eicom) as well as by a high-throughput mass-spectrometry method (Song et al., 2012, Anal. Chem., 84, 412-9). Analytes of interest included glutamate, GABA, dopamine, norepinephrine, serotonin, acetylcholine, histamine, adenosine, serine, glycine, and taurine. Title: Fibrin-based microenvironments for *in vitro* studies of adult neurogenesis

Authors: *L. HAGER[1], A. CLARK[2], E. PRICE[2];
[2]Biol., [1]Marshall Univ., Huntington, WV

Abstract: Adult neurogenesis is an on-going process in the mammalian brain and our laboratory is interested in harnessing adult neural stem cells for therapeutic applications. The subventricular

zone (SVZ) is a niche of neural progenitors whose normal function is to repopulate olfactory bulb neurons. These stem cells migrate from the SVZ to their destination via the rostral migratory stream (RMS). The long term goal of this research is to develop implantable fibrin-based hydrogels which are capable of forming a de novo migratory stream that steers migrating neural cells from their usual path into a new non-neurogenic region. For this approach to be successful, the matrix must provide the appropriate cues that signal migration, axonogenesis and dendritogenesis, integration and function. In the present work, we prepared small fibrin cylinders containing covalently crosslinked neurotrophins selected based on their predicted functional impact on adult neural progenitor cell maturation. We have incorporated VEGF and GDNF, alone, in combination, or sequentially, into these cylinders which were placed into tissue culture wells seeded with cultured neural progenitor cells. When VEGF and GDNF were both present, mature NF160+ neurons with complex neurites were seen growing along the matrix. Interestingly, when only VEGF or GDNF was present, cells were also observed migrating along the cylinder but lacked complex neurites. When VEGF was crosslinked into the cylinders and GDNF was added to the culture on Day 3, complex NF160+ neurites were again observed, suggesting that VEGF was required to render the neural progenitors responsive to GDNF. These findings lead to a model of neurogenesis where there is a temporal requirement for factors where specific neurotrophins are required to induce cellular responsiveness to subsequent factors. To provide additional mechanistic information that will lead to an engineered implant that can recapitulate the RMS, we generated a cylindrical matrix consisting of two smaller cylinders, one inside of the other. The inner cylinder was cast containing neural progenitor cells and the outer cylinder contained vascular endothelial cells. After several days in culture, the inner fibrin cylinder was degraded by the neural cells, which themselves migrated along the newly formed lumen of the outer cylinder, exhibited complex neurites and formed a three dimensional architecture with the endothelial cells. The findings from these *in vitro* experiments will provide guidance in the development of cylindrical implants that will direct endogenous neural stem cells into regions of interest, such as those damaged by traumatic brain injury or disease.

Title: Development of a colorimetric assay for the identification of novel compounds as potential therapeutics for Alzheimer's disease

Authors: P. L. FERNANDEZ[1], D. DOENS[1], O. LARIONOV[2], A. TRSITAN[1], A. KHAN[1], *G. B. BRITTON[1], R. LLEONART[1];
[1]INDICASAT AIP, Panama, Panama; [2]Univ. of Texas San Antonio, San Antonio, TX

Abstract: Alzheimer's disease (AD) is the most common form of dementia and represents a major public health problem worldwide. In recent years the potential relevance of microglia innate immune activation in AD has received more attention. Microglia are activated by Amyloid β (Aβ), generating a pro-inflammatory response that plays a critical role in AD pathogenesis. Aβ binds to CD36 and activates microglia to produce cytokines and neurotoxins leading to neurodegeneration. Disruption of this interaction could be relevant to reduce the inflammatory response induced by Aβ. We developed a novel assay to identify molecules able to interfere with the binding of Aβ to CD36. This assay was used to screen libraries of synthetic compounds. Our aims were to: 1) design and optimize an assay to screen for inhibitors of Aβ interaction with CD36, and 2) identify molecules able to impair the pro-inflammatory response mediated by the Aβ-CD36 interaction. For the development of the colorimetric assay we expressed and purified recombinant extracellular domain of the human CD36 protein, which was subsequently used to coat 96 well plates. After incubation with fibrillar Aβ, the complex CD36-Aβ was detected using a mouse anti-Aβ antibody followed by a antimouse HRP-conjugated antibody. The compounds interfering with the binding between CD36 and Aβ were detected by the reduction of the colorimetric signal. Ursolic acid was used as positive control of inhibition. Compounds identified by the assay were tested in a cell-based assay to evaluate their capacity to inhibit the secretion of inflammatory mediators by microglia stimulated *in vitro* with Aβ. The new assay was used for the screening of a total of 128 new synthetic compounds from four different libraries. Twenty five compounds showed inhibitory effect on CD36-Aβ interaction. Preliminary data show that four of those active compounds also have an effect on the microglia response evaluated *in vitro*. These results suggest that this novel assay represents a promising tool for the identification of small molecules targeting inflammation in AD pathogenesis.

Title: Exploring methods of cholinergic denervation of the rat ventral tegmental area

Authors: *J. L. FULLERTON;
SIPBS, Strathclyde Univ., Glasgow, United Kingdom

Abstract: Midbrain dopamine (DA) neurons in the ventral tegmental area (VTA) are involved in learning and contribute to the rewarding properties of drugs of abuse. The VTA receives glutamatergic, GABA-ergic and cholinergic inputs. The only known source of cholinergic input to VTA DA neurons is from the mesopontine tegmentum - the pedunculopontine tegmental and laterodorsal tegmental nuclei (PPTg, LDTg). Uniquely in the mesopontine tegmentum, cholinergic neurons express urotensin-II receptors (UII-R). Exploiting this expression, a selective toxin for mesopontine cholinergic neurons was created fusing diphtheria toxin and urotensin-II peptide (Dtx-UII). This toxin destroys cholinergic neurons after direct injection into the PPTg or LDTg but doing either of these only eliminates a proportion of cholinergic VTA input. Is it possible to inject Dtx-UII into the VTA to destroy all cholinergic terminals there? The effect of Dtx-UII on mesopontine cholinergic terminals was assessed through unilateral infusion into the posterior VTA (pVTA) of Dtx-UII (200µL, 3%). To determine whether complete cholinergic denervation of the pVTA could be achieved rats were perfused at various times after surgery (2, 4, 6, 8 & 10 days). Tissue was processed using vesicular acetylcholine transporter (VAChT) to label cholinergic neurons, and fluoro-jade C, which binds to neurodegenerating axons, dendrites and terminals. Control experiments were undertaken infusing ibotenate (180µL, 0.06%) into pVTA. Dtx-UII pVTA infusion did not change VAChT expression 2, 4, 6, 8 & 10 days after surgery. VAChT and fluoro-jade C immunohistochemistry was not altered, which would indicate that cholinergic terminals were not destroyed and that no neurodegeneration had occurred. Tissue infused with ibotenate produced a marked increase in fluoro-jade C positive cells in the pVTA. Further experiments could determine the effect of higher Dtx-UII concentrations: while the dose used here is effective in PPTg, UII-Rs are expressed at a lower level in VTA than PPTg/LDTg. Furthermore, because Dtx-UII is expected to act through retrograde degradation, it may require longer times to initiate cell death. This toxin holds potential to deepen our knowledge of the relationship between the mesopontine tegmental nuclei and VTA, aiding our understanding of how mesopontine cholinergic neurons regulate activity midbrain DA neurons and through them, corticostriatal activity.

Title: Real time observation of rodent cerebral metabolism by dissolution dynamic nuclear polarization

Authors: ***D. DOWNES**, B. LAMA, J. COLLINS, M. FEBO, J. LONG;
Univ. of Florida, Gainesville, FL

Abstract: *In vivo* magnetic resonance spectroscopy and imaging (MRSI) is a useful technique for measuring carbon metabolism in live animals, but is often limited because of poor signal-to-noise. Dynamic nuclear polarization (DNP) is a rapidly developing technique in the field of MRS, offering a highly sensitive enhancement to traditional MRSI. Stable isotopically labeled metabolites are hyperpolarized prior to MR spectroscopy allowing for a substantial increase in the carbon signal-to-noise ratio (SNR) of >10,000x. This gain in carbon SNR allows cellular metabolic pathways to be observed in real time. Integration of dissolution dynamic nuclear polarization (dDNP) into MRSI studies of a chronic addiction model is important for investigating changes in neurometabolic processes. Chronic administration of neuro-stimulatory agents has been shown to abate cerebral glucose metabolism in reward regions of the brain. It is our central hypothesis that dDNP can be used to observe this dysfunction in real-time for cocaine addiction and withdrawal. Divergence from normal citric acid cycle metabolism in chronic addiction will be quantified by elevated lactate production in regions of reward in the brain and will provide insight into mitochondrial function as an indicator of addiction associated cerebral damage. We have hyperpolarized metabolites of interest in a 5 T wide-bore dDNP instrument at ~1 Kelvin with a 140 GHz VDI microwave source. Phantom and animal studies have been performed with the use of an automated injection system coupled to a 4.7 T and 11 T MRI instrument.

Title: Adenosine as a parameter to determine the quality of the rapid microwave fixation of rat brain for the determination of cAMP and cGMP in braintissue

Authors: A. RASSOULPOUR, F. HELFRICH, *M. G. VAN DER HART;
Brains On-Line, South San Francisco, CA

Abstract: Cyclic adenosine-3',5'-monophosphate (cAMP) and cyclic guanosine-3',5'-monophosphate (cGMP) are important second messengers for intracellular communication. Illnesses and disorders that affect the brain can show an impaired intracellular communication. Quantification of these metabolites can elucidate regulation and dysregulation of these important processes, and serve as biomarkers for therapeutics that target cAMP/cGMP regulation Measuring cAMP and cGMP in brain tissue can be a challenging due to their rapid degradation by enzymes (i.e. phosphodiesterase's), which are still active postmortem. Using rapid microwave fixation, the enzymes are instantly deactivated and thus prevents the degradation. Unfortunately it is hard to determine the quality of the fixation. In this study we investigated if adenosine, an end product of cAMP degradation, could be used as a reliable parameter to quantify the successfulness of brain fixation. For this purpose we performed rapid microwave fixation followed by brain dissection. The prefrontal cortex, striatum and ventral hippocampus were collected and quickly frozen and stored until analysis. Tissues were homogenized in perchloric acid and assayed by LC-MS/MS for cAMP, cGMP and adenosine. It was found that concurrent measurement of adenosine was critical in determining sample integrity for cAMP and cGMP analysis by indicating which samples were not properly fixed. It was found that brain areas furthest away from the center of the beam had more often a significantly higher adenosine concentration than the brain areas located in the center of the microwave beam during the rapid

fixation process. Relative to samples with normal adonesine levels, samples displaying high adonesine levels had lower levels of cAMP concentrations at 64%(n=6) in the cortex, 60%(n=19) in hippocampus, 58%(n=16) in striatum and cGMP concentrations at 54%(n=6) in the cortex, 46%(n=15) in hippocampus, and 50%(n=14) in striatum. To test if this method could reliably measure differences in cAMP and cGMP after pharmacological manipulations animals were treated with Rolipram, a non-specific phosphodiesterase inhibitor. This yielded cAMP cortex concentrations higher than vehicle treated animals, while no significant difference was observed with respect to cGMP concentration in the brain.

Title: A rapid method of isolating purified population of Schwann cells for spinal cord transplantation

Authors: *W. WU, W. QU, X.-M. XU;
Neurolog. Surgery, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Accumulated evidence suggests that Schwann cell (SC) transplantation is one of the most promising cell therapies for repair after acute and chronic spinal cord injuries (SCIs). For clinical application, transplantation of autologous SCs is preferred to avoid immune rejection of grafted cells. Conventional SC culture method requires lengthy *in vitro* procedures to generate large quantity of purified SCs, which may miss the optimal therapeutic window following an acute SCI. Thus, obtaining large quantities of highly purified and viable SCs within a short period of time is very important in both experimental and translational SCI research. In 2012, Kaewkhaw et al. developed a new protocol utilizing customized DMEM depending on the preferential expression of D-amino acid oxidase (DAAO) in SCs (Kaewkhaw, R., et al. Nat. Protocol 7: 1996-2004, 2012). This method eliminated the fibroblast purifying procedure as required in other methods, and showed a great potential for rapidly isolating high purity SCs.

However, the biological properties of SCs isolated with this method remains unclear. In this study, we used green fluorescence protein (GFP) transgenic SD rats as the donor for isolating SCs. To exclude the possibility that the GFP gene may affect the property of SCs, we firstly used a traditional method to isolate SCs using sciatic nerve explant culture (Xu et al. J Comp. Neurol. 351:145-160, 1995) and compared SC cultures isolated from GFP transgenic (GFP-SC) and wide type SD rats (WT-SC). The result showed no significance difference between isolated GFP-SCs and WT-SCs in terms of purity and proliferation. We then cultured GFP-SCs using the freshly dissociate method of Kaewkhaw and compared them with the GFP-SCs cultured with the traditional method in terms of purity and proliferation. The result showed that SCs isolated from freshly dissociated adult sciatic nerves achieved a high purity (>99%) in a shorter culture period (19 days), as compare to the traditional method (44-48 days). At day 16, SCs were transferred from 3.5 mm dishes to a T25 flask and, at day 18, to a T75 flask. Using the new method, it took only 2 days for SCs to become confluent in a T75 flask, while it took at least 3-4 days when a traditional method was used, indicating that SCs proliferated faster with the new culture protocol. To approve the functionality of SCs isolated with the new method, an ongoing study is being conducted to determine the survival, migration , axon growth promotion, and myelination of grafted SCs in a rat spinal cord contusion injury model at the 10th thoracic level (T10).

Title: A method to determine *ex vivo* insulin responsiveness in synaptosomes isolated from frozen brain tissue

Authors: *W. FRANKLIN[1], G. TAGLIALATELA[2];
[2]Neurol., [1]UTMB At Galveston, Galveston, TX

Abstract: Alterations of insulin signaling in neurons have been linked to many disorders such as diabetes, inflammation, and Alzheimer's disease (AD). Synapses are rich of insulin receptors and insulin has been shown to be important to maintain synaptic health/integrity. Notably, decreased insulin signaling (insulin resistance) increases synaptic sensitivity to amyloid beta (Aβ), the toxic

protein that accumulates in AD, thus contributing to the cognitive decline that characterizes this neurodegenerative disorder. Therefore, studying the insulin signaling response at the synapse is an important approach to understand molecular mechanisms involved in disease-related neurodegenerative processes and test the effectiveness of potential new treatments. With this goal in mind, we have developed a method for studying the insulin responsiveness at the synaptic level by isolating functional synaptosomes from tissue and exposing them to insulin in the presence of ATP to detect receptor and associated pathway activation. Using this method coupled to Western blot analysis, we were able to detect insulin-driven phosphorylation of the insulin receptor (IR) as well as phosphorylation of other signaling elements in the insulin pathway including IRS1, AKT, and GSK3β. Furthermore, effective phosphorylation of the IR in isolated synaptosomes could be observed using either insulin or IGF-1, further indicating the presence of a functional IR that responds to multiple ligands as it naturally does in the CNS. We optimized this method by performing dose response curves of insulin and ATP as well as an insulin time course on IR activation and obtained reliable results using synaptosomes isolated from both fresh and frozen tissue from rats and mice. We have also examined the effect on the response of the insulin receptor, AKT, and GSK3β of storing isolated synaptosomes frozen for extended periods of time prior to insulin stimulation as well as determining the impact of varying post-mortem intervals prior to tissue collection. Our results showed differential impact on different elements of the insulin signaling pathway depending on varying experimental conditions, indicating the need for maintaining a tightly standardized approach across different experiments. In conclusion, we have developed a reliable method to measure *ex vivo* phosphorylation of the insulin receptor and associated signaling pathway. To the best of our knowledge, this is the first evidence of stimulation of isolated synaptosomes with insulin and a promising new technique to study the synaptic CNS insulin responsiveness under disease conditions.

Abstract: Studies of complex multicellular organisms would benefit from the ability to selectively manipulate the activities of any cell type of interest. Our ability to achieve this is currently limited by technology and available resources. Here, I explore the artificial use of intracellular proteins as signals for conferring cell specificity in gene manipulation. The Green Fluorescent Protein (GFP) is a useful marker of gene expression and thousands of transgenic GFP reporter lines have been made to label different cell types, particularly in the mouse nervous system. However, the utility of transgenic GFP reporter lines is limited to labeling purposes. I exploited this resource for cell-specific gene manipulation by constructing synthetic systems that become biologically active upon interaction with GFP. Using GFP-binding nanobodies derived from Camelid antibodies, I co-opted GFP as a scaffold protein to bring together complementary split proteins that, when in a complex, can regulate processes such as transcription and DNA recombination. I demonstrate the utility of these systems for selectively manipulating GFP-expressing cells in the mouse nervous system and in zebrafish, for applications such as developmental perturbations, electrophysiology and optogenetic interrogation of neural circuits. In addition to the above, I will discuss current efforts to simplify the complexity of GFP-dependent systems. Thus, my work expands the experimental paradigm for manipulation of specific cell types in multicellular organisms and provides novel tools and approaches for cellular-level analysis of biological processes in animals.

Title: Two-photon optogenetics with near-infrared light-activated cyclases and FRET sensors for studying the role of cAMP and cGMP in living neurons

Authors: *M. VALENCIA[1,2], T. T. LUYBEN[1,2], K. OKAMOTO[1,2];
[1]Lunenfeld-Tanenbaum Res. Inst., Mount Sinai Hosp., Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Optogenetics provides powerful tools to non-invasively manipulate neural activity and specific protein function by light. However, for studying intracellular signaling mechanisms involved in synaptic function, these optogenetic tools are not yet well established. Here, we describe two-photon optogenetics with near-infrared light-activated cyclases and FRET sensors for elucidating the roles of intracellular messengers cAMP and cGMP in the synapses of living neurons. To dissect the role of cAMP in synaptic plasticity, we have utilized a bacterial photoactivatable adenylate cyclase (PAC) which produces cAMP in response to blue light. We demonstrated photoactivation of PAC at the single synapse level by two-photon excitation light in cultured hippocampal slices. To expand our two-photon optogenetic approach for studying intracellular messengers, we optimized and established a near-infrared light-sensitive adenylate cyclase (NIR-PAC), a fusion of a photosensory PAS-GAF-PHY domain with a catalytic domain of adenylate cyclase (Ryu *et al.*, 2014), for two-photon photoactivation. Also, by mutating the enzymatic pocket of NIR-PAC, we engineered a near-infrared light-sensitive guanylate cyclase (NIR-PGC). To confirm light-dependent activation of these near-infrared light-activated cyclases, we excited each cyclase with LED light (660 nm peak) *in vitro* and measured cAMP or cGMP levels by ELISA. The intracellular messenger levels were raised within seconds after light stimulation, indicating rapid photoactivation. We then examined enzymatic activity across the two-photon excitation spectra *in vitro* to optimize the excitation wavelength. Two-photon excitation wavelengths greater than 1000 nm efficiently activated both NIR-PAC and NIR-PGC, suggesting the ability to control their activation at single synapses using two-photon microscopy. Since we have found that the two-photon excitation range of the blue-light sensitive PAC is up to 1000 nm, the two-photon excitation range of the near-infrared cyclases suggests the possibility to manipulate cAMP and cGMP levels separately using different wavelengths of two-photon excitation light in the same living neurons. By optimizing genetically-encoded two-photon FRET (Förster Resonance Energy Transfer) sensors for cAMP and cGMP, we validated the near-infrared light-sensitive cyclases in living pyramidal neurons of hippocampal slice cultures. We will discuss how these two-photon optogenetic technologies will serve as valuable tools for elucidating the role of postsynaptic cAMP and cGMP signalling cascades in living neurons.

Title: Two-photon optogenetics for controlling the activity of PDEs in living neurons

Authors: *F. BERGIN, K. OKAMOTO;
Samuel Lunenfeld Res. Inst., Toronto, ON, Canada

Abstract: Phosphodiesterases (PDEs) catalyze the hydrolysis of intracellular second messengers, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), which are essential for synaptic plasticity underlying learning and memory. PDEs have been targeted for drug discovery in a variety of psychiatric and neurodegenerative disorders including schizophrenia and Alzheimer's disease. However, the exact function of PDEs in synaptic plasticity is still unclear due to the lack of techniques to locally monitor and control their activity in the brain. Current pharmacological and genetic approaches for studying PDEs are limited by cellular precision and spatiotemporal specificity. Here we report the two-photon optogenetic tools to manipulate PDEs activity by light in a spatiotemporally precise manner, to study their synaptic function. Mammalian PDEs are divided into 3 types: cAMP specific (PDE4, 7, 8), cGMP specific (PDE5, 6, 9) and PDEs that hydrolyze both (PDE1-3, 10, 11). All types of PDEs are expressed in central nervous system such as hippocampus, cortex and striatum, suggesting their distinct roles for synaptic function. To establish photoactivatable PDEs, we utilized a recently described optogenetic strategy fusing a far-red light sensitive domain PAS-GAF-PHY to the catalytic domain of PDE2A (Moglich *et al*, 2014). We prepared a series of variants and optimized the 3 types of photoactivatable PDEs for PDE2, 4 and 5 *in vitro*. The light activation of photoactivatable PDE2 indicated the hydrolysis of applied cAMP and cGMP within seconds by light, indicating its strong photoactivation. In contrast photoactivatable PDE4 and 5 showed their photoactivation of hydrolysis only for cAMP (PDE4) or cGMP (PDE5), demonstrating their target specificity. Next, to study the synaptic level function in the mouse brain, we use two-photon microscopy to achieve activation of photoactivatable PDEs at the single synapse level in living tissues. To optimize the two-photon excitation light-dependent activity of each enzyme, we examined the excitation spectra of photoactivatable PDEs *in vitro*. We found the longer two-photon excitation wavelengths corresponding to the single photon excitation range of the far-red light sensitive domain efficiently activated these PDEs *in vitro*, suggesting the ability to control

its activation at single synapses. We will discuss their use in *in vivo* studies using hippocampal slice cultured neurons.

Title: Optical inactivation technology of synaptic AMPA receptors *in vivo*

Authors: *K. TAKEMOTO[1], H. IWANARI[2], T. NAGAI[3], T. HAMAKUBO[2], T. TAKAHASHI[1];
[1]Dept. of Physiol., Yokohama City Univ., Yokohama-Shi, Japan; [2]RCAST, The Univ. of Tokyo, Tokyo, Japan; [3]Inst. of Scientific and Industrial Res., Osaka Univ., Osaka, Japan

Abstract: Acute inactivation of synaptic neurotransmitter receptors *in vivo* with spatio-temporal precision should be a powerful tool to understand their roles in physiological functions. Among many molecules in synapse, AMPA type glutamate receptor, GluA1 is an especially known as important molecules for memory acquisition which is delivered into synapses in response to many types of learning and experience. Here, we developed an optical technology for acute inactivation of synaptic GluA1 receptors by CALI (chromophore-assisted-light-inactivation) *in vivo*. CALI uses a photosensitizer which produces short-lived reactive oxygen species, such as singlet oxygen, by irradiation with light. Singlet oxygen shows a half-radius of photodamage for approximately 3-4nm, which is smaller than the average protein-protein interaction distance (8nm) (Linden et al., 1992; Beck et al., 2002). Thus, CALI could promise the specific inactivation of a target protein with high spatial precision which is difficult for gene knockout and RNAi. Further, by using antibodies labelled with photosensitizer, we could inactivate a protein on the cell surface without damaging neighboring proteins. To develop the anti-GluA1 antibody fo CALI experiments, we raised and screened a monoclonal antibody against the extracellular domain of GluA1 to induce specific CALI by labeling with photosensitizer, eosin

(Takemoto et al 2011). In response to green light, one labeled-antibody effectively and specifically inactivated GluA1 receptors both in recombinant AMPA receptor expressing cells and endogenous AMPA receptor expressing neuronal synapses. Using this system, we will also talk about a novel *in vivo* optical technology for artificial memory erasure by *in vivo* CALI system. Our optical technology will permit their physiological roles in memory acquisition and formation to be analyzed with high spatio-temporal resolution, such as individual spines, and ultimately enable us to map out "the functional synapses" in memory system.

Title: Development of boron-doped diamond microelectrodes for human use: electrode engineering and fabrication

Authors: *J. TOMSHINE[1], K. BENNET[1], F. MANCIU[2], M. MARSH[1], M. SETTELL[1], E. NICOLAI[1], K. LEE[1];
[1]Mayo Clin., Rochester, MN; [2]Physics, Univ. of Texas at El Paso, El Paso, TX

Abstract: Introduction: Deep Brain Stimulation (DBS) is a neurosurgical intervention that has attracted widespread interest in recent years, yet the technique remains limited by its "open-loop" nature. That is, modern DBS implants do not automatically adjust their level of stimulation based on any measured physiological parameter, thus creating a potential for either over- or under-treatment. Fast scan cyclic voltammetry (FSCV) is a well-established analytical technique that is able to measure - *in vivo* - the neurotransmitters that are released as a result of DBS. However, existing electrode designs for FSCV rely largely on carbon fiber and degrade quickly at peak potentials above 1.2-1.4 V. This makes existing electrodes unsuitable for chronic implantation if neurotransmitters such as adenosine (whose oxidation potential occurs above this range) are to

be measured. This work presents the design and fabrication of a durable synthetic diamond-based electrode capable of measuring physiologically-relevant levels of neurotransmitter for far longer than prior carbon fiber-based electrodes. Methods: Hot-filament chemical vapor deposition was used to deposit boron-doped polycrystalline diamond coatings on sharpened tungsten substrates. The purity of the diamond coatings was evaluated by Raman spectroscopy. Longevity was evaluated *in vitro* by continuous application of the FSCV waveform over several days in buffer solution with periodic calibration using dopamine. Electron microscopy was used to image electrode tip degradation. Results: The diamond electrodes constructed in this work retained their sensitivity over a timespan that caused conventional carbon fiber electrodes to fail (5.2 million FSCV measurement cycles). The carbon fiber electrodes were physically degraded, while diamond electrodes remained unchanged (and sensitive to dopamine) following equivalent treatment. The diamond electrode tips also require more than 2 orders of magnitude more physical force to break - an important characteristic for long-term surgical implantation. Conclusion: The diamond electrodes presented here, coupled with fast scan cyclic voltammetry, provide a promising sensing platform for the design of a closed-loop deep brain stimulation device. While the electrodes used in this study were not packaged for chronic implantation, they maintained sensitivity for a number of cycles sufficient to make chronic implantation practical.

[4]Neurologic Surgery, Div. of Engin., Mayo Clin., Rochester, MN; [5]Ctr. for Nanotechnology, NASA Ames Res. Ctr., Mountain View, CA

Abstract: Background: Electrochemical methods for neuroscience research have traditionally employed a single carbon fiber, aspirated into a glass capillary, as an electrode. While this design has proven successful for detection of neurotransmitters *in vivo* and *in vitro*, it has some drawbacks: It is very fragile, and it can record neural activity only in a single small region of the brain. Here we describe the fabrication and characterization of a penetrating silicon-substrate based multiplex microelectrode array that utilizes aggregations of carbon nanofibers (CNF) as sensing elements. Methods: Device fabrication was performed on a silicon-on-insulator wafer using the following main steps: (1) metal conductor deposition; (2) Ni catalyst deposition; (3) CNF growth by plasma enhanced chemical vapor deposition; (4) CNF encapsulation with dielectric; (5) 1 μm removal of top dielectric layer to expose CNF tips and (6) deep reactive ion etch (DRIE) for electrode release from the base wafer. The resulting electrode design is 5 mm in length, 50 μm thick, and 120 μm at the widest point, with six sensor pads and approximately 40,000 nanofibers per sensor. Scanning electron microscopy (SEM) and atomic force microscopy (AFM) were performed to characterize the surface structure of the carbon nanofiber sensing elements. The electrode was then interfaced with a printed circuit board via adhesive and wire-bonding, and the connections were electrically insulated with a light-activated polymer resin. Subsequent *in vitro* electrochemical characterization was performed in a flow cell using the Mayo-developed WINCS Harmoni to perform fast-scan cyclic voltammetry (FSCV). Results: The fabrication steps highlighted above produced a functional multiplex electrode array containing 6 sensing pads per device. CNF growth and exposure was confirmed with SEM and AFM techniques. FSCV demonstrated the electrode was sensitive to both dopamine (DA) and oxygen (O2). Additionally, simultaneous detection of mixtures of DA and O2 on adjacent electrode pads with minimal crosstalk was demonstrated with the WINCS Harmoni system. Conclusion: Due to the advantages of multiplexing and simultaneous detection of multiple analytes afforded by the CNF microelectrode array, we believe that the initial testing of silicon-based CNF electrodes shows promise for future applications in the electrochemical detection of neurotransmitters, e.g. dopamine, serotonin, etc. Potential applications include elucidating the mechanisms of action of deep brain stimulation (DBS) and intraoperative neurotransmitter monitoring during neurosurgery. Funding: Support by NIH (R01 Ns75013) and the Grainger Foundation.

Title: Mechanistic modeling of spike-timing dependent plasticity of basal ganglia neurons

Authors: I. PROKIN[1], S. VALTCHEVA[2], L. VENANCE[2], *H. BERRY[1];
[1]INRIA, Villeurbanne, France; [2]Ctr. for Interdisciplinary Res. in Biology, INSERM U1050 / CNRS UMR7241, Col. de France, Paris, France

Abstract: Synaptic plasticity is a plausible support for learning and memory in single neurons. A recent plasticity paradigm is spike-timing dependent plasticity (STDP), whereby synaptic weight change is dictated by the relative timing of paired pre- and postsynaptic action potentials (AP). Notwithstanding the large volume of research on STDP, its dependence on underlying signaling pathways is not fully understood. To address this issue, we combined electrophysiology experiments with modeling of the implicated signaling network comprising the NMDAR and endocannabinoid (eCB) pathways. We have elaborated the model using experimental data obtained with typical STDP protocols (100 AP pairings at 1 Hz) at corticostriatal synapses. STDP at these synapses is known to be anti-Hebbian: long-term depression, LTD, is induced when the presynaptic AP occurs before the postsynaptic one (pre→post) whereas long-term potentiation, LTP, is induced by the reverse order (post→pre). The model reproduces this main feature. It was then validated against additional data consisting mostly in varying the number of AP pairings and manipulating astrocytic glutamate uptake (see the related experimental poster by Valtcheva and Venance). The model again reproduces all key experimental results considered. Together, confrontation with the experiments yielded the following insights: (i) the contribution of NMDAR and eCB pathway to STDP vary with the number of AP pairings: while NMDAR-dependent LTP and eCB-dependent LTD need large numbers of pairings, eCB-dependent LTP is expressed only with few pairings (5 to 25); (ii) eCB-dependent plasticity is thus bidirectional: its outcome (LTD or LTP) depends on the amount of eCBs produced during the protocol; (iii) STDP is controlled by glutamate uptake by the astrocytic glutamate transporter EAAT2 (GLT-1). This joint experimental-modeling approach has thus proven useful for the study of the molecular basis of synaptic plasticity; its further development might significantly advance our understanding of synaptic plasticity in normal and pathological conditions.

Title: A systematic approach to analyze the impact of p53 mutations on p53-mdm2 interaction using machine learning

Authors: *S. YEGUVAPALLI[1,3], K. CHITRALA[2], P. H. REDDY[4,3];
[1]Dept. of Zooloy, [2]Zoology, Sri Venkateswara Univ., Tirupati, India; [3]The Reddy Laboratory, Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [4]Cell Biol. & Biochemistry, Neurol. and Neurosci. & Pharmacol., Texas Tech. Univ. Hlth. Sci. Center, Garrison Inst. on Aging, Lubbock, TX

Abstract: BACKGROUND: p53 protein is known to play a critical role in mediating the several cellular mechanisms, including as cell cycle arrest, apoptosis, and cellular senescence. Its functions are largely implicated in several neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. Most importantly, the oncoprotein MDM2 is known to bind to the N-terminal transactivation domain of p53, which promotes tumorigenesis. The purpose of our study was to understand the physiological relevance of p53 and MDM2 interactions in tumors. METHODS: Machine learning has been used in several applications of biomedical research where for a given datasets an acceptable generalization will be obtained using different algorithms. In this study, a diverse predictive model was employed to perform predictions on the impact of mutations in p53-MDM2 interaction. p53 mutations were collected from the public domain databases and literature search using Pubmed. Molecular interactions between the complexes were analyzed using protein-protein docking servers. Mutations in the p53 transactivation domain were induced using pymol followed by the energy minimization. Predictive models for the mutant and native complexes were built using artificial neural network algorithms. RESUTS: Results showed that a large deviation in the total solvent accessible surface area, structure solvent energy and average gain in the complex formation properties of mutant p53-MDM2 complexes compared to the native ones. Neural network analysis showed that structural features are important for predicting the impact of mutants on p53-MDM2 interaction. CONCLUSIONS: Based on the analysis of results, it is evident that the integration of machine learning approaches can provide a promising inference on the impact of mutations on the protein-protein interactions

Title: Model-based control of spreading depression

Authors: ***S. VAN WERT**[1], S. J. SCHIFF[2];
[1]Engin. Sci. and Mechanics, [2]Neurosurgery, Engin. Sci. and Mechanics, and Physics, The Pennsylvania State Univ., University Park, PA

Abstract: Spreading depression is a wave-like neural phenomenon that occurs in the cortex of the human brain and is linked to disorders of the brain such as migraine, epilepsy, and stroke. We propose a cellular model of the brain that, with only differences in environmental conditions, replicates the cellular dynamics of these varying pathological phenomena, and with this model we create a model-based control scheme that could be used in novel treatment technologies for those pathologies in a clinical setting. The model's capability of unifying seemingly different pathological phenomena with the same set of modeled cellular dynamics is created by a few important changes to standard neural modeling. Notably among those changes are the tracking of the large deviations in the ionic concentrations of the cellular environment and also the tracking of the energy use and volume regulation of the cell as it responds to disruptions from homeostasis. These properties are critical for modeling of pathological dynamics like SD, but are typically ignored in standard computational neural models of healthy tissue. Building and investigating a model of spreading depression that tracks these variations allows us to determine best practices for understanding and treating or preventing the disorders it is associated with in real brain tissue. To demonstrate the possible use of this model in translational and clinical applications, we describe a model-based control mechanism for interacting with the cellular environment by application of electrical field as a route to possible treatment. Global application of electric field can both affect the transport of ions along diffusion channels that buffer extracellular ion concentrations space, and an electric field can also affect current running both along and across the membrane in a spatially extended neuron. In search of viable control schemes for potential use in treatment, we demonstrate the plausibility and effectiveness of several model-based control schemes to alter the neural dynamics so as to prevent or modulate

the pathological phenomenon of not only SD but related pathophysiological behaviors of seizure and stroke as well. The implemented controllers provide novel approaches for universal treatment of pathologies in neural tissue. These treatments would maintain a stable environment that avoids excessive demands on energy, as well as significant disruptions to the local ionic environment. This model-based control lays a foundation for medical technology that monitors critical features of brain dynamics and supplies an appropriate and safe treatment stimulus.

Title: Validation of a novel 3D particle tracking tool for next generation neuroscience microscopy

Authors: *S. V. ALWORTH[1], M. J. JONES[1], V. CHOU[2], D. VAN VACTOR[2], J. S. J. LEE[1]; [1]DRVision Technologies LLC, Bellevue, WA; [2]Dept. of Cell Biol., Harvard Med. Sch., Boston, MA

Abstract: Time-lapse, 3D imaging of functional neural networks, composed of many neurons connected through a complex web of synapses, is a promising approach for gaining in-depth understanding of how the central nervous system (CNS) works. Using high speed confocal fluorescence microscopy, 3D image sequences are routinely acquired to elucidate the development of functional circuits, as well as the molecular kinetics and interactions that drive CNS development or pathological degeneration. It is now possible to image more complex and intact neural circuits in the CNS *in situ* with high lateral and axial resolution. Imaging of these new model systems could unleash a new generation of scientific inquiries that would lead to new discoveries and therapies. However, 3D neuronal image sequences exhibit low signal to noise ratio (SNR) while the more physiological environment exacerbates the complexity of molecular particle motion. Therefore, quantification of particle dynamics and molecular interactions in these complex models is challenging due to the lack of adequate 3D image analysis methods. To meet the above challenges, we have developed a novel 3D particle tracking method and software prototype, designed for highly sensitive particle detection in low SNR images, and also for

adaptive tracking of particles with heterogeneous types of motion. Adaptive tracking is enabled through a general computational framework that represents object states and state transitions dynamically, and provides for state dependent feature point detection and track matching. In addition, two methods of track matching error correction are employed; one that uses motion energy independent of matching and other that uses user defined state profiles to guard against invalid state transitions. In this study, we use simulated images containing heterogeneous motion, variable particle densities and noise levels, and non-simulated biological images to validate the new methods. We quantitatively evaluate the robustness of the new method to different noise levels and particle densities, and benchmark against common particle tracking methods. Lastly, we compare to manual analysis on real, non-simulation 3D image sequences. Our objectives are that our new 3D tracking tool should 1) perform at least as well as our 2D tracking algorithms benchmarked previously using stand metrics from the IEEE particle tracking challenge (α, β, and the Jaccard similarity index for positions and tracks), and 2) that there should be no significant difference from the manual analysis on real images. We conclude that the new tool meets the objectives and compares well against conventional methods of 3D particle tracking.

Title: Neuronal network bump attractors augmented by calcium up-regulation of Ih in a multiscale computer model of prefrontal cortex

Authors: ***A. SEIDENSTEIN**[1,2], S. A. NEYMOTIN[3], A. FESHARAKI[3], M. L. HINES[4], R. A. MCDOUGAL[4], A. S. BULANOVA[3], W. W. LYTTON[3];
[1]CBE, NYU-Polytechnic Sch. of Engin., Brooklyn, NY; [2]Nbs, SUNY Downstate Med. Ctr., Brooklyn, NY; [3]Downstate Med. Ctr., Brooklyn, NY; [4]Yale, New Haven, CT

Abstract: Prefrontal cortex (PFC) is thought to be a site of short term memory based on persistent neuronal activity. Previous models have focused on the role of network connectivity via excitatory interconnections in maintaining activation to represent memory through bump attractors. We extended this model by taking account of roles of subcellular and cellular dynamics. A multiscale NEURON model was used to study dynamics across molecular, cellular and network scales. We focused on the role of calcium influence, via calcium-induced calcium release from endoplasmic reticulum (ER), on the hyperpolarization-activated cyclic-nucleotide gated (HCN) channels that produce Ih. This release was influenced by the network through the influence of metabotropic glutamate receptors (mGLUR) in excitatory neuron dendrites which produced IP3 through a G-protein mediation. The network itself was represented by 776 multicompartmental excitatory and inhibitory neurons arranged in the canonical cortical layers, and connected via metabotropic and ionotropic receptors (AMPA/NMDA, GABAA/GABAB). The network enabled individual neurons to maintain tonic NMDA synaptic activation to maintain sustained firing via mutual activation after a strong, brief excitatory stimulation, the classical bump attractor model of Wang et al (J Neurosci 19: 9587,1999). Activity was further augmented through cellular mechanisms, with higher availability of Ca up-regulating Ih, given preceding inhibitory-activation of Ih in the individual neuron through tonic bombardment of GABAA. GABAA therefore played a dual role -- preparing a population for greater augmentation through activation of Ih and also suppressing non-selected cells during the period of bump activation. Glutamatergic activation also played a dual role: metabotropically preparing cells by allowing higher ER storage of Ca prior to stimulation, and ionotropically maintaining activation during the bump. The interactions between the metabotropic and ionotropic inputs to the neuron demonstrated how multiple pathways could contribute in a complementary manner to persistent activity. The network showed a complex interdependence between synaptic weights, excitation/inhibition balance, firing rates, membrane depolarization, Ca levels, regulation of HCN, and induction of persistent activity. The ability to mediate activation at different time scales, and through different pathways, would be expected to protect against disruption, in this case providing stability for working memory.

Abstract: Electrical stimulation through direct electrical activation has been widely used to recover the function of neurons, primarily through the extracellular application of thin film electrodes. However, studies using extracellular methods show limited ability to reveal correlations between the cells and the electrical stimulation due to interference from external sources such as membrane capacitance and culture medium. Here, we demonstrate long-term intracellular electrical stimulation of undamaged pheochromocytoma (PC-12) cells by utilizing a vertical nanowire electrode array (VNEA). The VNEA was prepared by synthesizing silicon nanowires (SiNWs) on a Si substrate through a vapor-liquid-solid (VLS) mechanism, and then fabricating them into electrodes with semiconductor nanodevice processing. PC-12 cells were cultured on the VNEA for 4 days with intracellular electrical stimulation, and then a 2-day stabilization period. Periodic scanning via two-photon microscopy confirmed that the electrodes pierced the cells without inducing damage. Electrical stimulation through the VNEA enhances neuronal differentiation and neurite outgrowth by about 50% relative to extracellular stimulation under the same conditions. VNEA-mediated stimulation also revealed that cellular differentiation and growth in the cultures were dependent on the potential used to stimulate them. Intracellular stimulation using nanowires could pave the way for controlled neuronal differentiation and outgrowth studies in living cells.

Title: Sharing electrophysiological data and the CARMEN project

Authors: *L. S. SMITH[1], E. SERNAGOR[2];
[1]Univ. of Stirling, Stirling, United Kingdom; [2]Inst. of Neurosci., Univ. of Newcastle, Newcastle, United Kingdom

Abstract: Many journals and research funders now demand that researchers make their datasets, metadata, and processing software publically and permanently available once their work is published: indeed, repeatability of results and re-use of materials for cross-analysis requires this. Often the mechanism for archiving is unspecified. The International Neuroinformatics Co-ordinating Forum (INCF) keeps a list of re-usable Neuroscience (including Neurophysiology) resources at http://incf.org/resources/research-tools. In addition, the INCF's Electrophysiology Task Force maintains a list of resources for data sharing in (Neuroimaging and) Electrophysiology at http://tinyurl.com/d7f35qb. However, many of these are intended for specimen datasets, rather than data generated during research. The UK based CARMEN project (https://portal.carmen.org.uk) is a portal based collaborative facility for neuroscientists (and in particular electrophysiologists) to share data and tools for working on data. Started 2006, it has been providing a gradually improving service for about seven years. The system can translate many common formats into has its own internal format: it now also has the ability to generate a quick graphical display of datasets. Though successful for enabling geographically distributed groups to share data and techniques, it has been less successful at being used for publically available data. Neuroinformaticians are already convinced of the importance of data sharing, so it is imperative to find out what is impeding uptake by experimentalists. Following a questionnaire issued to users (and non-users) we found that the issues were partly ease of uploading (speed, and issues with metadata), difficulties in finding and using services and developing and using workflows. Many users only wanted archival capability, and found the system complex. Yet other users have used the system in a much more powerful way, performing historic cross-analyses which hopefully will pave the way for others to start using the resource to its full potential. Long term storage and archiving of data and processing techniques demands long term funding of infrastructure projects. Yet although publishers and funders want this, it remains difficult to fund such projects for the long term.

Title: NeuroGPS-Tree: Automatic reconstruction of a large-scale neuronal population with dense neurites

Authors: *S. ZENG;
Huazhong Univ. of Sci. & Technol., HB, China

Abstract: Tingwei Quan[1,2,3], Hang Zhou[1,2], Jing Li[1,2], Shiwei Li[1,2], **Qingming Luo[1,2], Hui Gong[1,2]*, Shaoqun Zeng[1,2,]*** [1]Britton Chance Center for Biomedical Photonics, Huazhong University of Science and Technology-Wuhan National Laboratory for Optoelectronics, Wuhan 430074, China [2]MoE Key Laboratory for Biomedical Photonics, Department of Biomedical Engineering, Huazhong University of Science and Technology, Wuhan 430074, China [3]School of Mathematics and Statistics, Hubei University of Education, Wuhan 430205, China To whom correspondence should be addressed. E-mail: huigong@mail.hust.edu.cn, sqzeng@mail.hust.edu.cn **Abstract** The mapping of neuronal circuits plays an important role in studies of the brain. Automatic reconstruction of neuronal populations, a key step in drawing neuronal circuits, remains a challenge due to the high density of neurites. Here, we show the dense reconstruction of a neuronal population by partially mimicking the strategy of an experienced technician. We progressively approach the right reconstruction by repetitively using statistical information about neuronal morphology at multiple scales. For neuronal populations not resolvable by the latest or best available methods, our method achieved a reliable reconstruction with recall and precision rates of approximately 80%. We also demonstrate the reconstruction of a population of 990 neurons within 3 hours and show the potential to quickly reconstruct large-scale neuronal populations.

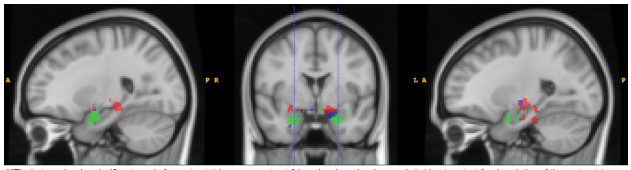
Title: Dissociable functional activation within MTL during pattern separation measured using high-resolution BOLD fMRI at 7 Tesla

Authors: *S. DAS[1], J. DUDA[2], J. WU[3], M. DAFFNER[4], M. ELLIOTT[5], L. MANCUSO[4], L. WISSE[5], P. YUSHKEVICH[5], D. WOLK[6];
[1]Univ. of Pennsylvania, Bear, DE; [2]Penn Image Computing and Sci. Lab., Univ. of Pennsylvania, Philadelphia, PA; [4]Neurol., [5]Radiology, [3]Univ. of Pennsylvania, PHILADELPHIA, PA; [6]Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Introduction: *In vivo* ultra-high resolution BOLD fMRI of human medial temporal lobe (MTL) at 7T was used to localize functional activation within small MTL subregions. A task operationalized episodic memory constructs of pattern completion/separation and recollection/familiarity, some of which have been shown to be dissociably subserved by different MTL subregions in animal studies, but not yet in humans. **Methods:** Eleven young healthy control subjects were imaged on the Siemens 7T scanner. Imaging included 0.8x0.8x0.8 mm^3 T1-MRI, 0.4x0.4x1.0 mm^3 T2-MRI, 1x1x2 mm^3 GRE-EPI, and a B0 map sequence for distortion correction. In an event-related fMRI paradigm, subjects viewed image pairs of common objects during study phase, and were later shown intact pairs, rearranged pairs, or novel pairs during test phase. They had to endorse only an intact pair as "old", "new" otherwise. Different combinations of trial type and response operationalized different memory constructs, and were modeled in the fMRI data. **Results:** Groupwise analysis examined the following activation contrasts in MTL: 1) Comparison of correct "new" endorsements of rearranged pairs vs. "old" endorsements of intact pairs, 2) Comparison of correct "new" endorsements of rearranged pairs vs. "new" endorsements of novel pairs. Based on models of pattern separation/completion and the underlying MTL substrates, these two contrasts were expected to produce dissociable activations within the hippocampus/MTL. The first condition resulted in primarily anterior clusters (total volume 9984 mm^3), and the second in primarily posterior clusters (total volume 4800 mm^3), while the volume of overlap between them was 824 mm^3 (see figure). **Conclusions:** Our study demonstrates the ability to dissociate functional activation between the anterior and posterior aspects of the hippocampus/MTL depending on the specific memory constructs under comparison. Finer scale assessment using hippocampal and MTL cortex subregions defined in high-resolution MRI may help further elucidate the substrates of episodic memory constructs.



MTL clusters showing significant voxels for contrast 1 in green, contrast 2 in red and overlapping voxels in blue (see text for description of the contrasts).

Title: Consistent data organization made easy: Versatile format for data and metadata

Authors: **A. STOEWER**[1], C. J. KELLNER[1], A. SOBOLEV[1], M. SONNTAG[1], J. BENDA[2], *T. WACHTLER[1], J. GREWE[2];
[1]Ludwig-Maximilians-Univ Munich, 82152 Planegg-Martinsried, Germany; [2]Eberhard Karls Univ., 72076 Tuebingen, Germany

Abstract: Managing neuroscience data requires the integration of information from multiple sources. Different types of recordings may be combined with elaborated stimulation, requiring background information or metadata to interpret them correctly. Storing such information consistently is an essential part of experimental research and depends crucially on available file formats. Many existing formats are vendor or domain specific, or provide only limited support for storing metadata along with the data. Here we present the NIX format [1], an open file format that is versatile enough to represent various kinds of data in conjunction with metadata to facilitate data organization and data retrieval in the lab, as well as data sharing. The format is compliant with the INCF requirements for storing electrophysiology data [2]. It enables storing recorded or derived data as well as all the meta-information about the experimental context, accounting for the relationships between data items. Data arrays are defined with units and dimension descriptors, so that the stored data can be readily interpreted as recorded quantities. The format further enables specifying the relationships between the data arrays and to describe points or regions of interest, such as areas in an image or events in a recorded signal. The NIX software libraries support direct access to these targeted parts of the data and the linked

metadata. This enables selecting specific subsets of the data, such as signals recorded from a certain electrode channel, or spike trains from a certain single unit in trials with a given stimulus. NIX stores data and metadata using the HDF5 format [3]. While it is possible to read and write these files using the standard HDF5 libraries, efficient use of the features of the NIX format is facilitated by specific libraries provided for different languages, including C++, Python [4], Matlab [5], and Java. Packages and installers for different platforms are provided, as well as detailed documentation, examples, and tutorials [6]. The NIX file format supports comprehensive annotation and efficient organization of neuroscience data, and the variety of libraries makes it easy to integrate access to data and metadata in the lab data collection and analysis workflow. Title: Parallel Reaction-Diffusion simulation in NEURON

Authors: ***C. TROPPER**[1], L. ZHONGWEI[2,3], R. A. MCDOUGAL[4], M. HINES[4], W. LYTTON[5];
[1]Dept. of Computer Sci., McGill Univ., Lake Placid, NY; [2]Dept. of Computer Sci., McGill Univ., Montreal, QC, Canada; [3]Computer Sci., NUDT, Chendu, China; [4]Neurobio., Yale Univ., New Haven, CT; [5]pharmacology and physiology, SUNY Downstate, brooklyn, NY

Abstract: We previously developed a stochastic parallel discrete event simulator (Neuron Time Warp), NTW was interfaced with 1D and 3D deterministic reaction diffusion simulators within NEURON. The objective of using stochastic simulation is to portray the variable effects of a small number of molecules in, for example, a dendritic spine. We have developed a threaded simulator, NTW-MT. The reason for developing the threaded version is to take advantage of multi-core architectures employed in parallel machines so that we can increase the speed of a simulation and to be able to simulate larger models. One thread takes care of communications while the others take care of computation. Communication between threads makes use of shared memory if the threads are in the same process and by MPI if they are in different processes. A multi-level queueing stucture is employed for the priority queue. Both NTW and NTW-MT make use of a stochastic simulation algorithm, the next sub-volume method (NSM), which is an outgrowth of the Gillespie algorithm. We simulated a discrete event model of a Ca wave on an un-branched apical dendrite of a hippocampal pyramidal neuron on both NTW and NTW-MT. The model we used was derived from a deterministic model (1). NTW-MT scaled well with the size of the model and its execution time scaled well with the number of cores. It performed much better then the process-based NTW as well as a multi-threaded version of NTW which did not employ its multi-level priority queue. While our results indicated that execution time scaled well with the number of processors, the number of rollbacks also increased and caused the decrease in execution time to flatten. Both dynamic window management and dynamic load balancing are necessary in order to contain the number of rollbacks. The window size controls the optimism of Time Warp, preventing an excessive number of rollbacks. We have previously developed AI based algorithms for dynamic load balancing and window management-we are going to implement them in NTW-MT (simulated annealing, multi-state Q-learning and genetic algorithms) shortly. Title: Molecular Networking of oxytocin in Brain- relevance to Alzheimer's pathology

Authors: *I. TEJADA, J. KOSAGISHARAF;
Ctr. for Neurosci., INDICASAT AIP, Panama City, Panama

Abstract: Alzheimer's disease (AD) is a complex neurological disorder with several unequivocally identified genetic risk factors. Among the several environmental factors proposed for AD, dietary molecules act as protective and also risk factors have been most compelling. In particular, diets rich in saturated fatty acids and deficient in antioxidants and vitamins appear to promote the onset of the disease, while diets rich in unsaturated fatty acids, vitamins, antioxidants, and wine likely suppress its onset?. Evidence suggests that diets rich in polyphenols and some spices suppress the onset of AD by scavenging free radicals and preventing oxidative damage. Further, Metal ions are known to catalyze the production of free radicals and induce neurodegeneration. Several studies have also identified metals such as Pb, Fe, Al, Cu and Zn play a role in AD pathogenesis. Metals, Oxidative stress, decrease in antioxidants etc, could possibly lead to AD pathology. We are investigating biological molecules present in the body which can manipulate the above biochemical complex situation. We developed theoretical model to understand the role of responsive molecules namely oxytocin in modulating Alzheimer's disease pathology. We developed networking models to understand how oxytocin interacts with different pathological events and develop protection strategy against neurodegenerative pathways. We used data mining, cluster model and predictive interactive pathway models. The focus is on how oxytocin modulates hypothalamus stimulation, APP processing, abeta aggregation modulations, overcoming oxidative stress and providing a clue on emotional failures etc. Using networking model data, we propose the preventive/therapeutic potential of oxytocin for Alzheimer's diseases (Ivana is awarded IBRO-SFN travel award 2015 and Rao KS is supported by SNI grant of SENACYT, Panama and this work is supported by Melo Brain Grant, Panama).

Title: Improving accuracy of site-specific selection pressure analysis of deeply conserved post-synaptic proteins

Authors: *M. PAJAK[1], C. R. BRAMHAM[2], T. I. SIMPSON[1,3];
[1]Sch. of Informatics, Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Dept. of Biomedicine, Univ. of Bergen, Bergen, Norway; [3]BIOSS, Edinburgh, United Kingdom

Abstract: Sequence conservation analysis of the post-synaptic proteome (PSP) revealed that some of the key synapse protein classes emerged in primitive organisms prior to the development of the nervous system. A common procedure in molecular phylogenetics is to use all available ortholog sequences of a target gene to construct a multiple sequence alignment (MSA). The number of annotated genomes grows constantly and this trend is likely to accelerate in the years to come. However, distribution of available annotated genomes on the tree of life is biased towards complex vertebrate organisms, especially mammals, which in turn biases the availability of orthologs for MSA. Here we have quantified the influence of this bias on the downstream phylogenetic analysis, specifically on site specific selection pressure estimates. In parallel we have tested the effect of eliminating poorly aligned columns of MSA which had been previously shown to improve accuracy of the analysis. In our study we discuss the overarching question of whether reducing the size of MSA (in both dimensions) can improve its informativeness for detecting sites under positive/negative selection pressure. Finally, we show the application of our benchmark workflow to a set of deeply conserved elements of PSP in a domain-centric selection pressure analysis setting.

Title: A novel approach to study network interactions in cortical cultures

Authors: A. WILDEMAN[1,2], J. E. JURELLER[3], J. C. WANG[1], J. D. MARKS[1], *W. VAN DRONGELEN[4,2];
[1]Dept. of Pediatrics, [2]Committee on Computat. Neurosci., [3]Inst. of Biophysical Dynamics NanoBiology Facility, Univ. of Chicago, Chicago, IL; [4]Dept Pediatrics, Univ. Chicago, Chicago, IL

Abstract: The difficulty in relating macroscopic, emergent phenomena to microscopic properties is a central problem in neuroscience, both in network physiology (e.g. memory, learning) and pathology (epilepsy, schizophrenia). Network function is determined by properties that emerge from the complex, nonlinear interactions between the nodes in the network and our aim is to develop a novel approach to study the effects of these interactions with high temporal precision, spatial resolution, and spatial range. Our methodology manipulates of neuronal connectivity to explore the effects of low-level network properties on emergent macroscopic behavior. We have designed a system in which cultures of dissociated neurons grown on a multi-electrode array (MEA) can be manipulated by the introduction of real-time feedback loops mimicking additional synaptic connectivity. This is achieved by illuminating a small area of the culture and thereby releasing caged neurotransmitter, in reaction to recorded activity elsewhere in the culture. To create the flexibility required to freely add connectivity anywhere within a culture, we incorporate a digital micromirror device (DMD), an array of many small, individually controlled mirrors. The DMD allows us to dynamically select sections of the culture to be illuminated. The 1024x768 DMD grants a 2 μm resolution when covering a square 1.6 mm MEA. We employ a custom high-power LED light source and have developed an optical setup to generate and guide light to the DMD and subsequently to the MEA. As natural synaptic connectivity occurs on a millisecond timescale, we implement the feedback loops, including spike detection on the MEA electrodes, artificial connectivity and the control of the DMD, on a digital signal processor (DSP), which is a dedicated processor embedded in the MEA data acquisition system and avoids the additional delay and jitter that would be introduced by having a PC control the feedback. Preliminary experiments have illustrated that we can alter the behavior of dissociated cultures of rat hippocampal neurons by feedback alone. Through the combination of MEA, DMD and DSP technologies, we are thus able to dynamically specify network interactions with micrometer and microsecond precision and create the possibility of manipulating connectivity on this scale in order to investigate its effects on emergent network properties.

Title: Whole exome sequencing identifies new genes associated with sporadic trios in ALS

Authors: K. B. AHMETI[1], *F. FECTO[1], K. B. AHMETI[1], Y. YANG[1], N. SIDDIQUE[1], J. YAN[1], M. PERICAK-VANCE[2], H.-X. DENG[1], Y. MA[3], T. SIDDIQUE[1];

Abstract: Whole Exome Sequencing has become a new means of identifying mutations in coding regions of the human genome. Fifty families of trios with sporadic sporadic ALS (50 trios), recessive ALS (2 families) were prepared using the Agilent SureSelect 70 MB kit and sequenced in Illumina HiSeq2500. The data were analyzed using a High Power Computing built in house. Open source bioinformatics tools such as BWA, SAMtools, GATK, Picard, and VCF as well as in house developed scripts and analytic models allowed us to identify novel variants. Statistical analysis of the coverage showed that over 99% of the exons were covered in most of the samples with average depth of 120x (range per sample was 70x-210x). An average of 550,000 to 750,000 variants per sample were generated. After filtering them further 400-700 novel variants were identified in the coding region. Subsequently, we focused on identifying common variants among all of the samples. The common variants were verified using conventional Sanger sequencing. Furthermore, to verify the statistical importance of these mutations mathematical modeling in logistic regression analysis was used to identify nuclear, mitochondrial and RNA pathways, which may have direct impact on the disease. We next performed Immunohistochemistry on autopsy tissue samples from patients to explore the

involvement of the identified genes/proteins in disease pathogenesis. In-vitro and *in vivo* cell modeling is currently underway to verify the functionality of identified mutations. Whole Exome Sequencing is a powerful tool that has allowed us to identify mutations in both familial and sporadic cases of neurodegenerative diseases.

Title: Hybrid 1d/3d reaction-diffusion in the neuron simulator

Authors: *R. A. MCDOUGAL[1], A. S. BULANOVA[2], M. L. HINES[1], W. W. LYTTON[2,3]; [1]Neurobio., Yale Univ., New Haven, CT; [2]Physiol. and Pharmacol., SUNY Downstate, New York, NY; [3]Kings County Hosp., New York, NY

Abstract: Neuroscience simulators provide a framework for combining experimental observations to make predictions about neurons and networks of neurons that are impossible or impractical to measure directly with current technology. Each simulator necessarily has a domain of applicability. The NEURON simulator, used in over 1500 publications, has traditionally focused on problems dominated by electrophysiology, but we recently introduced a reaction-diffusion module to facilitate the specification of problems of that type. Stochastic 3D simulations are essential for studying highly localized phenomena (e.g. calcium microdomains), but this approach becomes computationally infeasible as the problem size increases, as is necessary for calcium waves which can spread over a large portion of a pyramidal cell's apical dendrite. Using a cartesian mesh and a deterministic solver provides well-understood accuracy and stability, but requires tiny voxels to represent the shape of the dendrites which in turn force small time steps to ensure stability. Tetrahedral meshes can represent the morphology more accurately with less compartments, but these present their own difficulties. To avoid these

problems, we are introducing support for hybrid 1D-3D studies in NEURON. Each section of the morphology may be either simulated in 1D or 3D. Fluxes across a 1D-3D border are based on the concentrations in the end-segment of the 1D domain and on the edge disc of voxels in the 3D domain. We use a model of a propagating calcium wave to illustrate our approach. In the 1D version of our model, the gradient at the edge of the wave is sufficiently gradual that we did not expect significant variation across a dendrite. We verified this expectation with a 3D simulation stimulated by IP3 released at a single point. We then simulated calcium waves on traced pyramidal cells, with most of the dendrites in 1D and the soma and the proximal dendrites in 3D. By simulating the soma in 3D, we observed the wave slow and curve as it entered the soma. The speed of the wave as it enters the soma is a function of the amount of calcium sequestered in the ER, which is itself a function of previous electrical activity. The hybrid 1D/3D simulator provides a convenient and efficient tool for reaction-diffusion simulations that span multiple spatial scales.

Ctr., Chicago, IL, IL

Abstract: Only few histone modifications have been mapped in human brain. Trimethylated histone H3-lysine 4 is primarily distributed in the form of sharp peaks, extending in neuronal chromatin on average only across 500-1500 base pairs mostly in close proximity to annotated transcription start sites. However, it remains unclear whether a subset of H3K4me3 peaks could extend across much broader domains. Here we use next generation sequencing based methods to profile the epigenomic landscape of human, chimpanzee, and macaque prefrontal cortex (PFC) neurons from subjects with healthy controls and provide an innovative approach to identify broadest domain cell-type specific H3K4me3 peaks in neuronal and nonneuronal cells from prefrontal cortex (PFC) - a brain region that contributes to cognitive abilities unique to human - in comparison to nucleated blood cells in an unbiased manner. In PFC neurons, broadest peaks ranged in size from 3.9 to 12kb, with extremely broad peaks (~10kb or broader) related to synaptic function and GABAergic signaling (DLX1, ELFN1, GAD1, LINC00966). Broadest neuronal peaks showed distinct motif signatures, and were centrally positioned in prefrontal gene-regulatory networks. Approximately 120 of the broadest H3K4me3 peaks in human PFC neurons, including many genes related to glutamatergic and dopaminergic signaling, were fully conserved in chimpanzee, macaque and mouse cortical neurons. Exploration of spread and breadth of lysine methylation markings could provide novel insights into epigenetic mechanism involved in neuropsychiatric disease and evolution of neuronal genomes.

Title: Self-organized information routing and processing in neuronal networks

Authors: *C. KIRST;
The Rockefeller Univ., New York, NY

Abstract: Flexible information routing and context dependent processing fundamentally underlies the function of neuronal networks. How information may be specifically processed and dynamically routed in these systems is however not well understood. Here we show that in

complex networks information can 'surf' on top of collective dynamical reference states. Switching between collective dynamics induces fast and flexible reorganization of information routing between the network's units. We use this principle to show how networks can perform context-dependent processing in a self-organized way. In oscillatory Hopfield-Networks we show how multi-modal pattern recognition and context-dependent processing can be implemented by making use of collective network dynamical states. Our work more generically shows how collective reference dynamics can be assigned an important functional role during information processing and pattern recognition tasks. Our results have applications for the design and learning of information routing in neuronal networks where collective dynamics co-occurs with a communication function and the data analysis of recordings of neuronal network activity.

Title: Life after streamlines: Describing structural connectivity with Reeb graphs

Authors: *M. CIESLAK[1], J. SUN[2], L. VOLZ[3], S. SURI[2], S. T. GRAFTON[3];
[1]Psychological and Brain Sci., UCSB, Santa Barbara, CA; [2]Computer Sci., [3]Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Noninvasive study of white matter pathways in the human brain is typically achieved by performing fiber tracking on diffusion-weighted MRI. Fiber tracking produces a set of streamlines, which are arrays of 3D coordinates that in most cases trace the paths of axons through white matter. While visually compelling, streamlines can overestimate connectivity by tracking spurious paths and underestimate connectivity by failing to connect regions when their axons merge and split from a larger bundle. Here we present an algorithm that segments streamlines into coherently-moving “bundles” separated by merging or splitting events. These bundles form a spatial graph-like structure where nodes are merge/split events and edges are bundles. We demonstrate how this graph structure describes motor/premotor connectivity more

accurately than streamlines alone. The reproducibility of bundle segmentations is demonstrated across a cohort of 88 diffusion spectrum imaging streamline datasets.

Title: Reliability at a macroscopic level in recurrent neural networks: An approach based on canonical correlation analysis

Authors: *H. SUETANI;
Oita Univ., Oita, Japan

Abstract: Since the seminal work by Mainen and Sejnowski, how neural activities are *reliable* against stimuli is an important topic in neuroscience from the viewpoints of transmission of information and neural coding. It has been widely known that in the single cell level, spike timings are reproducible over different trials under the influence of noisy stimuli whereas constant stimuli lead to imprecise spike trains. In this paper, we study how the information of the stimuli from the outside can be maintained in neural activities as a *macroscopic* behavior, i.e., not in the single cell level but in the network level using computational neural network models. Preliminary results are shown in the below. Figure 1(a) shows several time series of three different recurrent neural networks (network connectivity is different each other) with 10^3 neurons subject to the same periodic input with small amplitude. Here, no one can see any reproducibility within the single as well as across different networks. How about the dynamics of a macroscopic level? Figure 1(b) shows time series of the first components of Principle Component Analysis (PCA) for three networks (different colors indicate different networks). No one can see any reproducibility in these again. On the other hand, when we apply *Canonical Correlation Analysis (CCA)*, we can see the same time series with the input periodic signal in the corresponding first components of CCA as shown in Fig. 1(c). PCA and CCA are methods of projections from high-dimensional data to lower-dimensional data. This result means that reproducible activities are hidden in the network level even if the stimulus is tiny and can be

detected by choosing a suitable direction of the projection. We will discuss further results in the presentation.

Title: Network models of sequence generation and memory

Authors: *K. RAJAN[1], C. D. HARVEY[3], D. W. TANK[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ; [3]Harvard Med. Sch., Boston, MA

Abstract: Cellular-resolution imaging of neural activity in PPC during a virtual memory-guided 2-alternative forced choice task [Harvey, Coen and Tank, 2012] has showed that individual neurons had transient activation staggered relative to one another in time, forming a sequence spanning the entire duration of the task. Motivated by these results, our goal here is to develop a computational framework that reconciles the emergence of biologically realistic assemblies or trajectories of activity states, with the ability of the same neural population to translate sensory information into long time-scale behaviors. We build an echo state network to test our hypothesis that during memory-based decision making, sensory cues set up an initial network state that follows the intrinsic dynamics of the brain area to generate activity underlying a behavioral response. We start with a firing rate network which exhibits rich ongoing dynamics correlated over numerous time scales. This network acts as a dynamic reservoir whose modes can be tapped to perform the task through minimal reconfiguration or partial in-network training (PINning), and not complete rewiring. During PINning, only the outgoing weights carrying the synaptic inputs from a subset of neurons in the network are subject to change. There is no external unit that feeds back network output, no learning of readout weights. The learning rule targets only as many units as required for accomplishing the task, the fraction varying with task demands. We show that the PINned network performs a timing task involving a sensory cue, its storage in

working memory during a delay period, and response to its retrieved trace. We change the fraction of trained units until the duration and shape of the sequential activation pattern in the network is comparable with PPC neurons imaged during the task. Further, we show that like the PPC, the network's activity is specific to cue/outcome pairing, temporally confined to a task epoch, and contains similar levels of extra-sequential noise. Notably, since no sequence-specific wiring diagram is embedded a priori units remain spatially intermixed, like the PPC, where there is no topological organization of active neurons. Finally, we study the properties and functional consequences of the synaptic connectivity matrix which is initially random but acquires non-normal features because of PINning. We are currently exploring whether such partially trained networks can be extended to simulate our ability to generalize across different task conditions.

Title: Probabilistic synaptic transmission and spike correlations in recurrent cortical networks

Authors: *M. LEONE[1], G. OCKER[2], B. DOIRON[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The origin of correlated spiking observed in cortical networks is currently unclear. Theoretical work shows that for large, dense networks, co-fluctuations of strong excitation and inhibition cancel one another, resulting in a network-wide asynchronous state of low mean spiking correlations. Most models of cortical networks tacitly assume that synaptic transmission is infallible, despite a wealth of experimental work to suggest otherwise. In this work, we study the asynchronous state of recurrent cortical networks where the probabilistic nature of synaptic transmission is taken into account, with a focus on the failure of transmitter release. As expected, synaptic failure of inhibition increases the mean firing rate and variability of spiking, even when the trial-averaged output of synapses for a given presynaptic spike train is held constant. However, in dense networks we also see a significant increase in the mean spiking correlations of the network, a result of the fluctuations in inhibitory currents becoming less able to track and cancel fluctuations in excitatory currents. This is counter-intuitive since the failure of synaptic

transmission is independent across synapses, and is at first glance a source of private fluctuations within the network. Our results suggest that the combination of synaptic transmission failure rates and the placement within the recurrent cortical circuit determine the impact of an inhibitory neuron subtype on network correlations. Finally, our results highlight the importance of considering the inherent stochasticity of synapses when studying the statistical activity of dense, recurrent networks.

Title: Development of a mathematical model of mitochondrial bioenergetics in cortical neurons

Authors: ***C. CADONIC**[1,6,2], E. THOMSON[1,6], W. SNOW[6], S. ROY CHOWDHURY[6], D. MCALLISTER[6], J. FIEGE[3], P. FERNYHOUGH[4,6], S. PORTET[5,2], B. C. ALBENSI[4,6,2]; [2]Grad. Program in Biomed. Engin., [3]Physics and Astronomy, [4]Pharmacol. and Therapeut., [5]Mathematics, [1]Univ. of Manitoba, Winnipeg, MB, Canada; [6]Div. of Neurodegenerative Disorders, St. Boniface Hosp. Res., Winnipeg, MB, Canada

Abstract: In this project, a mathematical model for mitochondrial function has been developed from oxygen consumption rate (OCR) and oxygen concentration data measured in the Seahorse XF24 Analyzer (Seahorse Biosciences). Measurements in the XF24 Analyzer were conducted on

embryonic-cultured cortical neurons from CD1 mice. Based on the biological mechanism of mitochondrial activity, a deterministic model was developed using biochemical kinetic modelling, and a stochastic validation model was developed using the stochastic simulation algorithm. The deterministic model was calibrated using the optimization genetic algorithm Ferret by fitting real-time OCR data. The model was then coded in MATLAB R2014a (Mathworks) for simulating mitochondrial bioenergetics in silico. To modulate the activity of the mitochondria, specific dysfunctions were introduced by injecting the inhibiting reagents oligomycin, rotenone, and antimycin A; and the uncoupling reagent carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP), during OCR measurements. To appropriately incorporate these changes, the model equations were adapted and then re-calibrated to the data for each biological condition. This indicated the flexibility of the model in addressing changes in the biological environment and the appropriate mitochondrial response. The model developed thus maintains the capacity to be expanded upon when calibrated to additional data sets, affording the ability to determine the mechanism of the kinetic changes required to represent biological results.

Title: Critical role of topography in determining spatio-temporal network dynamics in a large-scale model of hippocampus

Authors: *P. HENDRICKSON[1], G. J. YU[2], D. SONG[2], T. W. BERGER[2];
[2]Biomed. Engin., [1]USC, Los Angeles, CA

Abstract: This abstract describes a million-plus granule cell compartmental model of the rat hippocampal dentate gyrus, including excitatory, perforant path input from the entorhinal cortex, and feedforward and feedback inhibitory input from dentate interneurons. The model includes experimentally determined morphological and biophysical properties of granule cells, together with glutamatergic AMPA-like EPSP and GABAergic GABAA-like IPSP synaptic excitatory and inhibitory inputs, respectively. Each granule cell was composed of approximately 200 compartments having passive and active conductances distributed throughout the somatic and dendritic regions. Modeling excitatory input from the entorhinal cortex was guided by axonal transport studies documenting the topographical organization of projections from subregions of the medial and lateral entorhinal cortex, plus other important details of the distribution of glutamatergic inputs to the dentate gyrus. Information contained within previously published maps of this major hippocampal afferent were systematically converted to scales that allowed the topographical distribution and relative synaptic densities of perforant path inputs to be quantitatively estimated for inclusion in the current model. Results showed that when medial and lateral entorhinal cortical neurons maintained Poisson random firing, dentate granule cells expressed, throughout the million-cell network, a robust, non-random pattern of spiking best described as spatio- temporal "clustering". To identify the network property or properties responsible for generating such firing "clusters", we progressively eliminated from the model key mechanisms such as feedforward and feedback inhibition, intrinsic membrane properties underlying rhythmic burst firing, topographical organization of entorhinal afferents. Findings conclusively identified topographical organization of inputs as the key element responsible for generating a spatio- temporal distribution of clustered firing. These results uncover a functional organization of perforant path afferents to the dentate gyrus not previously recognized: topography-dependent clusters of granule cell activity as "functional units" or "channels" that organize the processing of entorhinal signals. This modeling study also reveals for the first time how a global signal processing feature of a neural network can evolve from one of its underlying structural characteristics.

Title: Biomechanics of membrane deformation under time-varying magnetic field - a shell model

Authors: *H. YE[1], A. CURCURU[2];
[1]Dept. of Biol., Chicago, IL; [2]Departmet of Physics, Loyola Univ. Chicago, Chicago, IL

Abstract: Background: Cells deform in a strong electric field (electrodeformation), suggesting an interesting control of cellular biomechanics by the electric field. An alternative method used to generate an electric field is by a time-varying magnetic field. References reporting the magnetic control of cellular mechanics have recently emerged. However, theoretical analysis of the cellular mechanics under a time-varying magnetic field is inadequate. Methods: We have previously developed an analytical theory to investigate the biomechanics of a modeled cell under a time-varying magnetic field (Ye and Curcuru, 2015). For computational reason, the model did not explicitly consider the capacitive properties of the membrane, which represents a complex boundary between the medium and the cytoplasm. In this work, we developed a shell membrane model to include the low-conductive, capacitive cell membrane. We provided detailed analytical solutions for the surface charges, electric fields and radial pressure across the membrane under a time-varying magnetic field. Frequency response of these measures were analyzed, especially for the frequency used in transcranial magnetic stimulation (TMS). Results: The induced surface charges interacted with the electric field to produce a biomechanical impact upon the membrane. The distribution of the induced surface charges depended on the orientation of the coil and field frequency. The direction of the radial force is a function of both the field frequency and the conductivity ratio (cytoplasm/medium). At low frequency, the deformation (pull the cells into a prolate shape or compress into oblate shape) purely dependents on the conductivity ratio. At relative high frequency, cell shape can transit from polate to oblate, for the low conductivity cases. Conclusions: This work provides an analytical framework and insights into factors affecting cellular biomechanics under a time-varying magnetic field. The analysis reveals many unique features of cellular biomechanics under time-varying magnetic field, in comparison with electric stimulation.

Title: Factors influencing current flow through the skin during transcranial electrical stimulation: role of waveform, tissue properties, and macro-pores

Authors: *N. KHADKA[1], B. GULEYUPOGLU[2], D. Q. TRUONG[2], V. PATEL[2], C. THOMAS[2], O. SEIBT[3], A. MOKREJS[2], M. BIKSON[2];
[1]Biomed. Engin., [2]City Univ. of New York, City Col., New York, NY; [3]City Univ. of New York,City college, New York, NY

Abstract: Fundamental questions remain about the mechanisms of transdermal current passage during transcranial electrical stimulation (tES) and approaches to optimize electrodes, waveform, and skin preparation to maximize tolerability. Examples of previously unexplained observations include 1) a higher impedance to DC (transcranial Direct Current Stimulation, tDCS) than to high-frequency stimulation, 2) skin lesions occur rarely at the electrode edges where prior models predict maximum current density, 3) abrasion appears to decrease tolerability in some instances (e.g. tDCS) and enhance it in others (e.g. Electroconvulsive therapy, ECT), 4) repeated stimulation sessions may enhance tolerability or increase irritation, 5) preference for gel or saline properties appears to vary across applications. We developed the first high-resolution FEM model of skin comprising sweat pores, epidermis, dermis, sweat glands, subcutis, hair follicles, and blood vessels. An analytical solution for skin permeability based on cylinders filled with saline to mimic sweat pores was also developed. We conducted experiments testing varieties of electrode assembly and characterized skin and gel response. Under the conditions tested, skin irritation reflects current passage rather than electrochemical burden. During tDCS, the epidermis present a significant captive barrier and current is predominately carried by sweat pores such that moisturizing the epidermis but not abrasion will increase tolerability. Regions of susceptibility are thus near larger sweat pores and not at electrode edges. During tES with higher frequencies, epidermal impedance decreases reducing required stimulation voltage and increasing tolerability. Thus depending upon the waveform applied, specific electrode design and skin preparation techniques can be rationally designed to enhance tolerability.

Title: Quantitative analysis on the impacts of dendritic morphology on neuron electrophysiology simulations

Authors: X. LIU, N. GOUWENS, Z. ZHOU, M. HAWRYLYCZ, C. KOCH, A. ARKHIPOV, *H. PENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: With the advent of semi-automated neuronal reconstruction techniques, neuroscientists have begun quantitatively analyzing morphometry at a large scale [NeuroMorpho.Org,Human Brain Project, BigNeuron] to investigate the diversity of the dendritic arborization and to provide input for neuronal simulations. Several studies have suggested that dendritic morphology directly influences neuronal firing activities [Mainen & Sejnowski, Nature 96']. However, how specific alterations in morphology affect electrophysiology modeling and simulation outcomes is still not well understood. Here we quantify the effects of dendritic morphology alterations on neuronal electrical behaviors in simulations based on single-cell electrophysiological recordings. As part of the Allen Cell Types Database, we have collected both the 3D neuronal morphologies and the corresponding physiology recordings for a number of individual cells representing a wide variety of neuronal types in the mouse cortex. We first use the recorded responses to subthreshold current injections to estimate three basic passive electrical parameters (intracellular resistivity, membrane resistivity and membrane capacitance) for each neuron via a model-fitting procedure. We then alter the morphologies by changing the diameters, length, and branch topology systematically and re-fit the electrical parameters with the newly-generated morphologies. We quantify the statistical differences in the estimated passive parameters to reveal the sensitivity to particular morphological adjustments. We also use active models of neurons (optimized to match the firing patterns of the recorded neurons) to investigate their sensitivity to these same alterations in morphology. Our study provides quantitative insights into how morphology variations affect physiological response in simulations as well as into the level of accuracy of morphological reconstructions needed for reliable physiology simulations.

Title: Reestablishing Ca^{2+} amplitude and speed during deep sleep in Alzheimer's disease with EEG-triggered TES/TMS: neuromodulation of abnormal columnar states

Authors: *J. F. GOMEZ-MOLINA[1], U. M. RICOY[3], J. VELEZ-M.D.[2], D. SEPULVEDA-FALLA[4];
[1]Intl. Group of Neurosci., Medellin, Colombia; [2]USA member, Intl. Group of Neurosci., New York, NY; [3]Biol., New Mexico Col., Northern New Mexico Col. NM, Española, NM; [4]Inst. of Neuropathology-, Univ. Med. Ctr. Hamburg-Eppendorf and Neurosci. Group of Antioquia, Fac. of Medicine, Univ. of Antioquia, Medellin, Colombia., Hamburg, Germany

Abstract: -INTRODUCTION. (1) Recent evidence shows that familial Alzheimer´s disease (AD)-associated presenilin-1 mutations alters calcium homeostasis in cellular models (http://www.ncbi.nlm.nih.gov/pubmed/22842534) and in fAD patients (Sepulveda-Falla, 2014), leading to neurodegeneration. (2) Previous computer simulations have suggested that in AD there are changes in the waveform of [Ca]i (increase in amplitude and speed) and this also occurs in deep sleep (Gomez 2003a,b). (3) *In vitro* experiments suggest that Ca-Channels have a frequency dependent behavior (Ricoy and Frerking 2014). (4) EEG-triggered TMS/TES (ETT) can amplify (or reduce) the amplitude of Calcium signaling (Gomez-Molina, SfN 2014). Here, we study the biophysical basis of this stimulation. -METHODS. Math-computer models. -THEORETICAL RESULTS. ETT can modify the amplitude and apparent speed of electrodiffusion of Ca2+ in a columnar structure. Fig. 1 -DISCUSSION. (1) If AD patients show increases in Ca2+-amplitude during wakefulness, should we reduce this amplitude during deep sleep or increase it? (2) Unpredictable effects of electrodiffusion of [Ca2+]o and effects on astrocytes should also be analyzed.(3) Experimental work is also required. -CONCLUSIONS. (1) Using ETT we can increase the Ca2+-amplitude and speed in macrocolumns with opposite local states to global EEG. This might improve function. (2) If local and global sleep present similar dynamics then reductions in amplitude can be expected during wakefulness after stimulation during sleep. (3) Weak and friendly stimulation is needed to avoid damage of delicate macromolecular nets around Ca-channels. (4) Presenilin mutations effect on Ca2+ signaling is characterized by increased intracellular levels mostly surrounding the ER, eventually affecting synaptic activity. This effect could result in excitotoxicity. Hence, alternatively, it could be desirable to reduce Ca2+ waveform amplitude by TES/TME stimulation in order to compensate ER Ca2+ leakage in neurons.

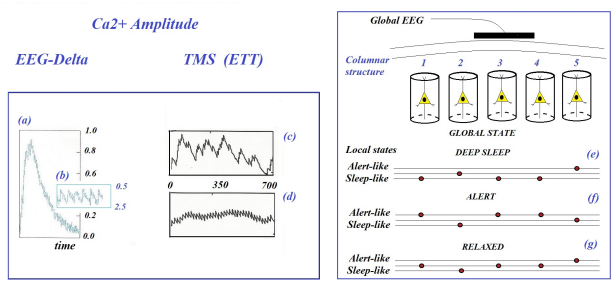

Fig. 1. Computer simulation. Ca 2+-amplitude is higher for bursting linked to EEG-delta (a) or local sleep in a columnar structure, than to tonic neural spiking associated to states of lower EEG-amplitude (b).

Computer simulation of the effects of EEG-triggered TMS (c) vs. TMS alone (d) in Ca2+-amplitude.

EEG-triggered TMS/TES (ETT) can be applied in a global state of deep sleep (e) when many columnar structures are in local sleep (columns 1, 3 and 4) but it can also be applied in global states of alert (f) or relax (g). In all these cases, the goal of stimulation is to change the state of column 2 –a column that is in an abnormal or pathological state. Column 5 is in a normal, physiological state, although this state is not of the same than the global state.

Title: Exploring the effects of spatial constraints on cell network formation in the dentate gyrus

Authors: *A. MERGENTHAL, T. BERGER;
USC, Los Angeles, CA

Abstract: The cross sectional geometry of the dentate gyrus changes dramatically over the septotemporal extent of the hippocampus. This geometry acts as a constraint on the formation of cellular networks between granule cells and the interneurons located within the hilus region of the dentate gyrus. It is not understood how these variations in network formation alter the cellular activity and computational roles of the cells which form these networks. We explored these effects using a large scale computational model of these cell networks. This model simulated the connections between entorhinal cortex cells, granule cells, basket cells, and HIPP cells. The NEURON simulation environment was used to construct this compartmental model. Cell numbers were one tenth of their measured or estimated populations. A three dimensional reconstruction of the rat dentate gyrus provided spatial measurements to constrain both axonal

and dendritic extents. These constraints provided a novel way to restrict connectivity between cells and provided a more anatomically appropriate simulated cell network. A second and third model were constructed each having the same cell numbers, types, and locations but changing the connectivity constraints such that one had no spatial restraints on connectivity while the other had a simple constraint based upon distance along the curve of the granule cell layer. The three alternate networks were then compared to see what effects the anatomical constraints produced in granule cell activity. Using these comparisons we can better understand how septotemporal variation in cross sectional shape effects the regional information processing roles of the dentate gyrus.

Title: Computational study of local field potentials in a heterogeneous 3D model of rat hippocampus

Authors: ***K. LOIZOS**[1], J. CLINE[1], G. YU[2], P. HENDRICKSON[2], G. LAZZI[1], T. BERGER[2]; [1]Univ. of Utah, Salt Lake City, UT; [2]USC, Los Angeles, CA

Abstract: A computational study was conducted to analyze different methods of simulating local field potential (LFP) recordings in a rat hippocampus model. Recorded LFPs summate the spatial temporal activity of the subregion surrounding the electrode. By including the tissue heterogeneity and complex behavior of the cellular network, the effect variation of these parameters has on the recorded potentials can be predicted. Multiple computational models of varying complexity were considered in this study, employing a multi-scale approach. A 3D discretized model of a hippocampus slice with multi-electrode arrays placed on the surface was utilized, constructed from a published atlas. It was discretized based on the tissue resistivity, implementing homogeneous properties for each tissue type in the hippocampus. Admittance method simulations were run, applying current sources to the electrode arrays. Generated voltages were then applied as extracellular voltage sources in a multi-cell compartmental model, which includes thousands of morphologically-unique granule cells, complex ionic membrane

channels, and innervating axons from entorhinal cortex. This process provides estimations of the reactive behavior of the network to electrical stimulation. The resulting membrane current due to any activated cells was then used to estimate LFPs at a given distance away, considering two methods. First, an analytical approach was considered, summing the contributions from all compartments in the network. Each value was computed using Ohm's Law, multiplying the membrane current by an approximate resistance based on the distance from the recording point and a uniform resistivity. Second, an Admittance Method simulation was conducted, following the simulation used to calculate the extracellular potential fields based on input current. For this simulation, the membrane currents were applied as the sources in a time-stepping simulation. The resulting potential field was then observed at the locations of recording electrodes. This method was then further expanded, incorporating the complex morphological data in the dielectric properties used to discretize the admittance model. By varying the complexity of the LFP calculations, we are able to compare results of different computational methods and with experimental data. In doing so, we provide data for deciding the necessary amount of computational complexity necessary for accurate predictions. In addition, the added parameters allow us to distinguish the contribution of individual cellular properties on the estimated LFP recordings.

Abstract: Scientific progress is increasingly enabled by data sharing. For example, astronomy and genomics have adopted data standards to enable research on shared data and the development of common data analysis tools. In contrast, most of neuroscience, including cellular-based neurophysiology, still takes place within boundaries of small laboratories and the communication between laboratories is largely by independent research papers. Little data is shared, and if it is so, the lack of a standard format causes labor overhead for customizing tools and hampers the comparison of data across laboratories. In the last 15 years various individual labs and initiatives have attempted to create a common data format for neurophysiology but none have found adoption by the larger community. To address this difficult problem, the Neurodata Without Borders--Neurophysiology initiative started in August 2015 with the goal to develop a common format between four large neurophysiology laboratories: the Buzsaki group at NYU, the Svoboda group at Janelia Farm, the Meister group at Caltech, and the Allen Institute for Brain Science. The result of the project is a common file format that represents a wide variety of neurophysiology data, including single-cell patch clamping, extracellular electrophysiology and optophysiology. The Neurodata Without Borders (NWB) format is implemented in HDF5 and is designed to store data in a self-documenting way. There is HDF5 support in Python, MATLAB and various programming languages including C++, making it a cross-platform solution. The storage schema is described by a specification language and it is extensible to support future scientific needs as well as lab-specific requirements. The format stores metadata about the experiment session and several varieties of time-series data, including measurements from electrodes, events, stimulus data and image stacks. It also stores the results of intermediate processing, such as spike waveforms, clustering data and unit times (electrophysiology), image segmentation and regions of interest (optophysiology) and positions (tracking). The initial NWB draft version has been released and is currently used to share data sets from the NWB collaborators at crcns.org. In addition, the Allen Institute for Brain Science has adopted the NWB format for all physiology experiments, including the electrophysiology characterization of single cells as a part of the publicly released Allen Cell Types Database. The NWB format will also be useful to other laboratories. Technical information about the format can be found at https://github.com/NeurodataWithoutBorders.

Title: Beer-lambert optical law applied to early steps of phototransduction

Authors: ***E. M. SALIDO**, L. SERVALLI, J. C. GOMEZ, C. VERRASTRO;
Natl. Technological Univ. (UTN), Ciudad Autónoma De Buenos Aires., Argentina

Abstract: Phototransduction classical models do not consider the reduction of available rhodopsin when it is activated by light and, consequently, do not account for the absorptance variation of the outer segment in different brightness conditions. The optical Beer-Lambert law describes the relationship between the light absorbed by a medium and its absorptance. This paper implements this concept and the bleaching phenomenon in equations that admit photons per second as input and resolve in active rhodopsins per second. In addition, this work compares the responses, both in active rhodopsins and in photocurrent, between a classical model of phototransduction developed by Forti et al. (1989) and a model proposed in this study. In Forti's equations, the amount of activated rhodopsin vs. light stimulus shows a linear relation while the new model saturates exponentially. As for photocurrent, the new model proved to behave equivalently to the experimental and theoretical data published by Forti in dark-adapted rods, while under light adapted conditions the new model fits significantly better to the experimental results obtained by Forti. This new model describes the early events involved in phototransduction, extends the light dynamical gain and it can be easily implemented in different types and species of photoreceptors.

Title: Single neuron model with multiple biological characteristics

Authors: *F. FENG, A. ALTURKI, A. NAIR, P. SAMARTH, S. NAIR;
Electrical and Computer Engin., Univ. of Missouri-Columbia, Columbia, MO

Abstract: Biophysical conductance-based models of neurons incorporate physiological information including morphology, current channels, and synapses. Such single cell models vary in morphological complexity from one to over 1000 compartments. Computational overheads necessitate the use of reduced order single cells in large model neuronal networks. However, in such cases, it is important that the reduced order models selected retain the key biophysical properties of biological cells. We hypothesize that in a single neuron, distinct groups of channels might be responsible for maintaining biological characteristics such as resting potential, sub-threshold oscillations, and spiking behaviors. Such a segregation also reduces the interference between currents and simplifies model development. This hypothesis is tested using a 1-compartmental biophysical model that reproduces the biological characteristics of two different biological neuron types reported in the literature. One of them is a CA3b hippocampal neuron (Hemond et al., 2008) and the other is a pyramidal neuron in the rodent lateral amygdala (LA) (Faber et al. 2001). Furthermore, we compare the characteristics of the LA single compartment model with 3-, 5- and 69- compartment versions previously developed by our team. The proposed single compartment methodology also provides analytical insights into the contributions of channels to the neuronal properties, e.g., frequency of the low- and high-threshold oscillations. We also propose a pre-filter module that simulates dendritic propagation and computation. This pre-filter is attached to the single compartment model to enable interfacing with other neurons in a network. The next step is to validate the proposed single cell model and pre-filter connection for synapses at the network level by replicating the network findings in Kim et al. (2013) that reproduced experimentally observed emergence of two different tone responsive cell populations after a Pavlovian auditory fear conditioning paradigm. That network model includes tone and shock as inputs, and also the effects of neuromodulators. For this validation, the single compartment cell model, together with the pre-filter synaptic

connection will be embedded into a larger 25,000 cell version of the 1000-cell model in Kim et al. (2013).

Title: Analysis of the dependence of spike generation on the past neuronal activity

Authors: *T. YAMANOBE;
Hokkaido University, Sch. of Med., Sapporo, Hokkaido, Japan

Abstract: Information is transmitted by spikes in nervous systems. However, it is not known which statistic of spikes is the information carrier. If information is encoded in the precise pattern of spikes, generation of each spike should not be dependent on the previous activity of the neuron. In artificial neural networks, the inputs to a single neuron model are transformed by an output function and the information carrier in artificial neural networks depends on the selection of the output function. Thus, it is necessary to examine how the input is transformed into the output at the single neuron level. In this study, we examine the dependence of the global dynamics of an impulse-driven stochastic neuronal model with spontaneous firing on the model and the input parameters. Phase transition curve has been used to describe the phase shift due to a single isolated impulse in the deterministic neuronal models with a limit cycle. In the previous study, we derived a stochastic version of the phase transition curve which is a Markov operator and describes the dynamics of the entire phase plane. The Markov operator governs the state density evolution of the stochastic neuronal model. To examine the effect of the relaxation time to the limit cycle on the global dynamics, we derive a Markov operator that describes the stochastic dynamics restricted to the limit cycle. These Markov operators can reproduce the response of the stochastic neuronal model to time-varying impulses. Using these Markov

operators, we investigate the difference between the steady state and the transient responses. For this purpose, we calculate the number of spikes between two consecutive impulses to relate the dynamics of the neuronal model to the measurable quantity. Each Markov operator can be decomposed into stationary and transient components by the mathematical properties. This allows us to evaluate the difference in the number of spikes per unit time between the steady-state and transient responses of the neuronal model. Our analysis shows how the spike generation depends on the past neuronal activity by changing the relaxation time, the noise strength, and the impulsive input parameters. Furthermore, we propose a scheme to check the dependence on the past neuronal activity by experimentally.

Title: Origin of the kink of somatic action potentials

Authors: *M. TELENCZUK[1], B. FONTAINE[2], R. BRETTE[1];
[1]Inst. De La Vision, Paris, France; [2]Lab. of Auditory Neurophysiol., Univ. of Leuven, Leuven, Belgium

Abstract: Hodgkin and Huxley (HH) described a model of action potential generation in their pioneering work in 1952, mainly based on experiments in the space clamped (isopotential) squid giant axon. Despite the general success of the HH formalism to model ionic channels across cell types and species, the isopotential HH model fails to account for some aspects of action potentials observed in cortical neurons. Specifically, somatic action potentials rise much faster in real neurons than predicted by the isopotential HH model, which appears as a « kink » at spike onset. Three mutually exclusive hypotheses have been proposed to explain this phenomenon : cooperativity of sodium channels [Naundorf et al., 2006], active backpropagation [Yu et al., 2008] and compartmentalization of spike initiation [Brette, 2013]. We tackled this problem by

computational modelling and theoretical analysis of spatially extended neuron models. We varied systematically the morphology of the neuron and distribution of the ionic channels along the cell, and tested how they contribute to the appearance of the kink. We asked three important questions: 1) How do sodium channels activate as a function of somatic voltage? 2) Is a big soma necessary for the phenomenon? 3) Is active backpropagation necessary? Our analysis reveals that sodium channels open abruptly in the axon initial segment, causing discontinuity in the somatic I-V curve recorded in voltage clamp. We also show that a big soma is necessary for the kink to be present while active backpropagation is not required. Finally, we created a simplified 2-compartmental model that displays the phenomenon, without active backpropagation. We conclude that the fast rise of spikes in experimental recordings is explained by compartmentalization [Brette, 2013] rather than by active backpropagation [Yu et al., 2008]. Title: Emergent anatomical and functional organization of place bias cells in the dentate in a large-scale biologically realistic model of the rat hippocampus

Authors: *G. J. YU[1], P. HENDRICKSON[2], D. SONG[2], T. W. BERGER[2];
[2]Biomed. Engin., [1]USC, Los Angeles, CA

Abstract: Grid cell input was incorporated into a large-scale, biologically realistic model of the rat hippocampus to investigate how behaviorally relevant input would be transformed due to the non-linearities and complexities present in the model. By varying levels of GABAergic feedback inhibition, the formation and shape of place bias cells in the dentate gyrus can be modulated. The anatomical organization of grid map properties in the entorhinal cortex and the topographic organization of projections between the entorhinal cortex and dentate gyrus resulted in a functional and anatomical organization of the properties of place bias cells in the dentate gyrus. The dorsal dentate granule cells exhibited place bias over smaller areas while ventral granule cells exhibited larger place bias. At 1/10th of the full scale of cell numbers, the hippocampal model consisted of entorhinal cortex layer II cells, granule cells, and basket cells with over 100,000 neurons and was modeled using NEURON. Granule cell models had individually generated morphologies and incorporated non-uniformly distributed active and passive membrane properties. The basket cells were approximated using a single-compartment model. The neurons were distributed in a space approximating the hippocampal dimensions based on published measurements. The topography of the projection between entorhinal cortex and dentate was constrained using anatomical data, and the connectivity between the granule cells and basket cells were similarly constrained. Excitatory synaptic coupling was mediated through AMPA-like synapses while inhibitory synapses were GABAergic. The entorhinal cortex cells were represented as heterogeneous Poisson spike generators whose time-varying mean firing rates were dependent on the individual grid map of a cell and the location of a virtual rat as it randomly moved in a square environment. The properties of the grid maps were organized along the dorsoventral axis of the entorhinal cortex with grid scales increasing in the ventral direction. The hippocampus serves an important role in the formation of episodic memories. However, it is yet to be fully understood how the hippocampus provides this function. In our large-scale hippocampal model, we were able to confirm several hypotheses about place field generation using biologically-realistic, spiking neurons. By incorporating behaviorally realistic inputs to the large-scale model, we hope to uncover, unknown phenomenon that can assist in confirming current hypotheses and drive the discovery of new hypotheses that can be tested experimentally to finally unravel the hippocampal mystery.

Title: Nonlinear modeling of calcium dynamics in glutamatergic postsynaptic spine for large scale simulations

Authors: *E. Y. HU[1], J.-M. BOUTEILLER[1], D. SONG[1], M. BAUDRY[2], T. W. BERGER[1]; [1]Biomed. Engin., USC, Los Angeles, CA; [2]Biomed. Sci., Western Univ., Pomona, CA

Abstract: Calcium in the postsynaptic spine plays a critical role in the activation and regulation of pathways that lead to a wide range of phenomena, from genome transcription to long term potentiation and even excitotoxicity. Postsynaptic calcium concentration is the result of influx from postsynaptic receptors, channels, and regulators within the synapse. Such intricate cellular mechanisms are still not fully understood and constitute an active area of research. The complexity and nonlinear nature of the dynamics make it difficult to elucidate how postsynaptic calcium dynamics can influence large neuron networks as well. Here we have developed an input-output (IO) model that captures the dynamics of a complex, detailed parametric model for postsynaptic calcium. Our goal is to better understand the mechanisms that influence postsynaptic calcium concentration, as well as evaluate the effect of calcium dynamics on a larger scale simulation. The calcium dynamics captured by the IO model consists of influences from both metabotropic and ionotropic glutamate receptors, calcium pumps, and contributions from the endoplasmic reticulum (ER). We show that our model is capable of accurately replicating the dynamics seen in the detailed parametric model with (i) little error and (ii) a substantial gain in computational efficiency, allowing the model to be used in large scale simulations comprising a large number of synapses and neurons. Use of this model may provide further insight into calcium dynamics both on a subcellular level and in a large network of neurons, and provide a better understanding of complex physiological processes such as long term potentiation and neuroplasticity.

Title: The role of cellular membrane properties in generating synchronous activity in inhibitory networks

Authors: *S. RICH[1], V. BOOTH[2], M. ZOCHOWSKI[3];
[2]Mathematics, [3]Biophysics, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Inhibition plays a vital role in generating synchrony in neural circuits. The established ING mechanism for generating synchrony in inhibitory networks has been thought of as independent of neural membrane excitability properties. We show this hypothesis does not fully encapsulate the formation of synchrony in inhibitory networks. We analyze synchronization for three different cellular excitability types, and for networks with low and high heterogeneity in the intrinsic cell firing frequency. Large scale, sparsely randomly connected networks were studied with each model. These models are typified by their IF (current-frequency) curve and their PRC (phase response curve), which quantifies the change in phase of the subsequent firing of a neuron in response to current pulses at various phases within its normal periodic firing. Type I neurons have a steep IF curve that can fire at arbitrarily low frequencies and a PRC that always shows phase advance in response to an excitatory pulse. Type II neurons possess a shallow IF curve and a minimum firing frequency, as well as a PRC showing a small phase delay in response to an excitatory pulse soon after firing. We also study Type II neurons with an M-type potassium current which acts as an adaptation current, promoting rebound firing following inhibition and causing the neuron to act more like a Type I neuron in the presence of inhibition. Our simulations in these networks show that Type I cells synchronize via the ING mechanism: full synchrony is observed for sufficiently long lasting synapses in networks with low cell heterogeneity, while high cell heterogeneity promotes partial ING-driven synchrony with full ING synchrony obtained for sufficiently high intrinsic mean cell firing frequencies. However, the picture is more complicated for Type II cells. Type II cells without an adaptation current exhibit spontaneous cluster synchrony in the case of low heterogeneity that can be driven to full ING synchrony, indicating a bistability. With high heterogeneity ING synchrony is not observed, as instead cluster synchrony occurs. Finally, in the Type II model with an adaptation current, networks can display either cluster synchrony or full ING synchrony dependent upon the intrinsic mean cell firing frequencies and the length of synaptic decay with a rapid transition between these regimes, independent of the degree of heterogeneity. These results show that the formation of synchrony in inhibitory networks can be complex and subject to neuromodulation by adaptation currents, and is not fully explained by synaptic properties as the ING theory suggests.

Title: Dynamic patterns in a two-dimensional neural field with refractoriness

Authors: *Y. QI, P. GONG;
Sch. of Physics, Univ. of Sydney, Sydney, Australia

Abstract: Formation of dynamic patterns such as localized propagating waves is a fascinating self-organizing phenomenon that happens in a wide range of spatially extended systems including neural systems, in which they might play important functional roles. Here we derive a type of two-dimensional neural field model with refractoriness to study the formation mechanism of localized waves. The model is able to generate a variety of localized patterns, including stationary bumps, localized waves rotating along a circular path, and localized waves with long-range propagation. We construct explicit bump solutions for the two-dimensional neural field, and conduct a linear stability analysis on how a stationary bump transitions to a propagating wave under different spatial eigenmode perturbations. The neural field model is then partially solved in a co-moving frame to obtain localized wave solutions, whose spatial profiles are in good agreement with those obtained from simulations. We demonstrate that when there are multiple such propagating waves, they exhibit rich propagation dynamics, including propagation along periodically oscillating and irregular trajectories; these propagation dynamics are quantitatively characterized. In addition, we show that these waves can have repulsive or merging collisions, depending on their collision angles and the refractoriness parameter. Due to its analytical tractability, the two-dimensional neural field model provides a modeling framework for studying localized propagating waves and their interactions.

Title: Optimal feature integration in a critical, balanced network model

Authors: *N. TOMEN, U. ERNST;
Univ. of Bremen, Bremen, Germany

Abstract: Recent experimental and theoretical work established the hypothesis that cortical neurons operate close to a critical state which describes a phase transition from chaotic to ordered dynamics. This state is suggested to optimize several aspects of information processing. However, although critical dynamics have been demonstrated in recordings of spontaneously active cortical neurons, the link between criticality and active, realistic cortical computation remains largely unexplored. In our study we focus on visual feature integration as a prototypical and prominent example of cortical computation. In particular, we construct a network of integrate-and-fire neurons with balanced excitation and inhibition which performs contour integration on a visual stimulus. The network consists of orientation hypercolumns with biologically plausible connectivity and serves as a model for part of an early visual area (e.g. V1 or V2). In dependence on synaptic coupling strength, the network undergoes a transition from subcritical dynamics, over a critical state, to a highly synchronized regime. Near the critical regime, the network settles into a state of irregular spiking activity with intermittent avalanches of spikes which propagate preferentially over cortical columns which are processing the contour elements. Hence presenting a visual stimulus with a target figure dynamically organizes the network into two parts: one with critical dynamics, encoding the ensemble of features making up the figure (i.e., the contour), and one with subcritical dynamics, encoding the background elements. To quantify the network's computational capabilities, we consider a task where the contour has to be detected on the left or right part of the visual field. ROC analysis based on firing rate distributions reveals contour detection performances are maximized (~60%) near the critical state. In contrast, synchronized events allow for near perfect detection: Using coincidence detectors, we find maximum detection rates of 99.9% around the critical point. In short, we show that for different measures, contour detection performance is always maximized near or at the critical state. At the same time, our paradigm provides a unifying account for stylized features of cortical dynamics (i.e. high variability) and contour integration (i.e. high performance and robustness to noise) known from experimental studies. Lastly, our findings imply that in experimental studies where the cortex is engaged in active computation, avalanche analysis needs to be restricted to neurons processing behaviorally relevant features in order to find signatures of criticality.

Title: Controllability of brain networks

Authors: ***S. GU**[1], F. PASQUALETTI[3], M. CIESLAK[4], S. T. GRAFTON[4], D. S. BASSETT[2]; [1]Applied Mathematics, [2]Dept. of Bioengineering, Univ. of Pennsylvania, PHILADELPHIA, PA; [3]Dept. of Mechanical Engin., Univ. of California, Riverside, Riverside, CA; [4]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Cognitive function is driven by dynamic interactions between large-scale neural circuits or networks, enabling behavior. Fundamental principles constraining these dynamic network processes have remained elusive. Here we use recent theoretical advances in network control theory to offer a mechanistic explanation for how the brain moves between cognitive states, drawn from the network organization of white matter microstructure. Using diffusion spectrum imaging data acquired from 8 healthy subjects in triplicate, we construct structural brain networks between 234 brain regions (nodes) linked by the number of white matter streamlines connecting them. We employ a simplified noise-free linear discrete-time and time-invariant network model of neural dynamics in which the state of brain regions depends on the connectivity between them. Using this model, we compute the eigenvalues of the controllability Gramian for each brain region treated as a control node and demonstrate that structural brain networks representing the human brain are theoretically controllable, but extremely difficult to control in practice. We then determine how brain areas constrain or facilitate changes in brain state by computing three regional controllability diagnostics: the average, modal and boundary controllability. Our results indicate that densely connected areas are average controllers, theoretically expected to facilitate the movement of the brain to many easily-reachable states, and we show that these areas are preferentially located in the default mode system. Weakly

connected areas, predominantly located in cognitive control systems, are modal controllers, theoretically expected to facilitate the movement of the brain to difficult-to-reach states. Finally, areas located on the boundary between network communities, predominantly located in attentional control systems, are boundary controllers, theoretically expected to facilitate the integration or segregation of diverse cognitive systems. As a whole, this body of work suggests that structural network differences between the default mode, cognitive control, and attentional control systems dictate their distinct roles in controlling brain network function. More generally, our results support the view that macroscale structural design underlies basic cognitive control processes via the fundamental mechanism of network controllability.

Title: Exponentially-many states and robust error correction in Hopfield networks

Authors: *R. CHAUDHURI, I. FIETE;
Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: Noise is ubiquitous in the brain, limiting how networks of neurons represent and propagate information. Consequently, the brain must encode signals redundantly and recover them in the presence of interference and noise. A fundamental question for neural computation asks how well neurons can do this: how many states can networks of neurons store and subsequently retrieve in the presence of noise? Current models yield either weak (i.e., sub-exponential) increases in representational capacity with network size or exhibit poor robustness to noise. The grid cell system in the entorhinal cortex has been shown to represent space with a capacity that scales exponentially with the number of cells and can in principle be robust to noise, but only with an appropriate decoder whose complexity is not yet well-characterized. We show that undirected graphs with Hopfield dynamics can have exponentially-many stable states

and, moreover, that errors in a finite fraction of nodes will be corrected by the dynamics, so that these states can be robustly recovered in the presence of noise. We construct these networks using sparse, bipartite expander graphs, which have previously been used to create novel, easily-decodable error-correcting codes. Such architectures combine sparse, weak constraints near-optimally to allow neurons to encode large numbers of states and to correct errors using simple, local dynamics. From a neural perspective these networks have a number of appealing features: they are sparse, can be constructed randomly, and connection strengths take values in a narrow range. Our results demonstrate that the structures of certain important error-correcting codes, wherein sparse constraints produce high-dimensional systems with large capacity and robustness, might apply to neural architectures.

Title: How distinct is computational complexity from Shannon information?

Authors: *A. R. CASTI;
Dept. of Mathematics, Fairleigh Dickinson Univ., Teaneck, NJ

Abstract: The complexity of a data set is a formal measure of symbolic structure that, like the better known Shannon Information, is measured in bits. In neuroscience, the Shannon Information has long been used to quantify a neuron's ability to encode and transmit information about a distribution of external stimuli. By comparison, complexity measures of neuronal output, such as spike trains, have received scant attention. Among other reasons, there appears to be no agreement on the best measure of neuronal complexity because most measures of it do not lend themselves easily to physiological interpretation. The best known complexity measure - the Kolmogorov Complexity - scales in proportion to the level of noise in the neuronal response, and thus may give a completely misleading picture of the underlying biophysics and neuronal circuitry that produced the response, and for what purpose. Further, because both the Shannon Information and complexity are intimately related to entropy, there is confusion regarding how distinct these measures really are. The primary aim of this work is to shed some light on this distinction for experimentally recorded and model generated spike trains of relay neurons in the visual thalamus. In this study, we use a physiologically interpretable complexity measure

introduced by Haslinger et al. (2010) - the computational complexity - that is derived from optimal Hidden Markov Models (Causal State Models) fit to spike train data. This approach determines the minimal number of "causal states" required to reproduce the statistical structure of the spike train, and distinguishes noise from intrinsic computational structure by defining the complexity as the entropy associated with causal state visitations in the data. We compare this complexity measure with the Shannon information of spike trains produced by a versatile model of relay neurons in the visual thalamus (Lateral Geniculate Nucleus), which includes calcium channels and feedforward/feedback inhibition to ensure a rich set of intrinsic causal states. We investigated the interplay between excitation and inhibition under a range of stimuli and model parameters, and asked whether parameters can be tuned to produce spike trains that are highly complex but have low Shannon information, and vice versa, or whether complexity and information are highly correlated. We conclude that computational complexity and Shannon Information are capable of generating distinct insights into neuronal spiking.

Title: Maintaining balance in networks with heterogeneous degree distributions

Authors: *R. PYLE[1], R. ROSENBAUM[2];
[2]ACMS, [1]Notre Dame, Notre Dame, IN

Abstract: The balanced network modeling paradigm captures several features of cortical networks: asynchronous and irregular spiking activity, dense recurrent connectivity and a cancellation between strong excitatory and inhibitory synaptic currents [1]. Balanced networks are often modeled using unstructured, Erdős-Rényi style random graphs, where the probability of connection between any two neurons depends only the neuron type. However, experimental data reveal a more intricate structure with neurons exhibiting large variability of in-degrees, out-degrees and synaptic weights [2]. We explore the notion of balanced excitation and inhibition in networks with heterogeneous connectivity structure. It was recently shown that power-law degree distributions cause a loss of balance [3]. We use a heterogeneous mean-field theory [4] to show that this conclusion relies critically on an assumption that in- and out-degrees are uncorrelated. Introducing correlations between a neuron's in- and out-degrees can recover the

balanced state, but leads to the surprising conclusion that neurons with a high in or out-degree have a lower firing rate. Our mean-field analysis is supplemented with simulations of biologically realistic neuron models. References 1. Van Vreeswijk, C., & Sompolinsky, H. (1996). Title: Plasticity-induced sensitization in recurrent E-I networks

Authors: *G. KUMAR[1], S. CHING[2];
[1]Electrical and Systems Engin., Washington Univ. in St. Louis, Saint Louis, MO; [2]Dept. of Electrical and Systems Engin. and Div. of Biol. and Biomed. Sci., Washington Univ. in St. Louis, St. Louis, MO

Abstract: The effects of short- and long-term plasticity on information processing in sensory networks remains a fundamental question in sensory neuroscience. Here, we use a combination of computational modeling and systems-level analysis to study how long-term plasticity shapes the sensitivity of E-I network to afferent excitation. Specifically, we implement a rate-based recurrent neuronal network, endowed with a Bienenstock, Cooper, Munro (BCM) synaptic adaptation rule. The network is impinged upon by high dimensional afferent inputs. At each moment in time, we perform a reachability analysis, based on methods derived from control theory, to study the geometry of the space of possible (i.e., inducible) output trajectories (i.e., network activity as a function of time). Our overall goal is to characterize how this geometry

changes, via the plasticity, as a function of repetitive stimuli delivered to the network. Using both numerical simulation and exact analysis, we found that recurrent E-I networks demonstrated highly specific spatial sensitization with respect to ongoing afferent excitation. In particular, we found that the space of reachable trajectories (neuronal activation patterns) contracts in the direction associated with the ongoing stimulus, while simultaneously expanding in orthogonal directions. In other words, the network de-sensitizes to the current stimulus, while at the same time, sensitizes to potential competing/distracting stimuli. Importantly, this sensitization is mediated strictly via the intrinsic dynamics and not via attenuation in the gain from the extrinsic input onto the network. Thus, our findings suggest that long-term plasticity enables a network to favor stimuli that are different/novel from ongoing activity. Further, our results show that such a property is innate to recurrent E-I networks, suggesting that such networks intrinsically support enhanced discriminability of novel inputs.

Title: A modeling study of the dynamics of memory retrieval

Authors: ***Y. GU**, P. GONG;
Science, Sch. of Physics, Complex Syst. Group, Univ. of Sydney, Sydney, Australia

Abstract: The capability of human memory system to retrieve task relevant items is remarkable. Evidence has been accumulated to indicate that memory retrieval process has certain regularities. For instance, in category fluency test, a paradigm used to study human memory retrieval (e.g., name as many animals as possible in one minute), semantically closely related items tend to be retrieved consecutively, forming a cluster, and the retrieval process switches between such semantic clusters. However, the frequency of such switches has been shown to be significantly (from 40% to 55%) lower in patients with Alzheimer's disease or the Parkinson's disease than that in healthy subjects. Despite the importance of this kind of switching process in memory retrieval, its dynamic nature and underlying neurophysiological mechanisms remain largely unknown. We develop a network model consisting of conductance-based integrate-and-fire

neurons. Excitatory neurons form several densely connected modules, each of which can be used to store a memory. A hierarchical structure is further imposed upon the inter-module wiring probabilities, representing similar structure found in both neuron coupling topology and semantic networks. We find that, when the excitation and inhibition is roughly balanced, the system spontaneously activates one neuron module after another; in this process, consecutive activations are separated by almost quiescent states. This dynamic process can be regarded as a free memory retrieval process. We further demonstrate that the semantic dependence of the free memory retrieval process and the heavy-tailed distribution of the inter-retrieval intervals, as found in psychological experiments, can be reproduced in our model. However, when the E-I balance or the hierarchical structure is broken, there is severe impairment in the memory retrieval performance. At the neurophysiological level, this result is consistent with the experimental observation that there exists an elevated excitation-inhibition ratio and a decrease of neural connections in patients with Alzheimer's disease or Parkinson's disease; at the behavioral level, this result is consistent with the fact that a significant deficit in memory retrieval is a typical syndrome of these patients.

Title: High dimensional firing rate dynamics in spatially extended asynchronous networks

Authors: ***R. ROSENBAUM**;
Applied and Computat. Mathematics, Univ. of Notre Dame, Notre Dame, IN

Abstract: Cortical circuits exhibit asynchronous, irregular dynamics which are often modeled computationally using networks of randomly connected integrate-and-fire neurons [1]. Such models produce complex microscopic dynamics – at the level of individual spikes – but these dynamics are largely unreliable from trial to trial. Macroscopic dynamics – at the level of firing rates – are highly reliable, but extremely simple, as they merely track feedforward input. Non-trivial neural computations require reliable responses with rich dynamical structure [2]. We propose that introducing spatial structure to asynchronous, irregular networks can impart rich and reliable firing rate dynamics. We combine spatial neural field theory with linear response theory to analyze the stability of homogeneous firing rates in spatially extended networks of

spiking neuron models. In doing so, we discover the presence of spatio-temporal pattern forming bifurcations that produce complex firing rate dynamics. We show that these bifurcations cannot be reproduced in simpler "firing rate" models that are often used to study spatially extended networks. Moreover, the dynamics produced by the bifurcations are equally high-dimensional, but more reliable than those produced by unstructured random networks with strong synaptic coupling [3]. Our results suggest that intrinsic spatio-temporal dynamics is a realistic model for the rich dynamics underlying non-trivial neural computations [2]. [1] Brunel, N. (2000). Title: Different models of network connectivity can explain “non-random” features of cortical microcircuits

Authors: *M. VEGUÉ, A. ROXIN;
Ctr. De Recerca Matemàtica, Bellaterra, Spain

Abstract: Network topology shapes the ability of neural networks to store and transmit information. In neuronal network models the topology is represented by a directed graph, which is a set of vertices (the neurons) and a set of directed edges that connect them in a precise manner (the synapses). One of the challenges of network modeling is, therefore, the construction of random graphs that reflect both the variability and the main structural properties of real neural networks. Erdös-Rényi (ER) graphs, defined by a single parameter p which determines the

probability of any directed edge, are among the simplest random models and have been used in a broad range of theoretical studies. Some experimental studies suggest, however, that cortical microcircuits are not well represented by ER models [1], [2]. Here we discuss several alternative classes of network models for fitting the available data: 1 - networks with distinct neuronal clusters, 2 - networks with spatially decaying connectivity, and 3 - networks with broad, correlated in-degree and out-degree distributions. We find that all three classes of networks fit the available data well, including doublet and triple motifs [1] and the increase in the likelihood of connectivity between neurons as a function of common neighbors [2]. Interestingly, networks of the third class, namely, with broad, correlated degrees, do not include any clustering, indicating that one should use caution in drawing inferences about such higher order structure from lower order statistics. Finally, we study the dynamics of networks of spiking neurons for each of the three classes of network connectivity. Specifically, we consider the networks in the so-called fluctuation-driven in which recurrent excitatory and inhibitory currents are large and balanced, leading to spiking statistics similar to that seen *in vivo*: e.g. CV of ISI near 1, low mean firing rate, broad firing rate distributions. In this regime we look for dynamic signatures of each network class which could be used to aid in distinguishing the underlying network structure. We find that the network response to transient stimuli can temporarily break the balance of currents in the stationary regime, thereby generating dynamics which is strongly shaped by the underlying network structure. Abstract: Objective: We propose electrode-position- and equivalent-current-dipole-source-localization (EDCL)-based brain functional connectivity networks (BFCNs), where the latter will

enable us to compare with the previous BFCN studies using fMRI. Methods: Nineteen-channel EEGs were recorded during an eye-closed resting state in two female Alzheimer's disease (AD) patients and five healthy subjects. Correlations between any two nodes were calculated by synchronization likelihood (SL). Results: Among the network parameters, there were remarkably significant differences in the small-worldness and the betweeness centrality between the AD patients and healthy subjects for gamma band and alpha, beta and gamma ones, respectively. Considerations: Electrode positions and the brain regions, obtained by the previous fMRI-based BFCN, with the high betweenness centrality were considerably similar, which was confirmed also by our EDCL-based one. Moreover, effects of medications on the AD patients will be visualized and examined by the present BFCNs.

Title: Quantifying neural information content: a case study of the impact of hippocampal adult neurogenesis through computational modeling

Authors: ***C. M. VINEYARD**, S. J. VERZI, C. D. JAMES, J. B. AIMONE;
Sandia Natl. Labs., Albuquerque, NM

Abstract: There are multiple perspectives on hippocampal function. Focusing upon the effects of information encoding and transformation occurring in the hippocampal loop, here we show some insight provided by a less conventional interpretation inspired by machine learning principles. We hypothesize that the role of the hippocampus in information processing is to restructure and refine the multimodal associative encoding provided by the entorhinal cortex (EC) through a high dimensional adaptive transformation in dentate gyrus (DG) and subsequent compressive encoding by the CA3. This computational process is analogous to a Support Vector Machine (SVM). However, unlike conventional SVM theory, the existence of adult neurogenesis in DG confers an adaptive high dimensional projection which impacts the resulting CA3

encoding (or discriminant in a canonical SVM). To explore this hypothesis as well as the impact of adult neurogenesis, we have developed metrics and computational paradigms to quantify neural information content. Neural networks have an intrinsic information content encapsulated by neural firing behaviors and constituted by their neural encoding. Shannon entropy is a fundamental method to quantize the amount of information in a variety of sources such as communication channels. Many approaches have been devised to apply this sort of information measure to neurons with mixed success. However, doing so typically requires knowledge of the firing behavior probability distributions for the neurons of interest (whether modeled or recordings), and furthermore often is only applicable for single neurons and not ensembles. We have observed that conventional compression methods may help overcome some of the limiting factors of standard techniques and allows us to approximate information in neural data. To do so we have used compressibility as a measure of complexity in order to estimate entropy to quantitatively assess information content of neural ensembles. Using Lempel-Ziv compression we are able to assess the rate of generation of new patterns across a neural ensemble's firing activity over time to approximate the information content encoded by a neural circuit. As a specific case study, we have been investigating the effect of neural mixed coding schemes due to hippocampal adult neurogenesis.

Title: An information-theoretical interpretation for neural modulation of spike-timing dependent plasticity: Towards cellular-based computational psychiatry

Authors: *T. ISOMURA[1], K. SAKAI[2], Y. SATO[2], K. KOTANI[3], Y. JIMBO[2];

Abstract: Friston's free-energy hypothesis, a candidate unified theory for learning and memory in the brain, predicts that neurons, synapses, and neuromodulators work in a manner to minimize free energy. However, electrophysiological data elucidating the neural and synaptic bases for this theory are lacking. Here, we propose a novel theory linking the information-theoretical principle with the biological phenomenon of spike-timing dependent plasticity (STDP) modulated by neuromodulators, which we have termed mSTDP. We proposed that an mSTDP algorithm is derived from an enhanced version of Friston's free energy (an information theoretical function) and analytically and numerically showed that dopamine (DA) and noradrenaline (NA) modulate the accuracy of principal component analysis (PCA) performed using the mSTDP algorithm. Specifically, synaptic connection strengths (an N-dimensional vector) were established such that in the absence of DA/NA, the neural output represented the first principal component (PC1), which is the direction where the information represented by the neural output is maximized (Infomax learning). DA up-regulation affected all connections of a neuron with all synapses attaining similar amplitudes, while NA up-regulation markedly decreased the amplitude of almost all connections except only a few ones, in a winner-takes-all manner. Next, we found that, in the case of 2-dimensional input, increasing DA concentration resulted in the shift of the preferred direction of the neuron to $\theta = \pi/4$, which indicates that both synaptic connections attained a similar amplitude, while increasing NA concentration tuned the preferred direction to $\theta = 0$ or $\pi/2$. Therefore, if DA or NA concentrations increase, neural networks shift to perform pattern completion or separation, respectively. These results are consistent with electrophysiological findings and validate the free-energy principle and mSTDP theory. Moreover, our algorithm can potentially be applied for computational psychiatry. Our results suggest that when DA concentrations are abnormal, neuron tends to regard their input as more highly correlated than it actually is and neural networks fail to represent the external world accurately; this can be used to design a computational model of hallucination and delusion, which are common positive symptoms of schizophrenia. On the other hand, when NA concentrations are abnormal, neurons tend to increase a specific synaptic connection and fail to perform appropriate processing; this finding can aid in building a computational model of NA contribution in memory triage and post-traumatic stress disorder.

Title: Measuring causality in simulations of large scale brain networks

Authors: *M. MANNINO[1], S. BRESSLER[2];
[2]Pscyhology, [1]Florida Atlantic Univ., Doral, FL

Abstract: Inferring causal relations between the nodes of large-scale brain networks can reveal network topology, connectivity, and function, and help uncover the neurobiological basis of cognition. Yet appropriate methodologies for measuring dynamic causality in brain networks remain varied and elusive. The application of directed functional connectivity analysis to simulated fMRI BOLD data can recover neural connectivity patterns and validate inferences from causality analysis of veridical fMRI BOLD data (Tang et al, 2012). However, simulated data has not previously been widely used because it has failed to capture important underlying neural mechanisms (Bressler et al, 2008). Here, we perform computational simulation and mathematical analysis on a neuroinformatics platform called The Virtual Brain (TVB) that simulates biologically realistic neural population data generated by a large-scale distributed brain network model. TVB is unique in the field of neural simulation in that it is organized at the mesoscopic level of large-scale brain networks with nodes that are neural populations. TVB provides a framework for evaluating various methodologies on biologically plausible simulated data (Wang et al, 2014). The overall objective of this project is to use a nonlinear dynamical system, specifically a neural mass model to generate time series data of a local field potential (LFP) signal, and use linear autoregressive modeling to analyze the data, thereby inferring causal relations in large-scale brain networks. Data are generated from two coupled oscillatory neural masses, with the Stefanescu-Jirsa 3D model in the TVB simulator governing the intrinsic dynamics of each population. Trials vary parameter values, including conduction velocities and model parameters that determine excitatory and inhibitory coupling. This approach allows comparison of Granger causal analysis of simulated and veridical BOLD time series to determine the directionality of influence in large-scale brain networks.

Title: Continuous parameter working memory in a balanced chaotic neural network

Authors: *N. SHAHAM[1], Y. BURAK[2,1];
[1]Racah Inst. of Physics, [2]Edmond and Lily Safra Ctr. for Brain Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: There has been considerable theoretical and experimental interest in the storage in working memory of continuous parameters, such as direction, color, or frequency. One of the main theoretical models of working memory of continuous parameters is local circuits in the brain that exhibit continuous attractor dynamics, where different values of a stimulus can be represented by different locations along a continuum of steady states. However, it has been unclear whether this theoretical idea is compatible with another proposal for the architecture of cortical circuits - the balanced network (van Vreeswijk and Sompolinsky, Science 1996, Neur Comp 1998). In previous work (Mato and Hansel, J. Neurosci 2013; Goldman and Lim, Nat. Neurosci 2013, J. Neurosci 2014) slow dynamics within a balanced network was achieved using complementary mechanisms, such as multiple synaptic time scales or short term plasticity. In this work we study a network with random connectivity which generates a balanced state. Using mutual inhibition between two balanced populations, we find an architecture for which the network can sustain slow dynamics in a certain direction in the mean-activity space. The persistence is achieved without using short term plasticity or multiple synaptic time scales. The slow dynamics make this balanced network an appropriate candidate for the storage of working memory. We find that the chaotic dynamics of neural activity in the balanced network drives diffusive motion along the attractor, similar to the dynamics of networks in which noise arises from intrinsic neural or synaptic mechanisms (Burak and Fiete, PNAS 2012). In addition to the diffusive motion, the network can exhibit systematic motion due to mistuning of the network parameters, and the overall dynamics along the attractor follows similar statistics to an Ornstein-Uhlenbeck process. Using analytical and numerical analysis, we show that the diffusion coefficient along the attractor is inversely proportional to the network size. Thus, the persistence of the network can be improved by increasing the number of neurons. In practice, ~10^5 neurons are sufficient in our model (with proper tuning of the synaptic weights) to achieve persistence times of several seconds, larger by several orders of magnitude than the single neuron time scale.

Title: Persistent delay activity in a neuron-glia network model

Authors: *M. DE PITTÀ[1,3], H. BERRY[3], N. BRUNEL[1,2];
[1]Dept. of Neurobio., [2]Dept. of Statistics, The Univ. of Chicago, Chicago, IL; [3]EPI Beagle, INRIA Rhône-Alpes, Villeurbanne cedex, France

Abstract: In primates performing delayed response tasks, the persistent increase of neural firing during the delay period is regarded as the neuronal hallmark of working memory that is the transient maintenance and manipulation of goal-related information for forthcoming actions. Several mechanisms have been suggested for the emergence of persistent delay activity, but it remains unknown whether it stems from intrinsic properties of neurons, the nature of their synaptic connections, or both. In recent years, astrocytes, the main type of glial cells in the brain, have been suggested as potential active players in neural function due to their ability to regulate synaptic transmission by releasing gliotransmitters, like glutamate or ATP, in an activity-dependent fashion. Because available models of persistent activity do not take into account astrocytes, we set to investigate the emergence of persistent delay activity in a spiking model of cortical neuron-glia networks focusing on one putative mechanism: the activity-dependent regulation of neurotransmitter release at excitatory synapses by gliotransmitters. Mean field analysis of the model suggests that long-lasting gliotransmitter-mediated increases of synaptic glutamate release could be responsible for the appearance of a persistent mode of high synaptic release that coexists with that of low synaptic release in the absence of astrocytic modulation. In this fashion, the transient increase of neural firing upon presentation of a stimulatory cue could trigger astrocytic modulation and switch synaptic release from low to high. In turn, high synaptic glutamate release could further promote astrocyte activation and modulation of synaptic transmission ultimately resulting in increased postsynaptic neural firing during the delay period. In this fashion, the increase in neural firing becomes persistent as long as gliotransmitter release from the astrocyte occurs. This mechanism is robust and could be observed both in single neurons as well as in a classical balanced cortical network model. Taken together, these results suggest a novel astrocyte-based mechanism for persistent activity, and provide experimentally

testable hypotheses for the possible involvement of astrocytes in cognitive tasks related to working memory.

Title: Interactions between neural circuits that mediate social and nonsocial behaviors

Authors: *J. HURTADO[1], D. F. RAMIREZ[1], T. J. SEJNOWSKI[2];
[1]Univ. Autonoma De Occidente, Cali, Colombia; [2]CNL, The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Understanding circuit-level mechanisms mediating aggression behaviors as well as how aggression, mating, and the associated synaptic circuits relate to each other remains poorly understood. In recent researches, optogenetic manipulations in certain brain nuclei in mice have shown the relationship of aggression circuits to those mediating opponent social behaviors, such as mating, and a nonsocial behavior as self-grooming [1]. Despite the new findings, relatively little is known about the circuit-level function of the neurons that control social behaviors. In order to give some insights and to continue providing approaches for explaining the mechanisms and processes that might control social behaviors, we have proposed a biologically inspired neural network model. First, we propose possible interactions among self-grooming, mating, and fighting circuits. Our model includes populations of neurons in the amygdala and hypothalamus as well as amygdalar-hypothalamic pathways to promote either self-grooming, mating, or fighting and pathways to suppress these behaviors. Second, the mathematical model is based on attractor networks with dynamical stability, which allows us to provide a framework for understanding the rich and complex neural activity patterns generated in recurrent networks. Finally, the model is examined with bifurcation analysis and computer simulations. The results demonstrate that the model exhibits stable steady states and thresholds for steady state transitions corresponding to some experimentally observed behaviors, such as aggression control. Title: Low-dimensional attractor of neural activity from optogenetic data

Authors: *P. G. LYNN[1], L. EVANS[2], S. OPRISAN[3], T. TOMPA[4], A. LAVIN[4];
[1]Col. of Charleston, New Smyrna Beach, FL; [2]Psychology, [3]Physics and Astronomy, Col. of Charleston, Charleston, SC; [4]Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: We used optogenetic mice to investigate the response of the medial prefrontal cortex (mPFC) local network to light stimuli delivered by a 473 nm laser through a fiber optics. Local field potential (LFP) recordings obtained with an optrode were band-pass filtered online between 0.1 and 130 Hz. The entire experimental protocol consisted of two successive two-second long recordings in response to (1) a 40 Hz, 10-pulses train, that lasted 250 ms with 10 ms pulse duration followed by a 15 ms break, and (2) a single pulse with 10 ms duration. We analyzed the response of the network to a single 10 ms duration light pulse using delay embedding method. We found that the dynamics could be reconstructed in a three-dimensional space. Our results open the possibility of designing a low-dimensional model for optical stimulation of the local network.

Title: Robustness of pair-correlated network activity in the presence of noise

Authors: *J. NEUMAN[1], W. VAN DRONGELEN[2], J. COWAN[3];
[1]Physics, [2]Pediatrics, [3]Mathematics, Univ. of Chicago, Chicago, IL

Abstract: One of the most important unsolved problems in neuroscience is the question of the nature of correlated activity patterns. *In vivo* experiments have shown that activity in neighboring cortical areas is more correlated and extends over a greater distance when no external stimulus is present (Nauhaus et al. 2009). Because random fluctuations are omnipresent across the whole nervous system and come in many forms, an understanding of the effect each source of noise has on spontaneous and stimulated modes is a significant topic to examine. In this modeling study, we investigate the effects of various noise types and strengths, as measured by the signal-to-noise ratio, on correlated activity between coupled populations of neurons. Our results show that the pair-correlations between a reference area and its neighboring patches of cortex in both spontaneous and driven regimes are qualitatively very robust to many different sources of noise. In particular, we use a stochastic single neuron Markov model to recreate intrinsic multiplicative neuronal noise and a network model to simulate additive synaptic noise. Both models are consistent with the experimental findings mentioned above when the network size is varied as well as the source of synaptic noise. Specifically, we have implemented noisy inputs, outputs, neuronal thresholds, and connectivity strengths for non-pathological biologically plausible signal-to-noise ratios ranging from 5-15 and found robustness in the pair correlation coefficient. This result has many potential implications. First, it says external stimuli play a significant role in brain dynamics. While this seems obvious, the comparison in strengths of peripheral drives to random variations is not trivial. Next, these findings suggest that many different sources of noise can be lumped together when studying behavior at large cortical scales. The specific noise variety is not a major consideration. Lastly, it says resting brain activity might be very stable to random fluctuations. This is particularly useful in helping the brain optimize its computational power.

Title: Calcium imaging reveals multiple conduction systems in hydra

Authors: *C. DUPRE, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Hydra is representative of the most primitive nervous systems. Yet, it turns out that it does not function like its structure (a nerve net) would suggest and there might be more to learn about neurons in hydra than previously thought. This cnidarian offers a convenient preparation for calcium imaging, especially because it is possible to image the entire animal simultaneously. Our experiments using such technique revealed multiple groups of neurons (or conduction systems) that are anatomically distinct and that fire simultaneously, together with a series of neurons that seem to fire independently. Accordingly, we are interested in dissecting the nervous system of hydra and answering the following questions: How many different circuits are there in hydra? What type of computation does each of these circuits do, and to what extent are these circuits dependent on each other? Answering these questions will help understand the properties of the most primitive nervous systems and how they produce the appropriate behavioral response to a given situation.

Title: Stability of strongly coupled inhibitory-excitatory networks with realistic synaptic dynamics

Authors: *K. DIPIETRO;
Applied Computat. Mathematics and Statistics, Univ. of Notre Dame, Notre Dame, IN

Abstract: Cortical circuits are believed to operate in a balanced or inhibitory-stabilized regime in which strong recurrent excitation is matched by strong inhibition [1,2]. Such networks are often modeled computationally using two-dimensional mean field equations such as the Wilson-Cowan model [1,3] or by using balanced networks of spiking units [2]. Both of these modeling approaches rely on the implicit assumption that inhibition is faster than excitation. The validity

of this assumption is not immediately clear. While the membrane dynamics of inhibitory interneurons are often faster than those of excitatory pyramidal neurons, GABAergic synaptic kinetics are generally slower than AMPA-mediated glutamatergic synaptic kinetics. We systematically address the question of how cortical networks can maintain a stable excitatory-inhibitory balance when inhibitory synaptic kinetics are slower than excitatory synaptic kinetics. We begin by extending the Wilson-Cowan model to a four-dimensional system that separates synaptic and neuronal timescales [4]. From this extended mean-field model, we derive concise conditions on the stability of excitatory-inhibitory balance in the asymptotic limit of strong coupling. We then verify and generalize the qualitative findings from the mean-field model using a numerical stability analysis of integrate-and-fire networks with biologically realistic parameters [4]. Title: Finding the right firing rate and growing the right synapses: maximizing the emergence of characteristic neural circuit features through maximal self-organization

Authors: *Z. TOSI;
Cognitive Science, Informatics: Complex Systems, Indiana Univ. Bloomington, Bloomington, IN

Abstract: The quantity and quality of our tools for probing the structural and behavioral features of neural circuits have rapidly improved in recent years, putting ourselves in a situation where data pertaining to these features is in abundance but models accounting for said features are somewhat lacking. Indeed, many models can account for at least some subset of these features,

but models which account for them more broadly are few and far between. Furthermore, the majority models that do exist tend to have one or more observed features parameterized into the network a priori, thus eliminating any possible insight as to how the parameterized features may come about. This has brought the demand for self-organizing features in neural circuit models to a much needed all-time high. Building upon the work of Jochen Treisch and colleagues' SORN (Self Organizing Recurrent Network) model (2009), the following (distinct) work sets out to self organize in a way which minimizes parameterized features and maximizes emergent features consistent with observed behavior in living neural circuits. By combining a form of intrinsic plasticity which promotes the emergence of log-normally distributed firing rates, with homeostatic plasticity, continuously applied additive spike timing dependent plasticity (STDP), inhibitory-STDP, resource-constrained synaptic potentiation, and STDP guided synaptic growth and pruning, the following network accomplishes that goal. The resulting network produces log-normally distributed firing rate and synaptic efficacy distributions, but also captures many aspects of the connectivity structure found in living neural circuits. These include a highly non-random correlation among incoming connections to neurons, heavy-tailed degree distributions, qualitatively similar node versatility distributions, and the emergence of rich-clubs in the network. Additionally, tests of the resulting network's computational power in terms of its kernel quality (separation ability) and VC-Dimension (generalization ability) suggest a high degree of computational ability. To the author's knowledge this is the first time a single network model has been able to account for all these features without explicitly coding them into the model, and would offer researchers the opportunity to "grow" highly realistic generic artificial microcircuits, as well as offer predictions as to how these many features may emerge in living organisms.

Title: Phase resetting induced by concurrent stimuli

Authors: *S. OPRISAN[1], K. M. VOLLMER[2], D. AUSTIN[3], L. EVANS[4];
[1]Physics & Astronomy, [2]Biol., [3]Physics and Astronomy, [4]Psychology, Col. of Charleston, Charleston, SC

Abstract: The PRC tabulates the transient change in the firing period of a neuron due to external perturbations, such as presynaptic stimuli. The PRC is the input-output transfer function of a neuron and is useful in predicting the phase-locked modes of neural networks. To measure the PRC, a single pulse is applied at different phases during the cycle. The open loop pulse applied to an isolated neuron mimics as closely as possible the presynaptic input received by the respective neuron when it is part of the neural network (closed loop). The single pulse produces transient changes of the firing period over multiple cycles, which are measured by PRCs of different orders. We focused only on the first order PRC that describes the transient change in the length of the cycle containing the pulse. Since neurons receive more than one presynaptic input per cycle, we generalized the single pulse PRC to the more realistic case of neural oscillators receiving two or more inputs per cycle. We used a conductance-based model neuron to estimate experimentally the two-stimuli PRC and compare the results against our mathematical prediction based on the assumption of instantaneous recurrent stimulation. Within the limits of the recurrent stimulation assumptions, we found that the newly introduced prediction for the two-stimulus PRC matches experimental measurements. Our new results open the possibility of a more realistic approach to predicting phase locked modes in neural networks, such as the synchronous activity of large networks during epileptic seizures.

Title: The anatomical origin of locally generated and induced oscillations in a model of the cortical microcircuit

Authors: *H. BOS[1], J. SCHÜCKER[1], M. DIESMANN[1,2,3], M. HELIAS[1];
[1]Inst. of Neurosci. and Med. INM-6, Inst. for Advanced Simulation IAS-6, Jülich Res. Ctr. and JARA, Jülich, Germany; [2]Dept. of Psychiatry, Psychotherapy and Psychosomatics, Med. Fac., [3]Dept. of Physics, Fac. 1, RWTH Aachen Univ., Aachen, Germany

Abstract: Fast oscillations of the population firing rate in the high gamma range (50-200 Hz), as well as slow firing rate fluctuations are ubiquitous in cortical recordings and have been hypothesized to be generated locally. Utilizing the recently established multi-layered spiking neural network model of a cortical microcircuit and our mean-field theoretical framework, we address the question of the anatomical origin of the observed oscillations by analyzing the spectra generated in the resting condition as well as under the application of constant and oscillatory input. Deriving the theoretical framework we perform a two-step reduction allowing for an incremental validation of first the prediction of the population firing rates and second the prediction of the population rate spectra. Building on previous work that derived the mapping of populations of leaky integrate-and-fire model neurons to a linear rate model using the response function of populations of neurons connected by exponentially decaying synapses, the mean-field framework is applicable to arbitrary circuitries set in the asynchronous irregular regime. In the resting condition the neurons in the model fire irregularly, displaying little synchrony on the population level. Increasing the external input to the excitatory population in layer 5 elicits slow rate fluctuations, reflected as elevated slow frequency components in the population rate spectra. Strengthening the input to the superficial layers triggers population oscillations in the gamma range, while individual neurons preserve low rates close to irregularity. We derive a sensitivity measure determining the anatomical connections within the circuit crucial for the generation of the peaks visible in the power spectra as well as their impact on the peak frequencies and amplitudes. We identify a sub-circuit located in layer 2/3 and 4 constituting the basis of the high frequency oscillations, while connections within and onto layer 5 determine the existence and strength of slow rate fluctuations. Since the sensitivity measure is derived from the mean-field theory we can analyze the robustness of these findings under changes of parameters in the neuron and synapse model and conclude on the actual contributions of the anatomical connections given their embedding in the full circuit. Exploiting the mean-field framework we generate predictions for the population-specific changes in the power spectra under various stimulation protocols. Inspired by published experimental studies, we analyze the responses of the circuit to oscillatory input and formulate predictions for the susceptibility of individual populations to specific frequencies.

Title: Sequence learning using pre-configured cell assemblies

Authors: *Y. LEOW, S. G. LALLÉE, C. Y. TAN;
Inst. For Infocomm Research, A*STAR, Singapore, Singapore

Abstract: Sequential events are inherent to ongoing experience, and the ability to represent coherent episodes while preserving sequential order is critical for planning future actions. Hippocampal neural assemblies have been shown to be activated in a sequential order reflecting behavioural content at a faster timescale during offline (eg. awake immobility & sleep) periods. Such replay sequences have been observed in both forward and reverse order under different behavioural states. Replay sequences provide a window to explore how the brain represents and preserves contiguity of ongoing experience and memories. Furthermore, they can also express sequences of novel trajectories that rats have never experienced, suggesting their possible involvement in navigational planning and the active construction of cognitive maps. Recent evidence also suggests that hippocampal replay sequences are able to represent the topological structure of complex environments (Wu & Foster, 2014). These sequences reflecting spatial structures can emerge rapidly after little experience. More recent findings demonstrate that rats can "preplay" spatial sequences during rest, even hours prior to exposure to the novel environment (Dragoi & Tonegawa, 2011). This suggests that rapid representations of novel sequences may arise from selection of pre-configured cell assemblies organised in a pre-existing temporal structure, rather than generated *de novo*. Using a model with pre-configured cell assemblies, we explore whether such a model can account for various properties of novel, forward and reverse replay sequences. We also use this model to make predictions about how these sequences can be used to build a cognitive map.

Title: Evoked responses in recurrent networks with multiple sub-populations

Authors: J. ALJADEFF[1], M. STERN[2], *O. BARAK[2];
[1]Neurobio., Univ. of Chicago, Chicago, IL; [2]Neurosci., Technion, Haifa, Israel

Abstract: We study the evoked responses of recurrent neural networks composed of multiple sub-populations of neurons ("cell-types") and a cell-type-specific connectivity rules. Recently we characterized the autonomous dynamics of such networks (Aljadeff, Stern, Sharpee, 2015). Significantly, the block structure of the connectivity matrix diverts the point of bifurcation from the quiescent state to a chaotic state, compared with networks with the same average connectivity strength but without structure (i.e. networks with a single cell-type). Furthermore, the autocorrelation structure of the global dynamics was more rich in the case of multiple sub-populations, compared with networks with a single population. These findings suggest that evoked responses would also depend on the cell-type-specific structure of the network, and not only on the average connectivity as in networks with a single cell-type. Previously it was shown for a network with a single population (and hence a single connectivity rule) that an the irregular spontaneous activity can be suppressed by a small amplitude input as long as its frequency is tuned to a band that depends on the average network gain (Rajan, Sompolinsky, Abbott, 2010). When the network is entrained by the stimulus, the intrinsic spontaneous dynamics are replaced with predictable correlated activity. In the network with multiple sub-populations, suppression of the spontaneous ongoing activity by an input is also observed. However the frequency to which the network is sensitive is now tuned by the parameters of the network: the size of each sub-population and the connectivity gain between every pair of sub-populations. If the connectivity gain in isolated regions of the network changes on a timescale slower than that of the spontaneous activity, for example through the effects of neuromodulation or neuro-glia interactions, this will change the properties of evoked responses in the entire network. The model studied by Rajan et al. is thought to be a step towards understanding the neural basis of stimulus and state-dependent attention. A limitation of this interpretation is that the stimulus that reduces the variability in the network (the "attended stimulus" that lies in a specific frequency band) is modified only if there are global changes to the gain in the network. By extending these results to networks with multiple sub-populations and characterizing their response properties we can develop an understanding of how local changes in a network can modulate the stimulus-

dependent suppression of variability, and therefore serve as a more realistic model of the neural basis of attention.

Title: Stochastic network plasticity as Bayesian inference

Authors: ***R. LEGENSTEIN**, D. KAPPEL, S. HABENSCHUSS, W. MAASS;
Graz Univ. of Technol. - ATU57477929, Graz, Austria

Abstract: Substantial experimental evidence (e.g. on spine motility, fluctuation of PSD-95 proteins) suggests that synaptic connections and synaptic efficacies are continuously fluctuating, to some extent even in the absence of imposed learning (see e.g. [1]). These findings raise the question how stable network function can be acquired and maintained in spite of these ongoing stochastic changes of network parameters. We present a novel conceptual framework for the organization of plasticity in neuronal networks in the brain that is based on stochastic variations of standard synaptic plasticity rules (e.g., Hebbian or STDP). The stochastic component of the plasticity rules continuously drives network parameters θ within a low-dimensional manifold of parameter space. This framework does not only explain how stable network function can be maintained in spite of ongoing parameter fluctuations, it also exhibits interesting new functional properties that have been posited from the perspective of learning theory [2, 3]. The low-dimensional parameter manifold represents a region where a compromise between overriding structural rules (such as sparse connectivity and heavy-tailed weight distributions) and good functional circuit properties is reached. Both structural plasticity [1] and synaptic plasticity can be integrated into this theory of network plasticity. This provides a theoretically founded framework for relating experimental data on spine motility to experimentally observed network properties. Furthermore, this framework endows neuronal networks with an important experimentally observed capability: Automatic compensation for network perturbations [4]. We

show that our alternative view can be turned into a rigorous learning model within the framework of probability theory. The low-dimensional parameter manifold can be characterized mathematically as the high probability regions of the posterior distribution of network parameters θ. More precisely, we propose that stochastic plasticity mechanisms enable brain networks to sample from this posterior, as opposed to the traditional view of learning as moving parameters to local optima θ* in parameter space. We demonstrate the advantages of this new theory in several computer simulations. These examples demonstrate how functional demands on network plasticity, such as incorporation of structural rules, automatic avoidance of overfitting, and inherent compensation capabilities, can be accomplished through stochastic plasticity rules.

Title: Temporal scaling in functionally feedforward recurrent neural network models

Authors: ***N. HARDY**[1], D. V. BUONOMANO[1,2];
[1]Neurobio., UCLA, Los Angeles, CA; [2]Brain Res. Inst., Los Angeles, CA

Abstract: The ability to encode time and generate timed responses is essential to learning, sensory perception, and motor control. A well-known feature of motor control is the ability to produce motor patterns, such as reaching, typing, and speaking, at a range of different speeds (temporal scaling). Though a number of models address how the brain times simple events, few have addressed how complex spatiotemporal motor patterns are generated and how such patterns could undergo temporal scaling. Previous work based on standard firing-rate recurrent neural networks (RNNs) (Sompolinsky et al., 1988; Jaeger and Haas, 2004) along with a recently described recurrent learning rule (Laje & Buonomano, 2013) has shown that the dynamics (the

neural trajectories) of recurrent networks can robustly encode time. Here we show that these neural trajectories can also account for temporal scaling. Specifically, RNNs can be trained to reliably complete the same autonomously generated trajectory at different speeds (i.e. trajectory durations). This is accomplished by delivering a constant tonic input speed signal that governs the speed of the current trajectory. Once trained, the network can generalize the speed of its dynamics in response to untrained speed signals. During temporal scaling training, the network converges to states in which very similar "parallel" trajectories in neural space are generated at different speeds. Because of the severe dimensionality reduction of the RNN patterns at the level of the output units, the output patterns are virtually indistinguishable other than the fact that they are temporally warped. Experimental results have shown that the neural trajectory of a population of neurons can encode time. These trajectories are often a functional feedforward sequence of activity (Hanloser 2002; Long et al, 2010; Paton, 2015). Here we establish that RNNs based on more realistic firing rate units (where activity levels are bounded between 0 and 1, and with distinct excitatory and inhibitory populations), can generate multiple distinct functional feedforward trajectories embedded within the same network and triggered by different stimuli. Importantly, these networks also exhibit temporal scaling and generalize to novel speeds. Our results describe a general computational framework for reliably producing, and temporally rescaling spatiotemporally complex and biologically relevant neural trajectories_thus capturing an unaddressed but fundamental feature of motor control. These findings have implications for the problem of temporal warping of motor patterns as well as the neural mechanisms underlying the generation of complex motor patterns.

Title: Dimensionality reduction and extrinsic modulation of cortical spiking networks

Authors: ***J. B. AIMONE**[1], C. E. WARRENDER[1], C. D. JAMES[2];
[1]Data-driven and Neural Computing, [2]Bio/Chem/Physical Microsensors, Sandia Natl. Labs., Albuquerque, NM

Abstract: Motor control and decision making regions of the cortex present a distinct challenge relative to sensory regions in that their inputs are less understood and their behavior is dominated by complex intrinsic dynamics. In recent years, *in vivo* characterization of these networks has benefited from analysis methods that investigate the population as a whole. These experimental studies have dovetailed with computational studies of intrinsically active balanced cortical network models. We describe how applying dimensionality reduction techniques, such as principal components analysis (PCA), to simulated cortical spiking networks can be used to describe the relationship between cortical networks and their behaviors. The recurrence and non-linear dynamics of cortical networks often makes their behavior borderline chaotic, and subtle changes to simulation conditions can make behavior of otherwise identical networks dramatically different. As a result, many modeling studies rely on statistical characterizations, such as ISI distributions, to compare the behavior of different networks. By using dimensionality reduction approaches to separate the temporal dynamics (e.g., PC trajectories) from the underlying behavioral manifold (e.g., PC basis sets), we can begin to directly compare the behavior of two networks that are parametrically varied. We first make a simple demonstration of this technique's utility by showing how some sources of noise, such as probabilistic synapses, preserve the underlying basis set; whereas forms of noise directed at network structure, such as synaptic weights, alter this basis set. We then use this technique to investigate how inputs interact with the intrinsic dynamics governed by the connectivity structure, and how outputs could separate input-driven dynamics from baseline dynamics. Finally, we use this technique to show how neuromodulation could result in dramatically different coding, greatly expanding the potential representational capacity of these networks. This approach could potentially help explain the interaction of internal and external dynamics during decision making and memory tasks in higher cortices.

Title: Automatic identification and classification of Hydra behaviors

Authors: *S. HAN, E. TARALOVA, R. YUSTE;
Biol. Sci., Columbia Univ., New York, NY

Abstract: Animal behaviors have been studied for centuries, but there is still a lack of efficient methods to automatically identify and classify all behaviors of an animal. Studies of animal behavior have been limited by the subjective and imprecise nature of human analysis, the limitation of the properties of human visual system and the slow speed of annotating behavioral data. Moreover, none of the major animal models allows the simultaneous observation of behavior and the complete neural activity from all neurons. Our group recently established a Hydra model with neuronal transgenic GCaMP6s, which allows the imaging of all neural activities while the animal is behaving. Here I have developed an automatic behavior identification and classification method for Hydra using machine learning approaches. I recorded behaviors from freely moving Hydra, extracted motion and shape features from the videos, and constructed a dictionary of these features. I identified behavior types using unsupervised clustering methods based on the dictionary, and trained classifiers for these behavior types. This method provides the opportunity of mapping the behaviors of Hydra and linking them to the neural activities. During evolution, Hydra is among one of the first species that developed a nervous system accompanied with a limited yet complex repertoire of behaviors. Studying the behaviors and the underlying neural networks of Hydra provides a unique opportunity of understanding the most basic rules of how nervous system compute and organize behaviors.

Title: Deep convolutional neural network inspired by development of visual acuity in Infants

Authors: *J. JUN, H. CHOI, J.-C. PARK, Y. JANG, D.-S. KIM;
KAIST, Daejeon, Korea, Republic of

Abstract: Deep learning is motivated by intuitions from structural and functional characteristics of the brain. Recent deep learning approaches such as convolutional neural networks (ConvNets) are breaking the records in various computer vision tasks especially large-scale Image recognition. After Convnet's success on the ImageNet Large-Scale Visual Recognition Challenge (ILSVRC) in 2012, various kinds of ConvNet architectures, learning methods and efficient regularization techniques have been introduced to improve their performance. Nonetheless, the gap between humans and machines is still large. Developmental studies of human's vision show that the human visual system rapidly develops after birth, especially in the first few years. Newborns only can detect changes in brightness or distinguish between stationary and moving objects, and their visual acuity is 12 to 25 times worse than a normal adult. After this period, the visual acuity starts to improve. In contrast, deep convolutional neural networks do not change the spatial frequency of input data during the training period. In this study, we hypothesized that the gradual change in spatial frequency of input data during the training period of ConvNets may decrease the overall training time. To this end, we utilized state of the art architecture of ConvNets for our subsequent experiments. The network consists of a number of convolution and pooling layers, followed by two fully-connected layers and a softmax layer. In order to measure the decrease in training time, we used CIFAR-10 image dataset to train our ConvNets. During training, we used input with fix-sized of 24 X 24 RGB image. At each training epoch, we gradually changed the resolution of the training images and passed the transformed data through the network. As a result, the trained model showed 91% classification accuracy on the test data. Additionally we found out that the overall training time was reduced compared to the conventional training method.

Title: Generation of age-specific atlases for the segmentation of pediatric brains from magnetic resonance images

Authors: ***A. J. METZGER**[1], A. BENAVIDES[2], V. MAGNOTTA[3], P. NOPOULOS[2];
[2]Psychiatry, [3]Radiology, [1]Univ. of Iowa, Iowa City, IA

Abstract: Quantifying tissue volumes and surface areas of the brain from magnetic resonance (MR) images during late neonatal and early postnatal development can provide valuable insight into genetic and environmental influence on brain maturation. To detect consistent differences between healthy and abnormal subjects, population studies require accurate processing of a large number of samples. Thus, the tools for the analysis of these images need to be automated. Many of the tissue classification and segmentation tools used to analyze neuroimaging data rely on anatomical priors which provide the probability of a voxel's tissue type based on spatial location. However, these likelihoods are typically based on data from adult subjects. The goal of this project is to develop three age appropriate atlases (neonatal, 1 year old, and 2 year old) that account for the rapid growth and maturational changes that occur during this period. Tissue maps from this age group were initially created using an expectation maximization (EM) algorithm and an adult atlas and manually correcting the resulting tissue maps. To minimize the required manual corrections, the adult atlas was registered to the pediatric scans using high-dimensional, symmetric image normalization (SyN) registration. The subject images were then mapped to an age specific atlas space, again using the SyN registration, and the resulting transformation applied to the manually corrected tissue maps. The individual maps were averaged in the age specific atlas space and blurred to generate the anatomical priors. The resulting anatomical priors were then used by the EM algorithm to re-segment the initial training set as well as an independent testing set. The EM algorithm classified each voxel into one of ten possible tissue types: cerebral spinal fluid, cortical gray matter, white matter, corpus striatum, globus pallidus, thalamus, hippocampus, cerebellar white matter, cerebellar gray matter, and venous blood. An atlas based on four pediatric subjects provided superior results as compared to the adult atlas. The new atlas was improved by incrementally segmenting more subjects, manually correcting those segmentations, and adding the corrected tissue maps to the collection used to create anatomical priors. The age-specific atlases were created to provide quantitative volumetric data to study developmental differences between infants born pre- and full-term. Future studies utilizing these atlases might look to make progress towards determining onset and progression of disease, effectiveness of treatment, and/or risk factors in a wide variety of pediatric neurological conditions.

Title: The effect of task complexity on the stability of functional network communities

Authors: *S. FUERTINGER[1], K. SIMONYAN[2];
[1]Dept. of Neurol., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Analysis of brain network communities provides important insights into the architecture of large-scale functional networks during a range of behaviors. However, questions arise whether modular network organization is stable across individual networks and whether it represents a characteristic signature of a specific behavior. To address these questions, we examined the stability of modular network partitions using community detection analyses of fMRI data acquired during four different conditions of increasing complexity, including the resting state, sequential finger tapping, meaningless syllable production, and meaningful speaking. In 14 right-handed monolingual English speaking healthy subjects, a 212-region whole brain parcellation was used to extract regionally averaged time-series, and zero-lag Pearson correlation coefficients were computed to construct weighted undirected graphs. Optimal modular network partitions were calculated by iteratively applying a heuristic community detection strategy. Partition distance (Pd) was quantified by calculating the variation of information between community affiliation vectors. The optimal partition of the group-averaged network for each condition was used as reference, and the stability of communities was assessed by performing a leave-one-out analysis. We found that resting-state formed six communities in the group-averaged network and showed a high degree of consistency within leave-one-out samples (Pd = 0.1±0.06, module N = 6.01±0.07) and high similarity to the group-averaged partition (Pd = 0.01±0.07). Task-related networks formed 5 communities during tapping, 4 communities during syllable production and 6 communities during speaking, all of which were stable across leave-one-out samples [module N = 5.2±0.73 (tap), 3.7±0.63 (syllable), 5.4±0.76 (speech)]. However, task-related networks exhibited somewhat reduced community consistencies with moderate deviations from the respective reference partitions [leave-one-out/group-averaged Pd = 0.16±0.05/0.20±0.03 (tap), 0.16±0.05/0.12±0.05 (syllable); 0.21±0.05/0.16±0.05 (speech)]. Our findings indicate that, while community architecture was specific to each examined condition, the stability of network communities was more sensitive to increased task complexity than to inter-subject variability.

Title: Time warping as a source of trial-to-trial neural variability

Authors: *P. N. LAWLOR[1], B. DEKLEVA[2], T. CYBULSKI[1], L. MILLER[2], K. KORDING[1]; [1]Physical Med. and Rehabilitation; Physiol., Rehabil. Inst. of Chicago, Northwestern Univ., Chicago, IL; [2]Physiol., Northwestern Univ., Chicago, IL

Abstract: One of the goals of modeling neural data is to identify and quantify types of variability. There are many such types, an important example of which is trial-to-trial variability: even when experimental conditions and behaviors are highly consistent, neural activity can vary considerably from one trial to the next. This is especially true for higher-order brain areas, where activity need not be tightly locked to sensory or motor events. For example, we can plan a movement, then choose when, and at what speed, to execute it. This observation motivates a type of modeling analysis that allows for neural responses with two key features: 1) variable offset in time between neural signals and external events, and 2) variable temporal scale allowing stretching and compression. To apply this idea to modeling, we have combined two well-known analysis tools: Generalized Linear Models (GLMs) and Dynamic Time Warping (DTW). GLMs have become a reliable analytical tool for neural data, but require the alignment of covariates to known or measured events in the real world. DTW provides a way to align two signals that differ by a warp (offset or scale), but lacks an underlying model of the signals being aligned. We combined the two by alternating between using DTW to “un-warp” the neural signal in each trial, and fitting the resulting un-warped signal with a standard GLM. We first applied this analysis framework to simulated single neuron activity generated from center-out reaching movements. The neuron’s spatial tuning curve followed cosine tuning and its temporal response varied between trials in offset and scale. Our approach correctly learned the warp for each trial, more accurately estimated the neuron’s tuning curves, and fit the data better than a GLM without time warping. We have also applied this framework to neural populations recorded from both macaque primary (M1) and dorsal premotor (PMd) cortex during a reaching task. Preliminary results suggest that time warping is present in both regions, and further, that the time warp for a

given trial is shared across neurons from the same region. For example, PMd activity related to reach target presentation varied in offset and stretch across trials, but was similar across neurons within a single trial. Future work will investigate whether accounting for time warp enables better decoding of behaviors such as reaching movements.

Title: Computer simulation of global brain dynamics at the neuronal resolution

Authors: *R. KOBAYASHI[1], M. SHIMONO[2];
[1]Natl. Inst. of Informatics, Tokyo, Japan; [2]Dept. of Physics, Univ. of Indiana, Bloomington, IN

Abstract: A key question in computational neuroscience is how microscopic components work together within the macroscopic brain scale. We demonstrate a computational model simulating the whole brain activity gathering neuronal components through columnar architectures (Figure). We used a Multi-timescale adaptive threshold model (Kobayashi et al., 2009) for the single neuron model, which is one of the most accurate models for reproducing the spike trains of a variety of cortical neurons *in vitro* (Gerstner and Naud, 2009). Before connecting through multiple brain regions, we tuned parameters about background inputs from subcortical nuclei and the ratio between excitatory and inhibitory synaptic strength on local neuronal circuits for sustaining activities within individual cortical regions (Potjans and Diesmann, 2012; Shimono and Beggs, 2014). We used a connectivity matrix provided from invasive tracing technique to sustain the accuracy, and especially the directionality of connectivity matrix (Deco et al., 2009; Shimono, 2013). Furthermore, the cortical network used in our study includes “weight” of connections (Markov et al., 2011). We reconstructed the number of neurons from the “weight”, and designed connections between neurons crossing different brain regions. The number of neurons at each brain region allowed us to integrate whole-brain network and neuronal dynamics

included in each brain region (Shimono, 2013). Computational modeling using non-invasive brain images is also important to use in cases of human brain structure (Izhikevich and Edelman, 2008). As summary, this computational model demonstrates a whole brain dynamics at the single neuron resolution for illuminating which parameter will be potentially critical to change the brain dynamics. Through the computer simulation, we will show a basis of understanding how optimally the brain structure is designed from the generated dynamics, including robustness against damages on the brain.

Title: Exploiting sensory reactivation from memory to validate directed functional connectivity measures with fMRI and MEG

Authors: *R. D. MILL[1], A. BAGIć[3], W. SCHNEIDER[3], M. COLE[2];
[1]Ctr. for Mol. and Behavioral Neurosci., [2]Rutgers Univ., Newark, NJ; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Mapping directions of influence within the human brain connectome represents the next phase in understanding its functional architecture. To this end, the efficacy of various methods of directed functional connectivity (also called effective connectivity) have been investigated in both the functional MRI (fMRI) and magnetoencephalography (MEG) literatures, primarily via recovering “ground truth” connectivity patterns embedded in simulated datasets. However, such approaches rely on numerous assumptions in the generative models used to simulate neuroimaging data. Hence, we explore a different strategy involving empirical data in which a ground truth directed connectivity structure could be anticipated with reasonable confidence. Specifically, we exploited the established “sensory reactivation” effect in episodic memory, in which the retrieval of sensory information leads to “reactivation” of regions

implicated in the perception of that sensory modality. We sought to implement a particularly powerful test by inducing a reversal in direction between visual and auditory brain regions across task conditions. Subjects underwent separate fMRI and MEG scanning whilst performing a paired associate task in which the onset of a visual stimulus cued retrieval of its auditory associate ("Visual-Auditory" condition), and the onset of an auditory stimulus cued retrieval of its visual associate ("Auditory-Visual" condition; see Figure). Task-evoked activation analyses of the fMRI and MEG data demonstrated reactivation in the auditory and visual cortices in the relevant retrieval conditions. Subsequent estimation of fMRI directed connectivity (via Patel's tau and IMaGES methods) recovered reversals in information flow in the anticipated directions, i.e. from visual to auditory cortices in the "Visual-Auditory" condition, and from auditory to visual cortices in the "Auditory-Visual" condition. These results complement simulation studies of directed connectivity, and begin to elucidate the dynamics that integrate brain regions during task performance.

Title: The role of fasciculation in forming the connectome of the Xenopus tadpole spinal cord: a computational study

Authors: *R. BORISYUK[1], R. MERRISON-HORT[1], O. DAVIS[2,1], S. R. SOFFE[3]; [1]Plymouth Univ., Plymouth, United Kingdom; [2]Brighton and Sussex Med. Sch., Brighton, United Kingdom; [3]Univ. of Bristol, Bristol, United Kingdom

Abstract: The neurons in the developing spinal cord of a Xenopus tadpole form a neuronal network that is able to produce behaviours such as swimming and struggling from an early stage. We use computational models to shed light on which features of development are important for the formation of network that can produce patterns of neuronal activity that correspond to behaviour. Previously, we have shown that an axon growth model guided by gradients of chemical cues can produce axonal trajectories that closely match the available anatomical data [1]. Furthermore, when the synaptic connectivity derived from these generated axons is mapped onto a large scale physiological model, the resulting network responds to simulated “skin touch” input by generating a stable pattern of anti-phase rhythmic activity which resembles that seen in real tadpoles during swimming [2], as well as reproducing other experimental observations such as transient synchrony [3]. In this presentation we study the effects of adding axon fasciculation and repulsion mechanisms to our growth model. Axon fasciculation is a process whereby a developing axon can detect the presence of another nearby axon and begin to grow along the existing axon; repulsion is the opposite process, where axons actively avoid each other. Both fasciculation and repulsion have been observed in the growth of commissural axons in the spinal cord of very early stage tadpoles [4] and the computational model is used to investigate the possible function of these processes. The growth angle is adjusted to include either repulsion or fasciculation to the nearest axon. These additional mechanisms of axon growth result in dramatic changes to the pattern of axonal trajectories and connection architecture. References 1. Title: How recurrent networks respond to complex stimulus sequences

Authors: ***A. P. PONZI**, J. R. WICKENS;
OIST, Okinawa, Japan

Abstract: Our ability to discriminate stimuli in predictable sensory streams improves with expectations of what stimuli may occur and when. Such streams entrain ongoing brain oscillations but how this happens and why it enhances discrimination is unclear. We previously showed [SFN 2014] that recurrent neural networks could generate anticipatory activity. We found that the neuronal and behavioural correlates of expectation emerge when weakly chaotic network oscillations are phase entrained by repetitive stimulus sequences. We show that stimulus presentations cause network phase resets. The network responses so generated are maximally discriminative when stimuli fall at their preferred phase in phase entrained networks. Discriminability increases continuously with both temporal regularity and stimulus type predictability. These factors also interact. Even random stimuli enhance target cue discriminability if streamed temporally regularly. Due to the gradual process of phase entrainment which occurs over multiple trials given stimuli show repetition dependent neuronal response while responses to unexpected oddball stimuli are large and distinct. Our results do not depend on specific network characteristics and are consistent with multiple streaming perceptual discrimination studies. Here we extend that study to investigate how networks respond to more complex types of hierarchical stimulus sequences such as occur in music, natural language and birdsong.

Title: Secondary data analysis of sert knockout and wild-type mice using fastica to isolate active circuitry

Authors: *D. MCCOY[1], A. GONZALES[2], R. E. JACOBS[3], V. D. CALHOUN[4], E. L. BEARER[1];
[1]Pathology, Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Computer Sci., Univ. of New Mexico, Albuquerque, NM; [3]Beckman Inst. of the California Inst. of Technol., Pasadena, CA; [4]The Mind Res. Network, Albuquerque, NM

Abstract: New applications of independent component analysis (ICA) to mouse brain MR imaging data will provide pathologists and biochemists interested in tract-tracing methodologies with techniques to analyze active circuitry. This is the first report applying ICA analysis to manganese-enhanced magnetic resonance imaging (MEMRI) of living mouse brains. We acquired T_1 weighted imaging data at $90^3 \mu m^3$ isotropic voxel resolution, capturing images of the same mouse at different time points after Mn^{2+} injection. Here we report a secondary data analysis of results from Bearer et al. (2009), using group ICA via the GIFT toolbox (http://mialab.mrn.org/software/gift), which produces spatial maps and associated time course behavior. This approach determines the post-synaptic uptake of Mn^{2+} from the injection site in the medial prefrontal cortex in wildtype C57/b6 mice and same strain mice with the serotonin transporter (SERT) gene knockout. In our original report we performed Student's t-tests between knockout and wild-type mice to reveal SERT circuitry differences. Correlation between active circuits by ICA reveals functional connectivity of subcircuits within the time points. Results show isolation of injection, ventricular and transport networks. Localization of monoamine transportation networks can lead to development of better pharmaceutical drugs.

Title: Braintrinsic: a virtual reality-compatible tool for exploring intrinsic topologies of the human brain connectome

Authors: *O. A. AJILORE[1], G. CONTE[2], A. YE[3], A. FORBES[4], A. LEOW[3];

Abstract: Thanks to advances in non-invasive technologies such as functional Magnetic Resonance Imaging (fMRI) and Diffusion Tensor Imaging (DTI), highly-detailed maps of brain structure and function can now be collected. In this context, brain connectomics have emerged as a fast growing field that aims at understanding these comprehensive maps of brain connectivity using sophisticated computational models. In this abstract, we present BRAINtrinsic, an innovative web-based 3D visual analytics tool that allows users to intuitively and iteratively interact with connectome data. Moreover, BRAINtrinsic implements a novel visualization platform that reconstructs connectomes' intrinsic geometry, i.e., the topological space as informed by brain connectivity, via dimensionality reduction. BRAINtrinsic is implemented with virtual reality in mind and is fully compatible with the Oculus Rift technology. Last, we demonstrate its effectiveness through a series of case studies involving both structural and resting-state MR imaging data.

Title: Mechanisms underlying the modulation of motor patterns during epidural electrical stimulation of the lumbar spinal cord

Authors: ***M. CAPOGROSSO**[1], E. FORMENTO[1], E. MARTIN MORAUD[1], G. COURTINE[1], S. MICERA[1,2];
[1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]The Inst. of Biorobotics, Scuola Superiore Sant'Anna, Pisa, Italy

Abstract: Epidural electrical stimulation of lumbar segments induces locomotor states in animal models and humans with spinal cord injury. However, mechanisms underlying motor pattern formation during stimulation remain enigmatic. It has been hypothesized that EES restores the capacity of spinal networks to orchestrate locomotion after a lesion by increasing cell excitability. This excitation “tunes” the spinal circuitry to a state that enables the use of sensory information as the main source of control and coordination in the absence of supra-spinal inputs. Despite the wide acceptance of this theory, a clear mechanistic framework is still missing to explain how EES achieves this excitation, within which ranges this interpretation is valid and how to leverage this understanding to improve rehabilitation. In particular, EES recruits the same afferent pathways that are, in this context, presumably acting as the main source of control. This raises fundamental questions on the impact of EES on the signals that are driving locomotion, and on its capacity to synergistically interact with the dynamics that encodes gait-related information. To address these questions, we developed a realistic computational model of excitatory proprioceptive pathways in the spinal cord, and we studied the effect of stimulation parameters onto the natural activity of neural afferent, efferent, and muscular responses during

locomotion. We designed a realistic biological-inspired model of the spindles (Group Ia and II) reflex network of a couple of agonist-antagonist muscles encompassing a realistic model of alpha-Motoneurons, Ia inhibitory interneurons, group II excitatory interneurons, group Ia and group II afferents. The network receives inputs from EES by computing the induced firing rate in the recruited afferents using a FInite Element Model. In parallel, the natural firing rate of the afferents during stepping, is estimated by the use of a realistic biomechanical model of the rat hindlimb implemented in OpenSim. During different stimulation protocols, the modulation of rhythmic motor patterns emerged from the continuous changes in the state of the hindlimb. Thus, sensory information acted as a source of control that supported the elaboration of complex motor patterns to stand and step over a broad range of velocities. Based on these results, we designed model-driven stimulation strategies that controlled the amount and timing of muscle activity in real-time. These algorithms automatically corrected bilateral deficits of gait and balance in spinal cord injured rats. The present results may play an essential role in the translation of this intervention into clinical applications.

Title: Reliability of structural connectivity hubs in human brain network

Authors: ***E. VACHON-PRESSEAU**[1], S. BERGER[2], P. TÉTREAULT[2], A. APKARIAN[2], M. N. BALIKI[2];
[1]Northwestern Univ., Chicago, IL; [2]Northwestern university, Chicago, IL

Abstract: Hubs are regions that occupy central positions in large-scale brain networks and distribute information due to their high number of connections with other regions. The traditional degree-based approach identifies hubs based on the number of connections nodes has with other

nodes in the network. An alternative method characterizes hubs based on their connections within a same sub network as well as based on their participation across several sub networks of the brain. Using this methodology, we studied structural connections of large-scale brain networks and examined the stability of hubs across time. We collected diffusion tensor imaging (DTI) in 21 healthy controls to examine the structural topological properties of large-scale brain networks. Each subject was scanned 3 times every 6 months. Connectivity matrices were generated for each subject at each scanning session (n = 63) by parcelling the brain into 457 nodes and constructing networks from the edges between nodes representing white matter tracks. The connectivity matrices were further thresholded at a link-density ranging from 0.02 to 0.10 with incremental of 0.01 and then binarized. A common structural network was constructed from averaging the connectivity matrices at link-density of 0.05. Modularity analysis performed on connectivity matrices across all densities revealed the presence of 7 stable modules. Based on this modular organization, nodes were characterized by within-module degree Z-score and participation coefficient (a measure between 0-1 indicating between modules distribution of edges). 16 nodes were denoted as hubs (Z-scores > 2.5) and half of them displayed participation coefficient greater than 0.5. These hubs were mainly located in posterior insula and subcortical structures such as the thalamus and the basal ganglia. Normalized mutual information (NMI) was used to quantify the similarity between individual subject modularity and the mean group module structure at each scan. No effect of time was observed on NMI ($F(2,20) = 1.15$; $p = 0.33$) or within-module degree Z-score ($F(2,15) = 0.32$; $p = 0.66$) across scanning sessions. Previous studies have shown that hubs in functional networks of the human brain are sparse, located in the precuneus with low participation coefficient. Here, we show that brain network constructed form DTI structural connections displayed multiple subcortical hubs with high participation coefficients and are highly stable in time.

Title: Intrinsic and dynamic functional network architectures shape task-evoked activation patterns in the human brain

Authors: *M. W. COLE[1], D. S. BASSETT[2], D. H. SCHULTZ[1];
[1]Rutgers Univ., Newark, NJ; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Investigations of brain function have largely bifurcated into focusing on either task activations or spontaneous brain activity correlations (resting-state functional connectivity). Recent evidence hints at a unification of these areas by demonstrating that task activation patterns correspond to resting-state functional connectivity patterns. However, the mechanisms underlying this correspondence remain unknown. We hypothesized that an intrinsic functional network architecture shapes activity flow among brain regions across both rest and task states. We tested this hypothesis in the human brain by modeling activity flow through functional networks, predicting each brain region's task activation as a combination of the task activations found in other brain regions. Predictions were accurate when resting-state functional connectivity governed the flow of activity. Predictions improved using task functional connectivity, suggesting dynamic updates to the brain's functional network architecture also shape task activation patterns. These results suggest activity flow through the brain's intrinsic functional network architecture provides a unifying framework for understanding activity across task and rest states, while dynamic modifications of that architecture refine activation patterns to allow implementation of task-specific functionality.

Title: A bidirectional interface for closed-loop hybrid neural systems

Authors: *F. D. BROCCARD[1], M. L. KHRAICHE[2], G. A. SILVA[2], G. CAUWENBERGHS[2]; [1]Inst. Neural Computation, [2]Bioengineering, UCSD, La Jolla, CA

Abstract: The coordination of distributed brain activity observed during many sensorimotor and higher cognitive processes largely depends on neuronal population activity. We propose an experimental and computational framework to investigate the dynamics of the interactions among functional neural networks. This framework is a closed-loop system composed of laboratory preparations of functional neuronal networks coupled to biologically realistic implementations of in silico neural networks implemented on software and/or biomimetic FPGA hardware. We present a proof of concept of this interface by establishing and maintaining a high level of synchronization between a biological network grown on a 256-channel multielectrode array and a spiking neural network model. The bidirectional interface may also provides a testbed for a new generation of neural prosthetics by allowing complex networks of any desired topology and level of complexity to be coupled with living neural tissue.

Title: Variational auto-encoder with convolutional neural network for complex image classification task

Authors: *Y. JANG, H. CHOI, J.-C. PARK, J. JUN, D.-S. KIM;
KAIST, Daejeon, Korea, Republic of

Abstract: These days deep learning have achieved much state-of-the-art performance in many machine learning tasks, such as image classification, object detection, speech recognition, and natural language processing. They utilize brain-like deep architecture consists of many layers of fully connected or convolutional layers to learn representation from the data to predict the correct answer for the specific target task. To train such deep architecture, recent deep learning models are largely dependent on labeled dataset, which is the pair of raw data and correct answer sets. However, these labeled dataset is scarce compared to unlabeled dataset, so in many tasks it is the bottleneck to develop human-level intelligence system. Furthermore, it is biologically implausible because human learns from the small volume of labeled data and mostly learn from unlabeled data. Many previous literatures have tried to overcome that limitation of learning systems by utilizing large volume unlabeled data like a human brain. However, most of them show severe performance degrade when labeled dataset is limited. In case of MNIST dataset, when we provide ten labeled examples per each digit best performance model gives 8.1 percent error rate. Meanwhile, variational auto-encoder records 3.33 percent of error rate. It is a breakthrough for the human-like learning system, which requires a small volume of labeled dataset to learn the appropriate representation of the given visual data. However, variational auto-encoder has its disadvantage. It is not trained well in case of networks with many layers so it cannot learn complex sets of images, such as large resolution general image classification task like ImageNet. Also, even it can use any kinds of neural network like convolutional neural network in principle, it cannot utilize such networks efficiently in practice. In this study, we suggest the model that learn from the large size of unlabeled dataset and small labeled dataset, which is similar to learning procedure in human. Our work uses the variational auto-encoder, but improve it by alleviating those limitations. To do that, we used convolutional neural network both in encoder and decoder parts of the variational auto-encoder. It gives more model capacity to learn more complex image dataset with fewer parameters. To test the effectiveness of our model, we perform two experiments on MNIST, CIFAR-10, and CIFAR-100 dataset. We perform image generation task to see that our model learns the appropriate generative model for various image dataset. Also, we perform image classification task. Our model shows reasonable performance improvement for semi-supervised learning setting.

Title: Stability of latency and topology in functional networks of the human neo-cortex

Authors: *J. CHAPETON, S. INATI, K. ZAGHLOUL;
NINDS, NIH, Bethesda, MD

Abstract: Perhaps the most important step in analyzing functional brain connectivity is the initial construction of networks from electrophysiological or imaging data. Here, we construct stable functional networks of the human cortex based on electrocorticographic data acquired from epileptic patients undergoing seizure monitoring. Specifically, we calculate the average mutual information between the voltage traces from a pair of electrodes for a range of time lags, which allows us to extract the strength, latency, and direction of the connection between that pair. For each patient we construct networks using short time blocks collected over several days in order to examine the temporal evolution of these networks. We compare the connectivity at different time points by calculating measures of similarity between adjacency matrices and by comparing the networks' topological metrics. We find that the extracted network connectivity is stable over time scales ranging from minutes to days. Notably, connections that persisted over multiple time blocks had latencies that were remarkably similar across different days. Although many studies have shown that functional connectivity can change dynamically in a matter of seconds, our results suggest that there may be functional relationships that persist over much longer time scales.

Title: Virtual slice in 3D: constructing and cutting a full-scale computational model of the dentate gyrus

Authors: *I. RAIKOV[1], C. J. SCHNEIDER[2], I. SOLTESZ[2];
[2]Anat. and Neurobio., [1]Univ. of California, Irvine, Irvine, CA

Abstract: The dentate gyrus is an integral part of the hippocampal formation that is thought to perform pattern separation of sensory inputs in order to facilitate context-specific encoding necessary for the formation and retrieval of memories (Neunuebel et al., J Neurosci. 2012; Leutgeb et al., Science 2007). We present a flexible and general computational methodology for the construction and functional simulation of neuroanatomically-detailed neuronal networks and its application towards a full-scale model of the rat dentate gyrus as well as slices of arbitrary thickness and position derived from it. The ability for automated slice model construction allows the modeling of reduced size networks without the need for synaptic weight scaling. Furthermore, it allows for a more direct comparison with the broad range of experimental results available for slice preparations of the dentate gyrus. The model incorporates a number of improvements over previous dentate modeling work. Most prominently, each granule cell has a computer-generated heterogeneous dendritic morphology in a realistic volume constrained by neuroanatomical reconstructions, using methodology previously described by the authors (Schneider CJ, Cuntz H, Soltesz I, PLoS Comput Biol. 2014 10(10):e1003921), with biophysical properties that agree closely with recent experimental literature and previous modeling studies. In addition, the model incorporates three new classes of interneurons, septotemporal density distributions of cells based on experimental measurements, and updated distributions of synaptic and electrical connectivity based on recent electrophysiological evidence. This work provides a powerful methodology for addressing the fundamental challenge of understanding how the specific morphological and spatial features of neurons relate to the function of whole regions of the brain. The flexibility and great increase in spatial resolution afforded by our methodology allows such questions to be investigated on multiple scales, from neurites and spines to circuits and systems.

Title: Diffusion-based connectivity of the thalamus to the default-mode network

Authors: *S. I. CUNNINGHAM[1], D. TOMASI[1], N. D. VOLKOW[2];
[1]Biomed. Engin., Natl. Inst. of Health, NIAAA, Rockville, MD; [2]Natl. Inst. of Health, NIDA, Bethesda, MD

Abstract: Neuroimaging studies have identified functional interactions between the thalamus and default mode network (DMN) in studies of mindfulness, disorders of consciousness, and anesthesia-induced unconsciousness. However, less is known about the structural connectivity of the thalamus to regions within the DMN. In this study, we used diffusion tensor imaging to segment the thalamus based on its probabilistic connectivity to 6 DMN regions of interest (ROIs). Data from 37 healthy control subjects (17 males/20 females, ages 23-35 years) was obtained from the Human Connectome Database. Diffusion-weighted data was acquired in a Siemens 3T Connectome Skyra (TR/TE/flip angle = 5.52s/89.5ms/78º) through 6 runs representing 3 different shells of b = 1000, 2000, and 3000s/mm2 and processed using FSL's FDT diffusion toolbox. Six ROIs were selected from the dorsal DMN, including: the angular gyrus (AG), hippocampus, midcingulate cortex (MCC), medial prefrontal cortex (mPFC), superior frontal gyrus (sFG), and precuneus. Parcellation maps for each subject were created using probabilistic tractography to determine the number of connections from each voxel of the thalamus that had a 50% chance or greater of reaching each ROI. Each voxel of the thalamus was then assigned to the ROI that received the highest number of connections from that voxel. Combined results from 37 subjects revealed a highly symmetrical representation of the DMN across both hemispheres of the thalamus. The AG, hippocampus, mPFC, sFG, and precuneus all had a statistically similar number of connections to both hemispheres of the thalamus (p's > 0.05), whereas the MCC was more largely represented on the right thalamus ($p = 0.0001$). When compared to thalamic subdivisions defined in the Oxford Thalamic Connectivity Probability Atlas, the location of each DMN segment followed known structural connectivity of the thalamus to the cortex as a whole: thalamus voxels projecting to the mPFC, sFG, and MCC were primarily contained in the thalamic subdivision that projects to the pre-frontal cortex (p's < 0.05); precuneus and AG connectivity was mainly associated with the thalamic subdivision that projects to the posterior parietal lobe (p's < 0.01); and thalamus voxels projecting to the hippocampus were primarily located in a subdivision that projects to the temporal lobe. These findings suggest that a white matter network exists between the thalamus and DMN that follows known thalamocortical projections. Future comparison of thalamic structural connectivity with functional connectivity to the DMN will help determine if this underlying structure helps facilitate functional involvement of the thalamus in the DMN.

Title: Neuronal wiring specificity within and across connectomes

Authors: *M. BERNING, M. HELMSTAEDTER;
Max Planck Inst. For Brain Res., Frankfurt am Main, Germany

Abstract: The computational capabilities of neuronal circuits are constrained by their structure. The degree to which circuit structure contributes to neuronal circuit function is unknown. One key open question is how much synaptic circuit structure varies between individuals. Obtaining constraints on this question is thus a key goal, but has been prohibitively expensive so far, since mapping even single local connectomes has consumed decades worth of work. Here we report the mapping of a second local connectome from mouse retina. We find that even rare cell types are preserved across individuals, that previously unknown connectivity rules between cell types are preserved, and we quantify the inter-individual single-cell wiring specificity in visual channels. This work provides quantitative bounds for the inter-individual variability of connectomes in the mammalian brain and provides a strong indication of high wiring specificity in the nervous system.

Title: Incremental learning of deep neural networks mitigating catastrophic forgetting

Authors: *H. CHOI, J. JUN, Y. JANG, J.-C. PARK, D.-S. KIM;
Electrical Engin., KAIST, Daejeon, Korea, Republic of

Abstract: For neural network models and other machine learning systems, catastrophic forgetting has been a serious problem for many years. When a network is trained on one task and then trained on the other, it tends to forget previously learned knowledge while obtaining new information from the second task. According to previous studies in human learning systems, the neocortical learning algorithm is robust to catastrophic forgetting; it continuously replays memories stored in the hippocampus and strengthens the tasks that are not recently performed. This complementary algorithm enables human beings to learn new tasks and concepts in online fashion while standard neural network models are not suitable for such online and incremental learning. In this work, we investigate the possibility of incremental learning of deep neural networks by mitigating the problem of catastrophic forgetting. The baseline model architecture is deep convolutional networks that are known to perform well on various computer vision tasks, and we use dropout as our regularization method. We propose two key ideas to apply incremental learning into deep neural networks. First, when new data comes into the network, the network is cloned into two different networks, one with increased capacity and the other with the same size. After a reasonable amount of training, we compare the performance of two different networks and select the one that performs better. This adaptive scaling mechanism enables the model to be more robust to catastrophic forgetting since it learns to find the optimum network capacity with respect to the amount of data. As a result, the network can naturally learn new things incrementally with less information loss. The second approach is to reformat the sequence of input data that goes into the learning system. Just like human learning, we first train the network with more easily recognizable examples, and continuously increase the complexity of data by showing a more challenging sequence of examples to the model. This curriculum learning approach also enhances the learning capacity of the network, therefore helping the model to learn things in incremental way. To test the robustness of the proposed learning algorithm to catastrophic forgetting, we perform two different experiments with increasing complexity. We start with a simple task, recognizing the MNIST handwritten digits, and then increase the difficulty to CIFAR-10 dataset. The adaptive incremental learning algorithm showed reasonable performance increase compared to standard gradient-based training algorithm.

Abstract: Despite being one of the five best characterized model organisms with all of its 302 neurons and almost its entire connectome precisely mapped, there is only sparse knowledge on how the Caenorhabditis elegans nervous system codes for its rich behavioral repertoire. The European Si elegans project aims at unravelling *C. elegans*‘ nervous system function by its hardware emulation and its biophysically accurate embodiment in a virtual behavioral arena. We present the final platform implementation strategy and the recent system integration steps with special focus on the user-friendly neural response model generation and behavioral experiment definition tools. We describe the unique features of the neural representations by custom-designed field-programmable gate array (FPGA) boards synaptically communicating through an electro-optical connectome. Each of the 302 FPGAs can be configured with a *C. elegans*-specific neural response model. Both user-friendly and expert model definition tools (e.g., LEMS-based, import/export from existing neural libraries) are at the user’s disposition. The hardware nervous system controls the behavior of a virtual representation of the nematode in a virtual arena. The physics-based simulation will allow scientists to test both published and hypothetical behavioral paradigms just as in a real laboratory environment. Users will have access to all biologically relevant variables to study the neural events governing a certain behavior. We furthermore will explain how users can actively contribute to the development of add-on functionality of the platform in a peer-participation approach. For further information, please visit www.si-elegans.eu.

Abstract: Electroencephalography (EEG) is a commonly used technique to measure large-scale electrical activity in the brain in both clinical and research settings. Despite its widespread use, the precise relationship between EEG measured at the scalp and the neuronal activity generated within heterogeneous networks containing multiple cell types is not well understood. This study aims to look at how network activity relates to current dipole moments and extracellular potentials generated by populations of neurons. Anatomically accurate, multi-compartment neurons were used to simulate the dipole moments resulting from action potentials and post synaptic potentials (PSPs) across a variety of cell types. For each cell type, compartmental current dipole moments were summed across the cell to generate a dipole response function (DRF) for each neuron that combined the cell's anatomical configuration and electrical activity to create a point source representation of the equivalent current dipole for the cell. A thalamocortical network (Bazhenov et. al, 2002) was created using a combination of single and two compartment spiking neuron models to represent underlying network activity. In the model, 100 pyramidal and 25 interneurons, representing somatasensory cortex, and 50 thalamocortical and 50 reticular neurons, representing the thalamus, were used to simulate slow wave sleep patterns. Spiking activity from the network was convolved with the DRF for each neuron type and summed across the population. The resulting current dipole for the population was then used to compute extracellular potentials and compared to recordings of drug induced slow wave sleep in cats reported in the literature. Results suggest that bursting patterns of spiking activity in pyramidal cells contributes significantly to the neuron's current dipole. Direct contributions of action potentials to the net dipole moment generated across neurons are typically small due to

their short duration and corresponding limited temporal summation. During bursting neurons generate multiple action potentials that create an envelope in the DFR that lasts for the duration (approx 70ms) of the bursting activity. This longer envelope could enable a summative contribution of spiking activity across the population to the net current dipole. These insights could lead to additional understandings of the relationship between EEG signals and neural activity within heterogeneous networks.

Title: Intrinsic functional connectivity in valuation- and salience-sensitive networks provide a neural classifier for Autism Spectrum Disorder

Authors: *M. GHANE[1], J. A. RICHEY[2], R.-A. MÜLLER[3], K. T. KISHIDA[4];

Abstract: Research on autism spectrum disorder (ASD) shows evidence of early deficits in visual processing and increasing problems with social and non-social decision-making throughout development. One possible explanation for these deficits may be decreased connectivity in lower-level sensory processing networks or changes in connectivity between low- and high-order processing regions. Resting-state functional magnetic resonance imaging (rs-fMRI) is increasingly used as a way to characterize group differences between individuals with ASD and those who develop along typical trajectories (TD). These indices are often used to characterize group-level differences, which are descriptive and fail to characterize individual differences. We demonstrate that, per individual, pairwise correlations between a-priori defined regions-of-interest (ROIs) in valuation- and salience-sensitive networks can be used to accurately classify individuals with or without the diagnosis of ASD. We included rs-fMRI data (3T GE

scanner) from 42 ASD (*M age* = 13.90, SD = 2.68) and 44 TD (*M age* = 13.12, SD = 2.83) adolescents. Data were slice time and motion correction, scrubbing for artifacts, and co-registration to a standardized MNI-152 T1 weighted image. To assess intrinsic connectivity between regions within and across valuation- and salience-sensitive networks we produced a matrix of pair-wise correlations between 28 regions identified by peak task-based activation coordinates from Litt et al., 2011. The correlation coefficients per subject were transformed using Fisher's z-transformation and differences between the two groups (ASD vs. TD) assessed using two-sample t-test. Those connections that showed significant differences at $p<0.05$ (N=17 connections) were selected for further analysis. Next, we sought to train a cross-validated predictive model using the identified connections, additional demographic variables, and an automatic variable selection and model regularization approach called the "elastic net" (Zou and Hastie, 2005). We use this modern machine learning procedure to fit a penalized logistic regression model, which began with 17 connections plus variables for age, sex, and handedness. The resulting model included 15 of the original 17 suspected connections and did not retain age, sex, or handedness. The cross-validated, out-of-sample performance, of the reduced model gave an area under the curve of 0.8994 and sensitivity and specificity of 71.43% and 77.27%, respectively. The retained variables suggest that a purely neural account via resting state correlations is sufficient to achieve high discriminability between ASD and TD diagnoses.

Title: Context-dependent filtering as an emergent property of high dimensional networks

Authors: *M. S. GOLDMAN[1], K. R. ALLEN[2];

Abstract: Context is an important factor for many aspects of cognition. Being able to attend to a single stimulus while filtering out other inputs has been a topic of great interest in both the experimental and theoretical literature. In a standard context-dependent decision making task, an animal is presented with two stimuli and a context signal indicating which of the two stimuli should be used to make a decision. An unresolved mystery for such tasks is how to reconcile the appearance of neural responses to distractor stimuli in the decision network with the fact that these stimuli do not significantly impact the integration of the target signal. Previous approaches have simply filtered out distractors before they reach the decision making circuit, or require networks with finely arranged separate attractors for each context. Our model only requires a single attractor, does not filter out distractors before they reach the decision making circuit, and works across a wide range of architectures. The critical observation upon which our results build is due to the statistics of high-dimensional spaces. In networks with large numbers of neurons, most patterns of neuronal firing will be orthogonal to each other. In the context of a decision making network in which evidence is accumulated along a line attractor, this means that high-dimensional input vectors will generically be orthogonal to the attractor direction. Thus, even if inputs arrive at the decision-making network and transiently cause neuronal responses, almost none of the input will be integrated unless the input vectors are specially arranged to align along the attractor. Therefore, filtering is the default operation of a large network, and a context signal must only act to rotate an incoming signal towards the attractor. Two stimuli can then be presented to the network, but only the one which is signaled by context will be integrated. This will not hold for small networks where the projection of a random distractor onto an integrating vector might be reasonably large. Here, the default operation is to integrate most inputs. We show this selective integration for a wide range of network architectures, with both linear and nonlinear neurons. Even for small rotations of the target signal, we see a drastic improvement in context-dependent classification accuracy when two competing stimuli are presented. These results provide a novel mechanism for context-dependent filtering in high dimensional networks. Furthermore, they illustrate how seemingly innocuous reductions to effective models with small numbers of units may discard critical network operations that require high dimensions.
