Title: Characterization of TRIP8b isoforms in the oligodendrocyte lineage

Authors: *K. LYMAN, A. P. ROBINSON, D. FISHER, R. HEUERMANN, Y. HAN, K. TIMMONS, X. CHENG, S. D. MILLER, D. M. CHETKOVICH;

Abstract: Hyperpolarization activated cyclic nucleotide gated (HCN) channels play an important role in limiting temporal summation and in setting the membrane potential of many cells in the brain. Their subcellular distribution is tightly regulated by an auxiliary subunit, Tetratricopeptide repeat-containing Rab8b interacting protein (TRIP8b). Interestingly, TRIP8b is extensively spliced and nine distinct isoforms exist. These isoforms have distinct (in some cases opposing) effects on the surface trafficking of HCN channels. Two distinct promoters (termed 1a and 1b for their first exons) lead to the expression of TRIP8b. Although 1a containing isoforms are known to be expressed in neurons, 1b isoforms are not. Moreover, knockout mice lacking the 1b isoforms show in tact neuronal HCN channel function suggesting that the 1b isoforms are exclusively expressed elsewhere. Recent work has identified the expression of TRIP8b isoforms containing 1b in mature oligodendrocytes. Here, we extend this work by characterizing the developmental regulation of TRIP8b isoforms in the oligodendrocyte lineage using biochemical and electrophysiological approaches. We find that 1b isoforms are only expressed in oligodendrocytes and that they are developmentally upregulated coincident with the onset of myelination. Additionally, we note that mature oligodendrocytes express 1b isoforms in addition to the 1a isoforms expressed by neurons.

Title: Characterization of the transcriptome of male and female hypothalamic neural/progenitor stem cells and the impact of glucocorticoids exposure

Authors: *K. A. FRAHM[1], M. E. PEFFER[2], J. Y. ZHANG[1], S. LUTHRA[3], A. B. CHAKKA[3], M. B. COUGER[6], U. R. CHANDRAN[3], A. P. MONAGHAN[4], D. B. DEFRANCO[5,2]; [1]Pharmacol. & Chem. Abstract: Exposure to excess glucocorticoids during fetal development has long-lasting physiological and behavioral consequences, although the mechanisms are poorly understood. The impact of prenatal glucocorticoids exposure on sexually dimorphic stress responses in juvenile and adult offspring implicates the developing hypothalamus (HT) as a target of adverse prenatal glucocorticoid action. To identify glucocorticoid receptor (GR) target genes, primary cultures of male or female HT-neural progenitor/stem cells (NPSCs) were treated with vehicle or the synthetic glucocorticoid dexamethasone (Dex, 100nm) for 4h and the transcriptome determined using RNA-Seq. Bioinformatic analysis identified relatively high levels of a number of genes regulating stem cell proliferation and HT progenitor function. While several genes are regulated equivalently by Dex in male and female NPSCs, others show gender specific responses. Interesting, while these cells express GR, only low levels of sex-steroid receptors are expressed, suggesting that sex-specific differentially regulated genes identified are mediated by genetic and not hormonal influences at this age. Our studies provide the first characterization and description of sexually dimorphic glucocorticoid-regulated pathways in HT NPSCs and may reveal target genes responsible for the long-term consequences of fetal glucocorticoid exposure in adulthood.

Title: Microrna-128 regulates proliferation and neurogenesis of neural precursors by targeting pericentriolar material 1 (pcm1) in the developing neocortex

Authors: ***P. KIM**[1], W. ZHANG[2], Z. CHEN[2], H. LOKMAN[1], L. QIU[2], K. ZHANG[2], S. G. ROZEN[1], E. TAN[1], L. ZENG[2], S. JE[1];

Abstract: During the development of the embryonic neocortex, the tightly regulated expansion of neural progenitor cells (NPCs) and their differentiation into neurons are critical for normal cortical formation and function. The failure of these processes is associated with various neuropsychiatric disorders including autism spectrum disorders (ASDs). However, the molecular mechanisms that regulate NPC proliferation and differentiation remain unclear. In this study, we demonstrate that microRNA (miR)-128, which has previously been shown to be misregulated in ASDs, regulates the proliferation and differentiation of NPCs by repressing pericentriolar material 1 (PCM1). Specifically, the ectopic overexpression of miR-128 reduces proliferation but promotes NPC differentiation into neurons both *in vivo* and *in vitro*. Overexpression of miR-128 suppressed the translation of PCM1, and the knockdown of endogenous PCM1 phenocopied the observed effects of miR-128 overexpression on NPCs. Furthermore, the concomitant overexpression of PCM1 and miR-128 in NPCs rescued the phenotypes associated with miR-128 overexpression, enhancing neurogenesis but inhibiting proliferation *in vitro* and *in utero*. Taken together, these results demonstrate a novel mechanism by which miR-128 regulates the proliferation and differentiation of NPCs in the developing neocortex.

Abstract: Microcephaly – reduced head circumference as a result of decreased brain size – is an important cause of developmental disability. Microcephaly is highly genetic and identifying and characterizing microcephaly genes has provided many new insights into the genetic mechanisms of neurogenesis. We have previously reported that loss of function mutations in *CHMP1A* cause microcephaly with pontocerebellar hypoplasia and short stature. *CHMP1A* encodes a member of the ESCRT complex, a protein complex required for cellular functions including activated receptor degradation, exosome secretion, and cytokinesis. To understand the mechanism of *CHMP1A* in normal brain development we have generated a Chmp1a gene trap (GT) mouse line and *CHMP1A* null human induced pluripotent stem cell (iPSC) lines. Homozygous Chmp1a GT mice show early postnatal lethality and reduced body and brain size by late embryogenesis with abnormal development of the cerebral cortex and cerebellum. By late embryogenesis, whole brain mass is reduced 10% in GT embryos compared to controls. At E17.5, Chmp1a GT mice have reduced cortical plate thickness, with greater reduction of late-born upper layers than of early-born deep layers. At P0, Chmp1a GT mice have reduced cerebellum size, a thin external granule layer, and fewer proliferating granule cell precursors, defects that resemble disrupted Sonic hedgehog signaling. Together, these findings suggest that Chmp1a is required for brain development through regulation of cortical and cerebellar progenitor cell proliferation. RNA sequencing of neural rosettes differentiated from human iPSCs provides further evidence for

CHMP1A's role in progenitor proliferation. We used RNA sequencing to measure global gene expression differences between 5-week-old *CHMP1A* null and control neural rosettes. Gene ontology (GO) term enrichment analysis identified clusters "mitotic cell cycle" and "regulation of neurogenesis" as significantly down regulated in the absence of *CHMP1A* and cluster "synaptic transmission" as significantly up regulated. In addition, the expression of several canonical markers of proliferating cortical progenitors was greatly reduced in mutant rosettes. These results provide further evidence that progenitor proliferation is disrupted in the absence of *CHMP1A*; this mechanism likely causes microcephaly in *CHMP1A* null patients and Chmp1a GT mice.

Title: Analysis of the Gpr56 e1m-EGFP transgenic marmoset

Authors: *A. MURAYAMA[1,2], J. OKAHARA[3], B. BYOUNG-IL[4], C. A. WALSH[4], E. SASAKI[3], H. OKANO[1,2];
[1]Marmoset Neural Architecture, RIKEN, BSI, Wako, Japan; [2]Keio Univ. Sch. of Med., Tokyo, Japan; [3]CIEA, Kawasaki, Japan; [4]Harvard Med. Sch., Boston, MA

Abstract: G-protein coupled receptor 56 (Gpr56) has been reported as a cortical malformation-related gene that is mutated in patients, leading to a distinctive phenotype termed bilateral frontoparietal polymicrogyria. Recent study (Bae et al., Science 2014) showed that a 15-base pair deletion mutation in a regulatory element of Gpr56 causes polymicrogyria selectively surrounding the Sylvian fissure bilaterally. A minimal 300-bp Gpr56 e1m promoter contains the cis-regulatory element around this deletion region, and the Gpr56 e1m promoter-lacZ transgenic mice suggested that this Gpr56 e1m promoter region might be important of the Sylvian fissure formation. In addition, Gpr56 mRNA expressed especially in outer radial glial progenitor cells in human neocortex, which suggested that it may play an important role in gyrification. But mouse

is a lissencephalic animal and limited to study gyrification. To study how the minimal 300-bp Gpr56 e1m promoter functions during corticogenesis, we generated the Gpr56 e1m promoter-EGFP (enhanced green fluorescent protein) transgenic marmoset. The common marmoset, Callithrix jacchus, is a small New World Primate, which has clear Sylvian fissure, and we can now genetically engineer its embryo. We injected a lentiviral vector, carried Gpr56 e1m-EGFP, into marmoset embryos, and obtained two founder marmosets (F0). Using their fertilized embryos, we generated F1 animals. We performed immunohistochemistry of the cerebral cortex. Most of the EGFP-positive cells existed in the subplate (SP) and the cortical plate (CP). Some of them expressed progenitor markers and possessed basal processes like outer radial glia cells, but the cell bodies were not in the outer subventricular zone but in CP. It may suggest that Gpr56 e1m promoter did not work in the outer radial glia but played a role in the progenitors migrating in the CP and other specific neurons in SP and CP to build the cerebral cortex.

Title: Dissecting the neurodevelopmental role of the microtubule-associated protein EML1, mutated in subcortical heterotopia

Authors: ***S. BIZZOTTO**[1], F. PHAN DINH TUY[1], M. KIELAR[2], D. ROMERO[1], A. HOULLIER[1], G. CANALI[1], E. WELKER[2], A. HOUDUSSE[3], A. CROQUELOIS[2], F.

Abstract: Subcortical band heterotopia (SBH) is a cortical malformation associated with intellectual disability and epilepsy, and characterized by the presence of a band of heterotopic neurons located in the white matter below a grossly normal cortex. Mutations were identified in the microtubule-binding protein Eml1/EML1 in the spontaneous HeCo ('Heterotopic cortex') mouse mutant, a model of SBH, and in patients exhibiting giant ribbon-like heterotopia. HeCo mice have misplaced progenitors and ectopic proliferation, which are likely to be the primary causes of their heterotopia. The role of Eml1 in neurodevelopment has not been previously studied. We found that during the neurogenic period in the mouse cortex it is expressed in both progenitors and post-mitotic neurons. We aimed to explore Eml1's function in progenitors. Our objectives were to search for Eml1 protein partners in mouse embryonic brain extracts and to study Eml1 association and role with respect to microtubules (MTs). Also, we wanted to perform cell biology studies *in vitro* and *in vivo* to study neuronal progenitor behaviour in the presence or absence of Eml1. We found that Eml1 shows a cell cycle-dependent localization, enriched along spindle MTs and at the midbody, suggesting a role in spindle function and/or in cytokinesis. Recombinant Eml1 partially co-localizes with MTs in epithelial cells and the purified protein binds directly to MTs *in vitro*. Proteomics studies identified a list of potential protein partners, and we are focusing our analysis on networks of proteins known to be involved in cell division. We knocked down the expression of Eml1 in wild-type E14.5 mouse embryos using *in utero* electroporation, specifically in radial glial cell progenitors. Reduced expression of Eml1 leads to loss of radial orientation and shift of somata to more superficial positions. Eml1 re-expression in knockdown and HeCo embryos rescues the position of progenitors. We are further exploring the consequences of Eml1 loss on MT dynamics and cell division. Protein partners are being assessed for their roles in these processes. These data will contribute to understanding mechanisms of progenitor constraint in the ventricular zone during corticogenesis, and add knowledge concerning the causes of heterotopia formation.

Title: The axon guidance receptor neogenin maintains adherens junction integrity by promoting assembly of the actin cytoskeleton

Authors: ***N. K. LEE**, A. WHITE, K. FOK, H. COOPER;
Queensland Brain Inst., Univ. of Queensland, Brisbane, Australia

Abstract: A fundamental process driving organogenesis in the vertebrate embryo is epithelial morphogenesis. Choreographed cell movements of simple epithelial sheets generate complex structures such as the neural tube, the precursor of the brain and spinal cord. Dynamic cellular behaviors including epithelial folding and lumen formation require the epithelial sheets to remain elastic but resilient in response to local cues. Epithelial integrity is maintained by specialized cadherin-mediated cell junctions called the zonula adherens (ZA), and the formation and stability of these junctions is wholly dependent on the indirect interactions between cadherin adhesion complexes and the circumferential actin cytoskeleton running parallel to the ZA (the actin ring). Specifically, the actin ring is essential in promoting junctional tension mediated through actomyosin contractibility, and failure to regulate actin dynamics such as turnover leads to loss of adhesion, ZA collapse and epithelial disintegration. Thus, the molecular pathways that promote actin nucleation specifically within the spatial confines of the ZA are crucial factors mediating the fidelity of organogenesis and nervous system development. Neogenin, traditionally known as an axon guidance receptor for both Netrin-1 and Repulsive Guidance Molecules (RGMs), is essential for key embryonic processes. Depletion of Neogenin or RGMa in the neuroepithelium of the early neural tube leads to the inability to establish apicobasal polarity due to a loss of adhesion and ultimately a failure in lumen formation(1). Using the established Caco-2 cell model for studying cadherin-based cell-cell adhesion in epithelial cells, we demonstrate that loss of Neogenin via siRNA knockdown prevents cadherin homophilic adhesion between adjacent cells, leading to a severe disruption of junctional contacts. Additionally, we show loss of junctional integrity in Neogenin knockdown cells is due to a significant decrease in actin turnover which leads to dramatic changes in junctional tension. Furthermore, loss of Neogenin also results in reduced G-actin incorporation into growing actin filaments at the junction. Together, these findings suggest a new unidentified role for Neogenin in epithelial stability and junctional maintenance by regulating cadherin-mediated adhesion and modulating junctional tension via actin nucleation. This role may provide an explanation into the neural tube defect observed due to the loss of Neogenin in the neuroepithelium. 1.Kee, N., et. al. (2008). J. Neurosci. 28, 12643-12653.

Title: Role of rab18 in development and degeneration of cerebellum

Authors: ***P.-C. WU**[1,2], H.-F. WU[1], C.-J. HONG[3], L.-S. KAO[1,4];
[1]Dept. of Life Sci. and Inst. of Genome Sciences, Natl. Yang-Ming, Taipei City, Taiwan; [2]Brain Res. Center, Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Dept. of Psychiatry, Taipei Veterans Gen. Hosp., Taipei, Taiwan; [4]Brain Res. Center, Natl. Univ., Taipei, Taiwan

Abstract: Rab GTPase proteins belong to the superfamily of Ras small G protein family. They coordinate multiple processes of membrane trafficking, including regulation of vesicle formation, transport, budding, tethering and fusion. In this study, we examined the physiological roles of Rab18 *in vivo*. Mutations of Rab18 are identified in patients with Warburg Micro Syndrome characterized by progressive limb spasticity, optic atrophy, hypoplasia of corpus callosum and cerebellum, suggesting Rab18 is involved in neurodevelopment. Recently, Rab18 is reported to be a candidate susceptibility gene of schizophrenia. Indeed, there is evidence for cerebellar pathology in schizophrenia, including decrease of Purkinje cells and reduction of cerebellar volume. In cultured cells, Rab18 is shown to cycle between cytosol and secretory granules and interact with secretory granules to repress exocytosis upon activation of the regulated secretory pathway, suggesting a role of Rab18 as a brake for secretion. Therefore, it is possible that Rab18 may control some secretory factors crucial for neurodevelopment. The Rab18-deficient mice showed severe hind limbs ataxia and reduced cerebellar size. We found that the foliation pattern of cerebellum was altered and the number but not the density of Purkinje cells was decreased at P28 in Rab18-deficient mice. At P7, the expression level of sonic hedgehog protein, the factor important for proliferation of granule cell precursors and secreted by Purkinje cells, was reduced in Rab18-/- cerebella. Yet the number of PH3-positive granule cell precursors in Rab18-/- cerebella was increased. Aberrant migration of developing granule cells was found as well. The processes of Bergmann glia, the crucial glia cells associated with migration of granule cells, were thickened in Rab18-/- mice. Furthermore, the expression level of

Deleted: in vivo

myelin basic protein, a myelination marker, and its distribution was lower and less complex but more condensed in Rab18-/- cerebella than in WT. In the 12-M old mice, the degenerating phenotypes of Purkinje cells were detected in Rab18-/- cerebellum, including decreased density of Purkinje cells, less organized dendritic arborization and degeneration of axonal terminal in deep cerebellar nuclei. In addition, gliosis was found in the internal granule cell layer and in Bergmann glia, and the expression of glial fibrillary acidic protein was significantly increased. However, no apoptotic evidence was detected at this age. Taken together, Rab18 is likely involved in the degeneration of Purkinje cells and proliferation and migration of granule cells during cerebellar development.

Title: Role of microRNA in histogenesis of the cerebrum in mouse embryos

Authors: ***R. HASHIMOTO**[1], I. KIHARA[2], A. MATSUMOTO[3], H. OTANI[3];
[1]Dept. of Clin. Nursing, Fac. of Medicine, Shimane Univ., Izumo, Japan; [2]Dept. of Sports and Hlth. Sci., [3]Dept. of Developmental Biol., Fac. of Medicine, Shimane Univ., Izumo, Japan

Abstract: We searched the microRNAs (miRNAs) which were related to histogenesis of the cerebrum in mice and analyzed their roles in the development of the cerebral cortex. We extracted total RNA from the cerebra of mouse embryos from embryonic day (E) 12 to E15, and analyzed the change in expression of over 2000 miRNAs using RNA microarray assay. We chose the top five miRNAs that increased the expression and the top five miRNAs that decreased in that period, and measured expression levels of these ten miRNAs with quantitative real-time PCR method. From these results, we chose let7b-5p, which showed the most increased miRNA level from E12 to E15, and analyzed the expression pattern using technique of *in situ* hybridization. Let7b-5p was expressed around nuclei of the part of cells in the intermediate zone of the telencephalon on E12, and it was expressed all layers, but was stronger in the ventricular zone of the telencephalon on E15. Using RNA interference to analyze the function of let7b-5b,

Deleted: in situ

we injected the double strand (ds) RNA of let7b-5p (DS group) which were labeled with fluorescein, and the ds RNA that has been confirmed not to affect the developmental process (control group) as the control treatment into the ventricle of mouse embryos on E13 using in-utero operation. We gave electrical stimulation at their heads for electroporation after injection. We collected the brains and measured their weight and size on E15. There was no significant difference in the brain size and weight between the DS group and the control group. However, roughness around the ventricle was observed, and irregularity of cell arrangement was detected around the cells in which the labeled dsRNA of let7b-5b was observed in the part of cerebral cortex by histological analysis. These results suggested that miRNA (let7b-5p) was involved in histogenesis of the cerebral cortex during embryonic period.

Title: NPAS1/NPAS3 regulation of DNA methylation in cortical inhibitory interneurons

Authors: ***R. GENOVA**[1], T. C. YIN[2], L. N. MCDANIEL[2], A. A. PIEPER[2];
[1]Univ. of Iowa Carver Col. of Med., Iowa City, IA; [2]Dept. of Psychiatry, Univ. of Iowa, Iowa City, IA

Abstract: Mutations in neuronal PAS domain proteins 1 and 3 (NPAS1 and NPAS3) have been identified in individuals with schizophrenia and autism spectrum disorders, but little is known about how these proteins contribute to disease pathogenesis. Mice deficient in NPAS1 and/or NPAS3 recapitulate behavioral and neurostructural features of major psychoses, and NPAS1 and NPAS3 were recently shown to reciprocally regulate the generation of inhibitory interneurons. Disrupted excitatory-inhibitory balance of cortical networks is thought to contribute to a number of neuropsychiatric conditions, and studies in patients with major psychoses have repeatedly shown aberrant DNA methylation patterns in inhibitory interneurons. Like NPAS1 and NPAS3, expression of the DNA methyltransferases DNMT1 and DNMT3a is primarily restricted to inhibitory interneurons. Because aberrant DNA methylation in inhibitory interneurons is associated with major psychoses, we are interested in investigating whether NPAS deficient mice

have similar epigenetic dysregulation. Preliminary data suggests that NPAS1 or NPAS3 deficiency alters cortical DNMT expression. We therefore hypothesize that NPAS1 or NPAS3 deficiency results in altered DNA methylation patterns via dysregulated DNMT expression in inhibitory interneurons. To characterize how the inhibitory interneuron methylome varies with NPAS1 and NPAS3 expression, we will utilize whole-genome bisulfite sequencing to identify DNA methylation patterns in inhibitory interneurons isolated via fluorescence activated cell sorting. Identifying regions of the genome with altered methylation patterns in NPAS1- or NPAS3-deficient animals may provide insight into epigenetic dysfunction in neuropsychiatric conditions.

Title: Understanding the role of minor spliceosome in mouse model for Microcephalic Osteodysplastic Primordial Dwarfism Type I

Authors: ***R. KANADIA**, M. BAUMGARTNER;
Univ. of Connecticut, Storrs, CT

Abstract: The importance of minor spliceosome in human development is underscored by the disease microcephaly osteodysplastic primordial dwarfism type I (MOPD-I), where the cardinal symptoms include, microcephaly and intrauterine growth retardation of limbs. The underlying molecular defect is that of compromised minor spliceosome function. The spliceosome executes splicing by base-pairing of small nuclear RNA (snRNAs) to consensus sequences flanking exon/intron boundaries. These consensus sequence are found in >99% of the introns in the mammalian genome and are recognized and processed by the major spliceosome consisting of U1, U2, U4, U5, and U6 snRNAs. However, there are divergent sequences at the exon/intron boundary that are found embedded within ~450 genes that cannot be recognized by the major spliceosome snRNAs. These minority introns are recognized and processed by the aptly named

minor spliceosome consisting of U11, U12, U4atac, U5 and U6atac snRNAs. The regulatory advantage afforded by the presence of a minor-intron in a gene that mostly consists of major intron is not clearly understood. Minor spliceosome snRNAs are expressed at a lower level than its major counterpart resulting in inefficient splicing and post-transcriptional damming effect to control protein production of these ~450 genes in the mammalian genome. Currently, there are no reports that define the role of minor spliceosome in mammalian development. To address this issue we have generated a U11 snRNA conditional knockout (cKO) mouse. While constitutive knockout is embryonic lethal (~E6), knockout of U11 in neural precursors via Emx1-Cre results in microcephaly at birth, which recapitulates the cardinal phenotype observed in MOPD-I patients. This allows us to deconstruct for the first time the molecular, cellular and behavioral deficits associated with MOPD-I in a mouse model. Currently, we are employing a custom microarray to interrogate en masse the successful splicing of minor introns in the developing U11-cKO brain, which will be complemented by RNAseq to interrogate transition in expression kinetics and minor intron splicing efficiency. In all, we report the recapitulation of microcephaly in U11-cKO mouse and will present the targets affected by loss of U11 and their function in regulating cell cycle of neural precursors that results in MOPD-I.

Title: Necdin downregulates EGFR signaling in cortical neural precursor cells to suppress gliogenesis

Authors: ***I. FUJIMOTO**, K. HASEGAWA, K. FUJIWARA, K. YOSHIKAWA;
Osaka university, Inst. for Protein Res., Suita, Japan

Abstract: Epidermal growth factor receptor (EGFR) is a receptor tyrosine kinase that controls the proliferation and differentiation of neural precursor cells (NPCs). Cortical NPCs committed to the astrocyte lineage express high levels of EGFR at late embryonic stages of mouse development. Necdin, a pleiotropic protein abundantly expressed in neurons and NPCs, suppresses cellular proliferation and apoptosis. We have previously shown that necdin interacts

with the NGF receptor TrkA, another receptor tyrosine kinase, to enhance NGF signaling and promote survival of sensory neurons (J Neurosci, 25:7090-7099, 2005). In the present study, we examined whether necdin interacts with EGFR in primary NPCs and controls gliogenesis. Primary NPCs were prepared from mice at embryonic day 14.5 and cultured in the presence of bFGF for 4 days. Immunocytochemical data showed that necdin was expressed in NPCs and co-localized with EGFR in the cytoplasm after EGF treatment. Co-immunoprecipitation assay revealed that necdin bound to autophosphorylated EGFR but not to unphosphorylated EGFR. Necdin interacted directly with the tyrosine kinase domain (TKD) of EGFR, and deletion of the EGFR C-terminal domain enhanced the interaction, suggesting that the unphosphorylated C-terminal tail interferes with the interaction between necdin and the TKD. Necdin failed to affect EGF-dependent EGFR autophosphorylation in NPCs but reduced the interaction between EGFR and Grb2, an adaptor protein that activates the ERK1/2 pathway. In NPCs prepared from necdin-null mice, phosphorylated ERK1/2 levels were significantly increased. Furthermore, EGF-dependent astrocyte proliferation increased significantly in necdin-null NPCs treated with cardiotrophin-1. These data suggest that necdin controls EGFR signaling and suppresses EGFR-mediated glial proliferation during embryonic cortical development.

Title: Guanine exchange factors regulate the neurogenic niche

Authors: *J. T. CAIN[1], S. KOH[1], D. TIMM[1], S. DUNCAN[1], R. O'TOOLE[1], T. SAMSON[2], E. S. WITTCHEN[2], K. BURRIDGE[2], J. M. WEIMER[1];

Abstract: Neurogenesis is a tightly orchestrated process and disruption of neural progenitor (NP) specification, migration, or differentiation has profound effects on the formation of the cortex. Radial Glia (RG) are specialized NPs with an apico-basal polarity consisting of radial processes making contact with both the ventricular and pial surfaces; these processes provide an instructive scaffold for the radial migration of neurons in the cortex. RG can undergo either a proliferative symmetric division resulting in two RG, or an asymmetric division resulting in one RG and either an immature neuron or intermediate progenitor (IP). The type of division is dependent upon the rearrangement of cytoskeletal machinery, which is controlled by members of the Par polarity complex and the Rho GTPase Cdc42. Rho GTPases, including Cdc42 and RhoG, serve as regulators of progenitor proliferation and fate determination. Rho GTPases are themselves regulated by guanine-nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs) which control the GTP-loading state of Rho GTPases. Because GEFs act as activators for Rho GTPases, we hypothesize that GEFs are critical to Rho GTPase-mediated regulation of neural progenitors through the neurogenic niche including their proliferation and migration in the developing cerebral cortex. To test this hypothesis we have focused on SH3-containing guanine exchange factor (SGEF): a GEF whose expression is restricted to defined neurogenic niches in the developing cerebral cortex, is an activator of RhoG and Cdc42, and whose deletion appears to have nominal consequences outside of the central nervous system. To examine proliferation and migration of neural stem cells SGEF-/- mouse embryos were harvested at key developmental time points, E15.5 and E18.5. Pregnant dams were pulsed with BrdU at either 1 or 72 hours prior to sacrifice. Proliferation of RG and IP were assessed with coimmunolabeling of Brdu and Pax6 or Tbr2. Cortical layer-specific markers were used to assess defects in cortical lamination. Our findings show that at E15.5, SGEF-/- mice have a reduced IP (Tbr2+) population while RG (Pax6+) are unaffected. By E18.5, the loss of SGEF results in reduced thickness of the cortical layers.

Title: Rhox8 expression in the developing and adult mouse brain and spinal cord

Authors: H. G. HUFFMAN[1], G. R. PRATHER[2], J. A. MACLEAN, II[2], *J. L. CHEATWOOD[1]; [1]Anat., [2]Physiol., SIU Sch. Med., Carbondale, IL

Abstract: Homeobox transcription factors govern many developmental events. The Rhox, -(X-linked reproductive Homeobox)-, genes are a recently discovered set of homeobox genes. Characteristically, the Rhox genes exhibit a complex spatially and temporally regulated expression pattern which varies in cell type during testis development and postnatally. Of all 33 mouse Rhox genes, Rhox8 is unique because it is the only one in the set that shows expression in the somatic cells in the embryonic testis. Rhox8, Rhox5, and Sox9 were all found to be highly expressed in positive control adult mouse testis tissue. Because it is a common phenomenon that highly-expressed testis genes also exhibit expression in the brain, often via an alternatively spliced message that may or may not produce functional protein, we sought to characterize Rhox gene expression in mouse and rat brain. Of these only Rhox8 had moderate expression in mouse cortex. As expected, Rhox8 and Sox9 mRNA are expressed in the adult rat and mouse brain, albeit at much lower levels than in the testis and ovary. Also, we found that Rhox8 mRNA is statistically upregulated at time point E13.5 compared to other time points in the developing mouse embryo. Females may express Rhox8 two-fold higher than males at E13.5 ($p=0.057$; more research needed at the time of abstract submission). Two genes related to Rhox8 expression, Sox9 and Gata1 were both expressed in the developing mouse embryo at all time points. Sox9 was also found to be expressed in rat cerebellum in all samples. Rhox5 mRNA was not detected in adult rat cerebellum, developing mouse embryo, or adult mouse samples. Expression of RHOX8 protein was detected via fluorescent immunohistochemistry in E13.5 tissue and adult tissue but not in E15.5, E17.5, and P1. Further research will aim to determine the location of expression. Rhox8 is expressed in murine adult total brain, cerebellum, cortex, and spinal cord. Ongoing studies in mice aim to determine female and male differences in expression of Rhox8, why Rhox8 is upregulated during E13.5 time point, why there is upregulation in the spinal cord and cortex, and to determine the full length Rhox8 transcript in the mouse brain.

Title: Long-term survival of newly formed neurons in the adult rat hippocampus following electroconvulsive stimulation - a stereological study

Authors: *M. V. OLESEN[1], G. WÖRTWEIN[2,3], B. PAKKENBERG[1];
[1]Lab. for Stereology and Neurosci., Bispebjerg Hosp., Copenhagen, Denmark; [2]Lab. of Neuropsychiatry, Dept. of Neurosci. and Pharmacol., [3]Section of Envrn. Health, Dept. of Publ. Hlth., Univ. og Copenhagen, Copenhagen, Denmark

Abstract: Objectives: We aimed to test the hypothesis that stress-induced depression and electroconvulsive stimulation (ECS) have opposing effects on hippocampal neurogenesis. Next, we wanted to examine if ECS leads to long-term survival of the newly formed neurons. Background: The neurobiological mechanisms underlying depression are not fully understood. One hypothesis states that hippocampal neurogenesis and neuronal differentiation may be important factors in the recovery from depressive episodes. Thus, opposing effects of depression and antidepressant treatment on neurogenesis have been found. However, most previous studies using semiquantitative or quantitative counting methods report conflicting data on the short-term effects on neurogenesis. Thus, studies using methods that represent state of the art in regard to stereological cell counting and research into the long-term survival of newly formed neurons is lacking. Methods: We used a validated rat model of depression, chronic restraint stress (CRS), in combination with a clinically relevant schedule of ECS. The behavioral effects of CRS and/or ECS were assessed in the forced swim test. To estimate neurogenesis, the total number of neurons and the volume of hippocampal subregions in rats surviving 24 hours as well as 3, 6 and 12 months we used a validated stereological cell counting method, the optical fractionator. Results: Our results show that CRS induces depression-like behavior, without significantly changing neurogenesis, the total number of neurons or the volume of the hippocampal subregions. Further, ECS prevents stress-induced depression-like behavior and acutely increases neurogenesis by ~250%. Approximate 60% of the new neurons survive for 3 months with a further decline to 50% following 6 and 12 months. One year after ECS, neurogenesis is significantly increased by ~150% compared to control. The total number of neurons and the granule cell layer (GCL) volume was not affected by ECS at any time point. Conclusion: We show that ECS increases hippocampal neurogenesis and that a significant part of the newly

formed neurons survive for at least 12 months. CRS do not changes neurogenesis, total number of neurons or volume of the hippocampus. Thus, previous findings of volumetric changes are not caused by cellular alterations in the GCL, rather they appear to be caused by alterations in other subregions and/or altered gliogenesis as well as angiogenesis.

Abstract: Primary cilia are slender plasma membrane protrusions, found in most mammalian cell types. They crucially sense, integrate and transduce physico-chemical extracellular stimuli and are modelled as performing Bayesian inference of cell's environment. Increasing evidence indicates that primary cilia are key coordinators of tissue- and cell type-specific signaling pathways during development and in tissue homeostasis and, when defective, are a major cause of human diseases and developmental disorders. Ciliary functions are, in particular, required for cerebellar differentiation and Shh-dependent proliferation of neuronal granule precursors (GCPs). The mammalian G-protein coupled receptor 37-like 1 (Gpr37l1) is specifically expressed in cerebellar Bergmann glia astrocytes and participates in the regulation of postnatal cerebellar granule neuron proliferation-differentiation, Bergmann glia and Purkinje neuron maturation. The Gpr37l1 protein interacts with the patched 1 (Ptch1) component of the primary cilium-associated, sonic hedgehog (Shh) receptor complex. We are investigating the functional

interaction between Gpr37l1 and Ptch1, as modulating the Shh-Ptch1-smoothened mitogenic pathway in primary cilia of murine cerebellum, during postnatal development and adulthood.

Title: Transgenic inhibition of synaptic transmission of new born neurons in dentate gyrus impairs learning and memory

Authors: *N. TANG;
Tongji Med. Col. Huazhong Univ. and Tec, Hubei, China

Abstract: The hippocampus plays an important role in learning and memory. The dentate gyrus (DG) subfield exhibits continued neurogenesis till adulthood. In the present study, we developed a generally applicable tetanus toxin (TeTX)-based method to generate transgenic mice, which permits inducible and reversible inhibition of synaptic transmission by restraining VAMP2 in the DG new born neurons (DGNBN). We found that blue light stimulating ChR2 retrovirus infected DGNBN induced EPSC in DG and CA3, but inhibition of synaptic output in DGNBN showed no response to blue light illumination. Moreover, morris water maze test and fear conditioning results indicated impaired hippocampus-dependent learning and memory in the above VAMP2 reduced transgenic mice. Our results demonstrated that DGNBN can integrate into preexisting circuits, and participate in the functions of learning and memory.

Title: The molecular basis of Mediator-linked neurodegenerative diseases

Authors: ***G. BANYAI**, Z. SZILAGYI, C. M. GUSTAFSSON;
Med. Biochem. and Cell Biol., Univ. of Gothenburg, Gothenburg, Sweden

Abstract: The Mediator complex has emerged as a conserved regulator of gene transcription from yeast to human. It is part of the general transcription machinery and acts as a bridge between transcription regulators and RNA polymerase II. It has a large core module and a small detachable CDK8 module, which consists of four proteins: Med12, Med13, Cyclin C and Cyclin dependent kinase 8 (Cdk8). Mutations in the CDK8 module subunits have been connected to various forms of cancer and neurodegenerative diseases. It has been shown that Alzheimer's patients had elevated RNA levels of cyclin C in their neurons and glial cells. Mutations in the *med12* gene are found in patients with intellectual disabilities, such as Opitz-Kaveggia (FG) syndrome, Lujan syndrome and Ohdo syndrome (Maat-Kievit-Brunner type). As the function of the Cdk8 module is so crucial in several cellular and developmentally important processes and has a growing medical importance, we set out to study the role of the Cdk8 module to cellular reproduction and differentiation in the simple eukaryote fission yeast. We have found that the control of Cdk8 activity is responsible for the timing of mitotic commitment, therefore is part of a control network that regulates cell division. Our present findings indicate that the Cdk8 activity is regulated by the Cyclin-CDK interaction *in vivo*, regardless of its connection to the Mediator complex. We also show that Cdk8 might be interacting with other cyclins when it is not bound to the core module. As the CDK8 module has a deep evolutionary origin and is highly conserved among diverged eukaryotes, we believe that our observations can help to understand the role of the CDK8 module in higher eukaryotes.

Title: Heparin Binding-Epidermal Growth Factor(HB-EGF) stimulates the proliferation of Müller glia-derived progenitor cells in avian and murine retinas

Authors: ***L. VOLKOV**, A. FISCHER, L. TODD;
Ohio State Univ., Columbus, OH

Abstract: Müller glia can dedifferentiate and form proliferating Müller glia-derived progenitor cells (MGPCs) with the capacity to regenerate retinal neurons. Heparin Binding-Epidermal Growth Factor (HB-EGF) may play a key role in initiating formation of proliferating MGPCs. HB-EGF has been demonstrated to be necessary and sufficient for HB-EGF formation in the zebrafish retina (Wan, et al. 2012). Currently, there is no information regarding the influence of HB-EGF in the regeneration of avian or mouse retina. We found that both hb-egf and egfr were rapidly and transiently increased following NMDA excitotoxic damage in the avian retina. In situ hybridization data suggests hb-egf is produced by Müller glia fcollowing retinal damage. In undamaged retina, intraocular injection of HB-EGF did not stimulate proliferation or downstream signaling pathways of canonical HB-EGF/EGFR signaling in either the chick or mouse retina. However, when paired with NMDA, HB-EGF was able to stimulate the proliferation of MGPCs in both avian and murine retina. Immunohistochemical data suggests that HB-EGF treatment following retinal damage stimulated the expression of the MAPK signaling components pERK and pCREB in Müller glia. Additionally HB-EGF stimulated pS6 signaling in Müller glia suggesting activation of mTOR signaling. Additionally, inhibition of EGFR reduced the proliferation of MGPCs in the avian retina after retinal damage. We conclude that HB-EGF plays a key role in the proliferation of MGPCs in both the chick and mouse retina and can be a considered a key target for stimulating the regenerative potential of MGPCs in the higher vertebrate.

Title: Directing neurite growth in collagen gel 3-dimensional neuronal culture

Authors: M. ANTMAN-PASSIG[1], K. BARANES[1], S. LEVI[1], *O. SHEFI[2];
[1]Fac. of Engin. and Inst. of Nanotechnology and Advanced Materials, Bar Ilan Univ., Ramat Gan, Israel; [2]Fac. of Engin. and Inst. of Nanotechnologies and Advanced Materials, Ramat Gan, Israel

Abstract: The ability to manipulate and direct neuronal growth has great importance in the field of tissue engineering, both for neuronal repair and potential medical devices. In-vivo, neurons grow and develop neurites in a 3-Dimensional (3D) extra cellular matrix (ECM) surrounding. Thus, imitating the 3D environment within a natural material as collagen is most important to simulate in-vivo conditions. We designed and developed a method to grow neurons in a 3D environment. A collagen hydrogel system was chosen as a 3D ECM analog to best mimic the natural environment of cells. We used primary leech (Hirudo medicinalis) neuronal culture and followed the growth of single cells for up to 7 days. We compared the neuronal growth in 3D to a 2D model and showed that neurons grown in 3D collagen gels develop significantly longer dendritic trees and neurites, while number of neurites originating from cell soma was smaller in 3D collagen gels. To manipulate neuronal growth we developed a method to align collagen matrix via inducing strain on collagen gels. We showed fiber directionality by analysis of light microscope images via Fast Fourier transform and by SEM imaging. Finally, we evaluated leech neurite extension within aligned gels. Using this method we've directed neuronal growth coinciding with collagen matrix orientation. We found no significant change in neurite lengths in aligned gels compared to control gels, demonstrating that cell growth and behavior does not alter except direction of growth. We have also developed a tunable platform to direct neurite growth in 3D by embedding nanoparticles and magnetic elements in a collagen gels which operate as topographic cues to guide neurite growth. Both these methods present a promising neuronal repair system in a realistic environment.

Title: Lingual ephrin-A's and ephrin-B's repel embryonic geniculate and trigeminal neurites *in vitro*

Deleted: *in vitro*

Authors: R. W. TREFFY, D. CHO, M. L. RUSSO, *M. W. ROCHLIN;
Dept Biol, Loyola Univ. Chicago, Chicago, IL

Abstract: Taste axons of the geniculate ganglion innervate pre-gustatory epithelium in fungiform papillae with high fidelity, and somatosensory axons from the trigeminal ganglion innervate the neighboring epithelium. Diffusible factors such as neurotrophins and semaphorins have key roles in guiding these afferents, but non-diffusible cues are also likely to be involved. Ephs and ephrins are cell surface molecules that act as ligands and receptors for one another, initiating signaling cascades that can cause repulsion, stabilization, or growth promotion of

axons. There are two classes of Ephs and ephrins: ephrin-A's are lipid-linked proteins that interact predominantly with EphA's, whereas ephrin-B's are transmembrane proteins that interact predominantly with EphB's. During intralingual axon targeting and target penetration in rats and mice, anti-ephrin-A3 labels the lingual epithelium, and anti-ephrin-A1 labels the transverse and longitudinal musculature. Antibodies against EphA5 and EphA7 label afferents within nascent fungiform papillae. To determine if ephrin-A's are capable of guiding axons we grew explants of geniculate and trigeminal ganglia on coverglasses coated with stripes of ephrin-A-Fc fusion proteins. Ephrin-A1, -A2, -A3, and -A4 repel geniculate neurites dose dependently *in vitro*. Trigeminal neurites are also repelled by these ephrins, though the repulsion is less robust. Together, these data are consistent with a guidance role for ephrin-A's during pathfinding and targeting of gustatory and somatosensory axons in the tongue. Ephrin-B2 is also expressed along the dorsal epithelium of the mouse and rat tongue by E15.5 and E18, respectively, just after axons penetrate the epithelium; and ephrin-B-Fc's are repellent *in vitro*. Combining intermediate concentrations of ephrin-A-Fc's and ephrin-B-Fc's in the same stripe results in additive repellent effects.

Title: Examining the structural determinants of Protocadherin-19 function in brain morphogenesis and epilepsy

Authors: ***S. R. COOPER**[1], J. D. JONTES[2], M. SOTOMAYOR[2];
[1]Dept. of Neurosci., [2]The Ohio State Univ., Columbus, OH

Abstract: Members of the cadherin superfamily mediate calcium-dependent cell-cell adhesion and mutations in them have been linked to multiple neurodevelopmental disorders. It is thought that selective adhesion mechanisms of various cadherin superfamily members may be important for proper neural circuit development. Much has been learned about the molecular mechanisms used by the subfamily of classical cadherins that include epithelial and neural cadherins (Ecad and Ncad). These classical cadherins interact tip-to-tip and exchange tryptophan residues that are

essential for adhesion. Interestingly, non-classical cadherins lack this tryptophan, yet they still form adhesive complexes. Protocadherin-19 (Pcdh19) is a non-classical member of the cadherin superfamily, and previous work suggests that it forms complexes with a distinct adhesive mechanism. Specifically, Pcdh19 mediates homophilic adhesion when in complex with Ncad, yet this adhesion is mediated by Pcdh19 itself and is independent of the classical Ncad tryptophan exchange. In addition, diverse missense mutations within the Pcdh19 extracellular domains have been implicated in epilepsy and mental retardation limited to females (EFMR). These mutations are believed to disrupt Pcdh19 directed adhesion and in turn disrupt proper neural circuit development. Here I present adhesion assays indicating which extracellular cadherin (EC) repeats are critical for adhesion. Of the six EC repeats of Pcdh19, only EC1 to EC4 are necessary; and of the five EC repeats of Ncad, EC1 to EC2 are sufficient to support adhesion of the Pcdh19-Ncad complex. We also present the first crystal structures of Pcdh19, including EC1 to EC4 at 3.5 å, EC2 to EC4 at 2.7å, and EC3 to EC4 at 2.5å resolution. These structures show potential dimer interfaces that could contribute to adhesion and provide a structural frame work to infer the biochemical and biophysical consequences of EFMR mutations on Pcdh19 function.

Title: The role of Down syndrome cell adhesion molecule in mouse retinofugal circuit development

Authors: *T. J. BURBRIDGE[1], A. M. GARRETT[2], Y. LI[1], T. L. SPENCER-SALMON[1], M. R. GRACE[1], E. STEIN[1], R. W. BURGESS[2], M. C. CRAIR[1];
[1]Neurobio., Yale Univ., New Haven, CT; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Down Syndrome Cell Adhesion Molecule (DSCAM) is involved in many processes in neural development including axonal guidance and branching, cell and neurite self-avoidance, and developmental cell death. Following reports of an enlarged midbrain and disrupted retinal

and retinogeniculate circuits in DSCAM knockout (KO) mice, we investigated the role of DSCAM in visual circuit development in the superior colliculus (SC). We found that retinocollicular projections in *Dscam* KO exhibited disrupted retinal axon laminar targeting, enhanced eye-specific segregation, and a striking axon "clustering" phenotype that disordered retinotopic continuity throughout visual SC in a regular "honeycomb" pattern. These circuit disruptions were developmentally regulated, interestingly becoming evident only after normal critical periods of refinement in the SC are complete. Using region-specific *Dscam* conditional knockout (cKO) mice, we also found that axon clumping and enhanced segregation were controlled in a region-specific manner by retinal DSCAM, while midbrain size and laminar mistargeting were specifically dependent on midbrain DSCAM. Further analysis of 'honeycomb' RGC axon clusters in the SC revealed that single retinocollicular axons in retinal *Dscam* cKO mice tended to respect interior and exterior cluster boundaries, and that the cell bodies of SC neurons were reorganized around RGC axon clusters in a pattern that resembled "barrels" in the somatosensory system. SC phenotypes caused by conditional *Dscam* deletion in the retina also depended on spontaneous activity, with disrupted early postnatal retinal spontaneous activity patterns largely nullifying the effects of retinal *Dscam* cKO on retinocollicular projections, although recordings of *in vivo* patterns of spontaneous activity in the SC were surprisingly normal until the age when anatomical (and physiological) clustering became apparent. Moreover, *Bax* KO mice, which have similar effects in the retina as *Dscam* KO mice, fail to show any retinocollicular axon phenotypes. We are currently testing the hypothesis that defects in *Dscam* KO retinal organization cause downstream circuit disruptions through activity-dependent refinement, with the potential concurrent necessity of DSCAM in retinal ganglion cell axons for axon self-recognition, avoidance, or branching during visual circuit development.

Abstract: Determination of the neuronal polarity plays a critical role in the brain development. However, at that process, the protein components in the plasma membrane, which mediates between the extracellular and the intracellular signals, have not been established well. We have previously reported that RNAi inhibition of glycoprotein M6a, one of the most abundant proteins in the growth cone membrane by our proteomic studies (Nozumi et al., PNAS, 2009), suppressed the axon formation on laminin. We also found that M6a formed a ternary complex with M6a-binding protein (M6BP) and its interacting protein, active formed Rap2 Here, we examined the relationship between this ternary complex and the laminin-induced polarity in the cortical neurons. According to the definition by Dotti et al. (J Neurosci, 1988), one of several neurites was finally specialized to an axon on 1-2 days after plating. However, on laminin, we found that an axon-like neurite selectively protruded at only a few hours after the plating. The M6a-ternary complex showed the asymmetric localization at the stage1 neuron on laminin, although at that stage, other well-known polarity determinants (e.g. Par3, CRMP2, and so on) remained to be still symmetrically distributed. In the M6a- or M6BP-knockout neurons, the rapid determination of the polarity by laminin was inhibited. These results indicated that the extracellular laminin signal accelerated the polarity determination of the cortical neurons through the M6a-ternary complex. shRNA knockdown experiments of M6a showed that suppression of M6a expression in the embryonic cerebral cortices inhibited morphological transition of migrating cortical neuron from multipolar to mono- (bi-) polar in the intermediate zone (IZ). We concluded that the above *in utero* results are consistent with our *in vitro* ones and that the M6a-ternary complex physiologically participates in the accelerated polarization.

Title: Massive expansion of protocadherin genes in the octopus genome

Authors: *Z. Y. WANG[1], C. B. ALBERTIN[2], O. SIMAKOV[3,4], T. MITROS[5], D. S. ROKHSAR[5,6], C. W. RAGSDALE[1];

Abstract: In vertebrates, protocadherins (PCDHs) are the largest group within the cadherin superfamily, with over 60 members in mouse and human. Genetic studies in mice have demonstrated that PCDHs are critical for neural circuit formation and that their diversity may play a key role in neuronal self-recognition. Within a cell, PCDHs form tetramers without any apparent isoform specificity. Intercellular binding, by contrast, is strictly homophilic (Schreiner and Weiner, 2010). The complexity of assembled extracellular cadherin tetramers allows for hundreds of thousands of specific cell-to-cell interactions. *PCDH*s are absent from the genome of the protostome model organism *D. melanogaster*, but the role of PCDHs in vertebrate neural circuit assembly appears analogous to that conferred in flies by *Dscam1* alternative splicing diversity. Cephalopods, which have the largest nervous systems among all invertebrates, are capable of extraordinary behaviors including complex problem solving, sophisticated tactile and visual learning, and adaptive coloration. Here, we report that the octopus has the largest number of *PCDH* genes found in any animal to date. We identified 168 *PCDH* genes in the genome of *Octopus bimaculoides*. The octopus complement of *PCDH* genes resembles vertebrate PCDHs in protein domain architecture. In both lineages, *PCDH* genes are found in clusters on the genome. Our transcriptome data indicate that *PCDH* genes are highly enriched in central nervous tissues such as the optic lobe and the supraesophageal brain, which contains higher centers of motor control, decision-making, and learning and memory. Phylogenetic analysis establishes that vertebrates and cephalopods independently evolved a large repertoire of *PCDH* genes. The extensive similarities between vertebrate and cephalopod *PCDH* genetic structure provide a striking example of convergent evolution between the two taxa, which are both noted for their large and complex nervous systems.

Title: Differential expression of δ-Protocadherins in identified neurons in zebrafish

Authors: ***J. D. JONTES**, S. COOPER, M. EMOND;
Dept Neurosci, Ohio State Univ., Columbus, OH

Abstract: The patterns of neural connectivity in the mature vertebrate nervous system are highly stereotyped, yet the mechanisms responsible for generating this organization are not known. Differential gene expression defines both regional compartments and distinct neuronal subtypes, but it remains to be shown how this molecular architecture contributes to establishing functional architecture. Among the molecules proposed to contribute to circuit assembly are the δ-protocadherins (δ-Pcdhs), a family of cell surface molecules that are differentially expressed in the developing nervous system. To investigate the involvement of δ-Pcdhs in the assembly of early neural circuits, we have generated recombinant BAC clones and BAC transgenic zebrafish lines for several of these genes. The larval zebrafish is an excellent system in which to address this question, as it is small and relatively simple, yet can mediate a range of complex behaviors. In addition, larvae are transparent and are ideal for live imaging. Using *in vivo* imaging of both fluorescently labeled transgenic lines and transiently expressing larvae, we have begun to map out the cell types and neural pathways defined by the expression of δ-Pcdhs at multiple stages of development. Neuronal types are identified on the basis of position, morphology and axon trajectory. We find that individual δ-Pcdhs are expressed in stereotyped complements of neurons throughout the nervous system. In addition, we have begun using GCaMP6s to look for patterns of activity in pathways defined by δ-Pcdh expression.

Title: Structural insights into the flrt/latrophilin complex in brain development

Authors: *D. ARAC-OZKAN;
Biochem. & Mol. Biol., Univ. of Chicago, Chicago, IL

Abstract: FLRTs are cell-adhesion molecules with emerging functions in cortical development and synapse formation. Their extracellular regions interact with Lphns to mediate synapse development, and with Unc5/Netrin receptors to control the migration of neurons in the developing cortex. Here, we present the crystal structures of FLRT3 in isolation and in complex with Lphn3. The FLRT3/Lphn3 structure reveals that Lphn3 binds to FLRT3 at a distinct site from Unc5, but at the same concave surface as the previously reported dimerization surface. Structure-based mutations specifically disrupt FLRT3/Lphn3 binding, but do not disturb their interactions with other proteins or their cell-membrane localization. Thus, they can be used as molecular tools to dissect the functions of FLRTs and Lphns *in vivo*. Our results suggest that Unc5 and Lphn3 can simultaneously bind to FLRT3 forming a trimeric complex and that FLRT3 may form trans-synaptic complexes with both Lphn3 and Unc5. These findings provide molecular insights for understanding the role of cell adhesion proteins in brain development.

Title: Role of Cdk5 in activity-induced gene expression and dendrite development

Authors: ***T. YE**[1,2,3], Z. LIANG[1,2,3], X. ZHOU[1,2,3], K.-O. LAI[1,2,3,4], A. K. FU[1,2,2], N. Y. IP[1,2,3]; [1]Div. of Life Sci., [2]Mol. Neurosci. Ctr., [3]State Key Lab. of Mol. Neurosci., The Hong Kong Univ. of Sci. and Technol., Hong Kong, China; [4]Dept. of Physiol., Univ. of Hong Kong, Hong Kong, China

Abstract: Proper dendrite growth and arborization in response to sensory experience are essential for neural connectivity and information processing in the brain. Although neuronal activity is important for shaping dendrite morphology, the underlying molecular mechanisms are not well understood. Here, we identified cyclin-dependent kinase 5 (Cdk5)-mediated transcriptional regulation as a key mechanism that controls activity-dependent dendrite development in neurons. Biochemical fractionation and time-lapse imaging demonstrated that Cdk5 became enriched in the nucleus in response to neuronal activity. Knockdown of Cdk5 impaired activity-induced dendritic growth; these defects could be rescued by wild-type Cdk5 but not the nuclear-localization deficient mutant, indicating that the nuclear localization is required for Cdk5 function in dendrite development. Genome-wide analysis revealed that Cdk5 function is mediated through activity-dependent gene expression, including that of brain-derived neurotrophic factor. These findings collectively suggest that the nuclear import of Cdk5 is crucial for activity-dependent dendrite development by regulating gene transcription during nervous system development.

Title: The Purkinje cell forest shapes the trees

Authors: *B. TORBEN-NIELSEN, E. DE SCHUTTER;
Okinawa Inst. of Sci. and Technol., Kunigami-Gun, Japan

Abstract: Purkinje neurons are at the heart of all theories about the olivo-cerebellar circuit as they provide the only output from the cerebellar cortex. Hallmark is their planar morphology in a plane perpendicular to the parallel fibers. Moreover, individual Purkinje neurons have very dense dendritic arborizations, a feature commonly referred to as space-filling. In a population, they neatly align and cover the available volume in both transverse and medio-lateral directions, so-called tiling. It remains an open question how individual neurons develop a mono-planar dendrite and how the alignment emerges in a population. Here we address both questions. To address these questions we use our recently developed computational framework, NeuroMaC [1], to simulate the simultaneous growth of large numbers of neuronal morphologies in virtual brain tissues. In order to study planarity and overall alignment of Purkinje neurons, we extended NeuroMaC to allow interstitial (lateral) branching and pruning of branches, which are experimentally demonstrated to play a crucial role in space-filling [2]. In this work, we hypothesized that the peculiar Purkinje neuron morphology emerges from three simple interactions with its environment. First, dendritic branches of one neuron are repelled by each other, a process called self-avoidance. Second, dendritic branches of different neurons repel each other. Third, all branches are to some extent attracted to the pial surface. Simulated somata were place on a regular lattice; 25 and 150 micron apart from each other in, respectively, the medio-lateral and transverse directions. In addition, pruning of branches took place early during simulated growth to match the experimental data [2]. We found that these simple rules yielded highly realistic morphologies exhibiting the hallmark planarity in the transverse direction. The planarity emerged because the repulsion between branches forced the neuron to occupy all available space, which was larger in the transverse than in the medio-lateral direction. We validated the resulting morphologies against exemplar adult data and developmental data and found a good statistical match. Moreover, alignment and tiling emerged in the population. We hence demonstrated that the notoriously complex Purkinje neuron morphology can be approximated by simple local interactions between growth cones. We also speculate on the necessity of a global organization mechanism that consistently aligns the cell bodies of Purkinje neurons in the medio-lateral direction. Title: E2F1 depletion in neurons results in loss of neurite arborization and changes in synaptic markers during neuron development

Authors: *J. LYMBEROPOULOS, J. H. TING, S. S. SCHLEIDT, J. N. WU, A. H. LEE, K. L. JORDAN-SCIUTTO;
Pathology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: E2F1 is a cell cycle transcription factor known for its role in regulating progression from G1 to S phase of the cell cycle. Surprisingly, E2F1 is localized in the cytoplasm of post-mitotic neurons where its role is largely unknown, and where it is unlikely to function as a transcription factor. Aged E2F1 mutant mice show behavioral and synaptic deficits, indicating that E2F1 is important for maintenance of synapses in aging. In addition, E2F1 has been shown to regulate apoptosis and contribute to neurodegeneration. However, its role in the post-mitotic developing neuron has not been described. We show that E2F1 expression increases during neuronal development peaking during synapse formation, indicating that it could play a role in the neuron as neurite outgrowth occurs and synapses form. Using complementary approaches, we have shown that loss of E2F1 results in decreased neurite arborization during a specific developmental period. In addition, loss of E2F1 results in decreased PSD95 and GAP43 levels during development. These data indicate that E2F1 plays an unexpected and novel role in regulating neurite outgrowth during development.

Title: Dscams promote self-avoidance by masking cell adhesion through both PDZ-dependent and -independent mechanisms

Authors: ***A. M. GARRETT**[1], A. L. D. TADENEV[1], A. KHALIL[2], P. G. FUERST[3], R. W. BURGESS[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]Dept. of Mathematics & Statistics, Univ. of Maine, Orono, ME; [3]Dept. of Biol. Sci., Univ. of Idaho, Moscow, ID

Abstract: During development, neurons balance attractive and repulsive signals to properly position cell bodies and neurites, and to form synapses with appropriate partners. The Dscams (from Down syndrome cell adhesion molecule) are Ig-superfamily members important for self-avoidance. *Drosophila Dscam1* promotes self-avoidance by generating up to 19,008 strongly homophilic isoforms, providing a code by which neurites can recognize and actively repel those from the same cell while still interacting with neighboring cells. Mammalian Dscams - *Dscam* and *Dscaml1* – serve a similar function without extensive isoform diversity. In the retina, mutant neurons of a given subtype form tight dendritic fascicles and lose their non-random mosaic spacing as their cell bodies pull into clumps. These clumps are homotypic, indicating that a shared cell-type identity promotes this interaction. In the wild type retina, processes from neurons expressing a single Dscam isoform overlap extensively with other cells expressing the same gene, suggesting that normal homotypic avoidance does not involve a strong repulsive mechanism. Reasoning that this self-avoidance was likely to involve intracellular signaling common to both DSCAM and DSCAML1, we chose to focus on the C-terminal PDZ-interacting domain: The sequences encoding the final ten amino acids of both DSCAM and DSCAML1 were replaced by epitope tag sequences to eliminate the canonical PDZ-interacting domains. These mutations completely recapitulated the null phenotypes in some cell types, but left others relatively unaffected, leading us to hypothesize that Dscams mask cell-type-specific repertoires of CAMs to prevent excessive adhesion, and that the PDZ-interacting domain is required to mask only some of these classes of CAMs. To test this, we focused on retinal ganglion cells labeled in *Cdh3-GFP* transgenic mice, a population that depends on DSCAM for self-avoidance and expresses a known repertoire of CAMs including *Cdh3* and *Cdh6*. We reasoned that if excessive adhesion provided by these Cadherins were normally masked by DSCAM, but were mediating unbalanced adhesion in our *Dscam* mutants, then Cadherin/ *Dscam* double-mutants would partially rescue the fasciculation phenotype. We quantified fasciculation in these double-mutants and found that indeed there is reduced fasciculation compared to *Dscam* null mice. We are currently testing other candidate adhesion systems in other cell types to ask if making double mutants with Dscam and PDZ-interacting CAMs can rescue fasciculation in cell types that require the PDZ interaction, and if DSCAM can mask multiple classes of adhesion molecules.

Title: Consequences of malformed versus signaling-depleted neuronal cilia during cortical development

Authors: A. PARKER[1], M. LE[1], J. COLEMAN[2], *M. R. SARKISIAN[1];
[1]Dept Neurosci, [2]Dept Pediatrics, Univ. Florida, Gainesville, FL

Abstract: Nearly all cortical neurons grow and maintain a primary cilium, but how signaling from these structures shape brain development is poorly understood. Our previous published work shows that malformation of cilia or loss of type 3 adenylyl cyclase III (ACIII) signaling from cilia during development results in the failure of cortical pyramidal neurons to properly elaborate dendritic arbors. Thus, we hypothesized that neurodevelopmental insults which lead to long-term changes in brain circuitry and function, such as early life seizures, would alter the developmental trajectory of neuronal cilia. By immunostaining for cilia markers, our recent data suggest that neuronal, but not glial ciliogenesis, is significantly disrupted by pentylenetetrazole-induced seizures during early neonatal development, leading to both acute and long-term changes in the length of cilia. Using a modified rabies virus to transynaptically label neurons within seized brains with GFP, our preliminary data suggest the seizure-induced ciliary changes overlap with a reduction in cortical neuronal connectivity. These observations have led us to ask whether changes in neuronal cilia structure affect dendritic development in a manner similar to changes in ciliary signaling. We are currently using *in utero* electroporation at E15.5 to deliver and compare the effects of CRISPR/Cas9 plasmids targeting Kif3a (to abrogate ciliogenesis) or ACIII (to disrupt cilia signaling) in specific postnatal developing neocortical neurons. This approach will allow us to test the hypothesis that a loss/reduction of ACIII from a neuronal cilium also impairs dendritic development and synaptic connectivity. The combined use of neuroanatomical, morphological and calcium imaging techniques to characterize subsets of neurons lacking key cilia signaling molecules will help to further define the importance of cilia in neuronal development and provide deeper insight into how common neurodevelopmental insults may alter the course of brain development and function.

Title: Dendrite arborization in cortical neurons depends on γ-Protocadherin-mediated homophilic matching with surrounding neurons and astrocytes

Authors: ***M. J. MOLUMBY**, A. B. KEELER, J. A. WEINER;
Biol., Univ. of Iowa, Iowa City, IA

Abstract: The α-, β-, and γ-Protocadherins (γ-Pcdhs) are cadherin superfamily adhesion molecules encoded by clustered gene families. The 22 γ-Pcdhs are combinatorially expressed in the CNS by neurons and astrocytes, and play critical roles in synaptogenesis, dendrite arborization, and the survival of subsets of neurons. We showed previously that the γ-Pcdhs promiscuously form cis-multimers that interact strictly homophilically in trans (Schreiner and Weiner, PNAS, 2010); the α- and β-Pcdhs were subsequently shown to interact in a similar homophilic manner. The Pcdh gene clusters thus have the potential to generate millions of distinct adhesive interfaces, providing CNS cells with molecular identities. We demonstrated previously that, in mice lacking the γ-Pcdhs in the cerebral cortex, pyramidal neurons exhibit severely reduced dendrite arborization (Garrett, et al., Neuron, 2012). This, combined with many studies of γ-Pcdh interactions *in vitro*, suggests that homophilic, adhesive γ-Pcdh interactions between neurons, and between neurons and glia, provide a positive signal for dendrite growth. However, in retinal starburst amacrine cells and cerebellar Purkinje cells, loss of the γ-Pcdhs resulted in aberrant dendrite fasciculation and self-crossing, suggesting that these molecules can mediate repulsive self-avoidance between a neuron's own dendrites. Here we provide multiple lines of evidence that homophilic matching of γ-Pcdhs in trans, between cells, is critical for proper formation of cortical neuron dendrite arbors. We demonstrate that expressing a single γ-Pcdh isoform in all primary neurons and astrocytes of the cortex *in vivo*, such that all cells "match" homophilically, greatly increases dendrite arborization compared to control mice. Additionally, astrocyte-specific loss of the γ-Pcdhs cell-non-autonomously decreases dendrite arborization in neurons, even though they retain their normal γ-Pcdh complement. Conversely, driving expression of a single γ-Pcdh isoform in an isolated cortical neuron, surrounded by wild-

Deleted: in vitro

Deleted: in vivo

type cells, decreases arborization in the transgenic neuron. Experiments in which cortical neurons expressing a particular γ-Pcdh isoform are co-cultured with other cortical neurons expressing the same, or a different γ-Pcdh isoform, support these *in vivo* data: dendrite arborization is greatest when a neuron is surrounded by homophilically matching cells. We conclude that, in cortical neurons, the γ-Pcdhs regulate dendrite arbor growth and morphology not through repulsive self-avoidance, but through positive homophilic trans-interactions between cells.

Title: The trafficking and localization of neuron-enriched endosomal protein (Neep21) in neurons

Authors: ***C. YAP**, L. C. DIGILIO, L. P. MCMAHON, B. WINCKLER;
Neurosci., Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstract: Neuronal endosomes are essential for membrane receptor trafficking in neurons. Endosomes participate in a variety of signaling events, as well as regulating the rates of recycling and degradation. Endosomal trafficking is thus at the center of receptor trafficking in neurons and participates in various neuronal functions, such as synaptic plasticity and axon outgrowth. Dysfunctions of the endolysosomal system have been implicated in a number of neurodegenerative conditions. As in other cell types, neuronal endosomes are regulated by a variety of endosomal regulators, which localize to different endosomal compartments. Neep21 (neuron-enriched endosomal protein of 21 kD) is a neuronal-specific endosomal transmembrane protein, localized to Golgi and endosomal compartments in the somatodendritic domain, and is important for trafficking of L1/NgCAM, AMPAR, and processing of beta-amyloid. In this work, we characterized the localization of Neep21 in detail and studied its trafficking and dynamic relationships with endosomal regulators rab5 and rab7 in neurons. We found that Neep21 co-localized with EEA1 and rab5, as expected from previous work. Neep21 also colocalized with Rab7 in the soma and along dendrites, but rarely colocalized with Lamp1, a lysosomal marker.

Importantly, we discovered that localization of Neep21 is regulated by Rab5 and Rab7. Overexpression of constitutively active Rab5CA (Rab5Q79L) retained Neep21 in enlarged early endosomes, whereas overexpression of Rab5 dominant negative (Rab5S34N) caused diffuse distribution of Neep21 along the plasma membrane of the soma and dendrites, and less vesicular-form of Neep21. Most importantly, we found that Rab5DN caused retention of Neep21 on the plasma membrane, and blocked endocytosis of Neep21 from the plasma membrane. In addition, endocytic trafficking of Neep21 from early endosomes is regulated by Rab7. Downregulation of Rab7 expression (by shRab7) and overexpression of Rab7 dominant negative (Rab7T22N) induced formation and accumulation of enlarged Neep21 early endosomes, indicating trafficking of Neep21 from early endosome requires Rab7. Interestingly, we found that Neep21 is also sorted to late endosomes for degradation as treatment with leupeptin, a lysosomal proteases inhibitor, induced accumulation of elongated- and enlarged-Neep21 endosomes in the soma and along dendrites, and treatment with protein synthesis inhibitor, cycloheximide, depleted the protein level of neep21 in neurons. This indicates that localization of Neep21 is not limited only to early endosomal compartment, it is also localized and trafficked toward late endosome/lysosome for its own degradation.

Title: High-resolution analysis of semaphorin3A effects on the dynamics of filopodia on the tips and shafts of developing dendrites using SLIM imaging

Authors: ***A. JAIN**[1], T. KIM[2], G. POPESCU[2], M. U. GILLETTE[1];
[1]Dept. of Cell and Develop. Biol., [2]Electrical & Computer Engin., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The intricate wiring of the nervous system relies on filopodial navigation to form complex interconnections between neurons through their axons, dendrites, and the cell soma itself. Until recently, cellular investigations into filopodial dynamics had focused primarily on axonal growth cone filopodia. Spurred by technological advances, scientists have now begun to explore the structural and functional landscape of dendritic filopodia. Here we investigate the role of Sema3A in guiding dendritic morphogenesis, spinogenesis, and synaptogenesis. We show that it acts not only at the level of the dendrites, promoting neurite survival and growth, but also at the level of the filopodia. Since there has been some evidence indicating a difference in filopodia borne along dendrite tips vs. those borne along dendrite shafts, we treat the two populations as distinct and tease apart their different responses. Structural analyses of numbers, lengths, and locations are complemented by studies of dynamic functional aspects, such as growth and shrinkage rates. This is made possible through Spatial Light Interference Microscopy (SLIM), an innovative quantitative phase imaging method for high-resolution, label-free imaging of live cells through interferometry (Wang et al., Opt. Express, 2011). SLIM permits measurement of the dry mass of live neurons at femtogram levels (Mir et al., Sci. Rep., 2014). This convergence of filopodial investigations and the technology for engineering micro-environments, when coupled with high resolution imaging and analysis, enabled new insights on local signals, including Sema3A, that initiate and establish neuron-neuron interactions at the filopodial level. A greater comprehension of such processes that shape the development of neuronal networks is helping unravel the mechanistic bases of developmental disorders and diseases.

Abstract: Neurons are highly polarized cells, extending distinct processes specialized to send (axons) and receive (dendrites) information. The accurate trafficking of the correct protein cargoes to either the axonal or dendritic compartments is required to maintain this polarity and therefore proper neuronal function. This process is regulated by dynein and kinesin motor proteins that move along the microtubule cytoskeleton. Importantly, the mislocalization of protein cargos or dysfunction of microtubule and motor proteins is implicated in a number of neurological disorders, including neurodevelopmental disorders such as mental retardation and autism. While axonal trafficking is well studied due to the uniform polarity of axonal microtubules, dendritic microtubule structure is more complex; thus, the motors that mediate dendritic trafficking as well as the dynamics of dendritic microtubules themselves remain largely unknown. We have utilized single molecule assays and live imaging in rodent hippocampal neurons to more fully characterize the function of kinesin in dendrites. Ultimately, our studies will help us to understand how the full repertoire of dendritic kinesins function to promote the functional specification of the dendritic and axonal compartments, and shed light on the little studied but essential process of dendritic trafficking.

Title: Ste20-like kinase is a regulator of dendritic arborization and excitation-inhibition balance in neocortical neurons

Abstract: Dendrite arborization and subsequent proper formation and maintenance of inhibitory and excitatory synapses are critical for the emergence of functional adult neuronal networks. Key regulators in forming and stabilizing dendritic arbors with their precise spatial arrangement of inhibitory vs. excitatory synapses have yet to be discovered. Here, we show that the Ste20-like kinase (SLK) has a key regulatory role in these processes. So far, SLK has been shown to be important for migration of fibroblasts by remodeling the cytoskeleton and for cell cycle progression. We show that shRNA mediated silencing of murine SLK or overexpression of the kinase dead (KD) SLK causes a striking and selective loss of distal dendritic arbors in neuronal cultures. Intraventricular *in utero* electroporation (IUE) of SLK shRNAs resulted in a similar cellular phenotype in cortical neurons, and additionally revealed a migration deficit of affected neurons. Surprisingly, the loss of distal, mainly excitatory input sites was associated with significantly elevated cortical excitability *in vivo*. A closer functional examination revealed a profound deficit in inhibition in affected neurons. Inhibitory synapse density and inhibitory transmission was progressively reduced at ages > P15. In contrast, excitatory synapses and neurotransmission were unchanged. Interestingly, neurons from human ganglioglioma tissue exhibited reduced SLK immunoreactivity in comparison to adjacent pre-existing control neurons, linking reduced SLK protein levels to an epilepsy-associated neuronal disorder. These data indicate a critical role for SLK during development particularly for dendritic arbor formation as well as the proper balance of dendritic inhibitory and excitatory synapses. They also suggest a role for reduced SLK protein expression in mediating functional changes and hyperexcitability in patients with ganglioglioma.

Title: The leucine-rich repeat transmembrane protein Lrig1 regulates dendrite arborization and social interaction in mice

Authors: *F. C. ALSINA, F. J. HITA, P. FONTANET, D. IRALA, F. LEDDA, G. PARATCHA;
Inst. of Cell. Biol. and Neurosci., Buenos Aires City, Argentina

Abstract: Dendrite size and morphology are key determinants for the functional properties of neurons and numerous neurodevelopmental and psychiatric disorders are mainly due to structural abnormalities of dendrites and their connections. Dendritic tree development is believed to result from the interaction between extracellular signals (such as neurotrophic growth factors), intrinsic modulators and electrical activity. Compared with the many identified factors that promote general dendritic growth and branching, little is known about the cell-type specific modulators that allow neurons to sculpt distinctive dendrite patterns. In the current study we show that Lrig1 - a pan-receptor tyrosine kinase associated protein that modulates many growth factor receptor signaling - is a physiological inhibitor of hippocampal dendrite morphogenesis and branching. *Lrig1*-deficient hippocampal neurons display an enhanced primary dendrite formation and proximal dendritic branching. Interestingly, *Lrig1* KO mice exhibit enhanced proximal dendritic arborization of hippocampal pyramidal neurons, low sociability and social interaction deficits. Taken together, our findings reveal an unexpected role of Lrig1 in the control of hippocampal dendrite development and plasticity, probably through the inhibition of neurotrophic growth factor-induced signaling.

Title: Assembly of the retinal direction-selective circuit is coordinated by starburst amacrine cells

Authors: *T. RAY, M. STOGSDILL, J. KAY;
Duke Univ., Durham, NC

Abstract: During retinal development neurons form parallel circuits tuned to convey specific features of the visual scene. At the inner plexiform layer (IPL) of the retina, neurons send their axons and dendrites to specific IPL sublayers where they form circuit-specific synaptic connections. The mechanisms employed by neurons to achieve such specificity are not well understood, but are of great biological importance because these processes are fundamental to sensory perception. To determine the mechanisms neurons use to form cell type specific connections we use the mouse direction-selective (DS) circuit as a model. Major components of the DS circuit include starburst amacrine cells, type 5/7 bipolar cells, and direction-selective ganglion cells (DSGCs) that coalesce at specific IPL sublayers to form synaptic connections. Here we test the hypothesis that starburst amacrine cells organize the formation of the DS circuit through homotypic repulsion and by expressing instructive cues for DS circuit cells. Starbursts stratify within the IPL before other DS circuit neurons placing them in prime position to organize the formation of the DS circuit. To determine how starbursts organize the DS circuit we devised a genetic strategy to label starbursts during early development and to perturb their dendritic patterning in the IPL. The latter was achieved by knocking out a gene, *Megf10*, that mediates homotypic recognition among starbursts. In the *Megf10* mutant, starbursts exhibit sporadic IPL errors including clumps and gaps in IPL innervation in addition to ectopic IPL layers. Disruption of starburst IPL stratification allows us to ask two key questions about the formation of the DS circuit: 1) Is homotypic repulsion needed for setting up the initial starburst IPL layers? 2) Do starbursts express cues that guide DS circuit neurons to the proper IPL location? We found that starburst IPL stratification is delayed in *Megf10*$^{-/-}$ mutants. Further, starbursts are instructive in recruiting DSGCs and type 5/7 bipolar cells to the appropriate IPL sublayer. DSGC IPL projections mirror the misprojections of starbrusts resulting in DSGC avoidance of IPL regions devoid of starbursts and innervation of ectopic starburst IPL layers, indicating starbursts attract the DSGCs. However, we found that type 5/7 bipolar cells can still project to IPL regions without starburst arbors. Additionally, we found that starbursts express repulsive cues for type 5/7 bipolar cells that target them to their precise IPL positions. These results demonstrate that starbursts actively guide DS circuit neurons, including other starbursts, to their appropriate IPL position by expressing guidance cues.

Title: Dendritic remodeling by the Angelman syndrome and autism protein E6AP

Authors: ***N. KHATRI**, J. GILBERT, M. NEE, H. MAN;
Boston Univ., Boston, MA

Abstract: Following growth and extensive branching of dendrites, structural maturation of neurons is characterized by a pruning process in which the extra, non-functional dendritic branches are actively removed. The timing of pruning and selection of specific dendrites determines the wiring of neural circuits and, ultimately, brain function. Angelman Syndrome (AS) and some autism spectrum disorders (ASDs) are caused by genetic disruption of E6AP, an E3 ligase that targets multiple proteins for ubiquitination and proteasome-mediated degradation. However, the neuronal function of E6AP remains largely unknown. We find that overexpression of E6AP leads to a reduction in dendritic arborization via dendritic pruning. We show that E6AP causes activation of the caspase proteases, a pathway known for local neurite degeneration and spine pruning. E6AP targets an endogenous caspase inhibitor for ubiquitination and degradation, therefore removing the inhibition of caspases and inducing the pruning process. Furthermore, we provide live imaging data suggesting that pruning occurs by distal fragmenting and shrinking of dendrites, eventually leading to the removal of entire dendritic segments. These findings provide novel mechanistic insight into our understanding of the physiological function of E6AP and the pathogenesis of Angelman syndrome and ASDs. Additionally, this study provides the first *in vitro* model of dendritic pruning in mammalian neurons.

Title: Role of ryanodine receptors in rat subventricular zone development

Authors: ***B. A. DOS SANTOS**[1], M. V. DAMICO[1], E. R. KINJO[1], G. S. HIGA[1,2], F. A. DOS SANTOS[1], A. H. KIHARA[1];

Abstract: During development of the central nervous system (CNS), the formation of the olfactory bulb occurs through the proliferation and migration of postnatal differentiated neurons from the subventricular zone (SVZ) close to the lateral ventricle. The activity of SVZ cells is modulated by the variation of intracellular calcium concentration, which in turn depends on external calcium and intracellular stores, localized in organelles such as mitochondria and endoplasmic reticulum. These organelles accumulate ryanodine receptors (RyRs 1, 2 and 3) that control the release of calcium into the cytosol. The aim of this project was to verify the role of these receptors and, consequently, the participation of intracellular calcium in the development of the SVZ cells. To this end, we first analyzed gene expression through the real time PCR technique of these receptors and also descriptive analysis related to the protein distribution by immunofluorescence in the SVZ of neonate animals in the day of birth (P0). We also evaluated Ki-67 colocalization with RyRs in order to analyze its accumulation in active phases of the cell cycle. Then we performed *in vitro* blockade of RyRs in SVZ cells, isolated from P0 animals with dantrolene (5 µM) during 4 hours. After the blockade, possible alterations were evaluated i) cell morphology; ii) neurite growth. For this, combined techniques such as immunohistochemistry and real time PCR were used, besides morphological evaluations. We observed lower gene expression of the three isoforms of RyRs in neonates compared to adults. Immunoflourescence analysis revealed that the three RyRs isoforms are similarly distributed throughout the SVZ of P0 animals. Besides, all isoforms accumulate in Ki-67-positive cells in neonates, demonstrating the presence of RyRs during the cell cycle. *In vitro* blockade of RyRs in primary cell culture from SVZ inhibited neurite growth, as well as avoided the progress of the circular morphology of the cells to a differentiated shape with increased dendritic branching, indicating that RyRs participate in important cellular maturation processes.Thus, we are able to disclose that RyRs

Deleted: in vitro

participate in the development of the cells from SVZ, which migrate and participate in the olfactory bulb circuitries.

Title: Requirement of neuronal ribosome synthesis for growth and maintenance of the dendritic tree

Authors: *M. HETMAN, L. SLOMNICKI, M. PIETRZAK, A. VASHISHTA;
Neurolog. Surgery, Univ. of Louisville, Louisville, KY

Abstract: The nucleolus serves as a principal site of ribosome biogenesis but is also implicated in various non-ribosomal functions including negative regulation of the pro-apoptotic transcription factor p53. While disruption of the nucleolus may trigger the p53-dependent neuronal death, neurotoxic consequences of a selective impairment of ribosome production are unclear. Here we report that in rat forebrain, neuronal maturation is associated with a remarkable expansion of ribosomes despite postnatal downregulation of ribosomal biogenesis. In cultured rat hippocampal neurons, inhibition of the latter process by knockdowns of ribosomal proteins S6, S14 or L4 reduced ribosome content without disrupting nucleolar integrity, cell survival and signaling responses to the neurotrophin BDNF. Moreover, RNA stress granules were formed suggesting diminished ribosome recruitment to mRNAs. Such a translational insufficiency was accompanied by impairment of BDNF-mediated dendritic growth. RNA stress granules and smaller dendritic trees were also observed when ribosomal proteins were depleted from neurons with established dendrites. Thus, a robust ribosomal apparatus is required to carry out protein synthesis that supports dendritic growth and maintenance. Consequently, deficits of ribosomal biogenesis may disturb neurodevelopment by reducing neuronal connectivity. Finally, as stress

granule formation and dendritic loss occur early in neurodegenerative diseases, disrupted homeostasis of ribosomes may initiate and/or amplify neurodegeneration-associated disconnection of neuronal circuitries.

Title: Keeping filopodia dynamic: exploring the role of miR-125b in dendrites using real time imaging

Authors: ***R. IYER**[1,2], T. KIM[3,2], G. POPESCU[3,2], M. U. GILLETTE[1,4,2];
[1]Cell and Developmental Biol., [2]Beckman Inst., [3]Electrical & Computer Engin., [4]Neurosci. Program, Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Developing dendrites encounter a multitude of stimuli that direct their growth and architecture. Cellular substrates respond to these stimuli, integrating extrinsic information to direct dendritic development. Of emerging interest in this process are microRNAs, small noncoding RNAs ~22 nucleotides long that can reversibly repress local translation. By responding to external cues sensed by dendritic filopodia, they participate in key decision-making processes in developing dendrites: where and how to grow and mature. We are focusing on miR-125b, a brain-abundant microRNA, to elucidate its role in the dynamics of filopdia and the corresponding changes in filopodial and dendritic structure. We inhibit miR-125b's activity in cultured hippocampal neurons during the early stages of development (4-7 DIV) as filopodia explore their microenvironment. Selective inhibition of miR-125b increases the width of filopodia, and negatively impacts dendrite development. To understand the effect of miR125b on

the dynamics of filopodia, we use an innovative imaging technique, Spatial Light Interference Microscopy (SLIM), an interferometry-based, label-free live imaging system that has topographic accuracy comparable to atomic force microscopy (Wang et al, Opt Express, 2011). Using SLIM, we show that the rate of filopodial extension and retraction is reduced significantly when miR125b is inhibited. We propose that miR-125b is critical in maintaining the filopodial phenotype early in dendrite development, and in laying the complex dendrite arbor. These high-resolution analyses reveal fresh insights into the process by which neurons integrate multiple external signals to establish the correct connections. Such insights are critical to understanding roles of miR125b in neurological disorders such as Fragile X Syndrome and Alzheimer's disease.

Title: Purkinje neuron axonal and dendritic markers during development *in vivo* and *in vitro*

Deleted: *in vivo*

Deleted: *in vitro*

Authors: T. FAULL, J. N. BATTYANYI, L. M. ROBERTSON, A. R. DEMCHAK, *M. E. MORRISON;
Biol., Lycoming Col., Williamsport, PA

Abstract: The cerebellum coordinates movement and balance. It is composed of only a few cell types including Purkinje neurons, whose dendrites receive inputs via synapses from over 200,000 granule cell parallel fibers and climbing fibers originating from the inferior olivary nuclei. The Purkinje neurons integrate these inputs, calculate motor error, and send corrective signals through their axons, which synapse onto the deep cerebellar nuclei. The early development of Purkinje neuron axons and dendrites is the subject of this study. The growth of Purkinje neurons in the mouse can be divided into several stereotyped stages. In the prenatal stage, the Purkinje cells are arranged in masses within the cerebellar anlage. From postnatal day 0 to postnatal day 3 *in vivo*, the cells extend numerous, very simple processes. As the cell continues to develop during the first two postnatal weeks, these processes recede back into the cell, and apical dendrites begin to appear. By the second or third postnatal week, the Purkinje neurons have a

Deleted: in vivo

highly branched dendrite studded with spines. This series of developmental changes is recapitulated in cell cultures made from neonatal mouse cerebella, with a slight time delay of a few days as the cells recover from the cell dissociation process. Knowing more about the nature of the early Purkinje cell processes could help in the design of treatments to support Purkinje cell regeneration after injury or in the face of cerebellar ataxias. Here we study the primitive processes of Purkinje cells in early postnatal mice and in cerebellar cultures derived from these mice: are they axonal, dendritic, both, or neither? Previous studies suggested that some individual early processes might express protein markers for both axons and dendrites. Interpretation of these results was limited by 2-color imaging, making it difficult to prove that these processes were indeed derived from Purkinje neurons. In the current study, 3-color immunohistochemistry of cryostat sections and immunocytochemistry of cultured cerebellar cells will be used to establish the locations of several proteins in developing Purkinje neurons, including calbindin D28k, MAP2 (a dendritic marker), and neurofilament H (an axonal marker).

Abstract: Appropriate dendritic arborization and synapse formation is vital for proper circuit formation. Numerous *in vitro* studies have elaborated on this process, but the *in vivo* environment is considerably more complex. Therefore, we are interested in studying this developmental process *in vivo* using chronic time-lapse imaging. We used cerebellar granule neurons (CGNs) as our model neuron since they undergo dendritic arborization and synaptogenesis post-birth from post-natal day 10-21 (P10-21). Using a new transgenic mouse line that sparsely labels only CGNs in the cerebellar cortex, we were able to characterize the dendritic and synaptic development of these neurons *in vivo*. A cranial window (approx. 1mm2)

Deleted: in vitro

Deleted: in vivo

Deleted: in vivo

Deleted: in vivo

was created on top of the cerebellar vermis (lobule 6/7) of neonatal mice (P6-7). Three days post-surgery, immature CGNs within the cranial window were imaged every day from P11-P23. A total of 9 CGNs from 4 animals were imaged; 6 were within 150µm of the brain surface while 3 were deeper than 200µm. All the cells had excess numbers of dendrites at the earliest time point (P12, 6 ±1 total dendrites) indicating immature CGN morphology. However, within three days (P15) all CGNs imaged had undergone dendritic pruning such that the remaining dendrites were the final surviving dendrites and no further additions or deletions from the dendritic arbor occurred (P23, 4.2 ±0.7 total dendrites). Concurrent with the decrease in dendritic number, the total dendritic length also reduced from P12 to P15 (P12: 99.89 ±0.97µm, P15: 74.34 ±8.17µm, p=0.03). However, after the establishment of final surviving dendrites at P15, dendritic length steadily increased but only until P18, reaching a maxima that was maintained from then on (P18: 90.57 ±5.79µm, P23: 91.08 ±9.01µm, p=0.48). Mature CGN dendrites end in a claw-like structure which is the site for both excitatory and inhibitory synapses. We observed claw formation in the maturing CGNs and found that all the immature CGNs developed a claw-like ending on at least one of their dendrites between P13-P15 with shallower CGNs developing earlier (at P13) while all the deeper CGNs developing later (at P15). This delay in development was also evident when comparing the time points the CGNs had a claw-like ending on all their remaining dendrites. Deeper CGNs reached this stage at P19 while shallower CGNs were morphologically mature by P17-18. Since no dendrite with a claw was retracted, it suggests an interplay between the processes of synaptogenesis and dendritic development. Hence, we are interested in the role of the claw and the pre-synaptic structures that synapse on to the claw in the development of CGN dendritic arbor.

Title: Age-related changes of collapsin response mediator protein 4 (crmp4)

Authors: ***T. KAWACHI**[1], A. TSUTIYA[1], H. MOTEGI[1], T. OKADA[1], R. OHTANI-KANEKO[1,2];

[1]Grad. Sch. of Life Sci., Toyo Univ., Gunma, Japan; [2]Bio-Nano Electronics Res. Ctr., Toyo Univ., Saitama, Japan

Abstract: Collapsin Response Mediator Protein (CRMP) was identified as the molecule required for the signal transduction related to the growth cone collapse of axons (Goshima et al., 1995). CRMPs are now known to consist of five homologous cytosolic proteins, CRMP1-5. It has been reported that all of them are highly expressed in the developing as well as adult brain. However, recent our *in situ* hybridization study revealed that signals of Crmp4 mRNA were occasionally detected in adults, though it was abundantly expressed during early postnatal period (Tsutiya & Ohtani-Kaneko, 2012). Our study also demonstrated that CRMP4 plays an important regulatory role in the growth of not only axons but also dendrites, suggesting its crucial function in building neural networks (submitted). On the other hand, it has been reported that the function of CRMP4 is controlled by phosphorylation of the molecule (Alabed et al., 2010; Fujisawa et al., 2011). However, which phosphorylation sites of CRMP4 are critical for neural developing remains unclear. Therefore, this study aimed to identify the amino acid residue of CRMP4 important for neural development. For the purpose, two dimensional gel electrophoresis (2DE) was used to examine expressional changes of different variations of CRMP4 during postnatal development of the mouse brain. Then we identified the phosphorylated residues with UPLC/MS/MS (SYNAPT G2, Waters) spectrometry analysis, whose expression was significantly decreased after postnatal day 7. We then studied the role of these phosphorylation sites of the molecule *in vitro*. Proteins in the cerebral cortex tissue from male postnatal day 0 (PD0), PD7, 8-week-old (Adult), and over 1-year-old (Aged) mice were subjected to 1DE and 2DE immunoblotting with antibodies against CRMP4 and CRMP4 phosphorylated at Thr 509 (pCRMP4). One DE immunoblotting showed that expressions of CRMP4 and pCRMP4 were significantly decreased in adult and aged mice, compared to those at PD0. Two DE immunoblotting revealed nine spots (No. 1 ~ 9) of CRMP4. All nine spots were dramatically decreased in adult brain, compared to those at PD0. Especially, expressions of 2 spots were rapidly decreased during postnatal period and significantly decreased at PD7, compared to those at PD0. Next, we identified some of phosphorylated residues of these 2 spots. Using mouse hippocampal cells (HT22 cell), we examined the effect of point mutations of these phosphorylation sites on neurite elongation and survival rate of cells.

Title: The mevalonate pathway in the development and survival of mouse Purkinje cells in culture

Authors: ***A. BARSZCZYK**[1], H.-S. SUN[2], Y. QUAN[1], W. ZHENG[3], M. P. CHARLTON[1], Z.-P. FENG[1];
[1]Physiol., [2]Surgery, Univ. of Toronto, Toronto, ON, Canada; [3]Fac. of Hlth. Science, Univ. of Macau, Macau, China

Abstract: Purkinje cells comprise an essential part of the cerebellar circuit, which underlies motor learning and some higher cognitive functions. The mevalonate pathway has important roles in cell survival and development. High cholesterol turnover is associated with dendritogenesis of Purkinje cells during postnatal development. In this study, we compared the effects of mevalonate pathway inhibition on mature and immature Purkinje cells in mouse cerebellar culture. We found that mevalonate pathway inhibition by mevastatin caused a loss of Purkinje cells. GGPP supplementation significantly attenuated this cell death, suggesting that GGPP is required for Purkinje cell survival. Selective inhibition of the squalene-cholesterol branch of the pathway resulted in developmental deficits, suggesting a crucial role for the squalene-cholesterol branch of the mevalonate pathway in the maturation of Purkinje cells. Given that abnormalities in Purkinje cells are associated with motor-behavioral learning disorders such as cerebellar ataxia, caution should be exercised with drugs that inhibit geranylgeranylation or the squalene-cholesterol branch of the pathway in the brain during development.

[2]Children's Hlth. Res. Ctr., [1]Sanford Res., Sioux Falls, SD

Abstract: KANK1 and ADD3 are cytoskeleton-modulating proteins expressed in neurons. These proteins cap growth at the dynamic (+)-end of actin filaments, and have been shown to influence diverse neuronal processes including vesicle recycling and dendritic spine remodeling. Mutations in *KANK1* and *ADD3* have been associated with heritable forms of cerebral palsy, although the underlying etiology has not been well characterized. shRNA-mediated knockdown of these genes resulted in statistically significant reductions in dendritic complexity in mouse primary neuron cultures as measured by Scholl analysis. Future work will examine the effects of knockdown on dendritic spine density and morphology in cultured neurons, as well as the *in vivo* effects on dendritic spines and arbors following *in utero* electroporations with shRNA-encoding plasmids.

Title: Effects of small peptides on protein interactions and dendrite branching

Authors: *H. MENON[1], H. CHAPMAN[2], M. SPALLER[2], B. FIRESTEIN[1];
[1]Cell Biol. and Neurosci., Rutgers, Piscataway, NJ; [2]Geisel Sch. of Med. at Dartmouth and Norris Cotton Cancer Ctr., Lebanon, NH

Abstract: Dendritic branching is essential for proper development of the neuronal circuitry. Interestingly, a number of neuropsychiatric diseases, such as autism, schizophrenia and Alzheimer's disease, display abnormal dendritic branching. We previously reported that the protein cypin (cytosolic PSD-95 interactor) is a key player in the process of dendritic branching. The interaction between cypin and PSD-95, via cypin binding to the first two PDZ domains of PSD-95, is essential for the promotion of stable dendrite branches. Cypin is a positive regulator of dendrite branching while PSD-95 inhibits dendrite branching. To test the importance of binding partners to the PDZ domains of PSD-95 in the regulation of dendrite branching, we are characterizing a set of small peptides that specifically bind to the PDZ domains of PSD-95. Our preliminary results indicate that a subset of the compounds alters the interaction between PSD-95 and cypin but possibly not between PSD-95 and another interacting molecule, neuronal nitric oxide synthase (nNOS). Our ongoing work will address whether the small peptides have an effect on dendritogenesis. These studies will allow us to understand how the dendritic tree is shaped and elucidate potential therapies for disorders that show aberrant dendrites.

Title: Regulation of cortical gabaergic interneuron function by the mental disorder susceptibility molecule cntnap2

Authors: *R. GAO, G. ZHANG, D. M. D. SAAVEDRA, P. PENZES;
Physiol., Northwestern Univ., Chicago, IL

Abstract: While complex neuropsychiatric disorders have equally complicated genetic etiologies, recent research revealed common disruptions of individual genes across multiple diseases, suggesting similar pathological mechanisms. For example, several genetic studies have established contactin-associated protein-like 2 (CNTNAP2) as a risk gene in mental disorders such as autism spectrum disorders, schizophrenia, epilepsy, and intellectual disability. Studying the function of CNTNAP2, therefore, can lead to unprecedented insight into shared susceptibility pathways of mental diseases. CNTNAP2 is a member of the neurexin superfamily, is highly expressed in the brain, and clusters potassium channels in the axon's juxtaparanodes. However, its function outside of the axon is less explored. Recent studies of CNTNAP2 knock-out mice revealed not only behavioral abnormalities and epileptic seizures, but also reductions of cortical interneurons and abnormal neuronal synchrony (Peñagarikano et al., 2011). In addition, CNTNAP2 knockdown in primary neuronal culture resulted in the reduction of both excitatory and inhibitory transmission (Anderson et al., 2012). Taken together, these data implicate CNTNAP2 in controlling E/I balance and behavior, possibly through cortical interneuron function. However, mechanistic studies verifying this hypothesis have not yet been established. To this end, we used a wide array of techniques including yeast-2-hybrid screening, confocal and high resolution imaging, biochemistry, and primary neuronal culture to dissect CNTNAP2's role in cortical interneuron function. Our data provide novel insight into the molecule's cellular mechanisms and provide clues to how its dysfunction may contribute to various mental disease etiologies.

Title: The X-linked intellectual disability protein KIAA2022 in neuron morphogenesis and synapse formation

Authors: *J. P. GILBERT[1], H.-Y. MAN[2];
[1]Biol., [2]Biology, Pharmacol. and Exptl. Therapeut., Boston Univ., Boston, MA

Abstract: Individual neurons must undergo processes of extensive morphogenesis and synapse formation to ensure proper neuronal connectivity and network function. Previous studies of autism spectrum disorders (ASD) have shown abnormalities in brain development, including axon and dendritic outgrowth, synapse formation and plasticity. Our earlier work has identified that loss of function of an X-linked gene, KIAA2022, was the etiological factor in a particular group of patients with intellectual disability and ASD phenotypes. KIAA2022 is a novel protein that lacks known molecular motifs, has no significant homology to other proteins and its neuronal function remains unknown. Using rat hippocampal neurons, we report that KIAA2022 shows a typical nuclear localization, indicating a role for KIAA2022 in gene regulation. We find that knockdown of KIAA2022 results in a marked impairment of neurite outgrowth, synapse formation and synaptic activity. Knockdown of KIAA2022 leads to an increase in total and synaptic N-cadherin levels, as well as an increased association between N-cadherin and δ-catenin. These results indicate that increased N-cadherin levels may sequester δ-catenin at the membrane, thereby preventing its downstream interaction with effectors of neurite morphogenesis and synapse formation. Our findings establish important roles for KIAA2022 in regulating neuronal development and provide insight into the molecular mechanisms underlying intellectual disability and ASD.

Title: Morphological characteristics of cerebellar interneuron Lugaro cells using with GFP-expressing transgenic mice line

Authors: ***T. MIYAZAKI**[1], K. F. TANAKA[2], M. WATANABE[1];
[1]Hokkaid Univ. Sch. Med., Sapporo, Japan; [2]Dept. Neuropsychiatry, Sch. Med. Keio Univ., Tokyo, Japan

Abstract: Cerebellar interneuron Lugaro cells (LCs) have fusiform cell bodies and extend horizontal bipolar dendrites beneath the Purkinje cell (PC) layer. Basic morphological properties of LCs are known, however, detailed neuronal characteristics have been unclear due to the lack of useful neurochemical markers. In the present study, we produced a transgenic mouse line, in which green fluorescent protein (GFP) was specifically expressed in LCs by KENGE (knockin-mediated enhanced gene expression by improved tetracycline-controlled gene induction) -tet system. In fluorescent *in situ* hybridization, most (~80%) LCs expressed both GAD67 and GlyT2 mRNAs as previously reported, however, a subset (~15%) of LCs expressed only GAD67 mRNA. In multiple immunofluorescence and double immunoelectron microscopy using with GFP immunolabeling and neuronal tracing method, LCs received inhibitory inputs from PC axon collaterals and excitatory inputs from climbing fibers (CFs), mossy fibers and ascending axons of cerebellar granule cells. Furthermore, we demonstrated that LCs formed dendritic meshwork beneath PC layer using cerebellar sections cut parallel with the layer. Interestingly, the extent of dendritic meshwork of given LCs was mostly confined to a cerebellar parasagittal zone as visualized by aldolaseC immunolabeling. We also investigated projection pattern of LC axons. LCs projected ascending and transverse axons to the molecular layer, where they formed symmetrical synapses with somatodendritic domain of inhibitory interneurons. Especially, ascending axons intensively innervated the soma of molecular layer interneurons (MLIs). In the developing cerebellum, LCs were generated from the ventricular zone around the birth and migrated to the PC layer with extending their dendrites from the both somatic apical ends. The zone-specific dendritic meshwork was completed by P10. These results suggest that LC receives zone-specific inputs from the early developmental stages and they strongly innervate MLIs on the same parasagittal zone by ascending axons. Considering that the orientation of MLIs and PCs is also organized into the cerebellar zone, LCs may constitute intrazonal microcircuit accompanying with MLIs and PCs, and regulate synchronous disinhibition of PCs on the parasagittal zone.

Title: Neuronal PARP regulates dendritic morphology in developing neurons

Authors: ***J. Y. HUANG**[1], K. WANG[2], J. P. ADELMAN[2], M. S. COHEN[1];
[1]Physiol. & Pharmacol., [2]Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The precise control of dendritic morphology is critical for proper neural circuit formation. Recent studies in mice demonstrate a role for nicotinamide adenine dinucleotide (NAD^+) in regulating dendritic morphology and cognitive function; however, the downstream effectors of NAD^+ that mediate these neuronal functions remain unknown. NAD^+ is not only a cofactor for oxidoreductases, but is also a substrate for a family of enzymes known as poly-ADP-ribose-polymerases (PARPs). These enzymes transfer the ADP-ribose unit from NAD^+ to amino acids on target proteins, a process known as ADP-ribosylation. ADP-ribosylation is an essential post-translational modification, but it is far less understood compared to other post-translational modifications, such as phosphorylation. To investigate the potential role of PARPs in neuronal development, we first analyzed PARP expression in the brain. One particular PARP, which we refer to as neuronal-PARP (n-PARP), was expressed at high levels in the embryonic rat brain. Knockdown of n-PARP resulted in a significant reduction of dendritic complexity in cultured primary hippocampal neurons and *in vivo*. Overexpression of n-PARP in primary neurons increased dendritic complexity. Taken together, our results demonstrate a role for n-PARP in the regulation of dendritic morphology during neuronal development. The identification of n-PARP as a critical regulator of dendritic morphology provides the first evidence that ADP-ribosylation plays a role in normal neuronal cell physiology.

Title: Cortactin binding protein 2 increases microtubule stability and regulates dendritic morphogenesis

Authors: ***P.-Y. SHIH**, Y.-K. CHEN, S.-P. LEE, Y.-P. HSUEH;
Academia Sinica, Inst. of Mol. Biol., Taipei, Taiwan

Abstract: Dendritic spines are important subcellular structure for neuron to receive the input from presynaptic neuron. Specifically, dendritic spines are the major locations of excitatory synapses in mammalian brain. Previous studies indicated that the development defects of dendritic spines may result in various neuropsychiatric diseases. Recently, we identified a neuron-specific gene, CTTNBP2, which regulates the formation and maintenance of dendritic spines by regulate Cortactin protein mobility. Besides, CTTNBP2 controls synaptic distribution of the protein phosphatase 2A. Here, we show that in addition to associating with F-actin cytoskeletons via the interaction with Cortactin, CTTNBP2 also associated with microtubules, increased microtubule stability and consequently regulated dendritic development. We identified that the middle (Mid) region of CTTNBP2 associated with microtubules. However, the association with the Mid region is not sufficient for microtubule regulation per se. The homo-oligomerization through the N-terminal NCC region of CTTNBP2 is also necessary. In cultured hippocampal neurons, knockdown of CTTNBP2 or expression of the Mid or NCC domain alone reduced the acetylation levels of microtubules and impaired early stage dendrite outgrowth and dendritic arborization. Our study suggests that CTTNBP2 influences both the F-actin and microtubule cytoskeletons and thus performs two distinct functions in neuronal morphogenesis: dendritic spine formation and dendritic morphogenesis.

Title: Pharmacological blockade of Na+/Ca^{2+} exchanger modulates the growth and development of Purkinje cell dendritic arbor in mouse cerebellar slice cultures

Authors: P. SHERKHANE[1], *J. P. KAPFHAMMER[2];
[1]Dept. of Biomedicine, Univ. of Basel, Inst. of Anat., 4056 Basel, Switzerland; [2]Univ. Basel, 4056 Basel, Switzerland

Abstract: Purkinje cells are the principal neurons of the cerebellar cortex and have an extensive and elaborate dendritic tree. Chronic activation of type I metabotropic glutamate receptors severely inhibits Purkinje cell dendritic growth. This effect is mediated by calcium influx through P/Q-type and T-type Ca^{2+} channels. Furthermore, the blockade of Plasma membrane calcium ATPase 2 (PMCA2) moderately inhibits the growth of the Purkinje cell dendritic arbor.

In contrast, the blockade of PMCA2 rescues the dendritic tree from the drastic reduction normally seen with chronic mGluR1 activation. These findings indicate that influx and extrusion of calcium plays a pivotal role in the development of the Purkinje cell dendritic arbor. The sodium-calcium-exchanger (NCX) is another calcium exchange mechanism in Purkinje cells which can mediate Ca^{2+} and Na^{+} fluxes across the synaptic plasma membrane in a bidirectional mode: the forward mode (Ca^{2+} efflux mode) and reverse mode (Ca^{2+} influx mode). We inhibited these modes by pharmacological treatments to study their effects on the development of Purkinje cell dendritic arbors. The blockade of either the forward mode by Bepridil or the reverse mode by KB-R7943 inhibited the growth and development of the Purkinje cell dendritic tree. However, reverse mode inhibition by KB-R7943 not only strongly reduced the size of the dendritic arbor, but also induced a thickening of the distal dendrites. The combined inhibition of both the modes had a profound negative impact on the dendritic development in Purkinje cells. We have also tested other benzyloxyphenyl derivatives like SEA0400, YM-244769 and SN-6 which preferentially block the reverse mode similar to KB-R7943 in cerebellar slice cultures. They showed similar effects on Purkinje cell dendritic development with their exception of the thickening distal dendrites seen in KB-R7943 treated slice cultures suggesting that this phenotype might be unrelated to blockade of the reverse mode. Our findings show that interfering with the function of the Na^{+}/Ca^{2+} exchanger profoundly affects Purkinje cell dendritic growth probably by altering the calcium equilibrium within Purkinje cell dendrites.

Title: Nicotine facilitates neurite outgrowth of primary cultured cells in superior cervical ganglia (SCG) and PC12 cells

Authors: ***S. TAKATORI**[1], F. TAKAYAMA[2], H. HINO[2], K. KIMURA[3], N. ONO[3], H. KAWASAKI[1];
[1]Matsuyama Univ., Matsuyama, Japan; [2]Okayama Univ., Okayama, Japan; [3]Fukuoka Univ., Fukuoka, Japan

Abstract: Background: Our previous report demonstrated that in *in vivo* study nicotine facilitates reinnervation of perivascular sympathetic adrenergic nerves, but not perivascular CGRPergic nerves, which were injured by topical Phenol-application in the rat-mesenteric artery and significantly increased levels of nerve growth factor (NGF) contents in superior cervical ganglia (SCG) and mesenteric arteries, but not dorsal root ganglia (DRG). In this report, we showed that *in vivo* nicotine produced increased levels of NGF receptor TrkA expression in SCG. Nicotine-induced increases in NGF contents and TrkA expression were inhibited by the nicotinic acetylcholine receptor (nAChR) antagonist hexamethonium pretreatment (Takatori S et al., Eur J Pharmacol, 748: 1-9, 2015.). To clarify possible mechanisms, the present study was investigated whether nicotine affects neurite outgrowth of primary cultured cells in SCG and PC12 cells *in vitro*. Methods: SCG cells were isolated from Wistar rats and PC12 cells purchased were primarily cultured for 5-7 days. Numbers of neurite outgrowth from cell body were measured in the absent (Control) or presence of nicotine (10-1000 μM), acetylcholine (ACh) (10-1000 μM) or NGF (10-100 ng/mL). Hexamethonium (100 μM) was incubated with nicotine for 5-7 days. Results: In SCG cells, nicotine concentration-dependently increased neurite outgrowth numbers from tyrosine hydroxylase-immunopositive SCG cells. The nicotine-induced increase in neurite numbers was dependent on the exposure time (8 to 24 hr/day) and significantly inhibited by combined incubation of hexamethonium. However, ACh had no effect on the neurite numbers. In PC12 cells, nicotine caused an increase in neurite numbers, which was blocked by hexamethonium (100 μM). NGF also markedly increased neurite growth numbers of SCG and PC12 cells. Conclusion: These results suggest that nicotine has a neurotrophic effect on perivascular adrenergic nerve innervation through activation of nAChR, similar to *in vivo* assay we previously evaluated.

Title: Postnatal development of dendritic structure of layer III pyramidal neurons in cerebral cortex of marmoset

Authors: *T. SASAKI[1,2], T. OGA[1,3], H. AOI[1,3], I. FUJITA[3,4], N. ICHINOHE[1,2];
[1]Dept. of Ultrastructural Research, Natl. Inst. of Neurosci., Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [2]Lab. for Mol. Analysis of Higher Brain Function, Brain Sci. Institute, RIKEN, Wako, Japan; [3]Lab. of Cognitive Neuroscience, Grad. Sch. of Frontier Biosci., [4]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communicat, Osaka Univ., Suita, Japan

Abstract: In the primate cerebral cortex, dendritic spines rapidly increase in number after birth up to infancy or mid-childhood, and then decrease towards adulthood. Abnormalities in these processes accompany several psychiatric disorders. We have been investigating the normal processes of spine formation/pruning in the cerebral cortex using the common marmoset as a primate model. In this study, we examined developmental changes of basal dendrites and spines of layer III pyramidal cells in the vision-related areas (prefrontal area 12, temporal area TE, primary visual area V1), and the medial prefrontal cortex (mPFC: granular area 8B/9, dysgranular area 14r, agranular area 24). Cells were intracellularly injected with Lucifer Yellow in lightly fixed slices, and reacted for Diaminobenzidine. Basal dendrites of more than 500 cells were reconstructed, and their morphological features were analyzed. The dendritic field areas and total dendritic length in areas 12, TE and the mPFC areas showed generally similar time course. They increase during the first 2-3 postnatal months, and then slightly decrease (areas 8B/9, 14r) or remain at similar levels (areas 24, 12, TE) until adulthood. In contrast, the change in branching complexity exhibited notable differences between the vision-related areas and the

mPFC areas. While the branching complexity in the vision-related areas monotonically increases up to adulthood, that in the mPFC areas reaches a peak at 2M, and thereafter slightly reduces or remains unchanged. In the six areas, the spine density concurrently increases up to 3M, and subsequently decreases with area-specific patterns. The peak spine density was higher in the mPFC areas than in the vision-related areas at all developmental stages examined. The total spine number of individual cells is higher in the mPFC areas than in the vision-related areas throughout all ages. In these areas, the total spine number was the highest at 3M except for area 14r (the peak occurred at 2M). Synaptogenesis occurs almost synchronously across the cortical areas. The net decrease ratio in the total number of spines is larger in all the granular areas examined (area 8B/9 (43.2%), area 12 (40.7%), TE (49.2%), and V1 (58.7%)) than in agranular area 24 (33.3%) and dysgranular area 14r (28.5%). Thus, cells in less granular areas of mPFC show more modest spine elimination than those in granular areas. These features may be related to the vulnerability of this region to psychiatric disorders. Search for the molecular mechanisms that underlie the developmental changes will provide further clues for an understanding of pathogenesis of developmental disorders.

Title: Activity-dependent regulation of radial glial cell proliferation by HDAC1 in the developing Xenopus tectum

Authors: ***W. SHEN**[1], Y. TAO[2], H. RUAN[1], X. GUO[1], L. LI[2];
[1]Hangzhou Normal Univ., Zhejiang, China; [2]First Affiliated Hosp. of Nanjing Med. Univ., Nanjing, China

Abstract: In the developing central nervous system (CNS), progenitor cells differentiate into progeny to form functional neural circuits. Radial glial cells (RGs) are a transient progenitor cell type that is present during neurogenesis. It is thought that a combination of neural trophic factors, neurotransmitters and electrical activity regulates the proliferation and differentiation of

RGs. However, it is less clear how epigenetic modulation controls the proliferation of RGs in the developing brain. We sought to explore the effect of visual activity and histone deacetylase (HDAC) on the proliferation of RGs in the visual optic tectum of Xenopus laevis. We used the thymidine analog BrdU (5-bromo-2'-deoxyuridine) with anti-BrdU antibody to measure the cell proliferation and brain lipid-binding protein (BLBP) antibody to label RGs in the whole-mount optic tectum. We found that the number of BrdU-labeled precursor cells along the ventricular layer of the tectum decrease developmentally from stage 46 to stage 49. The co-labeling of BrdU- and BLBP-positive cells showed that the majority of BrdU-labeled cells along the tectal midline are RGs. BLBP-positive cells are also developmentally decreased with the maturation of the brain. Furthermore, HDAC1 expression is developmentally down-regulated in tectal cells, especially in the ventricular layer of the tectum. Pharmacological blockade of HDACs using Trichostatin A (TSA) or Valproic acid (VPA) decreased the number of BrdU-positive, BLBP-positive and co-labeling cells. Specific knockdown of HDAC1 by a morpholino (HDAC1-MO) decreased the number of BrdU- and BLBP-labeled cells and increased the acetylation level of histone H4 at lysine 12 (H4K12). We also found that visual deprivation (VD) induces the increase of BrdU-positive precursor cells and BLBP-positive RGs. The VD-induced increase in precursor cells was blocked by HDAC1 knockdown with HDAC1-MO at stage 49 tadpoles. These data demonstrate that the proliferation of RGs are visual activity-dependent and HDAC1 regulates radial glia cell proliferation in the developing optical tectum of Xenopus laevis.

Title: Disruption of cortical circuitry development in glycine receptor alpha 2 knockout mice

Authors: ***J.-M. RIGO**[1], G. MORELLI[1], A. AVILA[2], N. AOURZ[3], I. SMOLDERS[3], B. BRÔNE[1], L. NGUYEN[4];

[1]Hasselt Univ., Diepenbeek, Belgium; [2]The Hosp. for Sick Children, Toronto, ON, Canada; [3]Fac. of Med. and Pharm., VUB, Brussels, Belgium; [4]GIGA Neurosci., Univ. of Liège, Liège, Belgium

Abstract: Previous studies have revealed an important role of strychnine-sensitive glycine receptors (GlyRs) in the cerebral cortex during neurogenesis. Specifically, absence of GlyR alpha 2 subunits in a genetically disrupted mouse model leads to defects in the interneuronal migration and proliferation of projection neurons. In order to evaluate the long-term consequences of these early defects, we examined the role of GlyRs during postnatal development of the cerebral cortex. Remarkably, GlyR alpha 2 knockout mice displayed a significant reduction in the number of parvalbumin positive interneurons at postnatal day 14 associated with a reduction of upper layer and layer V projection neurons of the cortex. Moreover, morphological and synaptic defects were assessed in the cerebral cortex of knockout mice by performing 3D reconstruction of single neurons and whole-cell patch-clamp recordings. Morphological studies of biocytin-filled neurons revealed altered dendrites growing and generation of spines. Furthermore, whole-cell recordings showed a substantial decrease in the frequency of inhibitory post-synaptic currents (IPSCs) and increase of excitatory postsynaptic currents (EPSCs). These preliminary findings are consistent with the idea that GlyRs might have an important role during the development of the cortical circuitry.

Abstract: During rat midbrain (MB) formation, dopamine neuron differentiation occurs between embryonic days (E) 9 to 15. During this process, the modifications of epigenetic marks in histones and DNA are essential for the expression of genes associated to the dopaminergic phenotype. The DNA demethylation process has an important role during neurogenesis, since increases of 5-hydroxymethylcitosine (5hmC) have been associated to transcriptional activation of neuronal genes. Recently, it was demonstrated that an injection of histamine (HA) in E12 decreases the number of mesencephalic dopamine neurons. In this work, we analyzed the presence of histamine receptors *in vivo* at two different stages: neural precursor cells and differentiated neurons. Next, we performed intrauterine injections at representative stages of MB neurogenesis (E10, E12, E14 and E16) to investigate if HA precludes the expression of Tyrosine Hydroxylase (TH), the rate limiting enzyme for dopamine synthesis. We found that embryos injected at E10 and E12 showed a marked decrease in TH staining, strongly suggesting that HA is acting on neural progenitors. To analyze a possible HA action mechanism, we looked for changes in the patterns of modified cytosines in the Th gene by bisulfite conversion and sequencing. Although we found a similar global percentage of modified cytosines in HA-treated embryos compared to controls, we found specific changes in the first intron of this gene. Furthermore, we analyzed the presence of 5hmC and 5-methylcytosine (5mC) marks, and found that HA injection decreased significantly the percentage of 5mC and 5hmC at intron 1 of Th gene to 52% and 63%, respectively, compared to vehicle-injected embryos. Surprisingly, when the pluripotency gene Oct4 was analyzed, we found that HA decreased significantly the percentage of 5mC to 46%, compared to controls. In the case of the housekeeping gene Gapdh, we did not find cytosine modifications in control embryos, nor in those treated with HA. Finally, we found that HA have a long-term effect on the dopaminergic system, since the administration of HA at E12 decrease neuronal fibers positive to TH six days after the injection. These findings will help us understand the molecular effects of HA during differentiation of dopamine neuron and to design strategies to counteract dopaminergic degeneration, responsible for Parkinson's disease. Supported by PAPIIT IN208713 and CONACyT CB09/131281.

Title: Histamine impairs midbrain dopaminergic development *in vivo* by activating histamine type 1 receptors

Authors: ***I. ESCOBEDO**;
Univ. Nacional Autónoma De México, México, Mexico

Abstract: Histamine (HA) regulates the sleep-wake cycle, synaptic plasticity and memory in adult mammals. Dopaminergic specification in the embryonic ventral midbrain (VM) coincides with increased HA brain levels. To study the effect of HA receptor stimulation on dopamine neuron generation, we administered HA to dopamine progenitors, both *in vitro* and *in vivo*. Cultured embryonic day 12 (E12) VM neural stem/progenitor cells expressed transcripts for HA receptors H1R, H2R and H3R. These undifferentiated progenitors increased intracellular calcium upon HA addition. In HA-treated cultures, dopamine neurons significantly decreased after activation of H1R. We performed intrauterine injections in the developing VM to investigate HA effects *in vivo*. HA administration to E12 rat embryos notably reduced VM Tyrosine Hydroxylase (TH) staining 2 days later, without affecting GABA neurons in the midbrain, or serotonin neurons in the mid-hindbrain boundary. qRT-PCR and Western blot analyses confirmed that several markers important for the generation and maintenance of dopaminergic lineage such as TH, Lmx1a and Lmx1b were significantly diminished. To identify the cell type susceptible to HA action, we injected embryos of different developmental stages, and found that neural progenitors (E10 and E12) were responsive, whereas differentiated dopaminergic neurons (E14 and E16) were not susceptible to HA actions. Proliferation was significantly diminished, whereas neuronal death was not increased in the VM after HA administration. We injected H1R or H2R antagonists to identify the receptor responsible for the detrimental effect of HA on dopaminergic lineage and found that activation of H1R was required. These results reveal a novel action of HA affecting dopaminergic lineage during VM development.

Title: Effects of calcium influx on interleukin-6-mediated neuronal differentiation of neural progenitor cells

Authors: *J. OH;
Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Effects of calcium influx on interleukin-6-mediated neuronal differentiation of neural progenitor cells Jisun Oh[1], Jong-Sang Kim[1], Michael A. McCloskey[2] and Donald S. Sakaguchi[2] [1]School of Food Science and Biotechnology (BK21 plus), Kyungpook National University, Daegu 702-701 Republic of Korea [2]Department of Genetics, Development and Cell Biology, Iowa State University, Ames, IA 50011 **Abstract** The purpose of this study was to investigate possible molecular mechanisms through which interleukin-6 (IL-6) induces neuronal differentiation of adult hippocampal neural progenitor cells (AHPCs). We previously reported that astroglial cells from neonatal rat brain produce soluble factors which enhance neuronal differentiation of AHPCs, and that IL-6 is an astrocyte-derived factor which specifically promotes neuronal differentiation of AHPCs. In the present study, we examined the influence of extracellular calcium and voltage-gated calcium channel antagonists on IL-6-induced neuronal differentiation of AHPCs. AHPCs were cultured in various concentrations of external calcium or with L-type voltage-gated calcium channel blockers. Our results demonstrate that extracellular calcium was critical for neuronal differentiation of IL-6-treated AHPCs, that a blockage of L-type Cav channels inhibited IL-6-enhanced neuronal differentiation of AHPCs, and that exogenous IL-6 treatment increased the percentage of AHPCs immunoreactive for an activated from of CREB (phosphorylated CREB). These results suggest that IL-6 may induce AHPCs to commit to a neuronal lineage by promoting extracellular calcium influx which leads to CREB activation. Our findings may provide insight into understanding injury-induced neurogenesis and have implications for developing cell-based therapeutic strategies using adult neural progenitor cells.

Title: Non-synaptic communication during early cortical column formation revealed by genetically encoded Ca^{2+} indicators

Authors: ***B. G. RASH**[1], J. B. ACKMAN[1], P. RAKIC[1,2];
[1]Dept. of Neurobiol., Yale Univ., New Haven, CT; [2]Kavli Inst. for Neurosci. at Yale, New Haven, CT

Abstract: Cortical columns are basic cellular and functional units of the cerebral cortex and are thought to be malformed in many brain disorders, but how they initially form is not well understood. Using the genetically encoded calcium (Ca2+) indicator, GCaMP5G, in the mouse embryonic forebrain we demonstrate that Ca2+ fluxes propagate bi-directionally within the elongated fibers of radial glial cells (RGC)s, providing a novel communication mechanism linking the stem cell and differentiative niches prior to synaptogenesis. Correlated activity in RGC fiber clusters heralded the development of early cortical columns, and high frequency Ca2+ transients featured prominently during initial neurogenesis and coordinated neuronal migration to the appropriate cortical columns. Furthermore, radially-oriented Ca2+ signaling was induced by Notch and fibroblast growth factor activity implicated in cortical expansion. Therefore, interaction of genetic and multiple Ca2+-dependent mechanisms shapes the formation of cortical columns by influencing the timing of neuronal genesis and mode and rate of migration. Finally, we show that prenatal exposure to Ca2+ activity-blocking drugs led to defects in cortical columns and connectivity.

Title: Underlying mechanisms of learning: the contribution of mature spines and GluA2 expression in CA3

Authors: ***A. ALLIGER**[1], A. AUBRY[2], P. A. SERRANO[1];
[1]Psychology, Hunter Col., New York, NY; [2]Psychology, CUNY Grad. Ctr., New York, NY

Abstract: Animals housed in environmental enrichment (EE), even for short or intermittent exposure periods, have shown robust morphological and biochemical changes compared to standard housed (SH) animals. Morphological factors of subjects housed in EE include but are not limited to increases in synaptic proteins and spinogenesis throughout the hippocampus. While total number of spines may be an important determinant of learning and memory, we are now recognizing that type of spine may also broaden our understanding of the neurological mechanisms of these behaviors. By combining Golgi staining with immunohistochemistry, we are able to quantify spine morphology and expression of synaptic proteins (GluA2 and PSD-95) within spines utilizing IMARIS software. After six weeks of EE, we measured 1) spatial learning via the radial arm maze (RAM), 2) spine density for filopodia, stubby, long-thin and mushroom spines and 3) the clustering of synaptic markers GluA2, and PSD95 in area CA3 of juvenile rats. Four treatment conditions of EE/no RAM, SH/no RAM, EE /RAM, and SH/RAM allowed comparisons between the expression of spine types and synaptic markers. For spatial learning assessment, animals were given three days of RAM training (10 trials per day) where 4 of 8 arms were baited. EE subjects performed significantly better on RAM over SH subjects measured with percent correct scores. A two-way (RAM x Housing) ANOVA revealed that EE/RAM animals exhibited a significant increase in mushroom spines compared to EE/no RAM, SH/no RAM and to SH/RAM animals. Separate two-way ANOVAs were run for the expression of GluA2 and PSD-95 in mushroom spines. The co-localization of GluA2 and PSD-95 increased in EE/RAM animals compared to SH/no RAM and SH/RAM animals. Furthermore, EE/RAM animals showed an increase in the expression of GluA2, PSD-95, and their colocalization in mushroom spines compared to EE/no RAM animals. A lack of increase of long-thin spines may be due to a possible ceiling effect of the already high levels of long thin spines established during the housing of EE. These results suggest that while the density of mature spine types increase

(including higher levels of synaptic GluA2 and PSD-95 expression) there is a decrease in immature spines during spatial learning. This is supported with previous results from our lab showing that EE prior to RAM increases filopodia and its expression of synaptic GluA2. Given that filopodia are thought to be pre-cursors to mature spines, our results suggest that as EE animals acquire spatial memory, filopodia mature into long-thin and mushroom spines. The increase in mature spine types may represent an underlying mechanism by which EE improves learning.

Title: Sonic hedgehog regulates motor neuron phenotype through calcium-dependent electrical activity in the embryonic spinal cord

Authors: ***Y. H. BELGACEM**, K. A. SPENCER, L. BORODINSKY;
UC Davis, Sacramento, CA

Abstract: Spinal cord injury is a debilitating condition affecting up to half million people every year in the world. Among the consequences of spinal cord trauma is the loss of motor neuron innervation of the skeletal muscle, highlighting the importance of devising therapeutic strategies for motor neuron regeneration. During nervous system development, spontaneous electrical activity generates a temporal window of plasticity important for neuronal differentiation and maturation. We have previously discovered that Sonic hedgehog (Shh), in the embryonic spinal

cord, controls spontaneous Ca^{2+}-mediated electrical activity in neurons through a novel non-canonical signaling pathway. In this study, we investigate the role of the Shh-Ca^{2+} signaling pathway on spinal motor neuron differentiation in *Xenopus leavis* embryos. We hypothesize that Shh, via Ca^{2+}-dependent electrical activity increases the number of motor neurons. We implanted beads loaded with drugs to manipulate Ca^{2+}-dependent Shh pathway in *Xenopus* embryos right after closure of the neural tube and processed tadpoles, 24 h later, for immunostaining. Results show that enhancing Shh signaling or Ca^{2+} spikes with SAG or veratridine, respectively, increases the number of cells expressing the motor neuron transcription factor HB9. In contrast, when inhibiting Shh signaling or suppressing Ca^{2+} spikes the motor neuron number decreases. Occlusion experiments reveal that Ca^{2+} spikes are downstream Smo activation in the regulation of motor neuron phenotype. To determine the molecular mechanisms underlying motor neuron specification driven by the Shh-Ca^{2+}-signaling, we search for potential activity-responsive elements within the 5' conserved regulatory region of the human hb9 gene shown to control hb9 expression. We found a cAMP-responsive element (CRE)-like sequence and an activator protein 1 (AP1) recognition site. We sub-cloned a 270 bp fragment containing these activity-responsive elements upstream of the firefly luciferase gene. Injecting this reporter construct in embryos shows, as expected, expression of luciferase in the motor neuron domain of the spinal cord. Results show that enhancing Ca^{2+} spike activity by either overexpressing Na_v2a or by incubating dissected spinal cords with veratridine, enhances luciferase expression. Mutating the CRE-like sequence had no effect on the activity-induced increase in luciferase expression, while mutating the putative AP1 site abolished this effect. Altogether, these results suggest that Shh regulates motor neuron phenotype by acting directly in neurons through a novel mechanism implicating electrical activity.

Title: The roles of gad1.1 regulation and calcium transients in neurotransmitter phenotype specification

Authors: *E. ABLONDI, A. CHALPHIN, M. SEHDEV, A. RAHMAN, L. SCHLEIFER, W. HERBST, M. LEFEW, L. ODORIZZI, P. KEMPER, M. SAHA;

Abstract: The acquisition of the appropriate balance of excitatory and inhibitory neurons is a vital step in the development of a functional nervous system, with misregulation of this balance implicated in disorders ranging from epilepsy to autism. While this system has been well-characterized in adult organisms, the mechanisms by which this phenotype is acquired during development are less clearly understood. In order to gain a more complete understanding of this process, we have analyzed the roles played by both 'hard-wired' transcriptional cascades and activity-dependent developmental processes. The former involves investigating the transcriptional activation of gad1.1, a gene which codes for the rate-limiting enzyme for GABA synthesis. GABA (gamma aminobutyric acid) is the primary inhibitory neurotransmitter in the vertebrate nervous system, and is therefore of great relevance to the eventual acquisition of appropriate excitatory/inhibitory patterning. Using Xenopus laevis as a model organism, we have used promoter analysis techniques to characterize the functional role of the upstream promoter region of gad1.1, and have identified distinct expression patterns under the control of various construct lengths. Additionally, sequence analysis methods have been utilized to identify evolutionarily conserved regions in this sequence through comparisons between Xenopus laevis individuals as well as individuals representing closely-related species, with the intention of identifying transcription factors involved in the process of neurotransmitter phenotype specification. We have also investigated a second major mechanism of neuronal phenotype acquisition, the spontaneous calcium transients that occur within developing neural cells. Previous research in the field has linked characteristic patterns of developmental intracellular calcium spikes to specific neuronal fates. Our lab has found no correlation between spike frequency and neurotransmitter phenotype; however, we are exploring novel methods of data analysis to investigate the relationship between neurotransmitter phenotype and general calcium activity patterns.

Title: Environmental temperature influences spinal neuron differentiation *in vivo*

Deleted: *in vivo*

Authors: *K. A. SPENCER, L. N. BORODINSKY;
Univ. of California Davis, Sacramento, CA

Abstract: During development differentiation of neurons is necessary for establishing the cell populations that will make-up the neuronal network in the mature nervous system. Embryonic Ca2+ activity modulates neuronal differentiation and we are interested in how the environment may influence this activity and the specification of neuronal populations. It is well established that environmental temperature regulates the rate of development in ectotherms, yet the specific impact temperature has on nervous system development is unknown. The purpose of the following study is to investigate how temperature influences spinal neuron differentiation in embryonic Xenopus laevis. We chose to examine the sensory and motor neuron populations in animals grown at different temperatures (14.5, 22.5 and 26.5°C) after reaching identical tadpole stages (stage 40). Immunostaining for HNK1, a membrane glycoprotein expressed in Rohon-Beard sensory neurons, indicates an increase in sensory neuron number in embryos grown at cold and warm temperatures compared to those grown at room temperature. Staining for Hb9, a transcription factor necessary for motor neuron maintenance, shows a 2-fold increase in the number of motor neurons in embryos raised at cold temperature compared to those raised at warm and room temperatures. Further analysis of morphological features of both sensory and motor neurons in embryos grown at different temperatures is underway. To investigate the mechanisms underlying these temperature-driven changes in neuronal specialization, we assessed the levels of spontaneous Ca2+ spike activity in embryonic spinal neurons. Previous results show that in the embryonic ventral spinal cord, Ca2+ spike frequency increases 2-fold in response to acute exposure to a cold temperature (14.5°C) compared to room temperature. In order to determine whether the acute change in activity persists, embryos expressing GCaMP6 were grown at different temperatures and time-lapse imaged at those temperatures. Preliminary results suggest that chronic exposure to a cold temperature also elicits an increase in Ca2+ spike frequency in the ventral spinal cord. Altogether these results show that temperature driven changes in Ca2+ spike activity are rapid, suggesting a non-transcriptional mechanism, and

appear to endure. Temperature regulation of sensory and motor neuron differentiation may depend on the changes in embryonic Ca2+ activity. The findings of this investigation suggest that the environment intervenes in the differentiation program of developing neurons to allow for the establishment of the best-equipped neuronal circuit for responding to the changing surroundings.

Title: Association of nitric oxide with the induction of interleukin 1 beta in microglia

Authors: ***K. NAKAJIMA**[1], K. SUDO[1], Y. TAKEZAWA[1], S. KOHSAKA[2];
[1]Soka Univ., Tokyo, Japan; [2]Natl. Inst. of Neurosci., Tokyo, Japan

Abstract: Microglia *in vitro* induced an inflammatory cytokine interleukin 1beta (IL-1β) together with nitric oxide (NO) and superoxide anion (O2-) by stimulation with lipopolysaccharide (LPS). In this study, we investigated the role of NO or O2- in the signaling mechanism by which IL-1β is induced in microglia. The LPS-inducible IL-1β was significantly suppressed by pretreatment with NO scavenger 2-(4-carboxyphenyl)-4,4,5, 5-tetramethylimidazoline-1-oxyl 3-oxide, but not by O2- scavenger N-acetyl cystein, suggesting the close association of NO with IL-1β induction. In fact, the pretreatment of microglia with inducible NO synthase inhibitor 1400w prior to LPS stimulation significantly reduced the production of IL-1β, and the addition of NO-donor S-nitroso-N-acetyl-DL-penicillamine (SNAP) into microglia led to the induction of IL-1β. These results suggested that NO induces IL-1β through a specific signaling cascade. LPS-dependent IL-1β induction was significantly suppressed by extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK) inhibitors and nuclear factor kappaB (NFκB) inhibitor, indicating that these ERK/JNK and NFκB serve in the cascade of IL-1β induction. As expected, ERK/JNK and NFκB were all activated in the SNAP stimulated microglia. Taken together, these results indicated that NO is an important signaling molecule for activating ERK/JNK and NFκB, whose activations are requisite to induce IL-1β in microglia.

Title: Peripheral local activation of oxytocin receptors inhibits the nociceptive activity of the spinal dorsal horn wide dynamic range neurons

Authors: *A. GONZALEZ-HERNANDEZ[1], A. MANZANO-GARCÍA[2], I. A. TELLO-GARCÍA[2], G. MARTÍNEZ-LORENZANA[2], G. ROJAS-PILONI[2], M. CONDÉS-LARA[2]; [1]Inst. de Neurobiologia, UNAM, Queretaro, Mexico; [2]Inst. de Neurobiología, Univ. Nacional Autónoma de México, Querétaro, Mexico

Abstract: The best described functions of the oxytocin are related to hormonal aspects associated to uterine contraction during parturition, lactation and more recently for its role in social behavior, but several studies have been suggested that this neuropeptide could act as a neuromodulator in the endogenous analgesia. Indeed, endogenous release of oxytocin upon the spinal dorsal horn after paraventricular nucleus stimulation inhibits selectively the nociceptive neuronal activity of Aδ- and C-fibers, an effect mediated by oxytocin receptors. In this sense, some reports suggests the expression of oxytocin receptors at peripheral level, but to our knowledge no study has yet reported a particular function of these receptors. The aim of the present study was to investigate in electrophysiological recordings, behavioral nociception tests and neuronal tracing the potential antinociceptive effect of peripheral activation of oxytocin receptors (OTR), In anaesthetized (2-3 % sevofluorane) male Sprague-Dawley rats we test the nociceptive responses evoked on the wide dynamic range (WDR) neurons at the lumbar segments (L3-L6) of the spinal cord. In these animals, extracellular unitary recordings were performed (4-8 MΩ). The nociceptive neuronal responses were evoked by 20 electrical stimuli (0.5 Hz, 1-ms pulse duration, 0.1-3.3 mA) delivered on the receptive field located in the ipsilateral (to recording site) hindpaw. Furthermore, in order to test the behavioral effects of peripheral actions of oxytocin on nociception we did experiments using the 1% formalin nociception test (50 µl formalin injected s.c. into the dorsal surface of the hindpaw). In both cases (electrophysiological and behavioral experiments) a dose-response curves were made. Additionally, using the neuronal tracers Fluoro-Gold® and Fluoro-Rubi® injected in the sciatic nerve we labelled the peripheral neuronal terminals; this tissue was also prepared to immunofluorescence to OTR, SP, CGRP and IB4. Our results show that peripheral local

administration (s.c.) of oxytocin is able to inhibit the neuronal activity of Aδ- and C-fibers but not Aβ-fibers. Furthermore, the formalin-induced nociception was blocked by oxytocin. In both cases, the effect was antagonized by the L-368,899 (OTR antagonist). Finally, we found that OTR is localized in the terminal neuronal endings localized in the hindpaw. Together, our results suggest that the peripheral OTR activation have a potential antinociceptive effect.

Title: Diverse postsynaptic signals produced by presynaptic somatostatin interneurons in the claustrum

Authors: ***Y. TANG**[1], G. J. AUGUSTINE[2];
[2]Lee Kong Chian Sch. of Med., [1]Nanyang Technological Univ., Singapore, Singapore

Abstract: Although it is well-established that somatostatin (SST) interneurons produce rapid inhibitory actions on their targets via postsynaptic GABAA receptors, it is not known what role co-release of SST may play in synaptic signalling. We have examined this by characterizing the postsynaptic actions of SST neurons in the claustrum. SST neurons were photostimulated in brain slices prepared from transgenic mice expressing Volvox channelrhodopsin-1 or Chlamydomonas channelrhodospin-2 (Front. Neural Circ. 7:160). Repetitive photostimulation (100 ms, 5 Hz, 5 s train) produced sustained activation of claustral SST neurons, while whole-cell patch clamp recordings measured resulting responses in other claustral neurons. In addition to inhibitory postsynaptic currents mediated by GABAA receptors, two changes in postsynaptic excitability were observed. Action potential duration was broadened in 48% of neurons, while the ability to fire trains of action potentials in response to depolarizing current pulses (1 s duration) was reduced in another 23% of neurons, changing their firing pattern from tonic to phasic. Both of these effects on excitability were long-lasting, persisting for 60 min or longer. The effect on repetitive firing is mediated by GABAB receptors, because this effect was eliminated by a GABAB receptor antagonist (GCP 52432) and was mimicked by a GABAB

receptor agonist (baclofen). SST is responsible for the prolongation of action potential duration, because this effect was blocked by a SST receptor antagonist (cyclosomatostatin) and was mimicked by application of SST. In summary, SST interneurons generate multiple postsynaptic signals, with GABAA receptors responsible for acute effects on postsynaptic membrane potential, while GABAB and SST receptors modulate different features of neuronal excitability. This diversity of signalling modalities potentially imparts great flexibility to circuits in which SST interneurons participate.

Title: Neuropeptide Y modulation of guinea pig intrinsic cardiac neurons

Authors: K. LUCKETT, E. A. POWERS, *J. C. HARDWICK;
Ithaca Col., Ithaca, NY

Abstract: Chronic heart disease, such as myocardial infarction (MI), produces remodeling of the autonomic nervous system, and induces an increase in sympathetic output, as well as remodeling of the intrinsic cardiac nervous (ICN) system located within the heart. Sympathetic fibers innervate the parasympathetic intracardiac neurons of the ICN and thus, increased sympathetic activity could lead to altered function within the cardiac plexus. To examine this possibility, we looked at the responses of parasympathetic cardiac neurons to the application of sympathetic neurotransmitters norepinephrine (NE) and neuropeptide Y (NPY). MI was surgically-induced in guinea pigs by ligation of the a branch of descending coronary artery on the left ventricle. After a four week recovery period, whole mounts of the intrinsic cardiac plexus were prepared for intracellular voltage recording, followed by immunohistochemical analysis. NE, NPY, Y1R and Y5R agonists were applied by local pressure ejection to individual neurons impaled with sharp intracellular electrodes for voltage recording. In control animals, NE and NPY each produced a small increase in neuronal excitability and simultaneous application of both substances did not differ from NE alone. NPY application and receptor-specific agonists demonstrated the presence of multiple NPY receptor isoforms present on the intracardiac neurons. In animals with MI, NPY

responses were blunted while NE responses were enhanced. However, simultaneous application of both NE and NPY showed a significantly greater effect in neurons from MI animals than was seen in control animals. IHC demonstrated NPY-positive fibers and cells within the cardiac plexus and the relative number of NPY-positive cells increased with MI. Taken together, these results demonstrate that MI, which has been shown to increase sympathetic output, alters neuronal expression and responses to NPY within the parasympathetic intrinsic cardiac plexus.

Title: Plasma opiates in subjects with chronic low back pain treated with Transcutaneous Electrical Nerve Stimulation

Authors: *C. I. EZEMA;
Univ. of Nigeria, Enugu, Nigeria

Abstract: Chronic low back pain (CLBP) is a well recognised cause of disability and absences from work. Transcutaneous electrical nerve stimulation (TENS) is being used for pain management in physiotherapy, but its mechanism of action remains controversial. This study investigated the plasma levels of beta-endorphin (BE), met-enkephalin (ME), prostaglandin E2 (PE2) and pain intensity among adult subjects suffering from chronic low back pain (CLBP) who were exposed to TENS. The study involved 63 age-matched adults, distributed into three groups, A, B and C. Subjects in group A were 32, had no CLBP and were exposed to burst modulation TENS, those in group B were 15, had CLBP and were exposed to burst modulation TENS, while those in group C were 16, had CLBP and exposed to placebo TENS. The TENS electrodes were placed at L1 and L5 for 30 minutes. At the beginning of the exposure (0 hr), and 1hr, 24 hrs, and 48 hrs after TENS exposure, blood samples were collected from the subjects for plasma BE, ME, PE2 assay using ELISA, while pain intensity was assessed using Numerical Pain Rating Scale. Analysis of variance (ANOVA) and Pearson's correlation tests were used in data analysis, level of significance set at $p < 0.05$. Results showed there was no significant difference in plasma levels of BE, ME and PE2 among the groups ($p > 0.05$), but pain intensity in group B was significantly lower than in group C only after 1 hr of exposure to TEN ($p < 0.05$). The findings suggest that the TENS in low back pain does not affect the levels of plasma opiates. This study

was not sponsored by any organisation or individual. **Key words:** Beta-endorphin, met-enkephalin, prostaglandin E2, chronic low back pain, transcutaneous electrical nerve stimulation.

Title: Sedative effect of a neuropeptid obtained from the posterior salivary gland of the mexican red octopus (Octopus maya) in mice CD1

Authors: E. GARCÍA -RAMÍREZ[1], *A. G. MARTINEZ[2], R. BUSTAMANTE-GARCÍA[3], S. RODRÍGUEZ-MORALES[4];
[1]Biochem., [2]Fac Quimica, UNAM, Mexico City, Mexico; [3]Biol., UNAM. Facultad de Química, Mexico city, Mexico; [4]SISAL, UNAM. SISAL, Mexico city, Mexico

Abstract: In recent years the search for peptide mediators such as neuropeptides (NP) grows exponentially because they are involved in diverse functions as nociception, analgesia, sedation, immune system, just to name a few. In the case of Octopus maya (O. maya), bioactive molecules with neurotoxic activity causing paralyzing effect from its posterior salivary gland (PSG) were extracted. Bioactives molecules from total soluble fraction were fractioned and a purified NP (in process of sequencing) was isolated. The NP was tested in order to identify sedative-like effects in CD1 mice using 7 groups with n = 6 mice (25± 5.0 g), doses 0.25, 0.5, 1.0, 2.0, 4.0, 8.0 and 100 mg/kg were administered i.p. Sedative-like effect was evaluated in 30 min, if the effect was observed a recovery time was recorded. The ED50 was calculated at 0.736 mg/kg by a probit analysis. At small dose (0.25 and 0.5mg / kg) abdominal contraction effect was observed but there was not sedative-like effect. The effect was detected between 15-30 min and the duration of the effect was up to 8 hours. The results shown that O. maya NP has a sedative-like effect around 1 mg/kg and below this dose, abdominal contraction and lower limbs effects were observed, after 24 and 72 h of observation neither adverse effects or death were presented. All animals had with free access to water and maintained under conditions indicated in the NOM 062 -ZOO-1999 and with international specifications for the production, care and use of laboratory animals standards.

Title: Modulation of dopamine release in the striatum by kappa opioid receptors

Authors: ***Q. QIN**[1,2], T. WESTERGARD[1], L. CHEN[1], G. LI[2], H. ZHANG[1];
[1]Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]Neurol., Harbin Med. Univ., Harbin, China

Abstract: Opioid receptors are expressed pre- and postsynaptically throughout the striatum, in addition to MSNs expressing endogenous opioid peptides. The kappa-opioid receptor system has both a large role in stress and stress-induced reinstatement for drug seeking. The role of kappa in drug addiction has been unique compared to the other opioids (mu and delta). In order to better understand the roles of kappa receptors (KORs) in modulating dopaminergic neurotransmission, we investigated the effects on the evoked dopamine release in the mouse striatal slices monitored with fast-scan cyclic voltammetry and amperometry. We found that there was no detectable tonic activation of KORs in the dorsal striatum (dSTR) whereas there was a tonic activation of KORs in the nucleus accumbens (NAcc) shell since selective KOR antagonist nor-binaltorphimine (nor-BNI) significantly enhanced dopamine release evoked by single pulse stimulation. Selective KOR agonist BRL52537 inhibited dopamine levels to 42 ± 5% of control in the dSTR and 49 ± 6% in the shell respectively. To determine the pathways/mechanisms behind inhibition of dopamine levels through KORs, we pretreated the slices with GABA receptor and nACh receptor blockers. In the presence of the blockers, BRL52537 inhibited dopamine release to a similar degree in the shell whereas different in the dSTR. We then used whole-cell patch recording to examine the modulation effect of KORs on cholinergic interneurons. Consistently, neither BRL52537 nor nor-BNI had any effect on the firing of cholinergic interneurons in the shell. In contrast, BRL52537 increased firing of cholinergic interneurons in the dSTR whereas nor-BNI decreased the firing. These data suggest that endogenous dynorphin opioids could inhibit dopamine level through activation of KORs on the dopamine terminals directly in the shell,

whereas the control of the dopamine level by KORs in the dSTR is a combination of action on dopamine terminals directly and through cholinergic interneurons indirectly.

Title: Orexin/hypocretin exerts postsynaptic excitatory effects and inhibits presynaptic excitatory inputs on reticulospinal neurons of caudal potine reticular nucleus

Authors: ***J. ZHANG**, N. YANG, Q.-C. QIAO;
Third Military Med. Univ., Chongqing, China

Abstract: Orexin, also called hypocretin, is produced by a specific group of neurons located in lateral hypothalamic/perifornical area. This neuropeptide has been substantially implicated in several basic physiological functions, such as the sleep/wake states and reward processes. Interestingly, our previous studies have provided evidence that orexin also plays an important role in motor control through directly exciting neurons in lateral vestibular nucleus (LVN). LVN has been well acknowledged to take an active part in the regulation of body balance and posture in a feedback fashion. In order to fulfill the motor function, however, the feedforward motor control mediated by reticulospinal descending system must coordinate with the LVN-mediated feedback motor control to orchestrate an integrated regulation of body balance and posture. Whether there is a direct modulation of orexin system on reticulospinal descending system-mediated motor control remains unknown. In the present study, therefore, the nervous circuitry of the caudal pontine reticular nucleus (PnC), a part of the reticulospinal descending system, was put into investigation. First, immunofluorescence results showed that orexin receptors are presented in the PnC in rats. In brain slice preparations and whole-cell patch clamp recordings, giant PnC neurons, the well defined reticulospinal neurons, are investigated after using

morphological and electrophysiological features to identify. All recorded PnC neurons showed response to orexin. Orexin induced an inward current on PnC neurons, via postsynaptic orexin 1 and 2 receptors, and decreased the frequency of mEPSC on PnC neurons, through a presynatic mechanism involving cannabinoid 1 receptor. The mechanism of activation of non-selective cation channels and closure of K+ channels underlying the postsynaptic effect was also revealed. Next, we further found that the amplitude of acoustic evoked EPSC on PnC neurons was decreased consistent with the orexin's presynaptic effects. Thus, taking advantage of acoustic-evoked startle motor behavior, which has been well known to be PnC-related, the combining post- and pre-synaptic effects of orexin on PnC can be investigated at the behavioral level. As a result, *in vivo* interference with the orexin system in PnC changed the amplitude and threshold of startle differentially. Considering that orexin deficiency results in cataplexy, a motor deficit characterized by sudden loss of postural muscle tone, and PnC holds a key position in control of muscle tone and posture, the present findings may provide more details concerning the relationship between the absence of orexin and the narcolepsy-cataplexy.

Title: Projection-target dependent effects of orexin and dynorphin on VTA dopamine neurons

Authors: ***C. BAIMEL**[1,2], S. L. BORGLAND[1];
[1]Hotchkiss Brain Inst., Calgary, AB, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Ventral tegmental area (VTA) dopamine neurons are a critical part of the neural circuits that underlie reward learning and motivation. Dopamine neurons send dense projections to many brain areas, and recent observations suggest that both the intrinsic properties and the functional output of dopamine neurons can be segregated on the basis of projection target. The output of dopamine neurons can be modulated by input from lateral hypothalamic orexin (also known as hypocretin) neurons. These neurons are critically involved in mediating both arousal and reward-seeking and can release both excitatory orexin peptides and the inhibitory kappa opioid agonist dynorphin. Orexin and dynorphin exert balanced but opposing effects on the firing of VTA dopamine neurons. However, whether orexin and dynorphin can independently

modulate different VTA circuits is unknown. We infused retrograde beads into either the lateral shell of the nucleus accumbens (NAcc) or the basolateral amygdala (BLA) of Pitx3-enhanced green fluorescent protein (Pitx3-eGFP) mice. We then used whole-cell patch clamp electrophysiology to determine the effects of orexin and dynorphin on the firing rate of BLA-projecting or NAcc-projecting VTA dopamine neurons. We found that NAcc-projecting dopamine neurons had greater leak conductance and a greater hyperpolarization-activated inward current (Ih) compared to those that project to the BLA. Moreover, the firing rate of NAcc-projecting dopamine neurons was more likely to be altered by saturating concentrations of orexin and dynorphin than were BLA -projecting dopamine neurons. These results suggest that orexin neurons may independently modulate VTA-NAc and VTA-BLA circuits. Because orexin neurons are a key regulator of dopamine neurons during motivated behavior, these results give further insight into the mechanisms by which orexin neurons regulate the output of the VTA.

Title: Pubertal expression of α4βδ GABAA receptors reduces discharge of CA1 hippocampus in an epilepsy model

Authors: L. YANG[1], H. SHEN[1], L. MERLIN[1], *S. S. SMITH[2];
[1]Physiol. and Pharmacol., [2]Dept Physiol Pharmacol, SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: More than half of children with epilepsy outgrow their seizures as they mature, yet the underlying mechanism is not yet understood. GABAergic inhibition increases at puberty due to the increased expression of extrasynaptic α4βδ GABAA receptors (GABARs, Shen et al., 2007) on dendritic shafts and spines, when the threshold for triggering an action potential is increased and spiking is decreased. This less excitable state is not observed in animals which do not express α4βδ GABARs, suggesting that these receptors increase hippocampal inhibition during adolescence. Therefore, we tested the role of extrasynaptic α4βδ GABA-A receptors (GABARs) in regulating ictal discharge of CA1 hippocampus in adolescent female mice. To this end, field excitatory post-synaptic potentials (fEPSPs) were recorded from the CA1 stratum radiatum of

hippocampal slices from pre-pubertal (~28-32 PND) and pubertal (~35-44 PND, assessed by vaginal opening) female wild-type or α4-/- mice at ~30o C using aCSF- filled microelectrodes and an Axoclamp-2A amplifier. Spontaneous bursts were induced by high K+ (8.5 mM) to mimic epileptic discharge (Traynelis and Dingledine, 1988). Cumulative coastline length, a measure of burst amplitude and duration, was assessed, as was the percentage of slices exhibiting ictal discharge. When evoked fEPSPs were recorded in response to increasing stimulation intensities, the input-ouput curve revealed a 30% reduced response at puberty ($P<0.05$), compared to pre-puberty, an outcome which was not observed in pubertal α4-/- hippocampus where responses were similar or up to 10% greater than pre-pubertal values. 8.5 mM K+ induced both ictal and interictal discharge in slices from pre-pubertal animals, with 69.2% exhibiting ictal discharge, a greater proportion than observed in pubertal slices (7.1%, $P<0.05$). The cumulative coastline length was more than 50% greater in pre-pubertal slices after 100 s exposure to high K+ (2594 ± 469 vs. 1651 ± 221, pubertal, $P<0.05$). However, recordings from pubertal α4-/- slices revealed seizure activity (57.1% ictal, 3742 ± 953, coastline length) similar to pre-pubertal, and significantly greater than wild-type ($P<0.05$). Bath application of 50 nM L-655,708, an inverse agonist at α5-containing GABARs, produced no significant effect on ictal activity in either pre-pubertal or pubertal hippocampus. These data suggest that pubertal expression of hippocampal α4βδ GABARs may selectively reduce pre-existing seizure activity during adolescence.

Title: Kalirin-7 mediates α4βδ GABAA receptor-induced synaptic pruning in pubertal female mouse CA1 hippocampus

Authors: ***J. PARATO**, S. AFROZ, S. SMITH;
SUNY Downstate, Brooklyn, NY

Abstract: During puberty (PND 35-44, onset identified by vaginal opening), dendritic spine density decreases by half in the CA1 hippocampus of female mice (Yildirm et al., 2008). Our

previous findings suggest that this loss of spines is due to the increased expression of α4βδ GABAA receptors (GABARs) which emerge on dendritic spines during the pubertal period (Shen et al., 2010). α4βδ GABARs generate a shunting inhibition, which impairs activation of NMDA receptors (NMDARs). Although NMDAR activity has been associated with spine maintenance (Alvarez et al., 2007), the precise mechanism for adolescent spine pruning is as yet unknown. Kalirin 7 (Kal7) is a rho-guanine nucleotide exchange factor localized to the post-synaptic density which is necessary for spine stability (Ma et al., 2003). It binds to the NMDAR which can regulate its activation. Thus, we tested whether Kal7 plays a role in adolescent synaptic pruning. We used immunocytochemical techniques to study Kal7 expression in hippocampus and used the Golgi stain to determine spine density changes from Z-stack projection photomicrographs. Spine counts were taken with a Nikon DS-U3 camera mounted on a Nikon Eclipse Ci-L microscope at 100X oil and analyzed with NIS-Elements D 4.40.00 software. Initially, we showed that pubertal synaptic pruning was prevented by increasing NMDAR expression (MK-801, 0.25 mg/kg, i.p., 5 d). Conversely, blocking NMDARs (memantine, Mem, 10 mg/kg, i.p., 5 d) in the pubertal α4 -/- mouse triggered synaptic pruning, resulting in a 50-60% decrease in spines ($P<0.05$), suggesting a role for NMDARs in spine maintenance during adolescence. Hippocampal expression of Kal7 decreased by 30% at puberty ($P<0.05$), an effect prevented by α4 knock-out, implicating α4βδ GABARs in eliciting the pubertal decrease in its expression. *In vivo* blockade of NMDAR with Mem reduced hippocampal Kal7 expression by half ($P<0.05$), suggesting that NMDAR activation maintains Kal7 expression. As predicted, Kal7 -/- mice exhibited reduced spine density in the CA1 hippocampus during puberty compared to wild-type mice (spines/ 20 µm: 16 ± 1.5, WT, vs. 9.4 ± 0.8, Kal7-/-, $P<0.05$). These data suggest that NMDARs increase Kal7 expression, which is necessary for spine stability. Impairment of NMDAR activation via α4βδ GABARs during puberty reduces Kal7 expression, reducing spine stability, thereby reducing spine density. These data suggest that α4βδ GABARs play a role in adolescent synaptic pruning by impairing NMDA receptor activation which reduces Kal7 expression.

Title: Perinatal hypoxia increases GABA release in the auditory brainstem during early development

Authors: ***M. A. HAROON**, S. Y. LEE, J. XU, C. GRANADOS, J. H. KIM; UTHSCSA, San Antonio, TX

Abstract: Perinatal hypoxia is a causative factor in many disorders, including neurosensory disorders, mental retardation and autism. One mechanism by which hypoxia/ischemia causes damage is an increase in glutamate-mediated excitotoxicity. Recent research has shown that neurons in brain slices can counteract the effects of excitotoxicity by increasing spontaneous GABA release (DeFazio et al, 2009). However, it is unknown if this applies to live animals that suffer perinatal hypoxic insults. We investigated medial nucleus of the trapezoid body (MNTB) neurons from hypoxia-exposed rats to find if this would increase GABA release as well as glutamate release, whether this effect is dependent on developmental stage, and if this would have a neuroprotective effect. In the postnatal first week (P5-P8), we found an increase in $GABA_A$ receptor-mediated spontaneous inhibitory postsynaptic currents (sIPSCs) and a decrease in the amplitude of evoked excitatory postsynaptic currents (EPSCs) in the perinatal hypoxia group. These results were confirmed by *in vitro* oxygen-glucose deprivation experiments on P7 brain slices. Immunohistochemistry demonstrated an increase in the co-localization of vesicular GABA transporter (VGAT) and vesicular glutamate transporter 1 (VGluT1) in the hypoxia group (P7) indicating an increase of GABAergic innervation to presynaptic calyx terminals as well as postsynaptic MNTB neurons. However, these changes are developmentally dependent, as GABA signaling returned to normal by P13-P17 in the perinatal hypoxia group. These results indicate immature MNTB neurons respond to hypoxic insult by increasing spontaneous GABA release, which may trigger the potential neuroprotective mechanisms against hypoxic injury in the neonatal brain.

Title: Rescue of a mutant GABA(A) receptor subunit by functional complementation

Authors: *L. G. JACKSON, R. L. MACDONALD, C. HERNANDEZ, N. HU;
Neurol., Vanderbilt Univ., Nashville, TN

Abstract: $GABA_A$ receptors are the primary mediators of inhibition in the brain. Mutations in $GABA_A$ receptor subunits have been identified in patients with genetic generalized epilepsy disorders (GGEs). These mutations have can affect the assembly, trafficking, ligand binding, and gating of the receptors, which can impair neuronal inhibition. A mutation identified in a family with generalized epilepsy with febrile seizures plus (GEFS+), including the severe epileptic encephalopathy Dravet syndrome, introduces a premature stop codon in the γ2 subunit, which results in the truncated subunit γ2(Q390X). This mutation reduces cell-surface expression of γ2-containing $GABA_A$ receptors in a dominant-negative fashion. In an effort to rescue the surface expression of functional receptors, γ2(Q390X)-containing $GABA_A$ receptors were coexpressed in a heterologous expression system with the γ2 C-terminal domain beginning at residue Q390 (CTD-390), and the surface expression of $GABA_A$ receptor subunits was assessed by flow cytometry. Surface expression of γ2 and γ2(Q390X) increased when coexpressed with CTD-390. In addition, electrophysiological studies indicate that mutant-containing receptors exhibit kinetic properties similar to wild type γ2-containing $GABA_A$ receptors. These results suggest that the dominant-negative effects of γ2(Q390X) can be overcome by independent expression of the missing C-terminal domain, and that rescue of the surface expression of γ2(Q390X)-containing $GABA_A$ receptors could increase inhibitory neurotransmission *in vivo*.

Title: Understanding the low affinity actions of benzodiazepines on GABAA receptors

Authors: ***M. C. MALDIFASSI**, R. BAUR, E. SIGEL;
Univ. of Bern, Bern, Switzerland

Abstract: Benzodiazepines interact with $\alpha_x\beta_2\gamma_2$ (x = 1, 2, 3 and 5) $GABA_A$ receptors modulating their function through binding to a high affinity site located at the α/γ interface. Together with the existence of this high affinity binding site (site 1), there is evidence for the existence of two low affinity sites for benzodiazepines. An inhibitory site (site 2) has been postulated to locate to the α/β interface. An additional modulatory site (site 3) is presumably located in the membrane and has been shown to be abolished upon combined mutation of residue $\beta_2$265 and homologous residues in other subunits (α_1S269I, β_2N265I, γ_2S280I). With the aim to further describe sites 2 and 3, we performed a detailed study of the properties of receptors carrying a single mutation, and also concatenated receptors carrying them. The consequences of the mutations on diazepam and flurazepam induced GABA modulation were studied, thus site 2 could be located more precisely. We studied also the effect of individual sites 3 mutations (α_1S269I, β_2N265I and γ_2S280I). While the concentration dependence of flurazepam was bell-shaped and independent of the three mutations affecting sites 3, that of diazepam was sensitive to the mutations. While mutation of α_1 and β_2 subunits abolished potentiation via sites 3, the mutation in the γ_2 subunit stimulated it. Thus, a site 3 for diazepam is putatively located to each subunit. In contrast, flurazepam fails to act at sites 3. CGS9895 has been postulated to act at the extracellular portion of the α/β interface. Both, the above mutations in the α_1 and the β_2 subunit abolished potentiation by CGS9895, while the mutation in the γ_2 subunit was without effect. If the membrane part of the receptor allosterically signals to the extracellular part of the α/β interface, it has to be postulated that membrane portions of both α and β subunits do this. Alternatively CGS9895 could act at site 3. The presence of the α_4 subunit in the $\alpha_4\beta_2\gamma_2$ receptor is considered to cause the receptor to be insensitive to diazepam. We observed that higher concentrations of diazepam potentiated GABA gated currents, indicating the presence of site 3 in this receptor.

Title: A novel role for autophagy in endogenous GABA-A receptor modulation

Authors: *A. M. ABRAMIAN, J. S. SOROKIN, C. D. MAKINSON, J. R. HUGUENARD; Neurol., Stanford Univ., Palo Alto, CA

Abstract: Abnormally synchronous neuronal activity is a common feature of seizures and current pharmacological management of epilepsy works at least in part through suppression of neuronal firing. It has been increasingly recognized that astrocytes, in addition to their well characterized role as supportive elements, have active roles in circuit development and regulating synaptic transmission. We have recently shown that an endogenously occurring benzodiazepine site ligand (endozepine), arising from the Diazepam Binding Inhibitor (DBI) protein, enhances GABAergic inhibitory synaptic transmission in the thalamic reticular nucleus (nRt), an essential region for regulation of generalized absence seizures. Mice lacking the DBI gene or the benzodiazepine (BZ) binding site on GABAA receptors in nRt neurons showed spontaneous absence seizures and increased susceptibility to chemoconvulsants. Astrocytes express the highest levels of DBI and utilize an unconventional autophagic pathway to secrete endozepines. In the present study, we utilize whole cell recordings in thalamic slices at near physiological temperature (32oC) along with pharmacology to acutely modulate the level of autophagy and determine if there is any modulation of GABAA receptor activity in nRt neurons. Consistent with an endozepine effect, locally perfused rapamycin (200 nM), which promotes autophagy, induces within minutes a significant increase in the half-width of spontaneous inhibitory postsynaptic currents (sIPSCs) in the nRt neurons (vehicle control: 6.80 -/+ 0.5 ms, n = 6; 200 nM rapamycin: 10.8 -/+ 1.0 ms, n = 6). This effect is blocked by flumazenil (FLZ), a silent modulator, or BZ site antagonist, that allosterically binds to the BZ site. These results demonstrate dynamically regulated autophagic secretion of an endozepine with GABAA receptor positive allosteric modulation (PAM) effects. Selective release of endozepines from astrocytes, and the subsequent reduction of nRt activity, may prove to have powerful seizure suppressing effects.

Title: Cysteine scanning of loop G residues in GABAA receptors

Authors: ***D. BAPTISTA-HON**, T. G. HALES;
Inst. of Academic Anaesthesia, Dundee, United Kingdom

Abstract: γ-aminobutyric acid type A ($GABA_A$) receptor is a pentameric ligand gated ion channel which mediates inhibitory neurotransmission in the brain. GABA binding to the orthosteric site, located at the interface between adjacent β (positive interface) and α (negative interface) subunits, activates the integral Cl^- channel. Residues responsible for agonist binding in the orthosteric site arise from 6 non-continuous loops: A, B and C from the β subunit, and D, E and F from the α subunit. High-resolution glutamate-bound crystallographic structures of the *C. elegans* glutamate activated chloride channel (GluCl), as well as acetylcholine-bound *E. Chrysanthemi* ligand gated ion channel (ELIC) infer residues on the β1 strand on the complimentary interface to stabilise bound ligand. Residues in the β1 strand are outwith any of the 6 known loops and therefore putatively named loop G. Arg37 in GluCl, and Phe19 in ELIC extends into the orthosteric binding site and stabilises bound glutamate, and acetylcholine, respectively. The homologous residues on the $GABA_A$ α1 subunit are Thr47 and Phe45, respectively. These residues, and others in the β1 strand, have not been implicated in agonist activity in mammalian Cys-loop receptors. We substituted Thr47 to Cys in the $GABA_A$ α1 subunit and transfected these, along with β2 and γ2 subunits into HEK-293 cells. Application of varying concentrations of GABA to voltage-clamped HEK-293 cells expressing α1(T47C)β2γ2 receptors reveal a reduced apparent potency (EC_{50} = 170 μM), when compared with α1β2γ2 receptors (EC_{50} = 18 μM). Application of MTSEA (10 mM) significantly reduced the size of the current evoked by a maximally efficacious concentration of GABA at α1(T47C)β2γ2 receptors, but not α1β2γ2 receptors, suggesting that Cys47 is accessible for modification. Modification was prevented if MTSEA was applied together with a maximally efficacious concentration (10 mM) of GABA at α1(T47C)β2γ2 receptors, suggesting that GABA can protect Cys47 from modification. Our preliminary data indicate that Thr47 in the putative loop G within the β1 strand influences the apparent potency of GABA. SCAM analysis reveals that this residue may be part of a water-accessible pocket where GABA binds. To characterise the contribution of other β1 strand residues to $GABA_A$ receptor function, we will investigate the effect of Cys substitution at other positions on the β1 strand.

Title: Somatostatin gabaergic interneurons regulate gastric circuit activity within the dorsal vagal complex

Authors: ***A. LEWIN**, S. VICINI, R. GILLIS, N. SAHIBZADA;
Pharmacol. and Physiol., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: The dorsal motor complex (DVC) regulates parasympathetic control of the stomach. Within the DVC there are three nuclei of importance: the area postrema, the nucleus tractus solitarius (NTS), and the dorsal motor nucleus of the vagus (DMV). The final parasympathetic output from the DMV projects to distinct regions of the stomach, each with specific functions. Of particular importance for our studies is the projection to the gastric antrum, which controls gastric motility. Previous studies have focused on the regulation of the NTS and the DMV, both of which are under tonic GABAergic control. *In vivo* microinjection of the GABAA blocker bicuculline into the NTS or DMV has profound but differential effects on motility. What has yet to be determined is the source of this GABAergic inhibition. The DVC contains a large population of somatostatin positive GABAergic interneurons (Sst-GABA) interspersed among all three nuclei. Sst-GABA interneurons have been shown to play integral roles in regulating the activity of other brain regions. Our studies focus on establishing Sst-GABA neurons as the primary source of GABAergic regulation in both the NTS and the DMV. We used transgenic mice expressing either an excitatory opsin (channelrhodopsin, CHR2) or an inhibitory opsin (archaerhodopsin, Arch T) under control of the Sst-cre driver. This allows specific excitation or inhibition of Sst-GABA neurons. Additionally, either the polysynaptic tracer pseudo rabies virus (PRV-152) or the monosynaptic tracer DiI was injected into the gastric antrum, which allowed visualization of neurons specifically associated with control of the gastric antrum. Electrophysiological recordings were then made from PRV-152 labeled neurons or DiI labeled neurons. Recorded cells were separated for analysis based on whether or not a cell exhibited a direct opsin current, allowing for groups of Sst-GABA neurons and non Sst-GABA neurons. CHR2 stimulation caused an inhibition of action potentials and an excitation of inhibitory post synaptic currents (IPSCs) in non Sst-GABA neurons located in the NTS or DMV. Interestingly, CHR2 stimulation also elicited an increase in IPSCs in Sst-GABA neurons both in the NTS and the DMV. ArchT stimulation resulted in an attenuation of post synaptic currents (PSCs) in both non Sst-GABA neurons and Sst-GABA neurons in the NTS and DMV. These studies indicate that output neurons in the DMV and potential output neurons in the NTS are under tonic inhibitory control from Sst-GABA neurons. Additionally, this data suggests that Sst-GABA neurons form a complex interactive regulatory network within both nuclei.

Title: Characterizing the guanidine compound interaction site in the GABA-A rho1 receptor

Authors: *H. D. SNELL[1], E. B. GONZALES[1,2];
[1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [2]Inst. for Aging and Alzheimer's Dis. Res., Fort Worth, TX

Abstract: GABAC, or GABAA rho, is a subclass of GABAA receptors composed entirely of rho (ρ) subunits located on the axonal terminal of retinal bipolar cells. GABAA-rho exhibits unique properties, such as insensitivity to select antagonists of the heteromeric GABAA receptors. A group of ligands, which possess a guanidine group, have been shown to influence GABAA receptors. This includes the acid sensing ion channel (ASIC) ligand, amiloride, most commonly used to treat hypertension, which is also most prevalent in those 60 years of age and older. Point mutations revealed the 15' mutation (I15'N) completely removed the stimulatory activity of amiloride, while the 19' mutation (N19'D) reversed the potentiation, resulting in inhibition. Thus we believe these residues are integral in mechanism of action these guanidino compounds with the GABA-A rho1 receptor. Our next step was to elucidate the orientation of the compounds, indicating if it is indeed the guanidine group that interacts with the receptor. We utilized 3 amiloride derivitaves, 5-(N,N-Hexamethylene)amiloride (HMA), benzamil, and phenamil. Both benzamil and phenamil alter the guanidine group, while HMA has a ring on the opposite end. Whole cell patch electrophysiology of wild type GABA-A rho1 shows that both benzamil and phenamil elicit no change in GABA induced current, while HMA has increased potency compared to amiloride and exhibits similar potentiation of current. Our findings suggest that the guanidino group on amiloride is interacting with the GABA-A rho1 receptor to potentiate activity. These results reveal a novel compound interaction with the GABA-A rho1 receptor and could aid in producing new pharmacological compounds containing this guandino

backbone. This also suggests contrary to previous studies, tamiloride could exacerbate retinal hypoxic disorders, such as diabetic retinopathy, prevalent in the aged population.

Title: SGE-516, a novel neuroactive steroid mediates an increase in the efficacy of tonic inhibition via an increase in the trafficking of extrasynaptic GABAA Receptors

Authors: ***A. MODGIL**[1], M. PARAKALA[1], M. R. KELLEY[1], D. HINES[1], M. A. ACKLEY[2], J. J. DOHERTY[2], G. MARTINEZ-BOTELLA[2], F. G. SALITURO[2], P. A. DAVIES[1], S. J. MOSS[1];

Abstract: In the dentate gyrus, neocortex, striatum and the thalamus tonic inhibition is largely dependent on GABAARs composed of α 4, β 2/3, and δ subunits. These receptors are particularly sensitive to allosteric modulation by neuroactive steroids (NAS). Modifications in tonic inhibition and fluctuations in endogenous levels of NAS are accepted to play critical role in epileptogenisis and numerous neuropsychiatric disorders. While the ability of NAS to allosterically enhance GABAAR gating is well established, we have recently shown that NAS can also exert persistent effects on the efficacy of tonic inhibition by increasing PKC-mediated phosphorylation of the α 4 subunit. This in turn increases the membrane expression and boosts tonic inhibition. We have examined both naturally occurring NAS as well as a novel synthetic NAS (SGE-516) that display improved physicochemical and pharmacokinetic properties. SGE-516 is a novel synthetic neuroactive steroid. We assessed the ability of SGE-516 to potentiate GABA currents in recombinant GABAA receptors. SGE-516 potentiated GABA currents at α 1

β 2 γ 2 subunits with an EC50 of 61nM and Emax of 219%. SGE-516 was also effective at prototypical extrasynaptic GABA receptors, potentiating GABA currents at recombinant α 4 β 3 δ subunits with an EC50 of 227nM and Emax of 646%. Also, we have examined SGE-516 in dentate gyrus granule cells (DGGCs) from hippocampal slices. A 10min exposure to 100nM SGE-516 followed by ≥ 30 min wash induced a ~ 2 fold increase in tonic current. This increase was prevented by inhibiting PKC with GF 109203X. To examine the allosteric effects of SGE-516, we treated the slices with 100 nM SGE-516 acutely and observed a small potentiation of tonic current in DGGCs of hippocampal slices. Our studies have shown that in addition to the allosteric modulation of GABAARs, a general mechanism for NAS to increase the efficacy of tonic inhibition via an increase in extra-synaptic GABAAR trafficking through a PKC mediated mechanism.

Title: Unraveling the epileptogenic properties of GABAA receptor subunit interfaces

Authors: ***C. C. HERNANDEZ**[1], V. C. SATPUTE[2], R. L. MACDONALD[1];
[1]Neurol., [2]Neurosci. Grad. Program, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: A number of mutations in $GABA_A$ receptor subunit genes (*GABRs)* that impair $GABA_A$ receptor function by causing gating or trafficking deficiencies have been described in patients with genetic epilepsies. Recently, *de novo* mutations in *GABRB3, N110D, D120N, E180G, Y302C,* and *GABRB1, F246S,* were associated with the severe epileptic encephalopathies Lennox-Gastaut syndrome (LGS) and infantile spasms (IS) by the Epi4K consortium (Allen et al., 2013). Up to now only three mutations in *GABRB3, P11S, S15F* and *G32R*, have been associated with childhood absence epilepsy (CAE), a mild epilepsy characterized by typical absence seizures. We found that that both LGS- and IS-associated *GABRB* mutations

significantly impaired $GABA_A$ receptor gating, which seemed to be structurally correlated with the location of the mutation in the receptor. Considering the severity of the epilepsy phenotype exhibited by patients with LGS and IS, we found that LGS-associated *GABRB3(D120N, E180G, Y302C)* mutations caused larger effects on $GABA_A$ receptor function than the IS-associated *GABRB3(N110D)* and *GABRB1(F246S)* mutations, and the CAE-associated *GABRB3(P11S, S15F, G32R)* mutations. While LGS-associated *GABRB3(D120N, E180G, Y302C)* mutations are in the β+α- subunit interface, which is directly coupled with the ligand-binding-channel-coupling pathway of the receptor, IS-associated *GABRB3(N110D)* and *GABRB1(F246S)* mutations are in the α+β-/γ+β- interfaces that are indirectly coupled by subunit rearrangements throughout the β-sheets/α-helices of the receptor. Interestingly, the *GABRB3(G32R)* mutation associated with the mild epilepsy, CAE, is located at the β- interface in the distal N-terminal α1-helix of the receptor where it was predicted to disrupt local salt bridges at the γ+β- interface important for assembly and function of $GABA_A$ receptors containing β3 subunits. Thus, it seems that the presence of mutations at the β+α- interface might cause major structural rearrangements of crucial domains important for translating ligand binding to channel gating of the $GABA_A$ receptor and could be associated with the severity of the channel dysfunction and the epilepsy phenotype. This work was supported by the NIH RO1 NS 33300 grant to RLM.

Title: Impermeant anions, fixed charges, and the driving force of GABAAR-mediated Cl- currents

Authors: *J. T. VOIPIO[1], K. KAILA[2];
[1]Dept. of Biosciences, Univ. of Helsinki, Helsinki, Finland; [2]Dept. of Biosci. and Neurosci. Center, Univ. of Helsinki, Helsinki, Finland

Abstract: The key role of the cation-chloride cotransporters (CCCs) KCC2 and NKCC1 in neuronal Cl- regulation and in setting the driving force (DF) of GABAA receptor-mediated Cl- currents has been demonstrated using electrophysiological, pharmacological and genetic approaches (1). Contrary to compelling evidence, it has been recently suggested that the DF and polarity of GABAergic currents are set by electrostatic (Donnan) effects by immobile anions acting on local Cl- concentrations and thereupon on CCCs (2,3). However, transmembrane ion currents dissipate energy, and passive immobile anions neither do work nor consume energy. Electrostatic effects can alter the concentrations of mobile ions in aqueous microdomains where binding of ions to CCCs takes place, but this has no effect on the free energy of ion transport which depends on differences between intracellular and extracellular bulk phases (1,4). The Donnan mechanism at a Cl- permeable membrane acts to establish an equilibrium distribution of Cl-, not a DF for Cl- current. If present, intracellular spatial gradients of immobile charges generate parallel cytosolic electrical potential gradients along which freely mobile ions equilibrate. This will result in identical shifts of membrane potential and the equilibrium potential of the ions, and there will be no changes in the transmembrane ionic DFs. Thus, Donnan mechanisms across a plasma membrane or along cytosol (2,3) cannot account for observations such as depolarizing and hyperpolarizing GABAergic Cl- currents in the axon initial segment and dendrites, respectively (5,6). Basic thermodynamic principles rule out the possibility of using microdomains of restricted water (3) as a source of energy for Cl- transport, and there is no evidence supporting the idea (2,3) that KCC2 expressed in CNS neurons transports ~500 water molecules along with one K+ and Cl- ion. We conclude that the ideas (2,3) on the role of immobile anions and restricted water in determining the polarity of channel-mediated Cl- currents conflict with thermodynamics and with the overwhelming amount of evidence demonstrating the role of CCCs in neuronal Cl- regulation. Title: Novel benzodiazepines selectively binding to α5-containing GABAA receptors

Authors: ***P. SCHOLZE**[1], R. PUTHENKALAM[1], M. TREVEN[1], J. RAMERSTORFER[1], M. M. POE[2], K. R. METHUKU[2], G. LI[2], W. SIEGHART[1], J. M. COOK[2], M. ERNST[1];

Abstract: In the mammalian nervous system, GABAA receptors exist in an enormous diversity of subtypes. Six α, three β, three γ, the δ, ε, θ, π, and three ρ subunits can, and most of them actually do, assemble into a multitude of different homo- or hetero-pentameric receptors, each of them displaying unique pharmacological properties. GABAA receptors are targeted by various clinically relevant drugs such as for example the widely prescribed benzodiazepines, which can exert many different effects, including anxiolytic, sedative, hypnotic, amnesic, anticonvulsant, and muscle relaxant actions. The different benzodiazepine-induced behavioral responses seem to be predominantly mediated by GABAA receptors subtypes containing specific α subunits. This precipitated a search for novel ligands that discriminate between different α-containing receptors. Some α5-preferring (selective) compounds have already been identified, such as the chiral imidazobenzodiazepine SH-053-2'F-R-CH3 (Gallos et al., 2015) and other structurally similar compounds (Puthenkalam et al, manuscript in preparation). The most selective compound among them binds to α5 with approximately 60-fold higher affinity compared to α1. Binding and efficacy selectivity however do not necessarily correlate. Some ligands exist, which bind to several subtypes with comparable affinity, but are "silent" or very weak allosteric modulators, at some subtypes, while acting as positive or negative allosteric modulators at other subtypes. The molecular determinants that lead to functional or binding selectivity on the GABAA-receptor α5-subunit are however still completely unclear. Aim of the current study is to compare the binding affinities and electrophysiolgical efficacies of several different benzodiazepines, in order to correlate structure with affinity or efficacy. In order to identify amino-acid residues on the α5 subunit, which lead to selective benzodiazepine binding and/or selective modulation of GABA induced currents, mutated subunits have been constructed. Those will be expressed in heterologous expression systems and tested using radioligand binding assays and oocyte electrophysiology. Title: Flumazenil alters GABAergic neurotransmission via direct channel modulation and changes in post-synaptic protein expression

Authors: *I. A. SPEIGEL[1], Q. XU[1], V. CIAVATTA[1], A. JENKINS[1], P. S. GARCÍA[1,2]; [1]Anesthesiol., Emory Univ., Atlanta, GA; [2]Res. Div., Atlanta VA Med. Ctr., Atlanta, GA

Abstract: Flumazenil has recently been demonstrated to relieve excessive sleepiness in patients who exhibit hypersomnia due to increased $GABA_A$ receptor function. The underlying mechanism for this treatment is still poorly understood. Flumazenil is best characterized as a $GABA_A$ receptor benzodiazepine binding-site antagonist, but behavioral measures in animals suggest a more complicated pharmacological profile. To investigate the action of flumazenil on GABAergic neurotransmission, we tested its effects on $GABA_A$ receptor channel function and related protein expression. Electrophysiological recordings in a HEK293 cell-based heterologous expression systemare consistent with flumazenil being a competitive antagonist of GABA at synaptic-type ($\alpha1\beta2\gamma2$) receptors. Flumazenil depresses chloride currents evoked by high concentrations of GABA, with little effect on currents evoked by low concentrations of GABA. Intrinsically, flumazenil shows weak agonist activity and evokes chloride currents in a sigmoidal dose-response relationship. In primary cortical neuronal cultures, protein measures show that 24 hour exposure to low-dose flumazenil increased β2 $GABA_A$ receptor subunit expression, while high doses had no effect. In contrast, flumazenil did not alter extrasynaptic receptor α4 subunit, GAD67, and neuroapoptic marker expression levels. A cell-titer blue assay of viability also suggests no overt evidence for altered rates of cell death. These results suggest that in addition to direct channel modulation, flumazenil is altering GABAergic neurotransmission by evoking an increase in synaptic-type receptor number. Preliminarily, we suspect that the low-dose flumazenil mediated increase in β2 subunit protein expression is a compensatory response to antagonized GABAergic neurotransmission and increased neural culture excitability. As a therapy, flumazenil can pharmacologically enhance GABA-ergic transmission and therefore may not be an effective treatment for general sleepiness in patients with normal GABA activity.

Title: Histone deacetylase inhibitors prevent chronic ethanol-induced adaptations in GABAA receptor subunit expression in cortical neurons

Authors: ***J. P. BOHNSACK**[1], A. L. MORROW[2];
[1]Pharmacol., [2]Pharmacol. and Psychiatry, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: There is increasing evidence that chronic ethanol exposure induces chromatin remodeling. Treatment with histone deacetylase inhibitors can prevent the behavioral and molecular effects of chronic ethanol exposure and withdrawal. Chronic ethanol exposure alters $GABA_A$-R subunit expression and function and contributes to the development of alcohol dependence and withdrawal symptoms. Thus, we investigated whether histone deacetylase inhibitors could prevent chronic ethanol-induced changes in $GABA_A$-R subunit gene and protein expression. We have previously shown that ethanol exposure of cortical cultured neurons recapitulates the changes in $GABA_A$ α1 and α4 subunit expression in cortex of ethanol dependent Sprague Dawley rats. Cortical neurons from PD0-1 Sprague Dawley rat pups were cultured for 18 days. Ethanol (50 mM) was added to the media for 4 hrs in the presence and absence of the HDAC inhibitors SAHA (300 μM) or TSA (500 nM) to examine changes in $GABA_A$ α1 and α4 subunit expression measured by qPCR and western blot analysis. Ethanol decreased $GABA_A$ α1 gene expression and increased $GABA_A$ α4 gene expression which was prevented by SAHA co-exposure. TSA also prevented changes in ethanol-induced decrease in α1 gene expression. We next analyzed changes in membrane protein expression using western blot and found that SAHA prevents the ethanol-induced decrease in $GABA_A$ α1 subunit and the increase in α4 subunit expression. Neurons treated with TSA also prevented decreases in α1 subunit protein expression. TSA nor SAHA treatment alone had any significant effect on either α1 or α4 subunit gene and protein expression. Next, we addressed the possibility that HDAC inhibition may have an effect on receptor trafficking. We found that SAHA prevents ethanol-induced decreases in $GABA_A$ α1

subunit surface expression. Finally, since PKA plays a role in chromatin remodeling we wanted to determine if PKA was involved in facilitating SAHA's ability to prevent ethanol-induced changes in $GABA_A$ subunit expression. We exposed cortical neurons to the PKA inhibitor RpCAMPs (50 μM) along with SAHA and ethanol. RpCAMPs exposure did not alter the effect of ethanol + SAHA on either α1 or α4 subunit gene expression compared to SAHA and ethanol treated neurons. This suggests that PKA is not required for SAHA to prevent ethanol-induced changes in $GABA_A$ subunit gene expression. Our results indicate that treatment with HDAC inhibitors reverses the effects of chronic alcohol exposure on $GABA_A$-R subunit expression. This work represents an additional line of evidence suggesting the use of histone deacetylases inhibitors for the treatment of alcohol use disorders.

Title: Astrocytes selectively regulate the expression of different GABA-A receptor subunits in cortical neurons

Authors: *A. BERRETTA[1,2], A. N. CLARKSON[1,2,3];
[1]Anat., Univ. of Otago, Dunedin, New Zealand; [2]Brain Hlth. Res. Ctr., Dunedin, New Zealand; [3]Fac. of Pharm., The Univ. of Sydney, Sydney, Australia

Abstract: Introduction GABA-A receptors are heteropentameric subunit complexes and the different subunit compositions influence the receptor's agonist affinity, chance of opening, conductance, and cellular localization (extrasynaptic or synaptic). Astrocytes play a crucial role in both the formation and function of synapses and the effects of astrocyte-secreted factors is well documented for glutamate receptors. However, the astrocytic influence on GABA-A receptors has been only partially investigated and the attention was only focused on the synaptic GABA-A subunits. Objective The aim of this study was to investigate whether factors released from astrocytes can influence the neuronal expression of GABA-A receptor subunits during neurodevelopment and after brain injury. Methods This study is based on an *in vitro* system that is constituted by two different primary cultures of pure neurons and pure astrocytes from cortex.

Deleted: *in vitro*

Astrocytes were cultured using different conditions. In injury condition, astrocytes were mechanically stretched to render them reactive. The astrocyte-conditioned media were collected and used to treat neuronal cultures. Changes in expression of various GABA-A receptor subunits were assessed using real-time PCR. Results Analysis of mRNA expression for the GABA-A alpha-4 (α4) subunit showed a significant and time-dependent decrease in neurons at 5 and 9 days after 24h-treatment with control astrocyte media. In addition, decrease in α4-subunit expression was more pronounced when neurons were treated with media collected from injured astrocytes. Surprisingly, analysis of delta (δ) subunit, an extrasynaptic subunit that preferentially coassemble with α4, revealed an increase in expression in neurons exposed to injured astrocyte media. Further, we found no significant differences in the expression β2 and γ2 subunits after exposure to media collected from either control or injured astrocytes. Conclusions α4 and δ subunit expression shows that astrocytes selectively regulate neuronal GABA-A subunits. The effects observed with injured astrocytes suggest that brain trauma or stroke might be associated with an astrocyte-mediated change of GABA-A expression. Future studies are planned to assess the location of these subunits around the surface of the neurons and the impact that this has on drug efficacy and function.

Title: A case for similarities between histamine receptor ligands and GABA-A receptor agonists

Authors: *D. B. WILLIAMS, J. P. CLAVIJO, J. J. KEITH-HARP;
Biol. Sci., Winston-Salem St Univ., Winston Salem, NC

Abstract: We studied another novel compound derived from the antihistamine diphenylpyraline (DPP). This compound belongs to various diphenylmethyoxypiperidines that were designed to be dopamine transporter (DAT) blockers, but also affect vascular contractions, and interact strongly with $GABA_A$ receptors. This new derivative (WSS-4a) contains two chlorines and an added butyl group; in contrast to ones previously characterized which had only two fluorines (WSS-2) or two methyl groups (WSS-16). We hypothesized that the presence of the large butyl group would decrease the $GABA_A$ action of these compounds. We expressed α1β2γ2s or α1β2 $GABA_A$ receptors in *Xenopus* oocytes and measured currents using a two electrode voltage clamp. Like

the previously reported DPP derivatives, WSS-4a induced significant amounts of current with a high affinity interaction. At α1β2γ2s receptors, the dose response curve fit a one site model. The EC_{50} was 0.011 nM with a maximal induced current of 69% of maximal (1 mM) GABA. The response seems similar for α1β2γ. However, the addition of the large butyl group did subtly affect the response. The Hill slope was less than one, in contrast to the difluoro- (WSS-2) derivative; and at the α1β2γ2s receptors, the decline in induced current seen with higher concentrations of WSS-2 was absent with WSS-4a. Therefore, the addition of the butyl group did have some effect. Questioning why these DPP derivatives have strong $GABA_A$ agonist activity, we used the jmol program to look for structural similarities between DPP, other antihistamines, GABA, and the piperidine GABA agonist THIP. We found a potential area of similarity based near the amine group and adjacent hydrocarbon backbone of these compounds. By targeting that area, and perhaps the location of the butyl group, we may be able to design more specific high affinity GABA ligands or antihistamines.

Title: Complex changes in GABAA receptor gating caused by mutations associated with alcohol preference

Authors: S. GULBINAITE, D. BAPTISTA-HON, F. ROBERTSON, *T. G. HALES;
Univ. of Dundee, Dundee, United Kingdom

Abstract: Spontaneous gating in the hippocampus and dentate gyrus contributes to persistent neuronal inhibition mediated by γ-aminobutyric acid type A ($GABA_A$) receptors . Bicuculline and picrotoxin block spontaneous $GABA_A$ receptor gating, while gabazine is ineffective. Single point mutations leading to P228H and L285R amino acid substitutions in the $GABA_A$ β1 subunit, associated with alcohol preference in mice cause increased spontaneous gating. To investigate whether these substitutions also cause spontaneous gating when introduced into α1 or other β subunits we expressed each within α1βxγ2 receptors in HEK293 cells for investigation by voltage-clamp electrophysiology. The level of spontaneous current (I_{spont}) blocked by picrotoxin was expressed as a percentage of the total current mediated by $GABA_A$ receptors (I_{total}) in whole-cell recordings. Both P228H and L285R substitutions increased I_{spont} (to 20-60% of I_{total}) in all β

subunit backgrounds. $GABA_A$ α1β1(P228H/L285R)γ2 receptors exhibited current overshoot following the application of either picrotoxin or GABA. Determination of the Cl^- equilibrium potential using voltage-ramp experiments revealed that I_{spont} depleted intracellular Cl^- and recovery from depletion contributed to the current overshoot. However, I_{spont} overshoot was also evident in outside-out patch recordings where there was no Cl^- depletion. This may indicate that I_{spont} initiates desensitization, which is alleviated by picrotoxin. Preliminary experiments examining the kinetics of GABA-evoked currents mediated by α1β1(P228H/L285R)γ2 reveal altered desensitization and deactivation kinetics. These findings have important implications regarding mechanisms of inhibitory neurotransmitter receptor gating and the effects of pathological channelopathies on their function.

Title: The effect of varying ratios of α4, β2, and δ cRNA subunits on the receptor stoichiometry

Authors: ***L. Y. HARTIADI**, N. ABSALOM, P. K. AHRING, M. CHEBIB;
Fac. of Pharm., The Univ. of Sydney, Sydney, Australia

Abstract: δ-containing GABAAR are exclusively expressed on extrasynaptic sites and mediate tonic inhibition. These receptors are important targets for neurosteroid, alcohol, and anesthetics and have been associated with numerous neurodegenerative and psychiatric disorders. Thus, δ-containing GABAAR are potential therapeutic targets for drug development. However, significant variation in the pharmacology of these receptors is often reported in recombinant systems. We hypothesize that differences in pharmacology of δ-containing receptors are due to variability in receptor stoichiometries. Two-electrode voltage clamp was used to study the influence of varying the amount of α4, β2, and δ cRNA injected to Xenopus oocytes. Concentration-response curves (CRC) to GABA were measured along with the modulation and direct activation by δ-selective compound 2 (DS2). GABA CRC at oocytes injected with α4+β2+δ cRNA in ratios of 1:1:1, 1:1:5, 5:5:1, 1:5:1, and 1:5:5 had EC50 values ranging from 140 to 720 nM. 300 nM DS2 elicited large inward currents of 68-103% of the maximum GABA-elicited currents at these ratios. CRC of GABA at oocytes that were injected with 5:1:1 and 5:1:5

ratio of α4+β2+δ had higher EC50 values of 1.6 μM. The activation of DS2 on the 5:1:5 and 5:1:1 ratios were significantly lower than other ratios ($P < 0.05$, one-way ANOVA). At least two stoichiometries were expressed and each of the expressed stoichiometry responded differently to GABA and DS2. Under our conditions, varying the amount of α4 and β2 but not δ has a substantial role in the stoichometry.

Title: Architecture and function of concatenated α4β2δ GABAA receptors

Authors: ***N. WONGSAMITKUL**, R. BAUR, E. SIGEL;
Univ. of Bern, Bern, Switzerland

Abstract: γ-aminobutyric acid $(GABA)_A$ receptors play an important role in inhibitory transmission in the mammalian brain. They are composed of five subunits surrounding a chloride channel. The major isoform of $GABA_A$ receptor are composed of two α, two β and one γ subunit(s). In many extrasynaptic receptors the γ subunit is replaced by δ. Diverse results were obtained with heterologously expressed α4β2δ receptors presumably because free α4, β2 and δ subunits can assemble into various subunit arrangements, depending on experimental conditions. We used concatenated receptors in which subunit configurations were predefined. α4, β2 and δ subunits were concatenated to dimeric and trimeric subunit constructs. Five pentameric $GABA_A$ receptors were built from the combination of trimers and dimers. The δ subunit was placed in any of the five positions in the α1β2γ2 receptor with γ2 replaced by β2. The resulting receptors were expressed in *Xenopus* oocytes and their electrophysiological properties were characterized using the two-electrode voltage clamp technique. Several combinations did not result in functional receptors. We chose only subunit combinations in which concatenated receptors elicited high current amplitudes to the agonist GABA in combination with the neurosteroid 3α, 21-dihydroxy-5α-pregnan-20-one (THDOC). In control experiments, it was tested if trimers or dimers alone formed functional receptors. We also determined the effects of the δ-selective positive modulator 4-chloro-*N*-[2-(2-thienyl)imidazo[1,2-a]pyridine-3-yl benzamide (DS2) on

functional concatenated receptors. We furthermore tested ethanol effects on the functional concatenated receptors. By using receptor subunit concatenation, we could derive the putative architecture of α4β2δ $GABA_A$ receptors.

Title: Modulatory effects of neurosteroids and thyroid hormones on GABA-evoked currents in cultured dorsal root ganglion cells

Authors: ***G. PUIA**, L. RAVEGNANI, F. RAVAZZINI, R. AVALLONE, R. BARDONI; Universty of Modena and Reggio Emilia, Modena, Italy

Abstract: Neurosteroids (NSs) and Thyroid hormones (THs, T3, triiodothyronine and T4, thyroxine) are important endogenous modulators of GABAA receptor (GABAAR) function (Puia and Losi, 2011). The involvement of NSs in several physiological and pathological processes has been largely acknowledged, among them pain transmission. Several studies revealed the antinociceptive properties of some NSs and demonstrated that they can induce a potent peripheral analgesia via a direct GABAAR allosteric modulation (Poisbeau et al., 2014). Very little is known instead of how THs affect synaptic transmission in structures devoted to pain transmission. Pain sensitivity is related to the thyroid status, indeed hyperthyroidism confers greater sensitivity to thermal noxious stimuli (Edmondson et al., 1990) and alters the nociceptive responses in rats (Bruno et al., 2005). Dorsal root ganglion (DRG) cells are primary sensory neurons playing important roles in pain transmission between periphery and CNS. By using the patch clamp technique in the whole cell configuration we analyzed the effect of THs and of some NSs (Pregnenolone Sulfate, PS, and Allopregnenolone, ALLO) on GABA-evoked currents in rat DRG cells grown in primary cultures T3, T4 and PS (from 500 nM to 50 μM) reduce GABA-evoked currents with an IC50 of 0.8±0.3μM for T3 (eff max =-42±9%), of 1.4±0.7 μM for T4 (eff max =-41±6%) and of 4.3±1.2μM (eff max =-60±8%) for PS. ALLO potentiates GABA-evoked current in DRG neurons with an IC50 of 1.3±0.8 μM and a maximal effect of 110±20%. To investigate the mechanism of action of THs and PS we applied increasing concentrations of GABA (5, 10 and 50 μM) to the same concentration of modulator (10 μM). The effect of T3, T4 and PS was not dependent on the GABA concentration used suggesting that they act in a non-

competitive way. The modulatory activity of THs and PS on sIPSCs amplitude and frequency measured in lamina II neurons of acutely dissociated spinal cord slices was also investigated. In conclusion, since DRG neurosteroidogenesis is a physiologically relevant process (Schaeffer et al., 2010), our findings suggest that NSs modulation of GABAAR in this cells could play an important role in pain transmission from periphery to spinal cord. Furthermore the decreased GABAAR activity induced by T3 and T4 result in a reduced inhibitory neurotransmission that could contribute to the increased pain sensitivity detected in hyperthyroid animals.

Title: Regulation of Inhibitory neurotransmitter GABAA receptor subunit genes by nuclear respiratory factor 2 in neurons

Authors: ***B. A. NAIR**, M. WONG-RILEY;
Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Nuclear respiratory factor 2 (NRF-2), or GA binding protein (GABP), is a unique transcription factor among E-26 transformation-specific (ETS) family, as the transcriptionally active complex is an obligate heterodimer or heterotetramer that is composed of two distinct proteins. The α subunit contains the ETS DNA binding domain that binds to the 'GGAA' or 'TTCC' motif, and the β subunit contains the transcriptional activation domain. Previous studies in our laboratory have revealed that NRF-2 tightly couples neuronal activity and energy metabolism by transcriptionally co-regulating all 13 subunits of an important energy-generating enzyme, cytochrome c oxidase (COX), as well as critical subunits of excitatory NMDA receptors such as Grin1 and Grin2b and Gria2 of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. What is unknown is whether NRF-2 also regulates inhibitory neurotransmitter receptor genes to achieve a more balanced transmission in neurons. To test our hypothesis that NRF-2 also regulates GABA, specifically GABAA receptor subunit genes, we used multiple approaches, including in silico analysis, electrophoretic mobility shift and

supershift assay (EMSA), chromatin immunoprecipitation (ChIP), real-time quantitative PCR, and western blots. We found that NRF-2 functionally regulates the transcription of GABAA receptor subunit genes. Interactions of NRF-2 with GABAA subunit promoters were verified with *in vitro* EMSA and *in vivo* ChIP assays of mouse visual cortical chromatin. Transient transfections with NRF-2 over-expression or shRNA vectors in cultured neurons indicated that over-expression increased the mRNA and protein levels of GABAA subunit genes, whereas silencing reduced their levels, indicating a positive regulation by NRF-2. The binding sites of NRF-2 are conserved among rats, mice, and humans. Thus, our results indicate that NRF-2 plays a key role in regulating the transcription of GABAA receptor subunit genes, and that it aids in maintaining a transcriptional balance between excitatory and inhibitory synaptic transmission in neurons.

Title: New tools to characterize allosteric modulators at the GABAA receptors

Authors: ***S. BERTRAND**, E. NEVEU, D. BERTRAND;
Hiqscreen, Vesenaz - GE, Switzerland

Abstract: Studies of the ionotropic ligand gated ion channels activated by the γ-aminobutyric acid (GABA) require the possibility to effectuate many experimental protocols ranging from the simple concentration-activation curves to more elaborate paradigms to evaluate the potency and efficacy of allosteric modulators. In this work we present new tools for testing ligand gated ion channels and allosteric modulators using a fully automated recording system that performs unattended experiments. GABAA receptors expressed in Xenopus oocytes using recombinant human cDNA's or cRNA's were automatically injected in oocytes using a micro syringe driven system (roboinject from Multichannel Systems). Recordings were conducted using the automated two electrodes recording system HiClamp (Multichannel Systems) and proprietary software (HiQScreen Sàrl). Determination of the concentration activation curves for different GABAA receptor subtypes including the α1β2γ2, α5β3γ2 or α4β3δ confirmed the adequation of protein expression as well as quality of the compound application. Specific experimental protocols were then designed to assess the effects of allosteric modulators of the GABAA

receptors including benzodiazepine, neurosteroids or zinc. The availability of a fully automated system allowed testing of a single concentration of a compound and comparison with control response on a single cell. These procedures were successfully employed to characterize the concentration-response of a series of allosteric modulators at different GABAA receptors and to establish the "fingerprint" of each receptor for a given sets of compounds. The good correlation between data obtained using this system versus results presented in the literature confirmed the value of these tools to further evaluate ligand gated ion channels. Moreover, this method allows a direct comparison of a series of allosteric modulator at different human GABAA receptors revealing the uniqueness of compounds that is of value for the development of new therapeutic treatments.

Title: Zolpidem enhances GABA-induced currents at (α1)3(β3)2 GABAA receptors via a novel binding interface

Authors: ***A. T. CHE HAS**[1], N. ABSALOM[1], A. CLARKSON[2], P. AHRING[1], M. CHEBIB[1]; [1]Fac. of Pharm., Univ. of Sydney, Camperdown, Australia; [2]Dept. of Anat., Univ. of Otago, Otago, New Zealand

Abstract: Zolpidem, an imidazopyridine, is one of the most widely used medications for sleep. Acting at GABAA receptors, it is known to bind between an α1+/γ2- subunit interface with preference for α1 subunit-containing GABAA receptors. Previous studies have found that the α1+/β3- interface is also capable of binding certain benzodiazepine site ligands. Therefore, we investigated the possibility of whether binary GABAA receptors composed of α1β3 subunits exist in different stoichiometries and whether zolpidem can modulate one stoichiometry over another. Two-electrode voltage clamp was used to study the effects of GABA and zolpidem at binary α1β3 GABAA receptors expressed in Xenopus laevis oocytes formed after injecting different α1:β3 cRNAs ratios (30:1 or 1:1). To ensure receptors contain an α1+/α1- interface, we also injected β3-α1 concatamers together with individual α1 subunit cRNAs. Currents from all

expressed receptors were recorded with either GABA or GABA EC5 co-applied with zolpidem. Different GABAA receptor stoichiometries composed of α1β3 were formed when we varied the cRNA injection ratio of α1:β3. Receptors that formed after injecting a 30:1 cRNA ratio were less sensitive to GABA (EC50 31 μM). In the presence of GABA EC5, the maximal concentration of zolpidem (1 μM) enhanced the GABA-induced current by 116%. The enhancement was blocked by 1 μM flumazenil. In contrast, α1β3 receptors formed from the 1:1 injection ratio were more sensitive to GABA (EC50 2.7 μM) and these receptors were insensitive to zolpidem enhancement. GABAA α1β3 receptors formed from injecting cRNA of β3-α1 concatamers with the α1 subunit closely matched the characteristics of receptors expressed from the 30:1 injection ratio. Zolpidem similarly enhanced the GABA-induced current, demonstrating that α1β3 receptors that contain an α1+/α1- interface are positively modulated by zolpidem. . The α1+/α1- interface is a unique site and may mediate in part the physiological effects of zolpidem.

Title: Characterisation of the pharmacological actions of kavain at $GABA_A$Rs

Authors: *H. C. CHUA[1], K. HØSTGAARD-JENSEN[2], E. CHRISTENSEN[1,2], A. JENSEN[2], I. RAMZAN[1], N. ABSALOM[1], M. CHEBIB[1];
[1]Fac. of Pharm., University of Sydney, Sydney, Australia; [2]Dept. of Drug Design and Pharmacol., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Kavain is one of the major kavalactones found in kava, a beverage prepared from the pepper plant *Piper methysticum* commonly consumed among the Pacific islanders and indigenous Australians for its anxiolytic and sedative properties. The mechanism of action of kavalactones remains elusive, but γ-aminobutyric acid type A receptors ($GABA_A$Rs) have been proposed to be a possible target. In this study, we evaluated the action of kavain at various $GABA_A$R subtypes expressed in *Xenopus* oocytes using the two-electrode voltage clamp technique. We found that kavain positively modulated α1β2γ2L receptors, but only at GABA concentrations below the EC_{45}. This enhancement effect does not require the α1 or the γ2L subunit as kavain also positively modulated α1β2 and β2γ2L binary receptors to similar extent.

Kavain showed poor selectivity as it was found to have comparable action across αxβ2γ2L (where x = 1, 2, 3 and 5) and α1β1γ2L receptors. In an attempt to identify the potential binding site(s) of kavain, we co-applied various $GABA_AR$ ligands with kavain at α1β2γ2L receptors. Flumazenil (10 μM) failed to antagonise the enhancement effect of kavain, further supporting the findings of previous studies that kavalactones act via a non-benzodiazepine mechanism. The co-application of GABA, kavain and other positive modulators such as diazepam, etomidate, allopregnanolone and propofol resulted in less-than-additive enhancement, suggesting the modulatory pathway of kavain might overlap with other allosteric ligands. In summary, this study demonstrates that kavain directly modulates $GABA_ARs$ via a novel, unknown mechanism. As kavalactones have been shown to have antianxiety effect with no addictive or withdrawal issues in clinical trials, understanding their pharmacology at $GABA_ARs$ may aid in the development of more effective therapeutics.

Title: Adolescent alcohol exposure induces layer-specific deficits in δ-GABAA receptor-mediated tonic currents in the adult prelimbic cortex

Authors: *S. CENTANNI, E. J. BURNETT, H. TRANTHAM-DAVIDSON, L. J. CHANDLER;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: The goal of the current study was to investigate the effect of adolescent intermittent ethanol (AIE) exposure on the adult GABAergic system in the prelimbic cortex (PrL-C). Long-

Evans rats were subjected to 4 cycles of AIE exposure by vapor inhalation between PD28-42. In control rats, patch-clamp electrophysiology in acute slices obtained at different postnatal ages revealed a developmental increase in the GABAA receptor-mediated tonic current in layer V pyramidal neurons. In slices from AIE-exposed rats, the amplitude of the tonic current was significantly reduced compared to controls when tested at PD 45, 60 and 90-120. This AIE-induced reduction in tonic current was found to reflect attenuation of currents mediated by δ-subunit containing receptors using the δ-GABAA receptor agonist THIP (1μM). This reduction in tonic current in the adult was observed in both male and female AIE-exposed rats. Interestingly, AIE did not alter tonic or THIP-mediated currents in layer II/III PrL-C, indicating the effect of AIE is specific to layer V pyramidal neurons in the PrL-C. In addition, facilitation of the tonic current by bath application of either ethanol or allopregnanolone was attenuated in slices from AIE-exposed adult rats compared to control rats. Immunohistochemistry and western blot analysis revealed no change in the expression of δ-GABAA subunits or their surface expression suggesting that the AIE-induced reduction in tonic current may relate to posttranslational modification that reduce channel conductance. Lastly, the critical role GABA plays in neural network synchronization and PFC-dependent cognitive function led to the hypothesis that AIE produces deficits on a probabilistic decision-making task in adulthood. Surprisingly, although AIE exposure resulted in deficits in some measures of behavioral flexibility associated with prefrontal function, we did not observe changes in performance on a probabilistic decision-making task. Taken together, these studies reveal that AIE exposure results in persistent deficits in δ-GABAA receptor-mediated tonic currents in the adult PrL-C that may contribute to deficits in PFC-dependent behavioral control in adulthood.

Title: Novel compounds with anesthetic activity

Authors: R. BAUR[1], M. C. MALDIFASSI[1], S. A. FORMAN[2], *E. SIGEL[1];
[1]Univ. Bern, CH-3012 Bern, Switzerland; [2]Anesthesia Critical Care & Pain Med., Massachusetts Gen. Hosp., Boston, MA

Abstract: Recently, we described experiment-guided virtual screening (EGVS), a method that was used to identify new ligands of the classical benzodiazepine binding pocket located at the extracellular α+/γ- subunit interface in $\alpha_1\beta_2\gamma_2$ $GABA_A$ receptors (Middendorp et al., ACS Chem. Biol., 2014). Diazepam interacts with high affinity with this site 1 and low affinity with the ill defined site 3 in the membrane (Walters et al., Nature, 2000). Site 3 probably corresponds to the large cavity homologous to the cavity occupied by ivermectin in *C. elegans* GluCl receptors. GluCl S260, homologous to the residue $\beta_2$265, forms an H-bond with ivermectin (Hibbs and Gouaux, 2011). Site 3 has earlier been shown to be abolished upon combined mutation of residue $\beta_2$265 and homologous residues in other subunits (α_1S269I, β_2N265I, γ_2S280I). The pharmacophore describing site 1 would be expected to also relate to site 3. Indeed, a number of compounds acting at this low affinity site were identified. First we determined the concentration response curves for all of the new compounds at $\alpha_1\beta_2\gamma_2$ $GABA_A$ receptors expressed in Xenopus oocytes. Subsequently we studied the effect on modulation of individual sites 3 mutations (α_1S269I, β_2N265I and γ_2S280I). While all of the new compounds were sensitive to the mutation in β_2, they differed in their reaction on the mutations in the α_1 and γ_2 subunit. New compounds were compared with propofol and etomidate. While modulation of propofol and etomidate were abolished by the mutation in the β_2 subunit, the mutation in the α_1 subunit did not change the response. Moreover the γ_2 mutation had different consequences for each, potentiation by propofol was reduced, whereas that by etomidate was increased. The novel compounds were tested *in vivo* for their anesthetic activity. LORR (loss of righting reflex) was determined in tadpoles at a concentration of 10 μM. In addition, a number of published modulators were assessed. Several of the compounds displayed anesthetic activity. In summary, we describe here novel potential anesthetics.

Title: Postnatal development of subcompartmental inhibition in prefrontal layer 2/3 pyramidal cells

Authors: G. RINETTI VARGAS[1], *K. J. BENDER[2];
[1]UCSF, Ctr. for Integrative Neurosci., San Francisco, CA; [2]Sandler Neurosciences Building, San Francisco, CA

Abstract: Behaviors that engage prefrontal cortical (PFC) circuits continue to mature through adolescence. This development parallels PFC network maturation, including the continued refinement of local GABAergic interneuron signaling. Chandelier cells are a subclass of parvalbumin positive interneuron that synapses exclusively on the axon initial segment of local excitatory pyramidal cells. These axo-axonic cells are thought to regulate large, high-order PFC networks, as their dendrites sample associative inputs from other cortical regions, and their axons diverge to synapse on hundreds of pyramidal cells. Chandelier cell maturation is thought to be critical for proper PFC development, as they undergo extensive anatomical refinement during adolescence. Whether they also undergo similar functional maturation during adolescence is unclear. While somatodendritic GABAergic synapses develop to hyperpolarize local membrane voltage after the first postnatal week, some reports indicate that prefrontal axo-axonic synapses continue to depolarize postsynaptic pyramidal cells well past this time point. Whether this suggests that chandelier cells act to excite pyramidal cell networks in mature PFC, or that these synapses mature to a more traditional inhibitory role far later than neighboring somatodendritic synapses is unclear. Here, we assayed the postsynaptic actions of dendritic and AIS-targeting inhibitory synapses throughout postnatal PFC development using 2-photon guided GABA iontophoresis targeted to pyramidal cell neurites. We found that chloride reversal potentials (E_{Cl}) could vary markedly between the axon and dendrite of layer 2/3 pyramidal cells in brain slices from preadolescent mice. Dendritic $GABA_A$ receptor activitation consistently shunted or hyperpolarized the membrane throughout adolescent development. In contrast, GABAergic potentials in the axon initial segment underwent a significant shift during adolescence, with depolarizing responses from resting Vm in neurons from pre-adolescent mice, and shunting or hyperpolarizing responses in neurons from adult mice. We are currently explorig the cellular mechanisms that underlie this adolescent shift in GABAergic function in the axon. These data define an adolescent period for axo-axonic GABAergic synapse development that is significantly delayed compared to neighboring synapses onto dendrites, and may define a major cellular component of PFC maturation during this time period.

Title: NR1/NR2A and NR1/NR2B NMDA receptor profiling in high-throughput patch clamp

Authors: G. KIRSCH, N. FEDOROV, Y. KURYSHEV, L. ARMSTRONG, *C. MATHES, A. M. BROWN;
Chantest Corp., Cleveland, OH

Abstract: Ionotropic glutamate NMDA receptors play fundamental roles in synaptic plasticity, memory and learning, and increasingly are targeted in drug discovery for neuropathic pain, ischemic stroke, Parkinson's disease, Alzheimer disease, and several forms of dementia. Multiple receptor isoforms with distinct brain distributions and functional properties arise by selective NR1 transcript splicing and differential expression of NR2(A-D) subunits. NR1/NR2A and NR1/NR2B represent the most abundant subtypes with well-documented biophysical properties and pharmacology in conventional, low throughput voltage clamp electrophysiology. Exploitation of recent advances in high-throughput patch clamp technology in drug discovery, however, requires assay optimization and characterization of the receptor subtypes. In this study we used IonWorks Barracuda, a high-throughput instrument that operates in 384-well format, population patch clamp (PPC) mode. Procedures were optimized to routinely obtain signals 1 - 2 nA (PPC mode, Z' values >0.6) in human NR1/NR2A and NR1/NR2B receptors stably expressed in HEK293 cells. Side-by-side comparisons of the pharmacological properties of human NR1/NR2A and NR1/NR2B receptors were performed with agonists, positive modulators, and competitive or uncompetitive inhibitors. We found that EC_{50} values for L-glutamate were 3.8 μM and 2.0 μM for NR1/NR2A and NR1/NR2B, respectively. NMDA behaved as a partial agonist at NR1A/NR2B (Emax ≈75% and EC_{50}=18-20 μM), whereas NMDA was a full agonist at NR1/NR2A (Emax ≈100%, EC_{50} = 100 μM). The EC_{50} values were consistent with literature data obtained with conventional manual patch clamp methods. As expected, glycine and D-cycloserine produced concentration-dependent potentiation of glutamate activation. Additionally, we confirmed subtype selectivity of the uncompetitive inhibitor, ifenprodil. NR1/NR2B receptors were inhibited in a concentration-dependent manner with IC_{50} = 19.3 μM, whereas NR1/NR2A receptors were unaffected. Our results demonstrate the potential of robust, high-throughput patch clamp assays for profiling new chemical entities against NMDA receptor subtypes.

Title: Involvement of ENaC on initiation of mechanically-evoked swallows in anesthetized rats

Authors: ***T. TSUJIMURA**, K. TSUJI, S. SAKAI, T. SUZUKI, M. INOUE;
Niigata Univ. Grad. Sch. of Med. and Dent. Sci., Niigata City, Japan

Abstract: Purpose: Mechanical stimulation to pharyngolaryngeal regions can readily evoke swallowing reflex which plays a role as airway defensive reflex. Because disordered laryngopharyngeal sensation is significantly related to the development of aspiration pneumonia, it is important to know how laryngeal sensory system regulates swallowing. The aim of this study was to investigate the role of amiloride-sensitive epithelial sodium channel (ENaC) in mechanically evoked swallows. Materials and Methods: Male Sprague Dawley rats anesthetized with urethane were used. Swallows were identified by supra- and infrahyoid electromyographic bursts accompanied by transient decreases in upper airway (UA)-flow or increases in esophageal pressure. Amiloride analogues (amiloride, benzamil, dimethylamirolide), ASIC inhibitors (mambalgine-1, diminazene) and gadolinium were applied topically (0.3-30 nmol, 3μl) to vocal folds. Swallowing threshold was measured for von Frey filament or electrical stimulation to vocal folds (n = 4-6 in each group). The number of swallows by capsaicin application (0.03 nmol, 3μl) to vocal folds or UA distension were also measured (n = 5 and 6, respectively). Results & Discussion: The mechanical swallowing threshold to larynx was significantly increased by glossopharyngeal (IX) and superior laryngeal (SLN) nerves transection (Control; median 0.008 [IQR, 0.008], IXx and SLNx; median 0.02 [IQR, 0.02-0.4], n=5 in each group) and the swallowing was completely abolished by IX, SLN, recurrent laryngeal and pharyngeal branch of vagus nerves transection. The mechanical threshold of swallowing was increased in a dose-dependent manner of amiloride analogues and gadolinium, but not ASIC inhibitors. The increased swallowing threshold by amiloride analogues and gadolinium was recovered after saline (10 μl) washout. The number of swallows by UA distention was significantly decreased following benzamil application (Control; 8.2±0.7 vs. 30 nmol Benzamil; 1.0±0.5). Benzamil unchanged swallow-related muscle activities in UA-evoked swallows. On the other hand, benzamil did not affect the initiation of swallows evoked by capsaicin and electrical stimulation.

Conclusion: We speculate that ENaC is involved in initiation of mechanically evoked swallows in larynx.

Title: Osmosensitivity in the enteric nervous system

Authors: ***P. KOLLMANN**, M. SCHEMANN, G. MAZZUOLI-WEBER;
Human Biol., Technische Univ. München, Freising, Germany

Abstract: Background/Objective: the enteric nervous system (ENS) is made up of hundreds million neurons having a distinctive property compared to all other neurons. They are located directly inside the wall of the gastrointestinal tract, in a key position, that allows them to sense and control all the gut physiological functions as secretion and motility. After water or food intake the osmolarity in the gastrointestinal lumen as well as in the blood undergoes profound changes. Earlier studies already revealed that luminal shift of osmolality alter gastrointestinal motility. Our hypothesis is that enteric neurons and/or glia which are strategically located between blood vessels and epithelial cells may sense and respond to intramural osmolarity changes. Methods: we used fast neuroimaging techniques with calcium or voltage sensitive dyes to record immediate reactions from neurons of the submucous and myenteric plexus *ex vivo*, in intact tissue preparations, and *in vitro* from primary cultured myenteric neurons. As a stimulus we briefly exposed the tissues/cells to hyper- or hypoosmolar stimuli (200 mOsm/Kg - 400 mOsm/Kg) by a controlled local perfusion system. With this method we were able to detect either changes in intracellular [Ca2+] or action potentials fired by the neurons. Volume changes of the neurons were also calculated. Immunohistochemistry was applied to characterize the responding cells. Results: here we report preliminary data on the response of enteric neurons to hypoosmolar as well as hyperosmolar stimulation. Cultured myenteric neurons showed an increase in intracellular [Ca2+] after local perfusion with hypoosmolar solution. They also showed an immediate and transient increase in volume (10% area increase, 236 mOsm/Kg)

Deleted: ex vivo

Deleted: in vitro

which peaked simultaneously with the peak in intracellular [Ca2+]. In the intact tissue preparations 14.4% of the neurons of the submucous plexus fired action potentials with a mean frequency of 1.64 Hz after a brief hypoosmolar (-100 mOsm/Kg) stimulation. A similar proportion of submucous enteric neurons (15.0%) showed responses to hyperosmolar stimuli (+100 mOsm/Kg). These neurons fired with a mean frequency of 0.81Hz after the stimulus application. Conclusion: The ENS contains cells that respond to hypoosmolar as well as hyperosmolar solutions with increased intracellular [Ca2+] and action potential discharge. These findings reveal for the first time that the enteric neurons are capable of sensing and react to changes in intramural osmolarity. Further experiments are needed to provide data for the functional relevance of this new enteric neuronal property.

Title: TRPM2 channels in octopus neurons of mice cochlear nucleus

Authors: ***R. BAL**[1], E. O. ETEM[2], Y. MORI[3];
[1]Gaziantep Univ., Gaziantep, Turkey; [2]Med. Biol., Firat Univ., Elazig, Turkey; [3]Dept. of Synthetic Chem. and Biol. Chem., Kyoto Univ., Kyoto, Japan

Abstract: TRPM2 is a Ca2+-permeable cation ion channels, which is member of the transient receptor potential melastatin family. TRPM2 is activated by reactive oxygen/nitrogen species (ROS/RNS) and ADP-ribose (ADPR) and is linked to cell death. In the present study, we aimed to study if TRPM2 channels are present in the octopus cells of mice posterioventral cochlear nucleus, if present, to characterize the biophysical and pharmachological properties and function of TRPM2 channels in octopus neurons. mRNA expression for TRPM2 were demonstrated using quantitative real-time reverse transcription-polymerase chain reaction (qRT-PCR), TRPM2 ion channel proteins were demonstrated by western blotting and also spatial localization of TRPM2 ion channel proteins on the cellular membrane of octopus neurons were visualized by immunohistochemical staining technique. Whole-cell patch clamp recordings were performed under current and voltage clamp condition in coronal slices from the mice cochlear nucleus

(VCN). TRPM2 agonists including ADP-ribose (ADPR) induced a small degree of depolarization in octupus cells, which were blocked by TRPM2 antagonists, flufenamic acid (100 μM), N-(p-amylcinnamoyl) anthranilic acid (50 μM) and 8-Bomo-cADP ribose (50 μM). In the octopus cells of the TRPM2- knock out mice, application of ADPR in the pipet caused significantly less depolarization of the resting membrane potential, 0.45±0.21 mV, which was not affected by specific TRPM2 antagonists (n=5). It is concluded that TRPM2 channels seems to be present and function to set the membrane potential in a depolarization direction in octopus cells of cochlear nucleus. Title: Osmoregulatory inositol transporter SMIT1 modulates ion channels by adjusting PI(4,5)P2 levels

Authors: G. DAI[1], H. YU[1], M. KRUSE[1], A. TRAYNOR-KAPLAN[2], *B. HILLE[1]; [1]Physiol. & Biophysics, [2]Univ. Washington Sch. Med., SEATTLE, WA

Abstract: Myo-inositols serve as intracellular osmolytes in osmoregulation especially for mammalian kidney and brain cells. They also are precursors of the phosphoinositides, major signaling lipids including $PI(4,5)P_2$. During hypertonic stress, the expression of Na^+/myo-inositol cotransporter SMIT1 (encoded by *SLC5A3* gene) increases, thereby accumulating more myo-inositols and elevating intracellular osmolarity. However, whether such myo-inositol accumulation affects phosphoinositide signaling and therefore ion channels has not been fully explored. In a heterologous expression system using human embryonic-kidney-derived cells, we tested the effects of overexpression of SMIT1 and myo-inositol supplementation on several ion channels whose dependence on $PI(4,5)P_2$ is well established. The following experiments suggested that $PI(4,5)P_2$ pools became elevated by this treatment. Overexpression of SMIT1 significantly accelerated the recovery of KCNQ2/3 channel current after $PI(4,5)P_2$ was depleted by activating either M_1 muscarinic acetylcholine receptors or voltage-sensitive phosphatases (Dr-

VSP). The inhibition of KCNQ current by low concentrations of M_1R agonists was delayed in cells treated with myo-inositol and SMIT1. Comparable results were observed for GIRK2 and TRPM7 channels, suggesting a mechanism of increased intracellular PIP_2 levels. Myo-inositol supplementation also speeded the return of fluorescent probes for $PI(4,5)P_2$ to the plasma membrane following brief $PI(4,5)P_2$ depletion. Further, other experiments using the rapamycin-recruitable phosphatase Sac1 and the P4M probe to specifically hydrolyze or visualize PI(4)P suggested that PI(4)P levels increased after myo-inositol supplement with SMIT1. Elevations of PIP and PIP_2 were directly confirmed by using a triple quadrupole mass spectrometer to assess relative levels of phosphoinositides. As might be expected, the IP_3 metabolism and IP_3-mediated intracellular calcium release were also altered after myo-inositol supplement, consistent with the notion of elevated $PI(4,5)P_2$ levels. Finally, we found that 24-h treatment with hypertonic solutions imitated the phenomena we observed with SMIT1 overexpression whereas pharmacological or siRNA treatment against tonicity-responsive enhancer binding protein (TonEBP) partially reversed the effects. These results show that ion channel function and cellular excitability are under regulation by several "physiological" manipulations that alter the $PI(4,5)P_2$ setpoint of cells.

Title: Electrophysiological properties of mechanosensitive neurons of rat dorsal root ganglions

Authors: ***W. CHANG**[1], V. VIATCHENKO-KARPINSKI[2], H. KANDA[2], J. LING[2], J. GU[2]; [1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Anesthesiol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Sensing mechanical stimuli is important in life but mechanisms underlying the transduction and processing of mechanical stimuli in the somatosensory system remain poorly understood. Mechanically activated (MA) ion channels and currents have been identified in somatosensory neurons including dorsal root ganglion (DRG) neurons and trigeminal ganglion neurons. DRG neurons that express MA channels not only play a role in mechanical transduction under physiological conditions, but also may be involved in chronical mechanical pain under

pathological conditions. In the present study, we used acutely dissociated DRG neurons and applied whole-cell patch-clamp recording technique to study MA currents and electrophysiological properties of DRG neurons that show MA currents. Cells were tested under both current-clamp and voltage clamp modes and classified by their sensitivity to mechanical stimulation, types of mechanically activated currents, profiles of voltage-activate currents, action potential firing properties and other electrophysiological properties. Obtained results may help us to further understand how mechanical stimuli are processed by the somatosensory system.

Title: Magnesium influx triggered by neural depolarization

Authors: *R. YAMANAKA, Y. SHINDO, T. KARUBE, R. TANAMOTO, K. HOTTA, K. SUZUKI, K. OKA;
KEIO UNIVERSITY, Yokohama, Kanagawa, Japan

Abstract: Magnesium ion (Mg^{2+}) is involved in a wide variety of biochemical reactions, and a multitude of physiological functions are known to require Mg^{2+}. Many reports suggest that Mg^{2+} deficiency is also involved in various neuronal diseases. Therefore, Mg^{2+} dynamics in neurons may play key roles in healthy neuronal functions. In facts, main excitatory neurotransmitter glutamate induced intracellular Mg^{2+} concentration ($[Mg^{2+}]_i$) increase in neurons. However, it has not been revealed whether neuronal activity under physiological condition modulate $[Mg^{2+}]_i$. This study aimed to explore the direct relationship between neural activity and $[Mg^{2+}]_i$ dynamics. In rat primary dissociated hippocampal neurons, the $[Mg^{2+}]_i$ and $[Ca^{2+}]_i$ dynamics were simultaneously visualized by a highly selective fluorescent Mg^{2+} probe KMG-104 and a

fluorescent Ca^{2+} probe Fura Red, respectively. The $[Mg^{2+}]_i$ increase was observed at the timings of spontaneous Ca^{2+} increase in neurons whose excitability was enhanced by treatment of voltage-gated K^+ channel blocker, TEA. And, the $[Mg^{2+}]_i$ increase was abolished in Mg^{2+}-free extracellular medium, indicating $[Mg^{2+}]_i$ increase is due to neural activity-induced Mg^{2+} influx. Next, to verify the occurrence of $[Mg^{2+}]_i$ increase concomitant with neural activity by non-pharmaceutical paradigm, we plated neurons on glasses coated with electrically conductive and optically transparent indium-tin oxide (ITO) films, which enables fluorescent imaging during neural stimulation. The $[Mg^{2+}]_i$ increase was detected at the timing of Ca^{2+} response with corresponding stimulation. The direct neuronal depolarization by veratridine, Na^+ channel opener, application induced $[Mg^{2+}]_i$ increase, and the $[Mg^{2+}]_i$ increase was suppressed by the pretreatment of non-specific Mg^{2+} channel opener, 2-APB. Overall, neural depolarization induced $[Mg^{2+}]_i$ influx from extracellular *via* 2-APB sensitive channel in rat hippocampal neurons.

Title: A PANX1 loss-of-function mutation identified from a patient with intellectual disability, hearing loss and endocrine disorders

Authors: ***R. SHI**[1,2], Q. SHAO[3], K. LINDSTROM[4], J. KELLY[3], A. SCHROEDER[5], J. JUUSOLA[6], K. LEVINE[6], J. L. ESSELTINE[3], S. PENUELA[3], M. F. JACKSON[1,2], D. W. LAIRD[3];
[1]Kleysen Inst. for Advanced Med., Winnipeg, MB, Canada; [2]Dept. Pharmacol. & Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada; [3]Dept. Anat. & Cell Biol., Univ. of Western Ontario, London, ON, Canada; [4]Div. of Genet. and Metabolism, Phoenix Children's Hosp.,

Phoenix, AZ; [5]Div. of Genet., Univ. of Rochester Med. Ctr., Rochester, NY; [6]GeneDx, Gaithersburg, MD

Abstract: Aberrant activation of pannexin channels is associated with CNS disorders including ischemic injury, epileptiform bursting and cortical spreading depression underlying migraine aura. We now report the identification of a disease-linked PANX1 mutation in a 17-year-old female patient with intellectual disability, sensorineural hearing loss and other systemic dysfunctions, including skeletal defects (kyphoscoliosis) and primary ovarian failure. Whole exome sequencing identified a homozygous PANX1 gene mutation (c.650G>A) resulting in an arginine to histidine substitution at position 217 (R217H). Using a multidisciplinary approach the consequence of the R217H mutation on the expression and function of Panx1 channels was assessed. When expressed in N2A, NRK, HEK293T and Ad293 cells, the glycosylation and trafficking to the cell surface of R217H was unaltered when compared to wild type Panx1, suggesting that the surface expression of R217H is not impacted. To assess the functional consequence of the R217H mutation, we performed tight-seal whole-cell recordings from HEK293T cells expressing R217H or Panx1. In cells voltage-clamped to -60 mV, pannexin current amplitude and reversal potential was assessed from applied voltage-ramps (±100 mV, 500 ms). Current amplitude at +100 mV in cells expressing R217H was reduced by 50% compared to wild type Panx1. In contrast no change in reversal potential was noted suggesting that reduced currents in R217H expressing cells could not be attributed to a change in ionic permeability. Both R217H- and Panx1-mediated currents were augmented by high extracellular potassium treatment (50 mM KGluconate), most notably at negative holding potentials. Nevertheless, high potassium augmented ramp currents in R217H expressing cells were reduced by 50% when compared to wild type Panx1. Confirming the specific contribution of Panx1-based channels, ramp currents from R217H and Panx1 expressing cells were suppressed by the pannexin blocker carbenoxolone. As Panx1 is permeable to solutes of up to 1 kDa, the functional consequence of the R217H mutation on dye uptake and ATP release was determined. Uptake of ethidium bromide and release of ATP in response to high potassium treatment was impaired in cells expressing R217H. Collectively, our functional studies monitoring ion flux, dye uptake, and ATP release demonstrate that R217H, associated with developmental abnormalities in a human patient, represents a loss-of-function mutation. The first three authors contributed equally to this work.

Title: Modulation of acid sensing ion channels by KB-R7943, a reverse Na+/Ca^{2+} exchanger inhibitor

Authors: ***T. LENG**[1], H. SI[2], Z. XIONG[1];
[1]Morehouse Sch. of Med., Atlanta, GA; [2]Sch. of Pharmacy, Anhui Med. Univ., Hefei, China

Abstract: KBR-7943, an isothiourea derivative, is widely used as a pharmacological inhibitor of reverse sodium-calcium exchange (NCX). It has been shown to have neuroprotective effects in animal models of brain ischemia; however, the detailed mechanism remains elusive. In the current study, we investigated the effect of KB-R7943 on acid sensing ion channels (ASICs), a novel family of proton-gated cation channels involved in ischemic brain injury, with whole cell patch clamp techniques. We found that KBR-7943 potently inhibits ASIC currents in primary cultured mouse cortical neurons in a frequency-dependent manner with an effective concentration starting from 3 μM. KBR-7943 shows a similar frequency-dependent inhibition on ASIC1a current expressed in Chinese Hamster Ovary (CHO) cells. In contrast to the ASIC1a current, ASIC2a current was not inhibited by KBR-7943 with concentrations as high as 100 μM. Interestingly, KBR-7943 slightly inhibits the peak amplitude but slows down the desensitization of the ASIC3 current. Together, our data demonstrate that KBR-7943 modulates acid sensing ion channels in a subunit dependent manner. As inhibition of ASIC1a is known to be neuroprotective, our data suggest that the modulatory effects of KBR-7943 on ASIC1a might be an underlying mechanism for its neuroprotective effects against ischemic brain injury.

Title: On estimating ion channel densities in model neurons from simulated patch clamp data

Authors: *S. G. CARVER;
Mathematics and Statistics, American Univ., Washington, DC

Abstract: The need to estimate parameters creates a difficult challenge in studies of detailed biophysical models of neurons. Some parameters, such as those concerning the kinetics of single ion channels, can be measured (or fit with sufficient precision) from isolated channels. Other parameters are not so easy to determine. Specifically, the densities of the various ion channels remain, to date, difficult to infer in a principled way from biological data. A realistic model cell can have many dozens, even hundreds, of these density parameters - the values can vary from location to location across the cell membrane. This poster will analyze the statistical problem of fitting ion channel density parameters based on simulated patch clamp data. With simulated data, we already have the correct answer, and we can explore assumptions making the inference sufficiently tractable and successful to a given confidence level. By changing assumptions, we explore the boundary between hard problems and easy problems. We quantify “hard” by the amount of data needed to estimate the channel densities with confidence. Using Monte Carlo integration, we compute the probability of falsifying an alternative model (with different channel densities) in favor of the true model. The falsification succeeds if the true model's likelihood is greater than the alternative's. We ask how much data (i.e. how many repetitions of the protocol) are needed to correctly select the true model with a specified confidence level (e.g. 95%). Our model patch contains channels of one or more known types. Here "known" means that all alternative models use channels with the correct kinetics, without fitting parameters. From the patch clamp data, we infer only the numbers of ion channels present (in the patch) of each type. Each estimate of channel density is the corresponding estimated number of channels divided by the patch area.

Title: A novel selective α7 nicotinic acetylcholine receptor allosteric modulator showing concentration dependent positive and negative allosteric modulation

Authors: *K. VEYS;
Neurosci. R&D, Janssen Pharmaceutica, Beerse, Belgium

Abstract: We have characterized a novel compound showing non-competitive allosteric modulation of the α7 nicotinic acetylcholine receptor. Functionality was tested by whole cell patch clamp using a fast perfusion system on human α7 nicotinic acetylcholine receptors co-expressing ric-3 in a GH4C1 cell line. At low concentrations (0.03 mM) positive allosteric modulation was observed up to 140% on a near maximal acetylcholine response (1.3 mM) and up to 350% on a small acetylcholine response (0.1 mM). We did not observe any direct agonist activity of the compound with either electrophysiological or radioligand binding studies. A compound, EVP-6124, has been previously shown to have comparative modulating effects. Interestingly, in our own recordings, EVP-6124 showed no positive modulation nor did it show the alleged partial agonist activity. These discrepancies are believed to arise from the experimental approach that was used. Unfortunately, limited solubility caused difficulties in determining the crystal structure of the compound-receptor complex and therefore prevented further study of the compounds actual binding site(s).

Title: α-dendrotoxin inhibits the ASIC current in dorsal root ganglion neurons from rat

Authors: *E. SOTO[1], A. BÁEZ[2], E. SALCEDA[2], M. FLÓ[3], M. GRAÑA[4], C. FERNÁNDEZ[3], R. VEGA[2];
[1]Univ. Autonoma De Puebla, Puebla Pue, Mexico; [2]Inst. de Fisiología, Univ. Autónoma de Puebla, Puebla, Mexico; [3]Fac. of Chem., Univ. de la República (UDELAR), Montevideo, Uruguay; [4]Inst. Pasteur de Montevideo, Uruguay., Montevideo, Uruguay

Abstract: Dendrotoxins are a group of peptide toxins purified from the venom of several mamba snakes. α-dendrotoxin (α-DTx, from the Eastern green mamba Dendroaspis angusticeps) is a well-known blocker of voltage-gated K+ channels and specifically of Kv1.1, Kv1.2 and Kv1.6. In this work we show that α-DTx inhibited the ASIC currents in DRG neurons (IC50 = 0.8 μM) when continuously perfused during 25 s (including a 5 s pulse to pH 6.1), but not when co-applied with the pH drop. Additionally, we show that α-DTx abolished a transient component of the outward current that, in some experiments, appeared immediately after the end of the acid pulse, suggesting that Na+ activated K+ current is involved in this outward current. Dendrotoxins are basic proteins with a net positive charge at neutral pH. When analyzed in detail, the potassium channel-blocking site of α-DTx and related toxins is formed by residues from the N-terminus and the beta-turn region of the Kunitz domain. Other compounds with known inhibitory action on ASICs are characterized by a strong positive charge at physiological pH. For example, PhcrTx1 has a net charge of around +5.0 at pH 7.4, and a similar charge has been observed for compounds such as aminoglycosides and FMRFamide-related peptides. A cationic domain on the surface of α-DTx may play an important role in the interaction of the toxin with some functional domains of the ASIC channels. A dual action like the one we have found for α-DTx has been reported for other peptide toxins previously considered to be selective. For example, APETx2, a peptide that reversibly inhibits homotrimeric ASIC3, was found to also target Nav1.2, Nav1.6 and Nav1.8-related currents. Our work shows that α-DTx also targets ASICs in the nanomolar range, thus constituting a new potential tool for the study of these channels. The discovery of molecules capable of modulating ASICs may contribute to better understand their function, and provide molecular backbones to design drugs with therapeutic potential. In any case, α-DTx should no longer be considered a selective K+ channel toxin given that it inhibits ASICs and Kv with IC50 in the nM range. Furthermore, our data indicate that many results already in the literature should be re-evaluated taking into account this new finding.

Title: Identification of a novel allosteric modulator of acid-sensing ion channel 3

Authors: ***A. AGHARKAR**[1], E. B. GONZALES[1,2,3];

Abstract: Acid-sensing ion channels (ASICs) are sodium selective channels that belong to the ENac/DEG family of ion channels. They are sensitive to changes in extracellular pH and are expressed in both the central and peripheral nervous system. There are multiple ASIC subtypes that are involved in different pathophysiological conditions, including neurodegeneration, and most recently, epilepsy. Crystal structure of chicken ASIC1 revealed that functional ASIC is a trimer with large extracellular domain that can interact with variety of ligands, and the focus of research has been to identify ASIC antagonists. The ASIC3 channel subtype is primarily expressed in DRG neurons and is involved in pain sensation, but may activate GABAergic interneurons. ASIC3 is modulated by nonproton ligands like 2-guanidine-4-methylquinazoline (GMQ) and agmatine. We have identified a guanidine compound with a different molecule structure than GMQ that allosterically modulates ASIC3. Here we characterize this guanidine ligand using whole-cell patch clamp electrophysiology and ASIC3 transfected CHO-K1 cells. We found that the ligand is able to activate ASIC3 channel at physiological pH of 7.4, similar to GMQ. Furthermore, the guanidine ligand alters low pH current and delays desensitization, indicating that the ligand may be an ASIC3 positive allosteric modulator. The activation by the guanidine ligand was found to be concentration dependent In the future, we will determine the effect of the guanidine ligand on the ASIC3 window current and identify potential binding sites within ASIC3.

Title: Afterhyperpolarization in thalamocortical neurons are mediated by calcium-activated chloride channels

Authors: ***G. HA**[1], K. SONG[1], H. KWAK[1], J. LEE[2], C. LEE[2], E. CHEONG[1];
[1]Yonsei Univ., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: In central nervous system (CNS), afterhyperpolarization (AHP) activated after single or multiple action potentials in neurons plays an important role in the modulation of neuronal excitability by limiting firing frequency and thus in the generation of spike-frequency adaptation. Previous studies have often categorized AHP into three groups according to its kinetics: fast AHP (fAHP), medium AHP (mAHP), and slow AHP (sAHP). Many of them have attributed mAHP to calcium-activated potassium channels, such as small-conductance (SK) and large-conductance (BK) calcium-activated potassium channels. We previously reported that calcium-activated AHP currents in thalamocortical (TC) neurons were mediated by multiple components including apamin-sensitive SK channels and niflumic acid-sensitive anion channels whose molecular identity was unknown. Here we investigated the calcium-activated anion channels mediating AHP in TC neurons. The analysis of the reversal potential of anion AHP currents whose amplitude exceeded SK currents indicated that their conduction is mediated by chloride channels. Calcium-activated chloride channels (CaCCs) are involved in many physiological phenomena, but the functional expression and properties of them in CNS have rarely been reported. We characterized the electrophysiological properties of CaCCs in TC neurons and investigated its molecular identity.

Title: Amyloid beta modulates opening of pannexin-1 channels during hypoxia

Authors: *L. A. PALMER[1], R. J. THOMPSON[2];
[1]Neurosci., [2]Cell Biol. and Anat., Univ. of Calgary, Calgary, AB, Canada

Abstract: Ischemic stroke is a condition during which blood flow is reduced in the brain, resulting in downstream hypoxia and cell death. Under low oxygen conditions, there is excessive neurotransmission and impaired neurotransmitter reuptake to astrocytes due to a loss of energy substrates (O_2 and ATP). This results in excess glutamate receptor stimulation, anoxic depolarizations (aDPs) and excitotoxicity. The aDP is well characterized, and pannexin-1 channels (Panx1) have been demonstrated to be an important contributing factor to ionic dysregulation during the aDP. Stroke survivors are at risk of developing neurodegenerative disorders such as Alzheimer's disease (AD). While the reason for this is not fully defined, it has been reported that brain hypoxia leads to increased production of the pathological form of the protein amyloid beta (Aβ). Aβ is aggregated into neuronal plaques in patients with AD, and oligomeric Aβ is thought to disrupt synaptic activity and initiate inflammation pathways, contributing to the common symptoms of the disease. Interestingly, little is known about the physiological role of Aβ, and less still is known of the reason behind its increased production during hypoxia. Our overall hypothesis is that physiological concentrations of Aβ can modulate responses to hypoxia. Using whole-cell patch clamp electrophysiology in pyramidal neurons of the CA1 region of the rat hippocampus, the aDP was assayed using low oxygen conditions. The results of this study have demonstrated that low concentrations of exogenous Aβ significantly attenuate the anoxic depolarization, and may be interacting with Panx1 in order to mediate this effect.

Title: Calcium signals in spinal cord inhibitory and excitatory neurons

Authors: *J. XIA[1], X. GAO[2], R. JEAN-TOUSSAINT[1], R. GAO[1], R. PAN[1], Y. TIAN[1], J. BARRETT[1], H. HU[1];

[1]Dept. of Pharmacol. & Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Pharmacol. of Chinese Materia Medica, China Pharmaceut. Univ., Nanjing, China

Abstract: Calcium signals are core transducers and regulators in many calcium-dependent signaling cascades. Cytoplasmic calcium signals are generated from intracellular calcium release and external calcium influx from plasma membrane Ca^{2+}-permeable channels. Neurons are endowed with a large repertoire of ion channels, receptors, transporters and plasma membrane Ca^{2+} ATPase that work together to regulate Ca^{2+} homeostasis. Although voltage-gated calcium channels (VGCCs) and ligand-gated cation channels were thought to be the primary channels involved in Ca^{2+} homeostasis in neurons, we have demonstrated that store-operated calcium channels (SOCs) are also important in mediating Ca^{2+} influx in the majority of dorsal horn neurons. Interestingly, we found that a small population of dorsal horn neurons did not have SOCE. This finding raises a question of which type of neurons express SOCs. To answer this question, we took advantage of a transgenic mouse expressing GFP driven by the GAD67 promoter to examine STIM1 expression in GAD67-GFP neurons from cultures and slices using immunohistochemistry. Our results showed that the majority of GABAergic neurons do not express STIM1. To determine whether SOCE is altered in GAD67-GFP neurons, we performed calcium imaging recordings in neurons from cultures and slices prepared from GAD67-GFP mice, and measured calcium release and SOCE induced by 1 μM thapsigargin (a Ca^{2+}-ATPase inhibitor). Consistent with the STIM1 immunostaining result, both calcium release and SOCE were much smaller in GAD67-GFP neurons than in non-GFP neurons. We then performed patch-clamp recordings to compare voltage-gated calcium currents (I_{Ca}) in both GAD67-GFP and non-GAD67-GFP neurons from cultures and spinal cord slices. There was no significant difference of low and high voltage-activated I_{Ca} between these two groups of neurons presumably due to large functional diversity of VGCCs in dorsal horn neurons. To further determine the cell types of SOC-expressing neurons, we took advantage of the cell type-specific expression of A-type of potassium channels which are mainly functional in excitatory neurons, and recorded A-type currents (I_A) and SOC currents in the same neurons. The majority of I_A-expressing neurons had SOC currents while non-IA-expressing neurons had no or very small SOC currents, suggesting that SOCs are mainly functional in excitatory dorsal horn neurons. Our results indicate that inhibitory and excitatory neurons have different calcium signals, which may underlie functional differences between these two groups of neurons.

Title: STIMs and Orai1 are responsible for mGluR1/5-mediated ERK activation in spinal dorsal horn neurons

Authors: *F. M. MUNOZ, J. XIA, R. PAN, R. GAO, H. HU;
Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Store-operated Calcium Channels (SOCs) are highly Ca2+-permeable cation channels that are intimately involved in the calcium influx pathway. Our previous study demonstrated that SOCs are expressed in dorsal horn neurons and STIM1/2 and Orai1 are responsible for SOC entry (SOCE). Importantly, we found that inhibition of SOCE attenuates pain hypersensitivity. However, how SOCs are involved in the pain process remains elusive. Our recent findings indicated that inhibition of SOCE reduced spinal ERK activation in collagen-induced inflammatory pain, suggesting that ERK is a downstream target of SOCE. We therefore investigated potential upstream activators of SOCs. SOCs can be activated by the release of Ca2+ from intracellular stores, a process that occurs via activation of the inositol triphosphate (IP3) receptor. It is well known that activation of mGluR1/5 results in production of IP3, which triggers the release of Ca2+ from ER. We hypothesized that activation of mGluR1/5 can lead to SOCE in dorsal horn neurons. We performed Ca2+ imaging and patch-clamp recording to determine the role of SOCs in mGluR1/5 activation and subsequent activation of ERK. Application of 100 μM Dihydroxyphenylglycine (DHPG) induced an initial transient calcium response, followed by a sustained phase in ~83% of total neurons. Pretreatment with 3μM YM-58483 (a SOCE inhibitor) had no effect on the initial calcium response, however, almost completely blocked the sustained response. DHPG-induced current was also blocked by YM-58483. To confirm that these events were mediated by SOC proteins, STIM1/2 and Orai1 were knocked down by transfection of individual siRNA. Orai1 knockdown caused a marked decrease in sustained Ca2+ increases, while STIM1 and STIM2 knockdown significantly attenuated sustained Ca2+ increases. DHPG-induced phosphorylation of ERK was also blocked by SOC inhibitors and by knockdown of SOC proteins. Together, our data suggests that mGluR1/5 activation leads to SOCE through SOCs, and contribute to mGluR1/5-induced ERK activation. Our findings reveal a novel link of SOCs to mGluR1/5 and to their downstream effectors in dorsal horn neurons. Currently, we are determining whether mGluR1/5 activation leads to translocation of STIM1 and STIM2 to further confirm activation of SOCs by mGluR1/5.

Title: Optimal sampling rate and anti-aliasing filter position for the detection of high frequency oscillations (HFOs)

Authors: *S. GLISKE, W. C. STACEY;
Univ. of Michigan, Ann Arbor, MI

Abstract: High frequency oscillations (HFOs) are becoming a well established biomarker of epileptic tissue. However, translation of this biomarker to clinical settings requires overcoming both scientific and technical challenges. One technical concern is the unknown required and optimal sampling rate and anti-aliasing filter position used when recording HFOs with intra-cranial EEG. Manufacturing companies are encouraging hospitals and clinics to replace their EEG recording equipment with newer models featuring faster sampling rates, but it is not yet known how high of a sampling rate is actually clinically useful. This study addresses that need using deidentified data acquired from 17 patients undergoing intra-operative monitoring for epilepsy surgery. The intra-cranial EEG data were acquired at greater than 20 kHz, then initially down-sampled to 5 kHz with an anti-aliasing filter position at 2 kHz. A standard set of HFO and artifact detections were determined from the data. HFOs were additionally detected with the data down-sampled to lower sampling rates (500 Hz to 2.5 kHz) or with an additional anti-aliasing filter applied (filter positions from 100 Hz to 1 kHz). HFO detections coincident with detected artifacts were redacted. The number of HFOs detected for each sampling rate and/or filter position were compared with the standard set of HFOs detected at 5 kHz--over 1 million HFOs. Many results were as expected, with the number of detected HFOs at or above 90% for anti-aliasing filter settings above 500 Hz or sampling rates above 2 kHz. Settings below these values resulted in less than 30% of the HFO detections, with the exception of 1 kHz sampling rate still having 70% of the HFO detections. These results were found to be frequency dependent. For example, for HFOs with peak frequency above 150 Hz, a sampling rate of 2.5 kHz already drops the number of HFOs to only 30%. Despite the dramatic changes in HFO detection sensitivity,

only minor changes were observed regarding the clinical correlation of HFOs with epileptogenic tissue.

Title: Hilbert analysis of the relation between respiration and LFP/ECoG

Authors: ***R. KOZMA**[1], D. HECK[2], Y. LIU[2], S. MCAFEE[2], R. REZAIE[3,4], A. BABAJANI-FEREMI[3,4], A. PAPANICOLAOU[3,4], J. WHELESS[3,4];

Abstract: Aim: Our goal is to analyze the frequency content of the relationship between the respiratory rhythm and local field potentials (LFPs) and electrocorticography (ECoG) signals. Introduction: Previous studies in mice indicate the presence of a statistically significant correlation between respiration and spike activity or LFPs (Ito et al., 2014). It is of great interest to analyze the robustness of such correlation in intracranial experiments with animals and in human cortical data. Of particular significance is the reliable demonstration that the measured correlation has cognitive relevance and it is not simply a manifestation of movement artifacts. Methods: The experimental approach and the obtained data in mice are described in (Ito et al., 2014); for human ECoG methodology, see (Wheless et al., 2009). The present study determines the amplitude and phase of analytic signals evaluated using Hilbert transformation, which has been widely used for cognitive monitoring and for brain imaging involving fMRI, MEG, ECoG, and EEG data (for a review, see Freeman et al., 2013). We conducted a systematic study of ECoG signals of patients at rest with a sliding frequency window of width 5Hz through theta, alpha, beta, and gamma bands (Kozma et al., 2012). We calculated the instantaneous frequency

of the ECoG signals and correlated it with the respiratory channel. Results: Our study indicates significant correlation between respiration and the instantaneous frequency of ECoG channels in the theta, alpha, and beta frequency bands. However, no clear correlation has been observed between respiration and gamma-band ECoG. Experimental results obtained by recording of human ECoG have been compared with LFPs from mouse. Conclusions: We observe a significant correlation between respiration and ECoG/LFP data, especially in the theta, alpha, and beta frequency bands, while no correlation has been detected at gamma frequencies above approx. 40 Hz. These results point to the importance of respiration on cortical neurodynamics, which cannot be attributed entirely to movement or other external artifacts. Hierarchical models of cortical neurodynamics provide theoretical support to such conclusions (Kozma et al., 2015).

Title: Respiratory modulation of brain activity

Authors: *Y. LIU[1], S. MCAFEE[2], R. REZAIE[3], A. BABAJANI-FEREMI[3], R. KOZMA[4], A. C. PAPANICOLAOU[3], J. W. WHELESS[3], D. H. HECK[2];
[2]Anat. & Neurobio., [1]Univ. Tennessee HSC, Memphis, TN; [3]Pediatrics, Univ. Tennessee HSC and Le Bonheur Children's Hosp., Memphis, TN; [4]Mathematical Sci., Univ. of Memphis, Memphis, TN

Abstract: Breathing is a basic rhythm of life, whose main purpose it is to secure oxygen supply for the body. Moreover, the respiratory rhythm and the depth of respiratory movements strongly influence cognitive and emotional states. For example, focusing on deep, slow breathing is a common strategy in anger management, meditation and general stress relief (e.g. 1,2). How respiration modifies cognitive and emotional states is currently unknown. We recently reported that respiration modulates rhythmic neuronal activity in the somatosensory whisker barrel cortex of awake mice and that olfactory bulb activity was the main driving force behind these respiration-locked oscillations 3. Here we ask if respiration modulates neuronal activity in other non-olfactory areas of the mouse brain and whether a similar phenomenon exists in humans. We recorded spike and local field potential (LFP) activity in mouse motor, visual and prefrontal cortices, as well as in the hippocampus. We used cross-correlation analysis and circular statistics to determine whether LFP and spike activity were significantly modulated in phase with respiration. In all areas of the mouse brain tested, we found that LFPs at the vast majority of recording sites (>80%) were significantly modulated by respiration. The number of single units where spike activity was significantly modulated by respiration varied between 10 and 32%, depending on the cortical area. The highest proportion of respiration-related single units were found in the trunk portion of the somatosensory cortex and the lowest proportion in the whisker motor cortex. To test whether respiration also influences neuronal activity in the human brain, we analyzed electrocorticography (ECoG) recordings obtained from patients with intractable epilepsy being considered for surgery. Cross-correlation analysis of ECoG and respiration signals from two patients revealed significant correlations between respiration and breathing at several cortical locations. We suggest that rhythmic cortical activity in mice and humans is directly modulated by respiration, most likely via respiration locked sensory inputs, and that this modulation may be the basis for respiratory modulation of cognitive and emotional states. 1Gaines, T. & Barry, L. Title: Relations between alpha power and the stability of motion-induced blindness

Authors: ***H.-M. SUN**[1], M. INYUTINA[2], R. VANRULLEN[2,3], C.-T. WU[4,5];
[1]Sch. of Occup. Therapy, Natl. Taiwan Univ., Taipei, Taiwan; [2]Univ. de Toulouse-Paul Sabatier, Toulouse, France; [3]Faculté de Médecine de Purpan, CNRS, UMR 5549, Toulouse, France; [4]Natl. Taiwan Univ., Sch. of Occup. Therapy, Taipei, Taiwan; [5]Dept. of Psychiatry, Natl. Taiwan Univ. Hosp. & Col. of Med., Taipei, Taiwan

Abstract: Motion-induced blindness (MIB) refers to a phenomenon in which a static target spontaneously disappears and reappears into consciousness when superimposed on a global moving pattern, despite the fact that it is constantly present in the display. The MIB paradigm has been used as a powerful tool to study visual awareness since it can produce conscious as well as unconscious perception within the same task. However, the neurophysiological correlates of the perceptual target disappearance during MIB remain unclear. Therefore, in the present study, we examined the dynamics of brain oscillations associated with the perceptual target disappearance due to MIB, which would help us to better understand the neural process that distinguishes the neural representation of a perceptually suppressed stimulus from the conscious representation of the same stimulus. Twenty-two participants performed a MIB task while their EEG was recorded. During the task, participants reported the perceptual disappearance and reappearance of a dot target (the MIB condition) by pressing and releasing a response key. We also included a control condition, which simulated the MIB condition with physical disappearance and reappearance of the dot target. The duration of the target disappearance in the control condition was based on the actual target disappearance durations recorded from the MIB condition. The average time between a physical disappearance and the key press in the control condition was used to estimate the onset time of the illusionary target disappearance in the MIB condition. We then tested whether power fluctuations in different frequency bands before the estimated MIB onset would predict the length of MIB. Our results showed a positive correlation across participants between alpha power before the estimated MIB onset and MIB duration ($r = 0.45$, $p = 0.04$), indicating that participants with stronger alpha power were also the participants who experienced longer MIB. However, no such correlations were found between the power activity in other frequency bands (e.g., delta, theta, beta, gamma) and the length of MIB. Therefore, the results suggest that alpha dynamics plays an important role in the changes in perceptual state and may help shape our visual experience.

Title: Enhanced thalamic GABAAR-mediated spill-over inhibition promotes electrocortical signatures associated with the induction of NREM sleep and anesthetic-induced loss-of-consciousness

Authors: *L. MESBAH-OSKUI[1], R. L. HORNER[2];
[1]Med., [2]Med. and Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Modulation of thalamic GABAergic signaling can trigger state-associated changes in electrocortical activity. There are three types of $GABA_A$ receptor ($GABA_AR$)-mediated inhibition: tonic (*i.e.*, extrasynaptic), phasic (*i.e.*, synaptic), and spill-over which requires both synaptic and extrasynaptic $GABA_ARs$. Importantly, the alterations in thalamic activity elicited by the general anesthetic etomidate require both synaptic and extrasynaptic $GABA_ARs$ *in vitro*. Here we test two hypotheses *in vivo*: 1) enhanced thalamic spill-over inhibition elicits changes in electrocortical activity that resemble those elicited by etomidate, such as increased 8-12Hz and 12-30Hz activity, decreased 1-4Hz activity, and increased spindle-like oscillations; and 2) thalamic T-type Ca^{2+} channels, which promote 1-4Hz signaling, do not mediate the changes in electrocortical activity elicited by enhanced spill-over inhibition. Microperfusion of the extrasynaptic $GABA_AR$ positive allosteric modulator DS2 (100uM), which promotes spill-over inhibition, into the ventrobasal complex of the thalamus elicited changes in electrocortical activity in wild-type mice ($n = 9$), but not in mice lacking $GABA_ARs$ ($n = 8$). During NREM sleep, DS2: (i) increased 8-12Hz and 12-30Hz power (both $p < 0.006$), (ii) decreased 1-4Hz power ($p < 0.009$), and (iii) increased spindle-like oscillations ($p < 0.001$) in wild-type mice. Blockade of T-type Ca^{2+} channels with TTAP2 (300uM) did not affect the changes in electrocortical activity elicited by either etomidate (30uM; $n = 7$) or DS2 ($n = 9$) at the thalamus (all $p > 0.180$). Both DS2 and etomidate at the thalamus were associated with an increase in the power of transient electrocortical signatures that have been associated with transitions into both NREM sleep and anesethetic-induced loss-of-consciousness. Specifically, DS2 and etomidate in

Deleted: *in vitro*

Deleted: *in vivo*

wild-type mice enhanced the transient increase in 14-20Hz power seen during transitions into NREM sleep (both $p < 0.03$). Microperfusion of DS2 or etomidate into the thalamus was further associated with increased time spent in NREM sleep in wild-type mice (both $p < 0.02$). Importantly, the effects identified with DS2 were not recapitulated with THIP (50uM), a direct agonist of $GABA_A$Rs, at the thalamus. Additionally, unlike both DS2 and etomidate, the effects elicited by THIP required T-type Ca^{2+} channel activation ($n = 9$; all $p < 0.05$). Collectively, these results implicate enhanced thalamic spill-over inhibition in mediating the electrocortical signatures that are associated with the induction of NREM sleep and anesthetic-induced loss-of-consciousness.

Abstract: Objectives. Children with autism spectrum disorder (ASD) show reduced mental flexibility, unusual repetitive behaviors, narrow interests and resistance to change, yet, they may demonstrate superior performance in the analysis of complex visual stimuli using local-details strategy. Neuroimaging findings relate the first to a failure in top-down executive inhibitory control of irrelevant interference, the second to bottom-up sensory processing and lateral inhibition. We hypothesize that reduced mental flexibility and inhibitory abnormalities in a child with ASD may be associated with low integrity of the Dorsal Visual Network (DVN), and in particular it's long-range dorsal frontal-parietal executive component, while the basic sensory occipital-parietal local network may remain relatively preserved. Methods. Children with ASD, ages 6-16, and matched healthy controls participated. We evaluated integrity of DVN components by examining the amplitude modulation and coherence of EEG resting state (rsEEG

protocol: 4 min fixation on a fine cross). Correlative analysis of Alpha band (8-13Hz) oscillations among the frontal-parietal and occipital parietal nodes was calculated. To test mental flexibility an Ambiguous Figure Test (AFT) and neuropsychological tests were used; for basic inhibitory control on a sensory level, the Embedded Figures Task (EFT) was used. The rsEEG, computing on the level of sensors included: 30sec alpha-band time windows; rsEEG alpha-power using custom script EEGLAB; average alpha coherence in regional clusters by custom MATLAB; Pearson's correlations. Results. Children with ASD showed: poor accuracy/prolonged time of figure-reversal in AFT ($p<0.03$), which strongly correlated ($r=0.82$; $p<0.005$) with low verbal proficiency. No group differences in accuracy or time of discrimination of figures in EFT were found. Increased rsEEG alpha synchronization indicate a significantly stronger connectivity between coupled frontal-parietal oscillators in the control as compared to ASD group ($p<0.02$), suggesting an incomplete development of this component of DVN in children with ASD. The correlative values for occipital-parietal oscillators present a similar pattern of connectivity in ASD and Controls. Conclusion. In agreement with prior studies, long-range rsEEG alpha connectivity among frontal and parietal nodes of DVN was significantly reduced in children with ASD. The coherence between occipital-parietal nodes was, however, comparable in both groups. This pattern of connectivity was correlated to low accuracy of reversal figure in AFT and low verbal proficiency.

Title: Use of photic stimulation to manipulate resting-state brain activity: a pilot study using high-density eeg

Authors: P. HICKEY[1], M. WHITMIRE[1], *E. J. WAMSLEY[2];
[2]Psychology, [1]Furman Univ., Greenville, SC

Abstract: Memory consolidation has been shown to benefit from short periods of waking rest, but the mechanism underlying this effect remain unknown. During eyes-closed rest, the

prevailing EEG rhythm is alpha (8-12 Hz). In this study, we aimed to experimentally manipulate resting-state alpha activity using photic stimulation, and to test the effect of this manipulation of verbal memory retention. 12 healthy participants underwent a 64-channel high-density EEG recording. A five minute baseline was recorded, followed by three consecutive 10min photic stimulation phases (10Hz, 25Hz, and a non-rhythmic sham). Each stimulation phase alternated between 30sec “on” periods with stimulation, and 30sec “off” periods when stimulation was paused. Prior to each stimulation, a list of 30 words was encoded and freely recalled. A delayed recall was completed after each stimulation phase. Following artifact rejection, we computed the spectral profile of “on” and “off” phases using a fast Fourier transform. 10 Hz stimulation significantly increased power in the 9-11Hz alpha range in occipital (p=0.04), central (p=.03), and frontal (p=.05) regions of interest (“on” vs. “off” comparison). In all regions, enhancement of alpha power (“on”/”off” ratio) was significantly greater during 10Hz stimulation, relative to sham (all p-values <.01). Interestingly, the alpha power at baseline was correlated with alpha enhancement during stimulation (p=0.009). Power was also significantly enhanced at the harmonics of the fundamental frequency, including 9-11 Hz (p=0.04), 19-21 Hz (p=0.01), 29-31 Hz (p=0.01), and 39-41 Hz (p=0.07) (stimulation vs. sham). The topography of the enhancement at harmonics became increasingly focused and more anterior at higher frequencies. In comparison, in the 25 Hz condition, there was no significant effect of stimulation. These observations indicate that photic stimulation is a successful way to both increase a target oscillation during eyes-closed rest, and to strongly affecting the harmonics of the fundamental frequency. Additionally, the magnitude of the effect appears to be dependent on the strength of the endogenous alpha rhythm. There were no statistically significant effects of stimulation on memory consolidation. However, the design of this proof-of-concept study may not have been optimal to detect this effect. In the future we hope to use photic stimulation to further explore the effect of resting-state EEG oscillations on memory consolidation.

Title: Cortical network dynamics of hallucinatory and dissociative states induced by ketamine

Authors: *L. D. LEWIS[1], O. AKEJU[2], D. W. ZHOU[2], R. A. PETERFREUND[2,3], E. N. ESKANDAR[2,3], S. S. CASH[2,3], E. N. BROWN[4,2,3], P. L. PURDON[2,3];

Abstract: The brain can generate a range of dissociative and hallucinatory states, both naturally during sleep, and pathologically due to disease or drug use. One drug that can induce these states is ketamine, which primarily acts as an N-methyl-D-aspartate (NMDA) antagonist. Ketamine is used clinically for analgesia and general anesthesia, and has recently been used as a treatment for major depressive disorder. At the high doses used for general anesthesia, ketamine produces unconsciousness and immobility. At lower doses used for analgesia, ketamine causes a dissociative state, in which patients may report feeling disconnected from their bodies and their environments and experience visual and auditory hallucinations, and low-dose ketamine has also been used as a research model of schizophrenia. We aimed to study the neural dynamics that occur during the ketamine-induced dissociative state. We recorded intracranial electrocorticography from four patients with medically intractable epilepsy undergoing an infusion of ketamine prior to clinically indicated surgery. Patients received 0.5 mg/kg ketamine over a 14 minute period, during which time they responded to auditory stimuli presented every 3.5-4.5 seconds. At the end of the infusion period, patients completed an abbreviated version of the Clinician-Administered Dissociative States Scale (CADSS). We found that all four patients entered a dissociative state, as measured by high scores on the CADSS scale. Widespread changes in cortical dynamics accompanied this change in state, most noticeably a strong increase in gamma (~30-70 Hz) power across frontal and temporal electrode sites. Low-frequency (<4 Hz) power underwent variable changes across cortex, and alpha (10-14 Hz) power declined in medial frontal contacts. In contrast, dynamics in the hippocampus changed very little during this state, suggesting that neocortex is more strongly affected by ketamine during the dissociative state. This regional heterogeneity suggests that the effects of low-dose ketamine occur within specific cortical circuits, and that altered dynamics in these circuits may contribute to the dissociative state reported during ketamine administration.

Title: Modulation of high-frequency oscillations and beta coherence in striato-cortico-limbic circuits following repeated sub-anesthetic ketamine exposure

Authors: ***T. YE**[1], M. J. BARTLETT[2], J.-P. WIEGAND[3], M. SCHMIT[3], S. J. SHERMAN[2], T. FALK[2], S. L. COWEN[4];
[2]Neurol., [3]Neurosci., [4]Psychology, [1]Univ. of Arizona, Tucson, AZ

Abstract: Ketamine is a common anesthetic that, when administered as an infusion at sub-anesthetic doses, has been shown in the clinic to be effective for the treatment of chronic pain and treatment-resistant depression. Recent data also show that a low-dose ketamine infusion paradigm did lead to long-term reduction of L-DOPA-induced dyskinesia (LID) in a rat model (20 mg/kg for 10 hrs) and Parkinson's disease patient case studies (0.15 - 0.3 mg/kg/hr for 72 hrs). Although the mechanisms underlying the anesthetic and medical applications of ketamine are unknown, data from recently published reports suggest that high-frequency oscillations (HFO) (> 100 Hz) and beta-band oscillations (13 - 30 Hz) in the striatum, hippocampus, and cortex are involved. While the effects of single-dose ketamine administration on oscillatory activity has been studied, little is known about the effect of repeated exposure, even less of how ketamine alters coordinated activity between the cortex, striatum, and hippocampus. In the present experiment, we explored these questions by repeated administration of sub-anesthetic doses of ketamine (20 mg/kg) to awake freely behaving rats implanted with arrays of electrodes that targeted the hippocampus, dorsal and ventral striatum, somatosensory cortex, and motor cortex. We recorded over a 10 hr period and administered ketamine (*i.p.*) once every 2 hrs while rats resided in their home cage (total of five injections). Our preliminary findings indicate that ketamine induces strong HFO (~135 Hz) and beta-band coherence between the ventral striatum and the CA3 region of the hippocampus. Furthermore, HFO coherence increased with repeated injection while beta-band coherence decreased. When the 2nd and final injections were compared, ketamine resulted in a 133% increase in HFO coherence and a 20% reduction in beta-band coherence between the ventral striatum and CA3. Similarly, ketamine induces HFO and beta-band coherence between motor cortex and dorsolateral striatum, with a 6% increase in HFO coherence and a 2% reduction in beta-band coherence between 2nd and final injections. The gradual increase in coherence and in HFO induced by successive injection of ketamine suggest

that ketamine induces lasting (hours) changes in limbic-striatal and striato-cortical connectivity. Such lasting changes may underlie the established improvement following ketamine treatment in patients experiencing chronic pain or depression and the similar benefit in the treatment of LID reported by our group.

Title: Exploring relationships between eeg theta/beta ratios, empathy, reward sensitivity, and anxiety

Authors: ***S. GARRETT-RUFFIN**, E. HERRING;
Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: By establishing relationships between neural oscillations and psychological disorders, researchers may be able to establish diagnostic markers and objective measures of treatment outcomes. For example, a well-established finding is increased resting electroencephalogram (EEG) slow wave/fast wave ratios in people with attention deficit hyperactivity disorder (ADHD). EEG theta (4-8 Hz)/beta (13-30 Hz) ratios are now used as part of the diagnosis for attention deficit hyperactivity disorder (ADHD). Larger T/B ratios are thought to reflect cortical under arousal, which is consistent with the under arousal theory of ADHD. The purpose of this study was to extend research on T/B ratios to affective traits. Similar to ADHD, affective traits such as empathy, reward sensitivity and anxiety are related to cortical arousal states which lead to a number of predictions: 1) T/B ratios would be positively correlated with empathy deficits; 2) T/B ratios would be positively correlated with reward sensitivity; and 3) T/B ratios would be negatively correlated with anxiety, with larger T/B ratios linked to less anxiety. The sample was composed of 30 right-handed female undergraduate students aged 20-27, with no history of neurological disease. EEG theta waves (4-8 Hz) and beta waves (13-30 Hz) were recorded under four conditions (eyes open, eyes closed, reading and listening) to yield a T/B ratio composite score. Active recordings were taken along the midline at two sites: Fz and Cz. Next, participants completed a number of affective measures: the Interpersonal Reactivity Index (IRI), the Behavioral Inhibition and Behavioral Activation (BIS/BAS) Scale and the State Trait-Anxiety

Inventory (STAI-t). The IRI consists of subscales designed to measure the cognitive (perspective and fantasy) and the emotional (empathy and personal distress) dimensions of empathy. The BIS/BAS consists of a scale measuring behavioral inhibition (BIS) and behavioral activation (BAS), comprised of the subscales BAS reward, BAS drive, and BAS fun seeking. The STAI-t provides a single anxiety trait score. All of the hypotheses were supported by the research. As predicted, T/B ratios were positively correlated with empathy deficits, specifically the personal distress subscale of Interpersonal Reactivity Index (Davis, 1980). Additionally, T/B ratios were positively correlated with reward sensitivity. Finally, T/B ratios were negatively correlated with anxiety, with larger T/B ratios linked to less anxiety. Future research will involve exploring the effects of empathy manipulations on T/B ratios.

Title: OLM interneurons promote theta activity the ventral hippocampus

Authors: *R. N. LEAO[1,2], S. MIKULOVIC[2], E. RESTREPO[2], S. PUPE[2], K. KULLANDER[2], A. TORT[1];

Abstract: Theta oscillations in the dorsal hippocampus are described as one of the most regular rhythms of the brain. This 4-12 Hz have been associated with multiple behaviors, especially with movement. On the other hand, theta activity in the ventral hippocampus has been implicated in emotions related behavior. It has been hypothesised that specific GABAergic interneuron subtypes play differential roles in driving hippocampal oscillations. Although different populations of hippocampal interneurons fire preferentially to specific phases of theta, phase-locking firing itself does not prove a causal role in theta generation. We found a specific subtype of oriens lacunosum-moleculare (OLM) interneurons expressing Chrna2 receptor differentially

distributed along the dorso-ventral hippocampal axis. Using optogenetic tools in anesthetised and freely behaving animals, we found that activation of this population induce prominent theta activity in the ventral but not in the dorsal hippocampus. Interestingly, the induced theta rhythm was not correlated with animals' movements. In treadmill experiments, we found that rhythmical optical stimulation of OLM neurons can either increase or decrease the coherence between dorsal and ventral hippocampus depending on the position of the optical fibre within the dorsoventral axis of the hippocampus. Taken together, our results provide the first evidence of a single morphologically defined cell population that in a network including pyramidal cells causally drives ventral hippocampal theta oscillations.

Title: Entrainment of parvalbumin+ interneurons *in vivo* depends on movement rather than theta oscillations

Deleted: *in vivo*

Authors: ***A. M. BARTH**[1], I. MODY[2];
[1]Neurol., [2]Neurol. and Physiol., UCLA Sch. of Med., Los Angeles, CA

Abstract: Impaired parvalbumin positive (PV+) interneuron (IN) function and gamma oscillatory activity have been identified both in patients and animal models of several neurological and neuropsychiatric disorders. Furthermore, recent findings show that optogenetic activation of PV+ INs can lastingly improve cognitive deficits observed in an animal model of schizophrenia. However, currently there are no data relating the ability of PV+ INs for orchestrating gamma oscillations to the behavioral/brain states in a healthy subject. In this study we addressed this missing link by optogenetically stimulating PV+ INs in the hippocampal CA1 region in awake head-fixed PV Cre x Ai27 mice. In agreement with previous findings, 40 Hz blue (473 nm) laser light stimulation induced the appearance of a 40 Hz local field potential

(LFP) component recorded in the hippocampal CA1 pyramidal cell layer. We also found that the magnitude of the evoked 40 Hz oscillations was significantly higher when the animal was moving, i.e., when theta oscillations were present in the LFP recordings, compared to epochs when the animal was motionless or no theta oscillations were present. The measured amplitudes of the LFP oscillations at 40 Hz were as follows (in mV units, n=6 mice): without laser stimulation no theta vs theta: 11.8 ± 0.6, 14.5 ± 1.6, p=0.16; during laser stimulation no theta vs theta: 17.0 ± 1.5, 24.2 ± 2.9, p=0.005 (2-way repeated ANOVA with Bonferroni correction). Because theta oscillations and movement of the animals are highly correlated (Pearson's correlation coefficient: 0.75, $p<0.0001$, n=6) the question arose whether it is the presence of theta activity or movement that regulates the ability of PV+ INs to generate gamma oscillations. To answer this question we carried out the same PV+ IN stimulation protocols following the injection of the local anesthetic lidocaine into the medial septum. Medial septal lidocaine injections reliably eliminated theta oscillations even when the animal was moving. Surprisingly, we found that when theta oscillations were blocked, the magnitude of the light-evoked 40 Hz oscillations in the LFP showed a robust dependency on the animal's mobility (n=4 mice, in the presence of lidocaine, without laser stimulation no move vs move: 8.6 ± 1.0, 9.8 ± 1.4, p=0.14; with laser stimulation no move vs move: 12.1 ± 1.1, 19.6 ± 2.3, p=0.008, 2-way repeated ANOVA with Bonferroni correction). Our findings are consistent with the idea that the ability of PV+ INs to orchestrate gamma oscillations is closely linked to the animal's mobility and is independent of the presence of theta oscillations.

Title: Phase synchronization analysis of K-complex and Sleep spindles using ensemble measure in healthy subjects

Authors: *C. S. NAYAK[1], N. MARIYAPPA[2], P. D. PRASAD[4], K. K. MAJUMDAR[4], T. KANDAVEL[3], A. B. TALY[2], S. SINHA[2];

Abstract: Background: K-complexes (KC) coupled with Sleep spindles (SS) are believed to arise from the synchronized, sleep-specific, burst-pause firing of large number of neurons making up the thalamo-cortical loop. This study aims to assess the change in phase synchronization indices (SI) during the peri-KC spindle period (PKP) on scalp electroencephalographic (EEG) recordings during sleep. Methods: Ten healthy subjects (mean age: 23.7±3.06 years; M: F = 5:5) were subjected to overnight polysomnography using 8-channel EEG. Eight KCs associated with SS (KC-SS) were visually identified in each participant and subjected to phase synchronization analysis using multichannel measure across all the 8 channels based on Frobenius norm (taking three equal time windows before, during and after KC-SS, each equal to the length of that KC-SS). Changes in SI were assessed for delta (δ; 0.5-3Hz), theta (θ; 4-7Hz), alpha (α; 8-12Hz) and beta (β; 13-30Hz) frequency bands. The mean ± standard deviation of SI at the three time windows during PKP were calculated for various frequency bands, and compared using repeated measures ANOVA (RM-ANOVA) followed by pair-wise comparisons ($p \leq 0.05$). Results: RM-ANOVA revealed significant changes in SI in PKP for the δ band, along with a significant increase in SI during and after KC-SS as compared to before KC-SS ($p < 0.001$). There was also a trend towards higher SI during KC-SS as compared to after KC-SS, although not statistically significant ($p = 0.636$). However, other frequency bands (θ, α and β) did not show significant changes in SI during PKP. Conclusion: This is the first study that has used ensemble measure to assess the cortical phase synchronization during PKP. The findings of this study support the previous view of quasi-synchronous firing during KC and SS, and may also suggest the persistence of such synchrony for some period after KC and SS have occurred. These findings may have implications in understanding the role played by phase synchronization in influencing the occurrence of epileptic activity during sleep.

Title: P1 in the somatosensory evoked EEG response solely reflects neural excitation: a concurrent EEG and LFP study

Authors: ***M. BRUYNS-HAYLETT**[1], J. LUO[1], A. KENNERLEY[2], S. HARRIS[2], L. BOORMAN[2], E. MILNE[2], N. VAUTRELLE[2], B. WHALLEY[1], M. JONES[2], J. BERWICK[2], J. RIERA[3], Y. ZHENG[1];
[1]Univ. of Reading, Reading, United Kingdom; [2]Univ. of Sheffield, Sheffield, United Kingdom; [3]Florida Intl. Univ., Miami, FL

Abstract: A proportional balance between neural excitation and inhibition is a fundamental principle that underlies normal brain function, and an imbalance has been implicated in a number of disorders such as autism, schizophrenia and Alzheimer's disease (Rubenstein et al. 2003; Palop et al. 2007; Lewis et al. 2012). Electroencephalography (EEG) can be used as a diagnosis tool for identifying the presence of brain related disease and disorders. Unfortunately, it is unclear how to isolate neural excitation from inhibition in the evoked EEG response. However, single neuron recordings show co-tuning of excitatory and inhibitory synaptic activity, and inhibition lagging excitation by several milliseconds (Wehr and Zador 2003, Okun and Lampl 2008). If this temporal lag can be observed at a population level the contributions of inhibition and excitation to the evoked EEG response can be isolated. We previously demonstrated, using a rodent model, that local field potentials (LFPs) could be decomposed into neural excitatory and inhibitory components (Bruyns-Haylett et al. 2014). Here we extend our previous findings using concurrent EEG and LFP recordings. The balance between neural excitation and inhibition was pharmacologically manipulated by micro-injecting subconvulsive concentrations of bicuculline (10μM), a competitive gamma-aminobutyric acid (GABAA) receptor antagonist, in the barrel cortex of anaesthetised rodents. We investigated changes in LFPs and EEG before and after infusion in response to electrical stimulation of the contra-lateral whisker pad. We found no statistically significant difference in the temporal dynamics of P1 in EEG responses between the control condition and after bicuculline infusion. This indicates that P1 may be solely associated with excitatory post-synaptic activity of the local neural population, and that P1 reflects the level of neural excitation in a cortical network. Furthermore, magnitude of the first negative peak (N1) increased after bicuculline infusion, suggesting that N1 is modulated by the degree of inhibition within a cortical network and related to the onset of inhibitory post-synaptic activity. Title: Efficient and comprehensive measurement of interregional phase-amplitude coupling and characterization through tensor decomposition

Authors: ***C. K. KOVACH**[1], P. E. GANDER[2], A. E. RHONE[1], M. J. SUTTERER[1], H. KAWASAKI[1], R. ADOLPHS[3], M. A. HOWARD, III[1];
[1]Dept. of Neurosurg., [2]Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [3]Humanities and Social Sci., Caltech, Pasadena, CA

Abstract: Cross-frequency coupling in the form of dependence between amplitude at one frequency and the phase of ongoing oscillations at a lower frequency (Phase-amplitude coupling, PAC) is a commonly observed feature of local field potentials, thought to reflect the time-regulation of excitability in neuronal populations. PAC has most commonly been considered within local populations, though recent work shows that it may also reflect long-range interactions across widely separated regions, with amplitude at one recording location linked asymmetrically to phase at another. Interregional PAC may therefore serve as a probe of large-scale network interactions, but comprehensive measurement of interregional PAC within large multi-channel recording arrays is computationally challenging. Equally challenging is the interpretation of the resulting sizable multi-way array of interactions. We describe an efficient and spectrally comprehensive approach to interregional PAC measurement and demonstrate its application to human ECoG data from four epilepsy patients under a variety of experimental conditions. Using tensor decomposition, we identify large-scale patterns of PAC associated with each condition and show that the time-domain representation of the coupling spectrum as an impulse-response function may provide crucial details on the nature of the coupling. The approach is validated in its ability to blindly recover an expected dependence between an EMG signal contaminant arising from the extraocular muscles and cortical post-saccadic evoked responses, showing that ocular EMG contamination may be a source of spurious PAC with a

characteristic spectral signature. In all four patients, PAC occurred between phase at a range of narrow-band frequencies intervals centered from < 1 Hz to high beta range (<30 Hz), coupled to a broad range of amplitude bands from 30 to 200 Hz. Resting with eyes closed was associated with coupling between high-gamma amplitude within both early visual and auditory cortices and alpha-band phase across a widely distributed network, which included dorsolateral prefrontal cortex and temporal pole. Video watching was associated with more focal intra-regional alpha-band coupling in early sensory cortices nested in delta-band fluctuations occurring over anterior temporal lobe and inferior frontal gyrus. These results confirm the presence of inter-regional PAC with narrow coupling spectra and show its potential for elucidating the organization of functional networks in the brain.

Abstract: BACKGROUND: In adults, electroencephalogram (EEG) characteristics observed during general anesthesia-induced unconsciousness consist of widespread slow activity (<1Hz), and frontal predominant alpha activity (8-12Hz) and coherence [1]. Evidence shows that EEG-

based indices developed and used in adults provide inaccurate assessments of anesthetic states in children, particularly in infants. The aim of this study was to characterize the spatial and temporal EEG characteristics in infants aged 0-6 months during the awake state, and maintenance of- and emergence from- sevoflurane general anesthesia administered for routine surgical care. METHODS: Continuous 32-channel EEG recordings were performed during the awake state, and during Maintenance of a Surgical State of Anesthesia (MOSSA) and emergence-from sevoflurane general anesthesia in 30 infants aged 0 to 6 months postnatal age. We analyzed EEG recordings with multi-taper-spectral and coherence methods, and video recordings of body movement. We compared the power spectrum and coherence within and between infants aged 0 to 3 months (n=11) and 4 to 6 months (n=19) during the awake state, MOSSA, and emergence (immediately after first body movement was observed) using the bootstrap approach. Coherence was estimated between frontal channels F7 and F8. RESULTS: During MOSSA: 1) all infants had slow (0.1 to 1Hz) and delta (1 to 4Hz) oscillations across the entire scalp; 2) theta (4 to 8Hz) and alpha (8 to 12 Hz) oscillations emerged from 4 months of age; 3) across all frequencies, the frontal power in the EEG was significantly greater in the 4 to 6 month-old infants compared to the 0 to 3 month-old infants; and 4) unlike in adults, all 0 to 6 month-old infants showed an absence of frontal alpha coherence. We also show that in the awake state, and during emergence (immediately after first body movement), power in the alpha, theta and beta bands was significantly lower compared to the MOSSA state in 4 to 6 month-old infants. CONCLUSION: We show that infants aged 0 to 6 months of age have markedly different EEG patterns from each other, and from adults under general anesthesia. These differences are likely due to differences in brain development and help explain why EEG-based indices provide inaccurate measures of anesthetic states in infants less than 4 months. Furthermore, they suggest the types of studies and analyses that are required to develop neurophysiologic-based strategies for anesthetic state monitoring in pediatric patients. Title: Optimizing repetitive brain stimulation using direct electrical recordings in human neocortex

Authors: ***M. FINI**[1], C. KELLER[1,2], C. HONEY[3], F. LADO[2,4], A. MEHTA[1];
[1]Dept. of Neurosurg., North Shore Lij-Hofstra Med. Ctr., Manhasset, NY; [2]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [3]Neurol., Montefiore Med. Ctr., Bronx, NY; [4]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Keywords: brain stimulation, ECoG, cortico-cortical evoked potential (CCEP), high gamma envelope (HGP) Background: Brain stimulation is increasingly used to treat psychiatric diseases yet the generators and underlying sustained network changes are not well-understood. We sought to elucidate these effects by applying electrical stimulation and recording directly to the human neocortex in epilepsy patients undergoing monitoring for surgery. Methods: Five patients undergoing surgical evaluation were enrolled. After electrode implantation, electrical responses were recorded in three conditions, with order counterbalanced across patients: 10Hz (4s train, 26s rest, 10min total); 1Hz (13 min train); sham stimulation. All conditions included 800 pulses. Current was adjusted with 4mA being used in most patients. Results: Stimulation pulses within the 10 Hz train induced both positive and negative voltage deflections in evoked CCEP amplitudes across various brain areas. Significant changes to the evoked responses were measured 2-15 minutes post stimulation with all evoked responses returning to baseline within 15 minutes. Modulated areas were correlated with distance from the stimulation site, strength of pre-stimulation CCEP amplitude, and resting HGP correlation with the stimulation site. Areas showing significant amplitude change exhibited a prestimulation CCEP amplitude 2.5 +/- 0.7 fold that of non-modulated areas and were located 60 +- 5% closer to the stimulation site. These effects were not observed for 1Hz or sham stimulation. Using a machine learning algorithm, modulated regions could be predicted with 77% accuracy using only pre-stimulus CCEP amplitude. Conclusions: Repetitive stimulation elicited changes that were predictable, short-acting, within 4.8cm of the stimulation site, and selective for the 10 Hz pulse rate. These results suggest the timing of pulses during repetitive stimulation can be modified to induce stronger and longer-lasting changes in brain networks. Both positive and negative CCEP deflections were observed, indicating that the 10 Hz stimulation significantly affects both excitatory and inhibitory networks. Modulated areas fell within a few centimeters of the stimulation site and, exhibited a strong pre-stimulation CCEP amplitude and resting HGP correlation with the stimulation site. These factors can be used to predict areas where significant change will occur. Future work will include improving statistical methods, including other stimulation parameters

(1 Hz, 20 Hz, theta burst), time-frequency analysis of CCEPs for HGP analysis, and multi-day stimulation to determine long term local network changes.

Title: Conditions for explosive synchronization in human brain networks during general anesthesia

Authors: M. KIM[1], G. A. MASHOUR[2,4], *U. LEE[3,4];
[1]Physics, POSTECH, Pohang, Korea, Republic of; [2]Anesthesiol. and Neurosci. Grad. Program, [3]Anesthesiol., Univ. of Michigan Med. Sch., Ann Arbor, MI; [4]Ctr. for Consciousness Sci., Ann Arbor, MI

Abstract: Background: Although there are a number of common neural correlates of sleep, anesthesia and coma, the recovery profiles of these states are radically different. To understand the reversibility of unconsciousness at a network level, we studied the topological and dynamical properties of brain networks in conscious and lightly anesthetized states. Methods: Multi-channel electroencephalograms (EEG) from seven healthy subjects and the weighted Phase Lag Index (w-PLI), a phase locking measure, were used to construct the functional networks across waking, transitional, unconscious and recovery states. We investigated the topological and dynamical properties that have been suggested recently as conditions for explosive synchronization (ES) in general networks: (1) disassortativity and (2) the frequency difference of coupled nodes. Furthermore, the suppressive rule, an inequality relationship for ES between local frequency difference and global network properties, was assessed to find out the local contribution for

conditions of ES. The brain region with the largest contribution to ES was identified for each EEG epoch during anesthesia to investigate the regional contribution across states. Results: Anesthesia disrupted the hub structure in the posterior parietal and occipital lobes, and the peak frequency of alpha power shifted toward higher frequency at the frontal region. The high disassortativity value of the waking state was significantly reduced and the frequency difference of coupled nodes was significantly increased in the unconscious state (Disassortativity: waking (Mean ± SD, -0.3590 ± 0.0538) vs. unconscious (Mean ± SD, -0.1458 ± 0.0408), $P < 0.001$, frequency difference: waking (Mean ± SD, 0.0043 ± 0.0021) vs. unconscious (Mean ± SD, 0.0149 ± 0.0051), $P < 0.005$, using repeated 1-way ANOVA with tukey's multi-comparison test). All values returned to baseline with the recovery of consciousness. The number of local nodes that facilitate ES with a small perturbation rapidly increased after induction. The trigger nodes for ES in the brain networks were variable across regions over time. Conclusion: Anesthesia suppresses the capacity of information integration by reconfiguring the brain network. However, the increase in conditions for ES suggests that the lightly anesthetized brain network is still in a strongly resilient state and that a small perturbation has the potential to trigger an explosive transition back to the normal network state. Further assessing ES conditions in brain networks during deep general anesthesia, sleep and coma may provide insight into the variable recovery profiles of these unconsciousness states.

Title: Effect of sleep restriction on EEG activity during deep isoflurane anesthesia

Authors: T. MARIAM, R. TADAVARTY, *P. J. SOJA;
Univ. British Columbia, Vancouver, BC, Canada

Abstract: Restricted sleep and its consequences are endemic to society. While sleep and anesthesia overlap in their overt characteristics, it is known that the loss of consciousness that occurs following inhalational anesthesia happens much sooner when sleep is restricted. However, few, if any studies have actually examined the effects of sleep deprivation on the

concentration-dependent effects that inhalational anesthetics exert on cortical EEG activity. Accordingly, we employed the phenomenon of EEG burst suppression events (Swank & Watson, 1949) as a reliable biomarker representing a deep surgical plane of anesthesia to address this issue. Male Sprague-Dawley rats (360-380 g) were divided in three groups (I-control, II-sleep deprived for 9 h, and III-recovery for 48 h, n=6/group). Rats in each group were initially anesthetized with isoflurane (ISO) using an induction chamber, the animals' trachea were then intubated and their head mounted in a stereotaxic frame. Cortical EEG (S1) was recorded bilaterally using stainless screw electrodes. The concentration of anesthetic (ISO%) was initially adjusted to produce a stable baseline EEG that consisted of large-amplitude slow-wave activity over a 30 min period. ISO was then increased in relative 0.5% steps of 0.5, 1.0, 1.5, and 2.0 while the number of burst events/min were automatically detected and quantified by a computer subroutine. In group I, the number of burst events/min at relative 0.5, 1.0, 1.5 and 2.0 ISO% measured 20.5 ± 1.5, 9.8 ± 2.3, 3.5 ± 0.7, and 0, respectively. In group II, the dose-related suppression of burst events by the same increasing relative ISO% was shifted to the right. The number of bursts events increased proportionally at the same 0.5, 1.0, 1.5 and 2.0 ISO% and measured 25.9 ± 1.9, 20.4 ± 1.8, 10.2 ± 2.0 and 1.5 ± 0.5, respectively. The dose-related ISO suppression of burst events in group III animals returned toward group I levels and measured 17.9 ± 2.5, 10.3 ± 1.8, 4.7 ± 0.7 and 0, respectively. Tukey's test following repeated measured two-way ANOVA indicated that the number of bursts/min at ISO% 0.5, 1 and 1.5 was significantly increased ($p<0.05$) in group II rats compared to group I rats, which reversed back to control level in group III rats. On the basis that burst suppression events reflect an inactivated brain with reduced metabolism, our findings on burst suppression events across the three groups of animals would suggest that sleep deprivation per se may enhance cerebral metabolism. Notwithstanding the obvious clinical relevance, our findings may provide a basis for more careful design of future animal studies investigating sleep and/or anesthetic mechanisms.

Title: Thalamocortical synchronization during propofol-induced unconsciousness

Authors: *F. J. FLORES[1,2,4], K. HARTNACK[1], A. B. FATH[5], S. E. KIM[2], N. KOPELL[6], M. A. WILSON[3], E. N. BROWN[1], P. L. PURDON[1];

Sch., Boston, MA; [5]Wellesley Col., Wellesley, MA; [6]Mathematics and Statistics, Boston Univ., Boston, MA

Abstract: In humans, loss of consciousness induced by the anesthetic propofol is accompanied by the appearance of frontally coherent alpha (8-12 Hz) oscillation in the EEG (Purdon et al. 2013). Modelling studies have suggested that these alpha oscillations arise from thalamocortical synchronization due to the potentiating effect of propofol on GABAergic synaptic transmission (Ching et al. 2010). To test this hypothesis, we recorded local field potentials simultaneously from pre-frontal cortex and midline thalamic nuclei in awake, freely behaving rats. To mimic the slow increase in inhibitory conductance used as a tuning parameter in the model, we administered propofol as a slow intravenous infusion whose rate was derived from an allometric pharmacokinetic model. We estimated loss of consciousness by assessing loss of the righting reflex. Beta (13-16 Hz) oscillations associated with behavioral hyperactivity appeared in both the thalamic and cortical sites before loss of consciousness. With loss of consciousness the beta oscillations transitioned to coherent alpha oscillations between the thalamus and cortex. Following loss of consciousness delta (1- 4 Hz) and alpha oscillations appeared in the pre-frontal cortex. During this period, thalamocortical coherence in the delta range is very high. The thalamic alpha oscillations are weaker, but alpha coherence is still present. Thalamocortical alpha coherence regains power prior to recovery of consciousness. Our results show that in rodents propofol produces the same oscillatory patterns observed in human EEG recordings. Our findings support the hypothesis that propofol-induced frontal alpha oscillations result from coherent thalamocortical activity that occurs at the point of loss of consciousness.

Title: Intracranial alpha dynamics and correlates of anteriorization during propofol general anesthesia

Authors: *D. W. ZHOU[1], V. S. WEINER[4], R. A. PETERFREUND[1,5], M. D. SZABO[1,5], E. N. ESKANDAR[2,6], S. S. CASH[3,7], E. N. BROWN[1,4,5], P. L. PURDON[1,5];

Abstract: Stereotyped signatures of general anesthesia in the electroencephalogram (EEG) have been recently studied and include dynamics now known to be caused by disruption of GABA-ergic thalamocortical networks driven by propofol, a GABA agonist. Among the key features of the EEG during propofol general anesthesia is the change in distribution of alpha power from posterior in the awake brain to anterior in the unconscious brain. The intracranial correlates of these dynamics are not well understood. We studied neural recordings from 14 patients with medically intractable epilepsy who had been previously implanted with intracranial depth and electrocorticography (ECoG) electrodes as general anesthesia was induced with propofol while performing a behavioral task. We demonstrate an anterior and medial shift of coherent alpha activity using frequency domain principle component analysis. We also show that anteriorization of alpha power is associated with two distinct phenomena. First, alpha power decreases in posterior sensory cortices (auditory and visual) as waking alpha oscillations are disrupted and slow oscillations increase during loss of consciousness. Second, de novo alpha rhythms begin in frontal and midline structures, including cingulate cortex and frontal white matter. In addition, we find that in a subset of posterior brain regions with alpha rhythms before loss of consciousness, task-related alpha dynamics in sensorimotor and auditory regions were disrupted during anesthetic induction. Regionally distinct alpha behavior in the frontal and occipital cortices suggests that thalamocortical connections to each brain region generate separate components of the alpha dynamics observed during induction of propofol general anesthesia. Therefore, intracranial recordings provide rich, region-specific detail to alpha dynamics previous studied in surface EEG.

Title: Evidence for slow oscillations and coherent theta and gamma oscillations during ketamine-induced altered arousal

Authors: *O. AKEJU[1], F. J. FLORES[1], K. J. PAVONE[1], M. A. WILSON[2], P. L. PURDON[1], E. N. BROWN[1];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Massachussetts Inst. of Technol., Cambridge, MA

Abstract: Ketamine is an N-methyl-D-aspartate antagonist that is used as an anesthetic, a research model for schizophrenia, and a fast acting treatment for major depressive disorder. At low doses, ketamine produces a dissociative state characterized by hallucinations, altered sensory perception, and analgesia, while at higher doses it induces a state of unconsciousness appropriate for general anesthesia. In contrast to other general anesthetic drugs, ketamine does not depress cerebral glucose utilization or cerebral blood flow, and it is associated with gamma oscillations in the electroencephalogram (EEG). The mechanisms underlying these contrasting states of consciousness and assorted neural effects are the subject of intense interest in neuroscience. We recorded the EEG during ketamine-induced anesthesia (2mg/kg). Immediately after general anesthesia induction, we observed a “slow-gamma” pattern (slow oscillations alternating with gamma oscillations; n = 12) that eventually transitioned to a “gamma stable” pattern. Both the slow-gamma and the gamma stable patterns were associated with increased theta oscillations (4-8 Hz) and decreased beta/gamma oscillations (10-20 Hz). The slow-gamma pattern was also associated with large amplitude slow/delta (0.1-4 Hz) and beta/gamma (20-50 Hz) oscillations. When we compared the coherence patterns of both ketamine patterns, we found that the coherence structure was similar for all frequencies studied (0.1-50 Hz). We next recorded ketamine-induced (150mg/kg) local field potentials (LFP) and single unit activity in the prefrontal cortex of Sprague Dawley rats. Single unit recordings revealed that gamma bursts

were associated with increased firing rate of pyramidal neurons, while slow oscillation bursts were associated with increased firing rate of inhibitory neurons. Our results suggest the following: (1) Active inhibitory circuits in the cortex are instrumental for the ketamine-induced slow oscillations (2) Ketamine mediated increase in gamma oscillations are likely secondary to the effects of ketamine on basket interneurons (reduced inhibitory tone) resulting in pyramidal neuron excitation (3) The slow-gamma pattern is not a state of neuronal burst suppression (4) Ketamine-induced theta and beta/gamma oscillations are coherent and likely function to reduce the dimensionality of normal cortical information processing networks. These findings will facilitate a more principled brain-state monitoring paradigm in clinical settings. Additionally, they may also aid research in the treatment of depression, pain disorders and schizophrenia.

Title: Effect of very deep isoflurane anesthesia on hippocampal plasticity

Authors: *R. TADAVARTY, T. MARIAM, P. SOJA;
The Fac. of Pharmaceut. Sci., The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Cortical EEG activity beyond the isoelectric line of very deep coma induced by inhalational anesthetics is poorly understood. Specific patterns of activity emerge in the electroencephalogram (EEG), as the dose of anesthetic is increased. In animal studies, isoflurane (ISO) is a commonly used volatile anesthetic. When ISO concentrations are increased, EEG activity changes from large-amplitude slow waves to recurring periods of bursts, followed by isoelectric EEG. The number of burst events proportionally decrease with increasing concentration of ISO (1-3%), beyond which the EEG consists mainly of randomly occurring

single or bursts of fast large-amplitude spikes. Additionally, at higher ISO concentrations, EEG activity between large-amplitude spike events is dominated by rhythmic low-amplitude oscillations (Anesth Analg 1994; 79:52-7, PLoS One 2013; 8(9):e75257). Although, hippocampus has been suggested as one source of these large-amplitude cortical spike waves during very deep ISO coma, the functional consequences within the hippocampal networks during this state are not known. The present study examined in-vivo effects of prolonged exposure to deep ISO (5%) on long-term depression (LTD) of excitatory post-synaptic transmission in the CA1 region of the hippocampus in-vitro. Male SD rats (400-600g) were initially anesthetized in an induction chamber, their trachea intubated and head mounted in a stereotaxic frame. Cortical EEG was recorded using stainless steel screw electrodes positioned in S1 bilaterally. Hippocampal slices were then prepared from either control (n=5) or test (n=5) animals exposed to deep ISO (5%) for at least 3 h. Field excitatory postsynaptic potentials (fEPSPs) were evoked at 0.05 Hz by stimulating the CA3 afferents, and recorded from the apical dendritic layer of CA1 pyramidal neurons. While a low-frequency stimulation (LFS; 1 Hz, 1200 pulses), reliably induced LTD in the control group, the time-course and extent of LTD was significantly altered in rats exposed to deep ISO (5%). Amplitudes of fEPSPs recovered to the pre-tetanic baseline levels in the test group in ~ 8 min post-LFS. At 20 min post-tetanus, LTD magnitude was significantly larger (fEPSP amplitudes as a % of pre-tetanic controls, 73.6 ± 5.2, n=5; Student's t test; $p<0.05$) in control animals when compared to the test group (109.9 ± 8.0; n=5). LTD's functional role(s) include among other things, fine tuning of overall excitability of hippocampal and cortical neural networks. The marked suppression of LTD observed in deeply comatose brains of adult animals would likely afford a shift toward excitatory processes, the consequences of which remain to be determined.

Title: Optogenetic and pharmacological manipulation of cortical excitatory/inhibitory balance: rescuing the effects of acute ketamine on cortical gamma band oscillations

Authors: ***J. M. MCNALLY**, S. THANKACHAN, R. W. MCCARLEY, R. E. BROWN; VABHS, Harvard Med. Sch., Brockton, MA

Abstract: Gamma band (30-80 Hz) oscillations (GBO) serve as a fundamental mechanism allowing coordination of neuronal activity during various cognitive processes. Abnormalities in GBO have been observed in a number of neuropsychiatric disorders such as schizophrenia (Sz), and appear to arise from dysfunction in the cortical circuitry responsible for generating such activity. It has been hypothesized that impaired NMDA receptor function in cortical interneurons is largely responsible for GBO abnormalities. This NMDA hypofunction has been suggested to alter the delicate balance in activity between the inhibitory and excitatory components of the cortical circuit (E/I balance), principally through reducing the activity of interneurons which express parvalbumin (PV). Sub-anesthetic doses of NMDA antagonists (e.g. ketamine) effectively model symptoms of Sz in humans and elicit Sz-like GBO and behavioral impairment reminiscent of Sz symptoms in animals. However, methods to correct ketamine and Sz-induced GBO abnormalities are lacking. Here, utilizing both optogenetic and pharmacological techniques, we investigated several strategies to upregulate PV interneuron activity, restore cortical E/I balance, and potentially rescue GBO. First, we focused on cortically projecting basal forebrain (BF) GABAergic PV neurons, which target cortical PV interneurons and modulate cortical activation/GBO (see Kim et al., 2015, PNAS 112(11):3535). Optogenetic inhibition of BF PV neurons in freely behaving mice (n=4) partially rescued the elevated spontaneous GBO activity elicited by acute ketamine (30 mg/kg). Further, tonic optogenetic excitation of BF PV neurons (n=2) induced an elevation in spontaneous GBO by itself. Second, we examined the type 5 metabotropic glutamate receptor (mGluR5), which is expressed by cortical PV neurons, and has been shown to facilitate NMDA receptor function. Studies have shown positive modulators of mGluR5, are capable of alleviating Sz-like behavioral deficits, and may provide a means to rescue Sz-related NMDA hypofunction. Here, using an *in vitro* slice model of GBO, CDPPB (10-20 μM; n=4), a positive modulator of mGluR5, while having no effect on the GBO alone, partially inhibited the acute potentiation of these oscillations by ketamine (100 μM). Together, these findings suggest that 1) optogenetic manipulation of the activity of BF PV neurons and 2) pharmacological facilitation of mGluR5 activity both may provide effective targets for modulating cortical E/I balance, and restoring normal GBO activity in Sz.

Title: Visual encoding is gamma phase dependent

Authors: J. CSATLOS[1], S. LINNERT[2], E. KORMANN[3], *Z. NADASDY[4,1,5];
[1]Dept. of Cognitive Psychology, Eotvos Lorand Univ., Budapest, Hungary; [2]Dept. of Psychology, Lancaster Univ., Lancaster, United Kingdom; [3]Dept. of Pharmacol. (MRC), Univ. of Oxford, Oxford, United Kingdom; [4]Neurotexas Inst. Res. Fndn., Austin, TX; [5]Dept. of Psychology, The Univ. of Texas at Austin, Austin, TX

Abstract: Gamma oscillations have been implicated in feature binding at different levels of visual information processing from low-level feature analysis (Gray & Singer, 1989) to conscious perception (Martinovic & Busch, 2011). However, their causal role in visual perception has long been debated. We have developed a new paradigm for testing the causal role of gamma oscillations in the segmentation of stimulus flow. Subjects were instructed to fixate and attend a rapid succession of 8 images of birds and cars (in separate blocks) flashed for 32 ms duration each, in an RSVP paradigm while 128-channel EEG was recorded. Each RSVP trial was followed by a visual recognition task where the participants were asked to identify the initial 8 images from a gallery of 16 images, half of which were new. The selected images were sorted into two groups: correctly recognized stimuli and incorrectly recognized. Failure of recognition could have been due to an encoding failure, a memory retrieval failure, or both. We analyzed the Hilbert transform of EEG of 15 adult subjects during the stimulus encoding at three frequency bands: theta, alpha and gamma (1-8 Hz, 9-15 Hz, 30-60 Hz, respectively). An average oscillation phase profile was computed from the EEG associated with the encoding of correctly recognized stimuli. This average phase profile of correct encoding was compared to the average phase profile of EEG oscillations associated with the failure of encoding, separately for each frequency band. We observed a significant phase difference between the correctly and incorrectly recognized stimuli in gamma band for the bird image dataset, but no similar difference was observed in other frequency bands and data sets. We validated the gamma phase difference in the bird image dataset by re-computing it after shuffling the image-response associations and the difference disappeared, proving that phase difference did not occur by chance. The largest difference was observed at occipital electrode positions, but occipital-frontal and occipital-temporal electrode groups also displayed significant phase differences. The phase difference emerged as early as 70 ms after stimulus onset, consistent with the earliest C1 component of visually evoked potential (Di Russo, Mart'nez, Sereno, Pitzalis, & Hillyard, 2002). This suggests that the encoding-related gamma phase difference could not be induced by the stimulus, but instead, the gamma phase sets a time window optimal for sampling the visual input. Hence, it is

not the stimulus that resets the gamma phase but rather the actual gamma phase that enables the processing of visual information.

Title: Intrinsic excitability measures track anti-epileptic drug action and uncover increasing/decreasing excitability over the wake/sleep cycle

Authors: ***C. MEISEL**[1], A. SCHULZE-BONHAGE[2], D. PLENZ[1];
[1]NIMH, Bethesda, MD; [2]Univ. of Freiburg, Freiburg, Germany

Abstract: Dynamic changes of excitability are relevant in both healthy and pathological cortical network dynamics. This is particularly highlighted by the pathological changes in excitability of cortical tissue commonly underlying the initiation and spread of seizure activity in patients suffering from epilepsy. Accordingly, controlling excitability using anti-epileptic drugs (AED) and monitoring their effect on network excitability is of prime importance for adequate clinical care and treatment. To date, adequate measures of excitability and action of AED have been difficult to identify. Recent insights into normal ongoing activity in humans, non-human primates and cortical *in vitro* preparations have identified measures such as (1) the distribution of clustered synchronized events, as well as (2) entropy and (3) global level of phase synchronization which characterize normal levels of excitability and quantify any deviation therefrom. Here, we explore the usefulness of these measures to quantify cortical excitability in humans using ongoing multi-day intracranial EEG recordings. We report a significant covariation of markers with the level of AED, a post-ictal drop and a characteristic 24-h time course which increases during the day and returns to baseline at night. Our results indicate that excitability in epileptic networks is effectively reduced by AED and suggest the proposed markers as useful candidates to quantify excitability in routine clinical conditions without the need of electrical or magnetic stimulation. The intradian time course of these metrics provides unprecedented evidence in humans for a homeostatic role of sleep: to rebalance cortical excitability.

Title: Intrinsic frequency biases across the posterior-anterior cortical hierarchy

Authors: ***M. S. MELLEM**[1], A. GHUMAN[2], S. WOHLTJEN[1], A. MARTIN[1];
[1]NIH, Bethesda, MD; [2]Dept. of Neurolog. Surgery, UPMC, Pittsburgh, PA

Abstract: Recent findings in primates suggest that intrinsic periodic spiking activity occurs on different timescales across cortical areas. An organization following the anatomical hierarchy

underlies the timescales such that activity in sensory areas occurs on faster timescales (50-150ms) while activity in higher-order areas occurs on slower timescales (>150ms). It is not yet known if a similar timescale hierarchy is present in human subjects. Additionally, measures in the primate studies have not considered that periodic activity within a brain area can occur at multiple frequencies. We hypothesized that, in humans, intrinsic neural activity in sensory areas would be biased towards higher frequencies (faster timescale) while higher-order areas would be biased towards lower frequencies (slower timescale). To test this, we examined the spectral power in multiple frequency bands across several ROIs from task-independent data using magnetoencephalography (MEG). Neuromagnetic responses were recorded from 13 subjects at 600 Hz using a 275 channel whole-head MEG system while subjects fixated for five minutes. The data was downsampled to 150 Hz and bandpass filtered from 1-50 Hz off-line. Structural MRIs were collected for each subject, dense cortical grids were created with Freesurfer, and the MEG signal was source localized using the minimum norm estimate inverse solution. Timeseries from six hierarchically-organized ROIs (V1, V2, V4v, fusiform gyrus, lateral prefrontal cortex, orbitofrontal cortex) were extracted. Spectral power was calculated for each ROI and normalized by the total power for each ROI. The group-averaged spectra revealed that most of the power was in either a low band (< 2Hz) or the alpha band (8-12Hz). Thus group power was averaged over each band for each ROI for further statistical analysis. A 2x6 ANOVA revealed a Frequency band X ROI interaction ($p<0.001$), and Spearman's rank correlation was used to investigate if intrinsic spectral power in these two bands followed the hierarchical ordering. Low frequency power increased from V1 up to Orbitofrontal ($rho = 0.94$, $p<0.05$), while alpha power decreased with increasing anatomical hierarchy ($rho = -0.89$, $p<0.05$). These results suggest two main conclusions: Not only are higher-order areas biased towards 1-2Hz relative to sensory areas, and sensory areas towards alpha frequency relative to higher-order areas, but that there is a gradient of power across the anatomical hierarchy for both frequency bands. Thus, intrinsic activity within a brain area occurs at multiple timescales with the amount of activity that occurs at fast and slow timescales biased based on the cortical hierarchy.

Title: Cooperation and specialization of the bilateral hippocampi in rodents

Authors: *Y. SHINOHARA, A. HOSOYA, H. HIRASE;
RIKEN, Wako, Japan

Abstract: In rodents, the left and right hippocampi are synaptically connected. Accordingly, the ipsi- and contralateral CA3-CA1 projections are termed as the Schaffer and commissural pathways, respectively. Although the existence of such anatomical connections has been known for nearly a century, relatively little is known about their projection topology, molecular composition, and physiology. By retrograde tracing, we characterized the relative contributions of CA3 and CA2 innervation to CA1 stratum oriens (s.o.) or stratum radiatum (s.r.). We find that CA2 predominantly projects to ipsilateral CA1 s.o. and this projection accounts for approximately 10% of the input. The largest source of innvervation to CA1 s.o. is the contralateral CA3. By contrast, the ipsilateral projection from CA3 is predominant in CA1 s.r. While the macroscopic connectivity of the interhemispheric CA3-CA1 projection appears to be symmetric, left-right asymmetry is apparent in spine morphology and synaptic molecule composition. We demonstrate that CA1 s.r. spines innervated by the right CA3 have contrasting spine morphology and ionotropic glutamate receptor subunits to those innervated by the left CA3. Finally, we demonstrate that enriched environment (EE) housing enhances the power and synchrony of interhemispheric theta-associated gamma oscillations in CA1 s.r. Interestingly, the gamma power increase is more prominent in the right side. On the other hand, the amplitude and left-right asymmetry of ripple oscillations were not significantly altered. In a separate set of EE rats, spine density increases are manifested in the right CA1 s.r. relative to the left of the same animal. These results suggest that experience influences the wiring and operational dynamics of bilateral hippocampi.

Title: Exploring the neural basis of the electrophysiological power spectrum

Authors: *R. GAO[1], B. VOYTEK[2];
[1]Cognitive Sci., UCSD, La Jolla, ; [2]Dept. of Cognitive Sci., UCSD, La Jolla, CA

Abstract: The power spectrum of meso- and macro-scale brain electrical recordings in the forms of the local field potential (LFP), electrocorticogram (ECoG), and electroencephalogram (EEG) are often described to be following an inverse power law relationship, given by P = AF^(-x), where F is frequency, P is power, and A and x are free parameters characterizing the power law. In the log-log domain, this relationship is represented by a linear trend with a negative slope of -x and a y-intercept of logA. This phenomenon has been well documented in empirical data, noting changes in A and x during various perceptual and motor tasks. In addition, recent computational models using population-spiking neurons have attributed these parameters to different biological mechanisms. While the power law formulation of the spectrum has proven fruitful, two key observations are unsatisfactorily accounted for. First, there have been reports of an increase in strictly high gamma power (>60Hz), resulting in a curling of the spectrum, without changes in the slope or intercept. Second, rotations of the spectrum resulting from a change in slope are observed to be about a frequency of ~25Hz, instead of 1Hz, which would be the case if only a change in x were to occur. Here, we argue that a strict inverse power law model is an incomplete description of the underlying processes giving rise to the power spectrum, and propose the addition of an additive term, i.e. F = AF^(-x) + B. Furthermore, we postulate that B, a broadband signal akin to white noise, arises from de-correlated (Poissonic) population firing engaged in local computation. Using a Poisson population model, we demonstrate that an increased firing rate leads to both an increase in gamma power (high frequency curling) and a rotation of the spectrum about ~25Hz. In addition, we validate our model by demonstrating an improved fit of the power spectrum derived from human ECoG and rat LFP data. In summary, the new formulation has both explanatory powers over the data and a sound neurophysiological basis, improving our understanding of the power spectrum of electrophysiological data.

Title: The characterization of calf brain cell nuclear membrane GlcNAc-specific lectin

Authors: *T. MACHARADZE[1], L. KHARAZISHVILI[2], G. KHAREBAVA[3], V. GVAKHARIA[4], N. MACHITADZE[4], R. AKHALKATSI[2];

Abstract: There is a little known about nuclear lectin features and function in nerve tissue cells. As it has been shown they participate in the protein-protein interaction, which is implemented by protein carbohydrate interaction. We studied rat brain cell nuclear membrane GlcNAc-specific lectins, but nothing was known about the same glycoproteins in calf brain. GlcNAc-specific lectins were obtained by Akhalkatsi et al. from calf (1 - 1,2 years old) brain cell nuclear membrane fraction using Chauveau method without chaotropic and reductive substances. So obtained protein fraction hemagglutination activity showed, that titre is equal 256 and specific activity is 341. From this protein fraction calf brain cell nuclear membrane GlcNAc-specific lectin has been obtained by affinity chromatography with column GlcNAc immobilized on tris-acrylle. After further rechromatography which was obtained by HPLC (Whaters, USA) on tandem columns Protein PAK 300 SW, U-60 showing four fractions with molecular masses 70kD and more: 63,10 and 1,6kD. Rechromatography of all four fractions showed maximum absorption in the ultraviolet area at 208-212nm, which points to the absence or presence of following amino acids: tyrosin and tryptophan in a very low concentration. The exception is the only 1,6kD fraction, which has the second maximum at 280nm. The calf brain cell nuclear membrane GlcNAc-specific lectin is a glycoprotein and contains carbohydrate 2,25 µg/100µg protein measured by Kolb and Kamishnikov. Specific activity of these lectins is equal 104,4 and it is thermostabile. In the structure of carbohydrate binding center of calf brain cell nuclear membrane GlcNAc- specific lectins take part Ca^{2+} and Mg^{2+} ions 2,90 µg and 0,7µg/100 µg protein correspondingly, which was showed with the influence different concentration of EDTA and EGTA on the hemagglutination activity. GlcNAc-specific lectins does not contain Mn^{2+} ion. The ions content in calf brain cell nuclear membrane lectins was measured by atomic absorption method.

Title: Intrinsic plasticity accompanies synaptic LTD in Purkinje cells

Authors: ***Z. YANG**, F. SANTAMARIA;
Biol., UTSA, San Antonio, TX

Abstract: Cerebellar Purkinje cells show activity dependent changes of intrinsic excitability in both behavioral learning and *in vitro* slice recordings. It is still unknown whether long term depression (LTD) of parallel fiber-Purkinje cell (PF-PC) synapse is associated with modulation of intrinsic membrane properties. We performed whole-cell patch-clamp recordings in slice from 16- to 23-day-old mice. PF-PC LTD was induced in voltage clamp mode by pairing parallel fiber stimulation and somatic depolarization. This protocol generated robust reduction of EPSC of about 40%. Intrinsic properties were recorded in current clamp mode before and after synaptic LTD induction. We found an increase of overall excitability in somatic recording after LTD induction. There was also a parallel decrease of sag ratio and an increase of input resistance at more hyperpolarized potential, indicating a reduction of h-current. We did not observe significant changes in afterhyperpolarization amplitude following action potential trains. The application of HCN channel blocker ZD 7288 occluded the increase of excitability without affecting synaptic LTD. Since there are two components in our LTD induction protocol, we further tested the excitability changes by somatic depolarization or parallel fiber stimulation only, in order to elucidate the stimulation pattern required for this intrinsic plasticity. We found that neither stimulation protocol alone can lead to overall excitability change, indicating the requirement of concomitant somatic depolarization and dendritic stimulation for intrinsic plasticity. Our results show that LTD induction enhances Purkinje cell excitability through downregulation of HCN channels. This non-synaptic plasticity may serve as a homeostatic mechanism and could affect future information processing by Purkinje cells.

Title: Spatiotemporal dynamics of calcium flux in the axonal initial segment

Authors: M. POPOVIC, *M. H. KOLE;
Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Vertebrate neurons have developed a complex arrangement of voltage-gated ion channels expressed at high densities in domains of myelinated axons to optimize action potential (AP) initiation, conduction and transmitter release. Although there is a wealth of information about the precise biophysical mechanisms by which calcium (Ca^{2+}) ions regulate the release of neurotransmitter at the presynaptic boutons, the origin and functional role of Ca^{2+} in the axon initial segment (AIS) and nodes of Ranvier remains poorly understood. To assess the spatial and temporal dynamics of axonal Ca^{2+} we filled thick-tufted rodent layer 5 pyramidal neurons with high-affinity 100 μM Oregon Green BAPTA 1 during whole-cell patch-clamp recording and used high-speed epi-fluorescence Ca^{2+} imaging to measure Ca^{2+} changes in the axon during subthreshold and suprathreshold membrane potential changes. Ca^{2+} signals were expressed as fractional fluorescence changes scaled to the dye saturating pulse (80 APs at 400 Hz) to eliminate the effect of different background fluorescence. It was found that excitatory postsynaptic potential (EPSP) like current injections (5 EPSPs at 100 Hz) triggered substantial Ca^{2+} in the axon and spatially confined to both the AIS and the nodes of Ranvier with the time-to-peak matching the depolarization duration, i.e. ~50 ms (n = 30). These subthreshold Ca^{2+} transients were voltage dependent and completely blocked by 200 μM cadmium. While suprathreshold Ca^{2+} transients were present in all axonal domains, the highest concentration occurred in a spatially restricted ~5 μm hot spot at the AIS (n = 10). The decay of calcium signal in the hot spot was slower than in the other axonal regions with ~33% increase in the decay time constant. Nimodipine preferentially blocked the subthreshold signals (by ~40%), whereas both Mibefradil and nickel preferentially blocked the suprathreshold signal (by ~50%) suggesting the involvement of voltage-gated L- and T-type Ca^{2+} channels (n = 6) as the sources of calcium at the AIS during EPSP integration and AP initiation, respectively. These results suggest that Ca^{2+}

signals in the AIS are highly compartmentalized and functionally segregated, capable to detect and participate in the integration of the co-incidence of synaptic inputs.

Title: Regulatory evolution and voltage-gated ion channel expression in squid axon: selection-mutation balance and fitness cliffs

Authors: ***D. MCKINNON**, M. KIM, D. D. MCKINNON, T. MACCARTHY, B. ROSATI; Stony Brook Univ., Stony Brook, NY

Abstract: It has been suggested that optimization of either axonal conduction velocity or the energy efficiency of action potential conduction predominates in the selection of voltage gated sodium and potassium channel expression levels in the squid axon. A population genetics model that incorporates the effect of mutation on channel gene regulatory function as well as developmental/phenotypic noise on channel protein expression was used to examine the role of these and other evolutionary forces on the selection of channel expression levels [1]. In this model, the accumulating effects of mutations result in degradation of gene regulatory function, causing channel gene expression to fall to near-zero levels, in the absence of positive selection. In the presence of positive selection, channel expression levels fall to the lowest values consistent with the selection criteria, thereby establishing a selection-mutation balance. The simulation results suggest the following conclusions: 1. Mutation of gene regulatory function will cause voltage-gated channel expression levels to trend towards the lowest levels consistent with any positive selection criteria acting on the system. This process will generally produce an energy efficient system, even in the absence of positive selection for energy efficiency. To convincingly argue that minimization of energy utilization is a critical constraint on the evolution of voltage-gated channel expression levels it is necessary to demonstrate that some other function, that is also important, is compromised in order to maximize energy efficiency, i.e. demonstrate that there are tradeoffs associated with the maximization of energy efficiency. 2. In

many cellular electrophysiological systems, including the squid axon, large regions of channel conductance parameter space can produce similar physiological performance. The inescapable effect of mutations in degrading gene regulatory function means that most of this parameter space will not normally be occupied *in vivo*, in the absence of some significant countervailing positive selection criteria. 3. Genetic variation in gene regulatory function within populations, and developmental/phenotypic noise within individuals, are major causes of individual variation in protein expression levels in most biological systems. These basic genetic/biochemical mechanisms are also likely to produce significant variation in channel expression in electrically excitable cells, without the need to resort to more complex mechanisms, such as activity-dependent homeostasis. Title: Circadian rhythm of redox state in hippocampal CA1 regulates neuronal membrane excitability

Authors: *G. NASERI KOUZEHGARANI[1], M. YU[2], M. U. GILLETTE[3];
[1]Neurosci. Program, [2]Mol. and Integrative Physiol., [3]Cell and Developmental Biol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Circadian rhythms regulate many aspects of metabolic homeostasis. At the cellular level, metabolic state manifests as redox state, the ratio of redox-molecule pairs, *e.g.,* glutathione disulfide (GSSG)/glutathione (GSH), that originates from reduction-oxidation reactions. We previously reported a novel model for the interdependency of the transcriptional-translational clock machinery, redox oscillation, and neuronal excitability in the hypothalamic suprachiasmatic nucleus (SCN, Wang *et al., Science* 2012; Gillette & Wang, *Antioxid. Redox*

Signaling, 2014). Does this interrelationship exist in extra-SCN brain regions? Here we focus on the hippocampus, where *Per* 2 clock gene expression in CA1 pyramidal cell layers undergoes a robust circadian oscillation, 180° out-of-phase with that of the SCN. We first evaluated neuronal excitability of CA1 neurons at various times of day in rat hippocampal brain slices using whole-cell patch-clamp recording. Based on recordings from 69 current-clamped neurons, we observed oscillations in membrane potential (Vm) that varied with circadian time (CT), such that neurons were hyperpolarized during the subjective day (-75.98 ± 1.77 mV, CT 7) and depolarized during the subjective night (-68.84 ± 0.64 mV, CT 14). Average resting Vm in midday (CT 5-7) was significantly more hyperpolarized than during the late day (CT 10-12), early night (CT 13-15), or late night (CT 16-20) (-74.99 ± 1.00, -71.43 ± 0.61, -68.46 ± 0.57, and -69.08 ± 0.85 mV, respectively, $p < 0.01$). Next, we assessed time-of-day changes in redox state. Glutathiolation, the capacity of proteins to incorporate reduced glutathione, was lowest in hippocampal tissue at CT 14. This corresponds to a more reduced state. Experimental manipulation of redox state rapidly altered membrane excitability. The reducing reagent, glutathione (GSH, 1 mM), depolarized Vm in a reversible manner. Average GSH-induced changes in Vm were dependent on CT and were significantly larger at midday (CT 7) than any other time ($p < 0.05$). Minimal effects were caused during early night (CT 14). In conclusion, both membrane excitability and redox state undergo circadian oscillations in CA1 neurons in rat hippocampal brain slices. This finding extends observations of coupled non-translational oscillators discovered in the SCN to the hippocampus, and raises questions about molecular and cellular substrates. Insights into these interdependencies are critical to understanding modulatory brain functions organized around the day-night cycle.

(CMMC), Cologne, Germany; [6]Univ. Hosp. of Cologne, Dept. I of Intrnl. Medicine, Ctr. for Endocrinology, Diabetology and Preventive Med. (CEDP), Cologne, Germany

Abstract: The midbrain dopaminergic neurons constitute an essential part of the reward/hedonic system in mammals. *In vivo* studies with combined electrophysiological recordings and behavioral tests showed that the prediction and detection of rewards can be correlated with three firing patterns of dopaminergic neurons: (1) a single spike pattern, (2) a burst pattern and (3) a hyperpolarized state in which the cell remains silent. *In vitro*, dopaminergic neurons have typically been described to be highly regular pacemakers that generate spikes in low frequencies between 1 and 10 Hz (Brain Res Rev. 2008; 58(2), 314-21). This pacemaker activity is intrinsically generated, since it persists in complete synaptic isolation. However, a subpopulation of dopaminergic neurons in the substantia nigra does not generate pacemaker activity, but fires with an irregular spike pattern. Interestingly, the number of irregularly firing dopaminergic neurons increases during ageing. The difference in the spike pattern between pacemaking and irregularly firing dopaminergic neurons seems to be induced by a change of the calcium-dependent pathways (J Physiol. 2010; 588(10), 1719-35 and J. Neurosci. 2014; 34(28):9310-8). We investigate age-dependent, metabolic modulation of the intrinsic electrophysiological properties of dopaminergic neurons. In previous studies we showed that insulin application depolarizes the membrane potential and an increases firing rate in dopaminergic neurons. Mice with an insulin receptor knock-out in dopaminergic neurons exhibited an increased body weight, increased fat mass, and hyperphagia (Cell Metab. 2011; 13:720-728). Here we ask if the irregularly firing dopaminergic neurons are also modulated by fuel sensing signals and whether the modulation differs from dopaminergic neurons with pacemaker activity. To address this question we use perforated patch clamp recordings of synaptically isolated dopaminergic neurons in acute brain slices. Acknowledgments: We thank Helmut Wratil for outstanding technical assistance.

Title: Axonal action potentials in hippocampal dendrite-targeting interneurons

Authors: ***J.-Y. WENG**, C.-C. LIEN;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Activity-dependent modulation of action potential (AP) waveforms occurs in axons of glutamatergic neurons and contributes to synaptic plasticity. Yet, how AP waveforms are regulated in GABAergic interneuron axons is unknown. Here, we combined whole-cell patch-clamp recording and voltage imaging to investigate APs in a typical dendrite-targeting interneuron, oriens-lacunosum-moleculare cells (OLM cells) in the rat hippocampal CA1 region. We found that axonal APs in a train had no accommodation in amplitudes and no broadening in AP width compared to APs in soma and dendrites. Pharmacological experiments indicate that Kv1- and Kv3-like channels underlie AP repolarization and prevent use-dependent AP broadening. Although axonal AP waveforms are not dynamically modulated by activity, AP propagation failures in axons were noted. Notably, axonal AP propagation failures can be reduced by the GABAA receptor blocker SR-95531, but enhanced by the GABAA receptor agonist muscimol. Our results indicate that OLM cells are featured by unique axonal AP signaling.

Title: Contribution of persistent Na+ current and muscarine-sensitive K+ current to perithreshold theta resonance in CA1 pyramidal neurons

Authors: *J. A. VERA, J. ALCAYAGA, J. BACIGALUPO, M. SANHUEZA;
Univ. De Chile, Santiago, Chile

Abstract: Most neurons from hippocampus and other learning- and memory-related areas have the ability to intrinsically generate subthreshold rhythmic activity at theta frequency (4-10 Hz), which may contribute to the strong theta waves observed during hippocampal-related behaviors like navigation or episodic memory formation. Pyramidal neurons from CA1 area receive theta rhythmic inputs from other brain regions, generating place fields. The way these neurons respond to perithreshold oscillatory stimulation and thus their possibility to translate frequency preference into spiking has been controversial; most evidence favors a non-resonant or integrator-like behavior while other studies suggest a resonant behavior. The ionic currents contributing to perithreshold behavior of pyramidal neurons are the persistent sodium current I_{NaP}, a depolarizing fast-activating current that develops above -70 mV and the slower activating, hyperpolarizing muscarine-sensitive K^+ current I_M, with -60 mV threshold potential. With current- and voltage-clamping we conducted a detailed characterization of perithreshold excitability of CA1 pyramidal neurons under oscillatory stimulation by somatic current injection. These neurons displayed two different perithreshold behaviors: 20% of them expressed resonant behavior and translated theta frequency selectivity into spiking (resonant cells), while the other 80% acted as low-pass filters with no frequency preference in their discharge (non-resonant cells). Measurement of I_{NaP} and I_M in the same cells revealed that at perithreshold membrane potentials the activation level of I_M was generally low, while that of I_{NaP} was high enough to depolarize the neurons toward spike threshold overcoming the subtle hyperpolarizing effect of I_M. This explains the more abundant non-resonant perithreshold behavior. After partial pharmacological block of I_{NaP} or subtracting it by dynamic clamp, it was possible to turn non-resonant behavior into resonant, demonstrating that the difference between both groups is the activation level of I_{NaP}. Furthermore, changing the activation range of I_M towards hyperpolarized potentials by dynamic clamp also transformed non-resonant neurons into resonant. We propose that the relative levels of I_{NaP} and I_M control perithreshold behavior of pyramidal neurons. The fact that these two currents are highly modulated by intracellular signaling and neuromodulators

provides a fast mechanism to tune perithreshold frequency preference and selective firing in CA1 according to cell and network activity.

Title: Cell-autonomous function of NMDA receptors in the development of intrinsic excitability of thalamocortical neurons

Authors: ***Z.-W. ZHANG**, G. HOU, M. PETERSON, H. LIU;
The Jackson Lab., Bar Harbor, ME

Abstract: Neurons and synapses undergo extensive changes in functional properties during early life. In newborns glutamatergic synapses contain few or no AMPA-type receptors (AMPARs) and synaptic transmission is primarily mediated by N-methyl-D-aspartate receptors (NMDARs). Synaptic maturation is associated with an increase of AMPARs at the synapses, and in many brain regions, this upregulation of AMPARs requires NMDAR-mediated signaling. Together with synaptic maturation, the intrinsic properties of neurons show dramatic changes during early life. These include negative shifts in resting membrane potential and action potential threshold, a reduction of input resistance, and an acceleration of action potential kinetics. Little is known, however, about the role of NMDARs in the development of intrinsic excitability of neurons. To address this important question, we deleted NMDARs in a fraction of neurons in the ventral posterior medial nucleus (VPm) of the thalamus using a transgenic Cre strain driven by the serotonin transporter (SERT). In SERT-Grin1 mutant mice, 30-60% of VPm neurons lack functional NMDARs while the remaining neurons have normal NMDAR function. We performed patch clamp recording in acute brain slices from VPm neurons with or without NMDARs. Neurons without NMDARs showed a much higher excitability than those with NMDARs. Compared with VPm neurons with NMDARs, those lacking NMDARs required much smaller currents for activation and showed a higher gain. In addition, neurons without NMDARs showed a reduction of HCN channel function, an increase in input resistance, and

smaller soma. There was no difference in the resting membrane potential or action potential threshold between cells with and without NMDARs, suggesting that the general health of VPm neurons was not affected by NMDAR deletion. In contrast to the effects of NMDAR knockout, deletions of AMPARs had no significant effect on intrinsic properties of VPm neurons. Our results suggest that NMDARs are required for the maturation of intrinsic excitability of thalamic neurons.

Title: Aloe vera linn (liliacee) increases brain sodium-potassium atpase activity in streptozotocine-induced diabetic female wistar rats

Authors: ***A. O. MAHMUD-IMAMFULANI**[1,2], E. O. ALAYE[2], B. V. OWOYELE[2]; [2]Physiol., [1]Univ. of Ilorin, Ilorin, Nigeria

Abstract: Background: Diabetes mellitus (DM) may affect the morphology and plasticity of the brain, leading to cognitive, memory, and electrophysiological impairment. Streptozotocine-Induced (STZ-induced) diabetes leads to a sustained up-regulation of facilitatory adenosine A2A receptors in the hippocampus. Brain Sodium-Potassium ATPase (Na+/K+-ATPase) enhance neuroprotection, memory consolidation and diminishes cognitive deficits. Thus, it has been observed that brain Na+/K+-ATPase activities is reduced in diabetic state in male animals. We therefore aim to determine the effects of caffeine (an adenosine receptor antagonist) on brain Na+/K+-ATPase activities in STZ-induced diabetic female rats. Materials and Methods: Four groups of 7 female Wistar rats each, aged 12-13 weeks old and weighing between 150-200g were used for the study. Group 1 were control; group 2 were diabetic untreated; group 3 were diabetic administered 300mg/kg BW Aloe Vera gel orally and group 4 were diabetic administered 300mg/kg BW Aloe vera pulp and gel. DM was induced with 50 mg/kg STZ. At the end of the experiments, rats were anaesthetised, brains were removed, weighed and homogenized in sucrose solution and kept at 40C. Protein determination and assay for the enzyme were carried out within 24 hours of sample collection. Na+/K+-ATPase activities were expressed as µmolPi/mg protein/hour x 10-3. Results: The results showed a significant ($P < 0.05$) decrease in Na+/K+-

ATPase activities of untreated DM group (250.9 ± 0.26) when compared with control group (415.6 ± 0.26). Also groups 2 and 3 treated with Aloe vera gel and Aloe vera pulp & gel showed significant ($P < 0.05$) increase in Na+/K+-ATPase activities (466.8± 0.48 and 473.5± 0.71 respectively) when compared with diabetic untreated group. Conclusion: In conclusion, the findings from this study shows that Aloe vera linn pulp and gel improves and restores the brain Na+/K+-ATPase activities in diabetic rats. Thus moderate Aloe Vera intake could be beneficial to brain functions in diabetic animals and man.

Title: Novel systems for isolation and functional analysis of adult NG2 condroitin sulfate proteoglycan-expressing cells

Authors: ***N. KIKUCHI(NIHONMATSU)**, X. YU, Y. MATSUDA, M. WATANABE, Y. TATEBAYASHI;
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: NG2 condroitin sulfate proteoglycan-expressing cells (NG2 cells) are widely distributed throughout the brain, both in gray matter and white matter, around 5% of all cells in the adult rodents. The cell cycle time of NG2 cells increased from early postnatal to adult by use of the accumulation of BrdU labeling cells and the production of oligodendrocytes is well known to decrease steadily during adulthood, suggesting that adult NG2 cells might play a more important role as the maintenance of physiological conditions rather than the production of oligodendrocytes and further that there are different characters between the adult and developmental NG2 cells. We have recently established a novel method to isolate and expand NG2 cells from adult rat brains (A-NG2 cultures). In the present study, we confirmed our culture systems for isolation and maintenance of A-NG2 cultures in detail. To isolate NG2 cells from other CSF cells, we used the buoyant density by a step gradient with OptiprepTM. A major thick layer at the lower density than microglias and neuronal stem cells was apparent after centrifugation, while a precipitation was found at the bottom of the tube (P fraction). After a

major layer was expanded on dishes more than for 30min, the supernatants including non-adherent cells and the debris were removed from dishes (sup-wash fraction). Western blot analysis reveled that sup-wash fraction and P fraction contained the debris or cells of microglias and myelin. A-NG2 cultures were effectively grown and maintained in basic fibroblast growth factor (FGF2) instead of platelate-derived growth factor (PDGF), suggesting that FGF2 was crucial for proliferation of adult NG2 cells, whereas many previous reports have shown that PDGF was required for proliferation of developmental NG2 cells *in vitro* and *in vivo*. The morphology of the A-NG2 cultures containing FGF2 was consistent with those of adult NG2 cells *in vivo*. B27 minus antioxidants (B27-AO) caused apoptosis and inhibited proliferation. Furthermore, we found the new functions associated with neurodegenerative disorder on adult NG2 cells by using our culture system. Taken together, our data is highly suggestive that A-NG2 cultures are novel systems for investigating the physiological mechanisms of NG2 cells in the adult brain.

Title: IL-1β impedes oligodendrocyte progenitor cell migration after chronic cerebral hypoperfusion

Authors: ***L. JIANG**[1], J. ZHANG[2], Z. CHEN[1], W. HU[1];
[1]Dept. of Pharmacology, Col. of Pharmaceut. Sci., Zhejiang Univ., Zhejiang, China; [2]Zhejiang Univ. Sch. of Med., Sir Run Run Shaw Hosp., Hangzhou, China

Abstract: Subcortical ischemic vascular dementia (SIVD) induced by chronic hypoperfusion is a common subtype of vascular dementia, with characteristics of white matter damage and

cognitive behavior impairment, yet the detailed pathogenic mechanism is still unclear. Our previous and others work imply that glial activation participates in the development of SIVD. IL-1β is one of the major proinflammatory cytokines secreted by glia, however, its role in SIVD is not appreciated. We found that IL-1β elevated from 1d to 7d and returned to baseline at 14d in corpus callosum after right unilateral common carotid arteries occlusion (rUCCAO). Administration of IL-1 receptor antagonist (IL-1Ra), from 1d to 7d (1 μg, i.c.v.), rescued the downregulation of MBP caused by hypoperfusion on 34d. Electron microscopy showed that IL-1 Ra treatment increased the number of myelinated axons after rUCCAO. In IL-1 receptor knockout (IL-1R KO) mice, there is no difference between rUCCAO group and sham group both in MBP expression and myelin numbers, while the percentage of axons with thin myelin increased after hypoperfusion. We also showed that IL-1 Ra reversed the decrease of NG2+ oligodendrocyte progenitor cells (OPCs) number in corpus callosum at 8d after hypoperfusion, however IL-1R KO mice did not display obvious loss of OPCs after hypoperfusion. Besides, by using Brdu labeling we confirmed that IL-1β did not affect the proliferation of OPCs in SVZ. However, we found that IL-1 Ra and IL-1R KO increased the number of Brdu+ NG2+ cells in corpus callosum after hypoperfusion, which suggests that IL-1β inhibits OPCs recruitment from SVZ to corpus callosum to inhibit remyelination. To further verify that, the proliferating newborn cells in SVZ are traced by retrovirus injection, and we found that IL-1Ra treatment elevated newborn cell number in corpus callosum, which can be reversed by co-treatment with IL-1β. In addition, IL-1R KO mice also exhibited the upregulation of newborn cell number in corpus callosum after rUCCAO. Moreover, IL-1 Ra administration significantly rescued the decrease of the discrimination index in object cognition test, the increase of escape latency during the acquisition trials and the reduction of time spent in the target quadrant in Morris water test at 28d after rUCCAO, while IL-1R KO animals did not exhibit any cognitive impairment after hypoperfusion, which suggests that IL-1β impaired learning and memory ability caused by hypoperfusion. In conclusion, the upregulation of IL-1β at early stage after rUCCAO results in poor remyelination after chronic hypoperfusion through blocking OPCs migration. So, IL-1β may serve as a potential therapeutic target for SIVD.

Title: Molecular compartmentation of cerebral white matter revealed with Perls iron stain

Authors: *N. M. SINGLETARY[1,2], J. M. DOOYEMA[3], D. A. GUTMAN[4], T. M. PREUSS[3]; [2]Neurosci. and Behavioral Biol., [3]Yerkes Natl. Primate Res. Ctr., [1]Emory Univ., Atlanta, GA; [4]Neurology, Psychiatry, Bioinformatics, Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Previous studies of iron-stained histological sections have characterized the distribution of iron in cerebral white matter as "patchy" (e.g., Connor et al., 1990, J Neurosci Res 27:595-611; Todorich et al., 2009, Glia 57:467-478). However, the three-dimensional distribution of iron staining has never been determined. To examine this distribution, we made serial reconstructions through human frontal and temporal cortex sections stained with the Perls DAB method, which preferentially stains for ferric iron. We stained 25 micron-thick formalin-fixed, paraffin-embedded sections from the frontal lobes of 16 humans, 14 chimpanzees, and 8 rhesus macaques for Perls DAB using identical incubation conditions and times. All tissues were collected at autopsy or necropsy in accordance with approved IRB and IACUC protocols. All three species showed the expected patchy patterns, but staining density was much greater in humans than in chimpanzees or macaques. Therefore, we carried out our serial reconstruction in humans. We mounted 19-30 consecutive 25-micron thick tissue sections from 3 separate paraffin blocks of temporal lobe cortex and 2 blocks of frontal lobe cortex onto slides and stained them for Perls DAB. After scanning the tissue sections into digital images, we registered the images with the bUnwarpJ function in Fiji (ImageJ), using blood vessels as landmarks. We normalized the contrast of the tissue sections before creating a three-dimensional reconstruction of the portion of the block using Fiji's Volume Viewer plugin. Examination of three-dimensional serial reconstructions reveals that Perls stain-rich and stain-poor territories form elongated and interdigitating "channels" through white matter on the order of 100 microns in cross-sectional diameter. Given the limited size of the reconstructions, we cannot state the exact length of the channels, but some cover the full 750-micron depth of the most complete reconstructions. The significance of these channels is unclear, but there are several possibilities. One is that these channels represent different fiber contingents within the white matter. Alternatively--or complementarily--the compartments represent different types of oligodendrocytes, one enriched in iron (or ferric iron) and one not.

Title: Olig2+ progenitors and gnas tumor suppressor in shh-medulloblastoma

Authors: *H. XUELIAN, L. ZHANG, R. LU;
Dept. of Pediatrics Cancer & Blood Dis. Inst. Cincinnati Children', Brain Tumor Ctr., Cincinnati, OH

Abstract: Medulloblastoma, the most common malignant childhood brain tumor, exhibits distinct molecular subtypes and cellular origins. Genetic alterations driving medulloblastoma initiation and progression remain poorly understood. Recently we identify GNAS, encoding the G-protein Gsα, as a potent tumor suppressor gene that defines a subset of aggressive Sonic Hedgehog (Shh)-driven human medulloblastomas. Ablation of the single Gnas gene in anatomically-distinct progenitors is sufficient to induce Shh-associated medulloblastomas, which recapitulate their human counterparts. Gsα is highly enriched at the primary cilium of granule neuron precursors and suppresses Shh-signaling by regulating both the cAMP-dependent pathway and ciliary trafficking of Hedgehog pathway components. Elevation of a Gsα effector, cAMP, effectively inhibits tumor cell proliferation and progression in Gnas mutants. Furthermore, we identify a population of Olig2-expressing progenitor cells are the major source of tumor-propagating cells. Deletion of Olig2 leads to a delay of tumor progression. Eliminating the mitotic Olig2-expression inhibits tumor initiation. Thus, our present studies identify a previously unrecognized tumor suppressor function for Gsα that acts as a molecular link across Shh-group medulloblastomas of disparate cellular and anatomical origins, and reveal that Olig2-expressing progenitors are the critical cell origin of G-protein-mediated SHH subgroup medulloblastoma, illuminating potential therapeutic avenues for SHH medulloblastoma by targeting G-protein and Olig2-expressing glial progenitors.

Title: Fkbp5/FKBP51 mediates excitotoxin-induced oligodendrocyte damage

Authors: ***S.-H. LIN**[1,2], S.-Y. CHUANG[1,2], Y.-L. GAN[1,2], Y.-H. LEE[1,2];
[2]Physiol., [1]Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: White matter damage, as defined by the axon-oligodendrocyte (OLG) damage and demyelination, is a major cause of functional disability and cognitive deficit in various brain injuries and neurodegenerative diseases such as ischemic stroke, Alzheimer's disease and schizophrenia. Our previous study has demonstrated the glucocorticoid receptor (GR)-mediated protection of OLGs against excitotoxicity via upregulating erythropoietin (Epo). Here we further revealed that a GR cochaperon FK-506 binding protein 51 (FKBP51, encoded by Fkbp5 gene), a GR target gene that mediates a negative feedback loop to maintain the homeostasis of GR activity and stress response, is elevated by excitotoxic AMPA stimulation in primary rat OLGs as well as excitotoxic NMDA stimulation in primary rat cortical neurons. The elevations of Fkbp5 mRNA and FKBP51 were accompanied with a reduction of myelin basic protein (MBP) and PLP expression in AMPA-treated OLGs, and these effects were reversed by a pretreatment with AMPA receptor antagonist CNQX. Furthermore, we found that knockdown of Fkbp5 expression with specific siRNA can attenuate the AMPA-induced MBP reduction and enhance Epo expression in OLGs. These results suggest that elevation of Fkbp5/FKBP51 may contribute to the excitotoxicity-induced demyelination process that leads to white matter degeneration.

Title: Models of plasticity and learning employing adaptive temporal delays

Authors: ***S. PAJEVIC**[1], P. J. BASSER[2], R. D. FIELDS[2];
[2]NICHD, [1]NIH, Bethesda, MD

Abstract: Temporal precision required in neural system processing can range from the sub-millisecond in sound localization and echolocation, to milliseconds and hundreds of milliseconds in perceptual and motor processing tasks. At a level of signal conduction through axons between individual neurons, the arrival time of action potentials from different neurons requires millisecond precision. It has been proposed that to achieve such precise timing, adaptive regulation of these temporal delays is required. Dynamic modulation of myelination potentially provides one mechanism to control impulse arrival times. However, the focus here is on general consequences of having adaptive time delays, rather than on the precise biological mechanism. We divide “delay plasticity” models into two groups based on the feedback mechanism they utilize. The first is activity-dependent delay plasticity (ADDP), in which the learning rule modifies the time delays based on the locally observed activity level; the second is temporal-mismatch delay plasticity (TMDP). These two learning paradigms were implemented using a framework of delay coupled non-linear oscillators and spiking neural networks with adaptive delays (where TMDP becomes spike-timing-dependent delay plasticity (STDDP)). In both these models we compare and contrast the roles played by synaptic and delay plasticity. We show how a simple local ADDP rule stabilizes a system of coupled oscillators and extend this finding to the case of spiking neural networks. The STDDP is studied in the context of temporal sequence learning. Traditionally, sequence learning has been modeled in terms of specialized neural network architectures implementing tapped delay lines, temporal sequence selection through the mechanisms of spike-timing-dependent plasticity (STDP), or through synaptic triads, and other mechanisms utilizing synaptic plasticity. In this work we introduce a simple feed-forward neural network for sequence learning that utilizes both STDP and STDDP as an effective model for comparing the two plasticity modes. Both detect a mismatch locally at the synapse, but the latter additionally requires retrograde transport, which is inherently slower. We argue that implementing both plasticity mechanisms is needed to provide an optimal trade-off between the speed on one hand, and the efficiency and precision on the other. Our results indicate that the delay plasticity, such as myelin plasticity, is a highly efficient way to make a system stable and learn temporally precise tasks efficiently.

Title: Role of A-type K^+ currents in synaptic integration and calcium signaling in NG2 glial cells

Authors: *W. SUN, D. DIETRICH;
Univ. Clin. Bonn, Bonn, Germany

Abstract: It is well established that NG2 expressing oligodendrocyte precursor cells receive direct synaptic inputs from neurons. The functional role of neuron-NG2 synaptic transmission still remains unclear. The morphological and physiological properties of neuron-NG2 synapses are similar to classic neuron-neuron synapses. However, the output of synaptic integration in NG2 cells differs from neurons due to the absence of action potentials. Thus, integration of excitatory post synaptic potentials (EPSPs) in NG2 cells is graded and does not follow "all-or-none" behavior. In this study we demonstrated that especially A-type K^+ currents play a pivot role for integration by curtailing EPSPs while the amplitude of EPSPs was barely altered due to compensatory recruitment of fast voltage-activated Na^+ currents. It has been speculated that neuronal activity could activate postsynaptic signaling pathways which are important for the proliferation and/or differentiation of NG2 cells. We discovered that Ca^{2+} signaling could be directly triggered by mock synaptic potentials through activation of voltage-gated Ca^{2+} channels. These somatic Ca^{2+} transients also back-propagated to distal dendrites. Interestingly, blockade of A-type K^+ currents significantly increased the fraction of detectable Ca^{2+} transients and also increased the amplitude of Ca^{2+} transients. Therefore, our results suggest that A-type K^+ currents are important for gating Ca^{2+} entry into NG2 cells. Finally, by combining 2-photon glutamate uncaging and 2-photon Ca^{2+} imaging, we revealed that in the absence of A-type K^+ currents, NG2 cells could discriminate additional synaptic inputs during an ongoing global postsynaptic depolarization. This discrimination was represented by local dendritic calcium signals at individual dendritic branches, and the somatic electrical response was hardly altered. Therefore it appears that local calcium signaling, gated by dendritic A-type K^+ channels, serves as a localization indicator for additional synaptic inputs in NG2 cells. In summary, our study suggests a pivotal role of A-type K^+ channels in gating synaptic integration and calcium signaling in NG2 cells, which is clearly different from classical synaptic integration known from neurons.

Title: Probing intracellular zinc status in developing and mature oligodendrocytes

Authors: *C. M. ELITT[1,2], J. WANG[2], A. BACH[2], C. J. FAHRNI[3], P. A. ROSENBERG[1,2]; [1]Neurol., Boston Children's Hosp., Boston, MA; [2]F.M. Kirby Neurobio. Ctr., Boston Children's Hosp. and Harvard Med. Sch., Boston, MA; [3]Sch. of Chem. and Biochem. and Petit Inst. for Bioengineering and Biosci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Zinc homeostasis is important for oligodendrocyte (OL) survival but remains poorly understood. Prior studies have demonstrated that increases in cytosolic mobile or free ionic zinc are essential for excitotoxic and nitrative injuries to mature OLs (Mato et al., 2013, Zhang et al., 2006) but few studies have been pursued in developing OLs. We hypothesized that zinc handling might be developmentally regulated in OLs. Mixed glia cultures were isolated from postnatal day 2 (P2) rat forebrains and grown for 10-17 days. Developing OLs were separated from microglia and astrocytes using selective detachment and then plated onto coverslips. Cells were maintained in the presence of platelet-derived growth factor (PDGF) and basic fibroblast growth factor (FGF) for 8 days prior to imaging. To produce mature OLs, PDGF and FGF were replaced by triiodothyronine (T3) and ciliary neurotrophic factor (CNTF). Zinc imaging was performed using Chromis-1, a new Zn(II)-selective ratiometric fluorescent probe that has been optimized for two-photon excitation fluorescence microscopy (TPEM). Baseline fluorescence measurements were collected in developing and mature OLs preloaded with Chromis-1 and then cells were treated with either exogenous zinc (1 nM) combined with sodium pyrithione (2 nM) or the transition metal ion chelator, N,N,N',N'-tetrakis(2-pyridylmethyl)ethane-1,2-diamine (TPEN, 10 μM). For each condition, we measured the two-photon excited fluorescence intensity through two band-pass filters (425-462 nm and 478-540 nm, respectively), and calculated the corresponding intensity ratio image for the two channels. The Zn(II) saturation of Chromis-1 was significantly increased in developing vs mature OLs as judged from the different intensity ratios of 1.25 ± 0.07 vs. 0.65 ± 0.12, respectively (n=5, $P<0.005$; total cells imaged included 158 developing OLs

and 169 mature OLs). Furthermore, the intensity ratio was decreased by chelation with 10 μM TPEN and increased by application of exogenous zinc at concentrations as low as 1 nM. Our data suggest that buffered cytosolic Zn(II) is downregulated as oligodendrocytes mature. Chromis-1 represents an important new tool for investigating zinc homeostasis in oligodendrocytes and other cells under physiologic and pathophysiologic conditions. Future studies will investigate the role of changing intracellular zinc levels in oligodendrocyte development and in response to injury.

Title: Oligodendrocytes beyond the precursor stage generate $Na_v1.2$-driven action potentials into early adulthood

Authors: ***E. BERRET**, K. JUN HEE;
Physiol., UTHSCSA, San Antonio, TX

Abstract: Oligodendrocyte maturation and axon-glial communication are required for proper myelination in the developing brain. Although axon myelination continues until early adulthood, the physiological characteristics of oligodendrocyte lineage cells remain largely understudied in mature brains. Oligodendroglia excitability is a potentially important mechanism for promoting axon myelination, but the necessity of Na^+ channel and electrical excitability of oligodendroglia in relation to their maturation to myelinating stage is controversial. We investigated the spiking properties of oligodendrocytes in their pre-myelinating stage (pre-OLs; CNPase-positive, NG2-negative) and compared them with spiking in oligodendrocyte precursor cells (OPCs, NG2-positive). We found two distinct classes of pre-OLs: one had typical passive membrane properties, while the other expressed substantial voltage-activated Na^+ currents and generated action potentials in response to depolarizing current injections. Electrophysiological, pharmacological, and immunostaining data demonstrate that spiking in excitable pre-OLs was driven by $Na_v1.2$ channels. Of particular interest is that excitable pre-OLs were detected

throughout postnatal development up to postnatal day 62. Thus, $Na_v1.2$-driven spiking is not limited to OPCs nor to a transient stage of brain development. Rather, spiking behavior of immature oligodendrocytes persists into the young adult brain. These results indicate that spiking in oligodendrocyte lineage cells is required for their normal differentiation and maturation.

Title: The integrated stress response in perinatal diffuse white matter injury

Authors: ***B. CLAYTON**, B. POPKO;
Univ. of Chicago, Chicago, IL

Abstract: Perinatal diffuse white matter injury (DWMI) is a disorder associated with premature birth, which is increasing in prevalence and leads to cognitive and behavioral deficits in 40-50% of preterm infants. PWMI is caused by hypoxic, ischemic, and inflammatory insults that damage oligodendrocyte precursor cells (OPCs) leading to reduced myelination. We are currently exploring the integrated stress response (ISR) in PWMI. The ISR is a conserved cellular stress response initiated by a variety of cellular stresses, which lead to phosphorylation of eIF2α through activation of one of four stress sensing eIF2α kinases. Phosphorylation of eIF2α inhibits global protein translation while selectively increasing the translation of the transcription factor ATF4. ATF4 induces the expression of cytoprotective proteins, including anti-oxidant enzymes. Importantly activation of the ISR is initially protective, while prolonged activation of the ISR in the face of unresolved stress can lead to apoptosis via CHOP. In non-neuronal cells hypoxia and ischemia activate the ISR, which provides protection from these insults. Here, we present data showing that the ISR is activated in OPCs following oxygen-glucose deprivation (OGD), an *in vitro* model of hypoxia and ischemia. Moreover, inhibition of the ISR sensitizes OPCs to OGD and enhancement of the ISR provides increased protection. Additionally, we present data

Deleted: in vitro

demonstrating that genetic manipulation of the ISR affects myelin outcome in mouse models of perinatal diffuse white matter injury. This study addresses the role of the ISR in survival of OPCs during hypoxia and ischemia and myelination in perinatal DWMI.

Title: Experimental ablation of NG2-expressing glial progenitor cells induced neuronal cell death by pro-inflammatory pathway

Authors: ***M. NAKANO**[1,3], Y. TAMURA[1,2], A. EGUCHI[1,2], M. YAMATO[1,2], S. KUME[1,2], Y. KATAOKA[1,2,3];

Abstract: Glial progenitor cells expressing chondroitin sulfate proteoglycan 4 (NG2) are termed as NG2 glial cells (or oligodendrocyte precursor cells). NG2 glial cells comprise the majority of proliferative cells in the adult central nervous system (CNS). They also can migrate, proliferate, differentiate and modulate the neuronal network in response to the alteration of surrounding environments, such as acute CNS injury or neuronal activation. Although NG2 glial cells have a compensating function to keep the constant cell density in the tissue, the ability gradually declines with aging. These findings support the hypothesis that NG2 glial cells maintain the homeostasis in adult CNS, and that the dysfunction of them leads to impairment of neuronal function and neurodegeneration such as Alzheimer's disease. To test this hypothesis, we have generated transgenic rats expressing herpes simplex virus thymidine kinase (HSVtk) under the control of the promoter for NG2 (NG2-HSVtk Tg rats). HSVtk is a suicide gene that converts ganciclovir (GCV), a synthetic analog of nucleoside into a toxic triphosphate form, which can be incorporated into genome and terminate DNA synthesis. Thus, proliferative cells expressing HSVtk are sensitive to GCV compared with non-dividing cells. Therefore, this strategy allows

selective ablation of NG2 glial cells in NG2-HSVtk Tg rats. By continuous administration of GCV into the lateral ventricle, we succeeded in rapid degeneration of NG2 glial cells in the surrounding area of the ventricle including the hippocampus. Following ablation of NG2 glial cells, hippocampal neurons were gradually degenerated. Moreover, expressions of interleukin (IL)-1β, IL-6 and TNFα were dramatically up-regulated following ablation of NG2 glial cells, and then a large number of activated microglial cells appeared. The expression of Bcl-2, anti-apoptotic gene, was also down-regulated after the ablation of NG2 glial cells. These data indicated that hippocampal neurons were vulnerable to neuroinflammation in the NG2 glial cell-ablated brain. To further investigate the mechanism of neuronal defect, we inhibited the IL-1β pro-inflammatory pathway by the co-administration of IL-1 receptor antagonist (IL-1ra), which is an endogenous competitive antagonist for IL-1 receptors. The treatment of IL1ra attenuated the neuronal cell death induced by ablation of NG2 glial cells. These results suggested that the ablation of NG2 glial cells leads to neuronal cell death through the pro-inflammatory IL-1β pathway.

Title: Gray matter NG2 cells release exosomes that contain non-alpha GFAP isoforms and NG2

Authors: *R. JABS[1], J. WALTER[2], M. VAN STRIEN[3], E. M. HOL[3], C. STEINHÄUSER[1], K. GLEBOV[2];
[1]Inst. of Cell. Neurosciences, Univ. of Bonn, Bonn, Germany; [2]Dept. of Neurol., Univ. of Bonn, Bonn, Germany; [3]Dept. of Translational Neurosci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: NG2 cells are the only non-neuronal cells in the CNS that receive synaptic input from pre-synaptic neurons. Post-synaptic signals are sensed by a variety of voltage- and ligand-

activated ion channels. However, the physiological relevance of this synaptic signaling is enigmatic. It is known that NG2 cells express multiple Ca2+-signaling pathways. In other glial cell types, namely microglial cells and oligodendrocytes, neurotransmitters activate Ca2+-dependent signaling pathways that regulate the release of glial exosomes. Finally, it has been shown that cleaved NG2 is able to modulate neuronal networks in an activity-dependent manner. This experimental evidence raises the question whether NG2 cells also release exosomes. In this study we demonstrate first Simvastatin-evoked release of exosomes from Oli-neu cells, a well-established culture model of NG2 cells. Oli-neu derived exosomes contain the marker proteins Alix, insulin degrading enzyme (IDE), and flotillin-1. In addition, we also demonstrate the presence of glial fibrillary acidic protein (GFAP) and NG2 itself as cargo of the exosomes. PCR analysis revealed different non-alpha GFAP isoforms in Oli-neu cells. Immunoblotting of exosome preparations indicated at the protein level non-alpha GFAP isoforms being part of exosome cargo. Fluorescence microscopy revealed a close spatial association of flotillin-1, IDE and GFAP in the soma and also in the typical fine processes of Oli-neu cells. Next we analyzed authentic NG2 cells in acute brain slices and combined electrophysiological recordings with single cell RT-PCR. These experiments detected mRNA for GFAP isoforms in NG2 cells and also confirmed the absence of the GFAP alpha isoform *in situ*. Taken together, our results indicate exosomal release of non-alpha GFAP isoforms and NG2 from NG2 cells. This pathway might allow efficient feedback signaling from NG2 cells in response to synaptic input from neuronal pre-synapses.

Title: Jam2 inhibits somatodendritic myelination of neurons by oligodendroglia

Authors: ***S. REDMOND**[1], Y. ESHED-EISENBACH[2], F. MEI[1], L. OSSO[1], Y.-A. SHEN[1], S. Y. C. CHONG[1], E. PELES[2], J. R. CHAN[1];

Abstract: It has long been known that myelination occurs solely around neuronal axons. It has previously been shown that oligodendrocytes, the myelin-forming cells of the central nervous system (CNS), are able to myelinate nanofiber substrates above a certain threshold diameter, in the absence of any molecular cues. Interestingly, the gray matter of the CNS contains super-threshold diameter somata and dendrites, which are never myelinated. Utilizing a purified spinal cord neuron myelinating coculture system, we show that the somatodendritic compartment is not myelinated *in vitro* when neuro-glial signaling is intact. When dynamic signaling between neurons and oligodendrocytes is interrupted by chemical fixation, oligodendrocytes no longer avoid wrapping myelin membranes around neuronal somata and dendrites *in vitro*. We have utilized the spinal cord neuron myelinating coculture system to screen for novel signaling molecules that modulate oligodendrocyte myelination of somata and dendrites. We have identified Junction Adhesion Molecule 2 as necessary and sufficient to inhibit oligodendrocyte myelination. Taken together, this work furthers the understanding of the nature of attractive, permissive and/or inhibitory signals that shape CNS myelination.

Abstract: Oligodendrocyte precursor cells (OPCs) are widely distributed throughout the central nervous system. They generate myelinating oligodendrocytes (OLs) during postnatal brain development. Also in adult age OPCs produce new OLs which restore myelin-sheaths in conditions resulting in loss of myelin. OPCs express ionotropic receptors for glutamate, and are involved in synaptic signaling with neurons. Those receptors are located at the postsynaptic sites

of neuron - OPC synapses. It has been suggested that the glutamatergic synaptic input plays a role in the OPCs' proliferation or differentiation, but the results are ambiguous. In freely behaving mice many neurons fire bursts or short trains of action potentials, but the functional properties of axon - OPC synapses during repetitive neuronal activity have not been investigated. Studies on neuron - OPC synapses generally focused on the responses of OPCs to single or double pulse stimulation. Here we investigated the synaptic response of OPCs to different train stimulations of callosal axons *in situ*. We also studied the effects of different stimulation paradigms applied to callosal axons in freely behaving mice, on OPC proliferation and differentiation *in vivo*. We found that the response of an OPC to repetitive stimulation of callosal axons in brain slices consisted of two components: phasic and asynchronous. The phasic response was time-locked to the stimulation pulse while the asynchronous responses continued for up to several hundreds of milliseconds after the stimulation ceased. Stimulation of callosal axons with 20 pulses at 25 or 100 Hz triggered substantial potentiation of the phasic response; while stimulation with 20 pulses at 300 Hz the potentiation was negligible. The rate of asynchronous responses also depended on the stimulation frequency: if the number of pulses was kept constant, 300 Hz trains triggered the least, while 25 and 100 Hz trains triggered the most asynchronous responses. If the stimulation frequency was kept constant, the asynchronous component was more pronounced after the longer than after the shorter trains. Our data demonstrate that callosal OPCs in brain slices use synapses with axons to detect different pattern of axonal activity. To test whether OPCs respond in a distinct way to different patterns of stimulation also *in vivo* we repeatedly stimulated the corpus callosum of freely moving mice with 20 pulses at 25 or 300 Hz. We found that the 25 Hz stimulation significantly increased both the proliferation of OPCs and their differentiation into OLs, whereas 300 Hz stimulation didn't. Thus, proliferation and differentiation of OPCs *in vivo* may depend on the pattern of neuronal activity.

Title: Functional role of AMPA receptors during differentiation of oligodendrocyte precursor cells in mouse corpus callosum

Authors: ***T.-J. CHEN**[1], A. GALL[1], I. EHRLICH[1,2], M. KUKLEY[1];
[1]Werner Reichardt Ctr. for Integrative Neuroscien, Tübingen, Germany; [2]Hertie Inst. for Clin. Brain Res., Tübingen, Germany

Abstract: Oligodendrocyte precursor cells (OPCs), the progenitors of oligodendrocytes (OLs), are widespread in the grey and white matter regions of the central nervous system. OPCs in grey and white matter receive glutamatergic synaptic input from neurons. Transition of OPCs to the premyelinating stage is accompanied by the rapid removal of glutamatergic synaptic input, including downregulation of AMPA receptors (AMPARs). Furthermore, treatment of cultured cerebellar slices with AMPA causes a decrease in the percentage of O1+ cells, as well as in the level of CNP mRNA, pointing to the fact that AMPA application reduces differentiation of oligodendrocyte lineage cells. Based on these findings, we hypothesized that alteration of AMPAR-mediated signaling in OPCs may influence their differentiation into OLs. To test this hypothesis, we first verified the composition of AMPARs in callosal OPCs of NG2DsRed mice at postnatal day 13-17 (P13-17) using electrophysiology. We found that AMPAR-mediated axon-glia currents displayed linear current-voltage (I-V) curve indicating that OPCs contain the GluA2 subunit. Next, we used a viral approach to modify the properties of the GluA2 subunit in different ways specifically in OPCs. Each modifying construct was tagged with green fluorescent protein (GFP) and virus was stereotactically injected into the corpus callosum of mice at P10-12. Animals of the control group received injection of a virus expressing GFP alone. Properties of infected cells were assessed 3-5 days post-injection. To test specificity, we performed immunohistochemistry on brain slices using NG2 and CC1 antibody to label cells of the oligodendroglia lineage. We found that more than 90% of GFP+ cells were NG2+, CC1+, or NG2+CC1+ indicating that the virus specifically targeted cells of the oligodendroglia lineage. To verify the success of GluA2 subunit modification, we recorded the I-V curve of AMPAR-mediated currents in OPCs. We found that in OPCs transfected with a modifying construct, the I-V curve changed from linear to inwardly rectifying indicating that AMPARs with modified properties substituted the endogenous receptors in OPCs *in vivo*. Finally, we studied the effect of AMPAR modification in OPCs on the differentiation of OPCs into mature OLs *in vivo*. We found that this resulted in a reduced percentage of CC1+GFP+ cells within the total population of GFP+ cells, indicating a decrease in differentiation of OPCs into mature OLs. Together, our data suggest that during development glutamatergic axon-OPC signaling through AMPARs containing the GluA2 subunit is a key factor for OPCs differentiation in mouse corpus callosum.

Title: Axo-glia interaction preceding CNS myelination is regulated by bidirectional Eph-ephrin signaling

Authors: *L. S. LAURSEN, C. LINNEBERG, M. HARBOE;
Aarhus Univ., Aarhus, Denmark

Abstract: In the central nervous system, myelination of axons is required to ensure fast saltatory conduction and for survival of neurons. However, not all axons are myelinated, and the molecular mechanisms involved in guiding the oligodendrocyte processes towards the axons to be myelinated are not well understood. Only a few negative or positive guidance clues that are involved in regulating axo-glia interaction prior to myelination have been identified. One example is laminin, known to be required for early axo-glia interaction, which functions through α6β1 integrin. Here we identify the Eph-ephrin family of guidance receptors as novel regulators of the initial axo-glia interaction, preceding myelination. We demonstrate that so-called forward and reverse signaling, mediated by members of both Eph and ephrin subfamilies, has distinct and opposing effects on processes extension and myelin sheet formation. EphA forward signaling inhibits oligodendrocyte process extension and myelin sheet formation, and blocking of bidirectional signaling through this receptor enhances myelination. Similarly, EphB forward signaling also reduces myelin membrane formation, but in contrast to EphA forward signaling, this occurs in an integrin-dependent manner, which can be reversed by overexpression of a constitutive active β1-integrin. Furthermore, ephrin-B reverse signaling induced by EphA4 or EphB1 enhances myelin sheet formation. Combined, this suggests that the Eph-ephrin receptors are important mediators of bidirectional signaling between axons and oligodendrocytes. It further implies that balancing Eph-ephrin forward and reverse signaling is important in the selection process of axons to be myelinated.

Title: Organization of oligodendroglial paranodal junctions requires the netrin-1 receptor Unc5b

Authors: ***O. DE FARIA, JR**, J. M. BIN, A. SADIKOT, T. E. KENNEDY;
BTRC, Montreal Neurolog. Inst. / McGill Univ., Montreal, QC, Canada

Abstract: Netrin-1 and its receptors direct cell and axon migration in the developing CNS. After development is complete, netrin-1 continues to be expressed in the mature CNS and is involved in multiple aspects of adult brain function, including the maintenance of axonal-oligodendroglial paranodal junctions. We have found that the expression of the netrin-1 receptor Unc5b is upregulated in the adult brain, and is enriched at the axonal oligodendroglial paranodal junction of myelinated axons. Our findings indicate that oligodendrocyte-specific deletion of Unc5b *in vivo* does not alter myelin abundance, but in contrast, in the absence of Unc5b, axoglial paranodes become severely disorganized, with glial loops detached and everted away from the axon, along with mild disruption of compact myelin ultrastructure. As a result, caspr-1 immunoreactivity disperses along the axon, consistent with the aberrant invasion of paranodal components into the adjacent specialized domains. Furthermore, we report that mice lacking Unc5b exhibit a reduced life span. Together, our data reveal a novel contribution for Unc5b to the axoglial apparatus that is required for normal paranode organization.

Title: Cerebrospinal fluid biomarkers are associated with medial temporal lobe pathology in preclinical AD

Authors: *A. P. MERLUZZI[1], D. C. DEAN, III[1], C. M. CARLSSON[1], S. C. JOHNSON[1], O. C. OKONKWO[1], J. M. OH[1], N. ADLURU[1], G. SURYAWANSHI[1], H. ZETTERBERG[2], K. BLENNOW[2], S. ASTHANA[1], H. ZHANG[3], A. L. ALEXANDER[1], B. B. BENDLIN[1]; [1]Univ. of Wisconsin - Madison, Madison, WI; [2]Univ. of Gothenburg, Gothenburg, Sweden; [3]Univ. Col. London, London, United Kingdom

Abstract: Background: Alzheimer's disease (AD) is characterized by an accumulation of amyloid plaques and neurofibrillary tangles, yet less is known about how these pathologies progress in preclinical AD. Using a novel multi-shell diffusion-weighted imaging technique, we hypothesized that AD pathology measured in cerebrospinal fluid (CSF) in an at-risk population would be associated with altered neural microstructure in the medial temporal lobes (MTL) - regions which are implicated in early AD. **Methods**: CSF was obtained via lumbar puncture from cognitively healthy participants (n=65, age=61.7 ± 6.26) recruited from the Wisconsin Registry for Alzheimer's Prevention study. It was then analyzed to detect the AD biomarkers neurofilament light protein (NFL), Aβ42, Aβ40, sAPPβ, total tau (tTau), phosphorylated tau (pTau), and the inflammatory markers MCP-1 and YKL-40. Participants also underwent Hybrid Diffusion Imaging (HYDI), and modeling was accomplished with Neurite Orientation Dispersion and Density Imaging (NODDI) to produce measures of neurite density (dendrites and axons), their orientation dispersion, and free water fraction. Linear regression was used to test the relationship between the ratios sAPPβ/Aβ42, tTau/Aβ42, pTau/Aβ42, and Aβ42/Aβ40 on neural microstructure using voxel-wise analysis (SPM12). **Results**: Controlling for age and sex, ratios of sAPPβ/Aβ42, tTau/Aβ42, and pTau/Aβ42 were associated with increased free water fraction in bilateral MTL, and most robustly in the left MTL. In contrast, Aβ42/Aβ40, sAPPβ, tTau, pTau, NFL, Aβ42, and the inflammatory markers were not associated with altered neural microstructure in these regions. **Conclusions**: Left medial temporal lobe structures may be especially susceptible to AD pathology in preclinical populations. In particular, the tTau/Aβ42 and pTau/Aβ42 results suggest a critical role for tau pathology in early AD, but only in conjunction with amyloid deposition. In contrast, the fact that Aβ42/Aβ40 was not associated with an increase in free water fraction suggests that amyloid pathology alone is not sufficient for producing alternations in neural microstructure. Though it is not known what the increase in interstitial water represents at the cellular level, it may be the result of atrophy, axonal loss, inflammation, or myelin alterations. However, the lack of association between NFL and the inflammatory markers on NODDI parameters in these regions argues against axon damage or inflammation. While more studies are needed to determine the precise underlying pathology, these findings further inform the preclinical picture of AD and shed light on the mechanisms of neural injury.

Abstract: Alzheimer's disease (AD) touches 44.4 million people worldwide. AD diagnosis is time-consuming and remains challenging despite progresses in medical imaging and availability of CSF markers. However, identification of pre-dementia stages of the disease remains elusive, rendering stratification of patients enrolled in clinical trial inoperative. This study was designed to confirm the association and to validate the performances of the blood-based ADFlag® test in

the identification of pre-dementia stages of AD. 204 MCI patients enrolled in the Pharmacog cohort were included. A random set of 65 patients, annotated with CSF amyloid-beta peptides (Aβ), Tau and pTau circulating level, hippocampal atrophy and a battery of neuropsychological assessments including MMSE, ADASCog and Boston Namning Test (BNT) were used as a training set. The level of expression of proteins constitutive of the ADFlag® panel was measure in all blood samples, their profile were used to define signatures to differentiate 4 different groups of patients including 3 pre-dementia groups (subjective cognitive impairment (SCI), early mild cognitive impairment (eMCI) and late mild cognitive impairment (lMCI)) within the training set cohort. ADFlag® classification was further validated on a set of 90 patients. In line with the Pharmacog trial design, the ADFlag® panel identified mostly MCI patients, segregated into eMCI (30.0%) and lMCI (51.1%). SCI and putative AD patients were also identified. Consistent with disease progression the age, gender bias, cognitive scales and hippocampal atrophy reflected a proportionally more severe clinical tableau of the disease with the ADFlag® classification. There was no direct association between the ADFlag® classification and Aβ42 level in the CSF, however, a logistic regression analysis showed a significant intercept between Aβ circulating level and ADFlag® classification. This analysis also revealed a significant association between ADFlag® classification and the ADASCog, MMSE and BNT demonstrating a good coherence of this novel diagnostic tool with progressive cognitive loss. Overall, the classification performances of the ADFlag® test were tested against the original diagnostic using a ROC analysis. It showed a predictivity of 72% for SCI patients, 81% for early MCI patients, 82% for late MCI patients and 90% for patients most-likely affected by AD. The ADFlag® panel thus represents one of the first, easy to use blood test, that in combination with standard assessments, can provide physicians with objective information to support stratification of pre-dementia AD patients.

Title: Increasing class separation through isometric transformations in Alzheimer's disease diagnostic

Authors: *F. V. CHIRILA, D. L. ALKON;
Blanchette Rockefeller Neurosciences Inst., Morgantown, WV

Abstract: Many natural phenomena require data classification and increasing separation between two or more data sets. Most of data sets can be linearized through mathematical transformations or they can be linearized locally, i.e. with small variations of related input parameters. Here we propose an algorithm for data classification and increasing separation between linear data sets based on isometric transformations. The practical validation of this method is demonstrated with two Alzheimer's disease diagnostic assays, based on human skin fibroblasts, and lot-to-lot variation of fetal bovine serum. However, the method we propose is general, and has practical application not only for Alzheimer's disease diagnostic but also for other fields such as machine learning, neural networks, data mining, gene expressions, pattern recognition, cognitive psychology, or astronomy. To demonstrate this generality we also validated this algorithm on randomly generated data sets with a 10% additive noise. Different lots of fetal bovine serum had been found to cause changes in the assay outputs. The overlap probability between the Alzheimer's disease (AD) group and age-matched control (AC) group is 1.2x10-2 for the five lots of fetal bovine serum used in this study. The overlap probability after the algorithm application drops ~7 orders of magnitude to 5.5x10-9. The percent increase in separability is augmented at least two orders of magnitude for the five lots of fetal bovine serum used in this study.

Abstract: Development of early diagnosis platform of AD in a simple and non-invasive way using blood is urgently required. Using the isobaric tagging for relative and absolute quantitation (iTRAQ) proteomic approach, we analyzed differentially expressed proteins (DEPs) of mild cognitive impairment (MCI) and AD patients, compared with cognitively normal controls. Serum samples of control, MCI and AD which were selected according to their PiB-PET scores were used for iTRAQ experiment. We have identified 121 DEPs and showed a network model of them based on bioinformatics tools. To check the possibility of these DEPs as potential biomarkers, we estimated the levels of several proteins in serum which were increased in MCI and AD from the iTRAQ result by performing ELISA and some of these proteins showed significant difference among these individuals. Therefore, we suggest that these DEPs from iTRAQ experiment and bioinformatics analysis have possibilities as early detectable biomarkers of MCI and AD.

Abstract: Alzheimer's disease (AD) is a cognitive neurodegenerative disorder characterized by two hallmark pathological lesions in the brain architecture, amyloid plaques and neurofibrillary tangles (NFT). These are caused by the aberrant accumulation of Aβ and tau proteins. Changes in protein levels of these neuropathological hallmark proteins in the cerebrospinal fluid (CSF) are currently used as biomarkers of brain amyloid deposition and neurodegeneration in AD diagnostics. To test for potential novel AD biomarkers and to investigate whether CSF can tell us more about development and progression of AD we have examined CSF of individuals with AD (n=13), MCI (n=11), FTD (n=11) and cognitively normal controls (n=4). Proteins were identified using liquid chromatography tandem mass spectrometry (Orbitrap Fusion) and quantified using a label free method. Mass spectrometry analysis identified a profile of 905 proteins. Among these app. 50 were changes between controls and AD, 20 MCI versus AD. Our preliminary results suggest significant changes among CSF proteins between healthy age-matched individuals and MCI and AD. These potential novel CSF biomarkers reflecting the ongoing neurodegenerative processes may allow us to confirm further and distinguish different stages of AD.

Title: On-chip detection of tau mutants and 3R:4R tau ratio based on tau's binding affinity to taxol stablized microtubules

Authors: *S. P. SUBRAMANIYAN[1], M. C. TARHAN[2], S. L. KARSTEN[3], H. FUJITA[2], H. SHINTAKU[1], H. KOTERA[1], R. YOKOKAWA[1];
[1]Kyoto Univ., Kyoto, Japan; [2]LIMMS, Inst. of Industrial Science, The Univ. of Tokyo, Tokyo, Japan; [3]NeuroInDx Inc., Signal Hill, CA, USA, Signal Hill, CA, CA

Abstract: Introduction: Tau protein is a neuronal microtubule (MT) associated protein (MAP) which regulates MT-kinesin dependent fast axonal transportation. Point mutations in tau affecting the binding affinity to MT and splicing site mutation altering 3R:4R tau ratios are biomarkers for early onset of neurodegeneration. Here, we present an on-chip tau detection device comprising of a MT reservoir, channel and an arrowhead shaped collector region, to detect different 3R:4R ratio and major 2N4R mutations (V248L, G272V, P301L, V337M and R406W) using the MT-kinesin system. The detection is based on tau's isoform and mutant specific binding to taxol stabilized MTs, and their interference with kinesin-MT binding. An increase in tau decoration on MTs resulted in lowering of MT-kinesin binding, TAMRA-labeled stabilized MTs decorated with tau isoforms and mutants were assayed in kinesin coated microfluidic device. MTs binding and gliding in reservoir were concentrated at collector region for fluorescent intensity (FI) measurement. By measuring FI at collector we were able to detect the type of tau decorating the MTs, undecorated MTs were taken as control. We differentiated 1:0 vs 0:1 1:0 vs 1:3, 3:1 vs 1:1 and 3:1 vs 0:1 3R:4R tau ratios ($p<0.05$), and the five mutants were differentiated from wild 2N4R. Experimental method: Tau detection device was fabricated through UV-lithography technique. In brief, MT reservoir, channel and collector were micro fabricated on SU8 photo resist coated on a glass substrate. Wild and mutant tau (1 μM) and different ratio 3R: 4R taus (0:1, 1:3, 1:1, 3:1 and 1:0) were incubated with taxol-stabilized TAMRA-labeled MTs (0.5 μM) at 37°C for 30 min off-chip. These MTs in the motility solution were introduced into the device selectively coated with kinesin. The MTs binding and gliding in the reservoir region were concentrated into the collector and FI images were acquired. The images were processed using ImageJ and the FIs were plotted. Results: FI at collector region were significantly ($p<0.05$) lower for MTs decorated with 0:1 vs 1:0, 1:0 vs 1:3, 3:1 vs 1:1 and 3:1 vs 0:1 3R:4R respectively. Further, the FI at collectors of device assayed with 2N4R tau MTs were significantly lower than mutants. Among mutants, FI for P301L was highest followed by V337M, G272V, V248L and R406W. Conclusion: We found that the kinesin-MT molecular system has a potential to differentiate 3R and 4R taus as well as different 3R:4R ratios, and wild from mutant taus. The degree to which mutations affect the tau binding strength can be determined through this method. The detection system can also be extended to analyze other MAPs and motor proteins.

Title: Difference in prevalence of neurogenic markers and regulatory mirna in non-demented with Alzheimer's neuropathology

Authors: *D. BRILEY[1], B. KRISHNAN[2], R. WOLTJER[4], G. TAGLIALATELA[2], M.-A. MICCI[3];

Abstract: Alzheimer's Disease (AD) is characterized by dementia, cognitive declines and the presence of amyloid beta plaques and neurofibrillary tangles in the brain. Recent work has identified a group of subjects who remain cognitively intact despite the presence of neuropathological features associated with fully symptomatic AD. These Non-Demented with Alzheimer's disease Neuropathology (NDAN) subjects represent a unique population in which to study the cellular mechanisms underlying this extraordinary resistance to cognitive decline. Here we tested the hypothesis that preserved cognitive function is correlated with a greater degree of neurogenesis in the hippocampus, a site important for its role in memory and most affected by AD, and determined its potential epigenetic regulation by specific miRNAs. Methods. Paraffin-embedded human tissue representing AD, NDAN, and age-matched healthy control was stained using established immunohistochemical techniques for SOX2, Ki67, doublecortin (DCX), and NeuN. All nuclei were counter-stained using Hoechst. Tiled images of the whole DG were collected to allow for unbiased evaluation of the region, which can vary between subjects, and regions of the DG. Cells positive for each marker were manually counted using ImageJ, and normalized to the total number of cells present in a field (Hoechst-positive objects counted). Fields reflecting different features of the DG (granular layer, sub-granular layer, and hilus) were evaluated separately. Laser Capture Microdissection was used to isolate cells from specific regions of fresh-frozen human hippocampus sections. RNA was isolated and probed using qRT-PCR for miRNA known to regulate neuronal precursor proliferation and maturation. Results. NDAN subjects demonstrate increased expression for markers of neurogenesis, compared with

AD in a site-specific manner. The proportion of DCX and NeuN positive cells were enhanced in the hilus of NDAN compared with AD sujects. Various miRNAs with roles in neurogenesis and neuronal maturation (eg. miR-25, miR-, miR-132) were identified as being altered in NDAN compared with control and AD subjects, and particularly miR-25, while increased in AD, was significantly reduced in NDAN. Conclusions. Our data show that the number of progenitor cells in the hippocampus of NDAN subjects is increased as compared to AD subjects, and similar to controls. Furthermore, increased number of progenitor cells in NDAN may be driven through epigenetic modulation as suggested by differences in the level of expression of specific miRNAs. These data strongly suggest that increased neurogenesis correlates with preserved cognitive function in NDAN subjects.

Title: Neuro-cognitive mechanisms of simultanagnosia following posterior cortical atrophy

Authors: *J. NEITZEL[1,2], M. ORTNER[3], M. HAUPT[1], P. REDEL[1], C. SORG[2], K. FINKE[1]; [1]Ludwig-Maximilians-Universität, Munich, Germany; [2]Dept. of Neuroradiology, [3]Dept. of Psychiatry, Technische Univ. München, Munich, Germany

Abstract: A significant minority of Alzheimer’s disease patients suffer from atypical focal syndromes such as posterior cortical atrophy (PCA). PCA is dominated by initially isolated progressive higher visual and visuo-spatial impairments. One of the major clinical manifestations is simultanagnosia which is the inability to perceive multiple visual objects at the same time. Although widely studied in stroke patients, little is known about the precise neuro-cognitive mechanisms contributing to simultanagnosia in neurodegenerative diseases. This study aimed to (i) specify changes in basic attention parameters underlying symptoms of simultanagnosia, (ii) assess the link to grey and white matter damage, and (iii) integrate those findings into a neuro-

cognitive model of simultanagnosia following PCA. To this end, simultaneous perception of multiple visual objects was tested in 10 PCA patients with verified AD pathology (measured by Pittsburgh compound B positron emission tomography) and 10 healthy aged-matched controls. The critical outcome measure was the percentage of incorrect object identifications. Using whole and partial report of briefly presented letter arrays based on the mathematically formulated 'Theory of Visual Attention' we furthermore quantified and compared visual attention parameters across study groups. Patients demonstrated a specific slowing of visual processing speed, while visual short-term memory capacity was preserved. Furthermore, voxel-based morphometry yielded extensive reductions of grey and white matter in parieto-occipital and thalamic brain areas. Among PCA patients, those with slower processing speed showed more severe symptoms of simultanagnosia. Interestingly, the degree of individual atrophy of white but not of grey matter regions was associated with processing speed. Based on these findings, we propose atrophied white matter commonly observed in PCA leads to slowing of visual processing speed which underlies the overt clinical symptoms of simultanagnosia.

Title: Identification of exosomal proteins specifically released following Aβ1-42 protofibril treatment in co-cultures of primary neurons and glia

Authors: *E. NIKITIDOU[1], P. EMAMI KHOONSARI[2], G. SHEVCHENKO[3], L. LANNFELT[1], K. KULTIMA[2], A. ERLANDSSON[1];
[1]Dept. of Publ. Hlth. and Caring Sciences, Uppsala Univ., Mol. Geriatrics, Uppsala, Sweden;

[2]Dept. of Med. Sciences, Uppsala Univ., Cancer Pharmacol. and Computat. Med., Uppsala, Sweden; [3]Dept. of Chemistry, Uppsala Univ., Analytical Chem., Uppsala, Sweden

Abstract: Decreased Aβ1-42 and increased levels of tau/phospho-tau in cerebrospinal fluid (CSF) indicate biochemical changes typical for Alzheimer's disease (AD). These biomarkers are a useful tool in AD diagnosis, but in order to follow disease progression and monitor drug intervention additional biomarkers, with a more dynamic expression pattern, are needed. Exosomes are small membranous vesicles formed by the invagination of the membrane around cytoplasmic materials. Exosomes have been implicated to have a pathogenic role in AD and it is likely that their content changes during the disease progression, making them a suitable source for biomarkers. The aim with the present study was to identify potential AD biomarkers, by comparing the content of exosomes and larger microvesicles released from primary neurons and glia in the absence and presence of Aβ1-42 protofibrils. Neural stem cells derived from embryonic mouse cortex were differentiated to a mixed culture of neurons, astrocytes and oligodendrocytes and exposed to Aβ1-42 protofibrils for 2 or 5 days, or left untreated. Uptake, degradation and toxicity were studied by immunocytochemistry and time-lapse microscopy. After clearing the sample from any remaining cell remnants, the culture medium was collected and ultracentrifuged to isolate exosomes and larger microvesicles. The presence of exosomes and larger microvesicles was confirmed by transmission electron microscopy (TEM) and their content was analyzed using mass spectrometry. Our data shows that astrocytes effectively engulf Aβ1-42 protofibrils, but store rather than degrade the ingested material. Aβ1-42 protofibrils did not directly induce cell death of neurons or glia, but time-lapse microscopy reveals that exposure of Aβ1-42 protofibrils results in extremely large astrocytic vacuoles, which are not seen in control cultures. The vacuoles appear to collapse and TEM analysis confirms that the cells secrete a variety of microvesicles, including exosomes. Exosomes were successfully isolated from the cell medium and display a disc shaped form. Mass spectrometry analysis revealed over 600 unique proteins that were expressed in exosomes and larger microvesicles. These proteins are involved in various cellular processes, including transcription, translation, inflammation and lysosomal degradation and some have previously been linked to AD. We have selected a few proteins that we consider to be of particular interest and we will next compare their expression in exosomes derived from CSF of AD patients and healthy controls.

Title: The effects of running on hippocampal vasculature and memory in a mouse model of amyloidosis

Authors: *E. MALISZEWSKA-CYNA[1,2], J. J. OORE[1], M. THEODORE[1], L. A. M. THOMASON[3], A. DORR[3], M. M. KOLETAR[3], J. STEINMAN[4,5], J. G. SLED[4,5], B. STEFANOVIC[3,5], I. AUBERT[1,2];

Institute, Toronto, ON, Canada, Toronto, ON, Canada; [4]Mouse Imaging Centre, Hosp. for Sick Children, Toronto, ON, Canada; [5]Dept. of Med. Biophysics; Univ. of Toronto, Toronto, ON, Canada

Abstract: Alzheimer's disease (AD) is associated with cerebrovascular impairments including altered vascular density, increased tortuosity, and capillary fragmentation. Moreover, global hypoperfusion has been found to correlate with amyloid-β accumulation and exacerbated cognitive decline. Targeting the microvasculature is gaining recognition as an important therapeutic strategy for AD. The difficulty in devising such treatment lies in part in the complexity and multitude of factors involved in AD pathology. Physical exercise has the potential to prevent or delay some pathologies associated with AD, including vascular compromise. In addition, physical exercise has the potential to alleviate the burden associated with accumulation of cerebral amyloid angiopathy (CAA) on the vessel walls. We hypothesize that running has beneficial effects on brain microvasculature in a mouse model of amyloidosis. After developing plaque deposits and cognitive deficits, mice were placed for 3 months in a cage equipped with a spinning disk. After 3 months, animals were assessed for spatial memory with the Y-maze task. Subsequently, animals were injected with Methoxy-XO4 to visualize amyloid deposits. 24 hours post injection the animals were perfused with the Nile red enriched Mercox resin to visualize the microvasculature. The brains were then isolated, dehydrated and placed in a clearing solution for 3 days. The complete microvasculature and amyloidosis of the hippocampus was imaged by 2-photon fluorescence microscopy at 512 x 512 nominal in-plane resolution, every 2.5 um, over 0.5 x 0.5 cm x 0.1 mm region using 780 nm excitation. The microvascular network was identified using multi-scale, semi-automated tracking algorithm while CAA was manually segmented using the Imaris software. Pilot data suggest a decrease in capillary diameter and an increase in vessel count, volume and branching in non-running transgenic mice when compared to non-transgenic littermates. The above parameters derived for the vasculature in transgenic running animals were not statistically different when compared to non-transgenic

littermates. CAA surface area and volume were also significantly lower in running compared to non-running transgenic mice. Finally, spatial memory was maintained at higher levels in transgenic running mice compared to transgenic sedentary mice. The importance of vascular health in cognitive function for AD is receiving increasing interest. This research has the potential to provide new treatment options, including promotion of an active lifestyle to prevent or delay AD pathology, ultimately providing a better quality of life in the elderly population and in AD patients

Title: Evaluation of 11C-BU99008, a radioligand for the imidazoline-2 binding sites, as a marker of reactive astrocytosis in a mouse model of Alzheimer's disease

Authors: ***N. MIRZAEI**, R. J. TYACKE, D. J. NUTT, M. SASTRE;
Dept. of Med., Imperial Col. London, London, United Kingdom

Abstract: Amyloid-β (Aβ), which is the main component of neuritic plaques in Alzheimer's disease patients, is believed to induce the activation of microglia and astrocytes in the vicinity of the amyloid deposits, leading to a neuroinflammatory response. Temporal changes in glial activation states are relatively unknown. Live imaging techniques such as positron emission tomography (PET) have enabled measurement and longitudinal monitoring of changes in microglial markers. We have recently developed a new PET tracer for astrocytes [^{11}C](2-(4,5-dihydro-1H-imidazol-2-yl)-1-methyl-1H-indole) ([^{11}C]BU99008), to longitudinally monitor astrocytic activation. This ligand has a high affinity for imidazoline-2 binding sites (also known as I2-imidazoline receptors), which are expressed relatively selectively by astrocytes. We investigated the potential use of this tracer in a mouse model of amyloid pathology. *Ex vivo* binding studies were performed using [^{3}H]BU99008 to characterize the distribution pattern and density of these receptors in 5xFAD mice (females; 6 months old) compared to aged-matched

Deleted: Ex vivo

wild-type controls by autoradiography. Higher [^{3}H]BU99008 binding was detected in the cerebral cortex and hippocampus of 5xFAD brains and more specifically in the subiculum and cortical layer 5. Interestingly, amyloid burden and the expression of astrocyte marker GFAP were significantly increased in the same areas as determined by immunohistochemistry. To further evaluate the regional distribution and cellular localisation of imidazoline receptors, we used two antibodies against Nischarin, a functional imidazoline receptor candidate. The Nischarin staining patterns co-localized with GFAP expression. In conclusion, these results strongly confirm the specificity of the radioligand [^{11}C]BU99008 as a potential marker of reactive astrocytosis and support its use as a human PET tracer for astrocytes.

Title: Disrupted rich club organization in Alzheimer’s disease and subcortical vascular dementia

Authors: ***C. E. HAN**[1], H.-J. KIM[1], W. LEE[1], S. SEO[2], J.-K. SEONG[1];
[1]Korea Univ., Seoul, Korea, Republic of; [2]Dept. of Neurol., Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: The recent advances in magnetic-resonance (MR) imaging techniques and the graph theoretical analysis of the whole brain networks revealed that a few central brain regions are highly interconnected with each other than the others, called ‘rich clubs’ (van den Heuvel and Sporns 2011). This rich club organization has a crucial role in brain’s global communication, and thus was affected by various diseases (van den Heuvel et al. 2013, Ray et al. 2014). Though dementia significantly deteriorates the quality of life in the elderly, it is not well studied yet how dementia changes rich club organization (Daianu et al. 2013). In this study, we investigated rich club organization of patients with dementia; especially, its two common types, Alzheimer’s disease (AD) and subcortical vascular dementia (SVaD). Since their pathological hallmarks were distinct, we hypothesized that they exhibit different disruption pattern of rich clubs in the structural networks. We recruited 61 AD patients with AD, 39 patients with SVaD, and 36 age-, and gender-matched normal controls (NC), and collected their T1-weighted and diffusion-weighted MR images using a 3-Tesla MR scanner at Samsung Medical Center. Institutional Review Board of Samsung Medical Center approved this study, and informed consent for participation was obtained from every participant. We constructed white matter brain networks using MR images, whose nodes are anatomically distinct brain regions defined by automated anatomical labeling (AAL) template (Tzourio-Mazoyer et al. 2002), and whose edges represent relationship between any pairs of two brain regions quantified through deterministic tractography (Mori and Barker 1999). We investigated rich-club organization of these structural networks following van den Huevel et al. (2011). We constructed group-averaged networks for NC, AD, and SVaD, and computed their rich-club coefficient normalized by 1000 degree-preserved random networks. Though all groups showed rich club organization, rich club coefficients of disease groups were higher than NC’s. While the rich club connections were mostly preserved, the local and feeder connections of disease groups reduced differently. The global efficiency was significantly decreased in both diseases but still strongly correlated with the rich club connections consistent with the literature (van den Heuvel et al. 2013). In conclusion, even with dementia, the structural network of brain follows the rich club organization and its rich club connections play a crucial role in global communication. Our study showed that AD and SVaD disrupt the rich club organization in different manners.

Title: Comprehensive screening of amyloid-β aggregation inhibitors by a microliter-scale high-throughput screening system with quantum dot-based imaging technology

Authors: *K. TOKURAKU, T. TAKAHASHI, Y. BABA, R. TAGUCHI, Y. HASHI, K. UWAI;
Dept. of Applied Sci., Muroran Inst. of Technol., Muroran-Shi, Japan

Abstract: The amyloid hypothesis is widely known and accepted as the pathogenesis of Alzheimer's disease (AD). In the hypothesis, the aggregation and accumulation of amyloid-β (Aβ) peptides in the brain is considered as the primary influence driving AD pathogenesis. Therefore, we believed that the Aβ aggregation inhibitors have a potential to become lead compounds for anti-AD agents. We recently reported a real-time imaging method of Aβ aggregation using quantum dot (QD) nanoprobes (Tokuraku et al., PLOS ONE 4, e8492, 2009). Subsequently, we developed a microliter-scale high-throughput screening (MSHTS) system for Aβ aggregation inhibitors based on the fluorescence imaging technology with QD nanoprobes (Ishigaki et al., PLOS ONE 8, e72992, 2013). This novel screening system could be analyzed with 5-μl sample volume, and estimated the activity of Aβ aggregation inhibitors as a half-maximal effective concentration (EC50). In this study, we tried to screen Aβ aggregation inhibitors by the MSHTS system from ethanolic extracts of about 100 kinds of plants containing land plants and seaweeds. The results revealed that almost more than 90% of the tested extracts showed inhibitory activity for Aβ aggregation, although the EC50 values were widely distributed (EC50: 0.001-10 mg/ml) among plant families. We also found that the ethanolic extracts of the Lamiaceae family showed significantly higher activity than the average of tested extracts, and an active compound in the Lamiaceae family was rosmarinic acid. Since the plants belonging Lamiaceae family, such as Salvia officinalis (sage) and Melissa officinalis (lemon balm), had already been reported to have memory-improving properties in old European reference books published hundreds of years ago, it is possible that the effect involves the inhibitory activity for Aβ aggregation of rosmarinic acid. Moreover, we also evaluated boiling water extracts of seaweeds by the MSHTS system. The results suggested that polysaccharides in the boiling water extracts of seaweeds affected morphology of Aβ aggregates and showed Aβ aggregation inhibitory activity.

Title: AD biomarker changes based on cortical thickness patterns

Authors: *J. ROH, J. HWANG, C. KIM;
Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: Background: Neuropathologically defined subtypes of Alzheimer's Disease (AD) have represented distinctive atrophy patterns and clinical characteristics in patients with AD. Cortical thickness based clustering of AD patients represented comparable results with autopsy findings culminating into 3 atrophy patterns: medial temporal (MT); diffuse (D); and parietal dominant (P) subtypes. It is not assessed, however, whether the new clustering method based on cortical thickness can reflect pathophysiologic changes in AD. Methods: A total of 77 AD subjects from the Alzheimer's Disease Neuroimaging Initiative (ADNI) 2 dataset who completed 3T MRI, 18F-Fludeoxyglucose (FDG)-PET, 18F-Florbetapir-PET, and cerebrospinal fluid (CSF) study were enrolled for analyses. After obtaining cortical thickness using a CLASP algorithm, a hierarchical agglomerative cluster analysis was performed using a Ward's clustering linkage to classify AD patients. FDG and Florbetabir PET data were compared among the groups using region of interest based analyses after controlling for age, gender, education, and intracranial volume. Differences in neuropsychological tests and CSF levels of amyloid-beta (Aβ) and tau were assessed among the groups. Results: Cortical thickness-based clustering methods demonstarated three patterns of cortical thinning in AD patients: MT subtype (19.5%), D subtype (55.8%), and P (24.7%) subtype. Patients in the P subtype (67.5±7.4 years) were younger than MT (74.8±7.9) and D (76.1±6.6) subtypes (p=0.0002). Patients in the P subtype represented more glucose hypometabolism in the left inferior parietal, right superior parietal, and left middle occipital cortices, which matches well with regions with cortical atrophy. Patients in the MT subtype revealed more glucose hypometabolism in left hippocampus and bilateral frontal cortices

compared to the other 2 subtypes. Patients in the P subtype represented marked Aβ accumulation in most of brain regions, including superior, middle, inferior frontal cortices, superior, inferior parietal cortices, and precuneus measured by florbetapir-PET. Neuropsychological test results and levels of CSF revealed no difference among the groups. Conclusion: The findings that the P subtype represented more glucose hypometabolism and more accumulation of Aβ than the other groups and that the MT subtype had more glucose hypometabolism in compatible brain regions including the hippocampus indicates cortical thickness patterns can reflect pathophysiological changes in AD.

Title: A novel multiplex immunoassay enables detection of Alzheimer’s disease biomarkers in small volumes of cerebrospinal fluid

Authors: *L. CHEN, D. DROLL, A. J. SAPORITA, J. MISTRY, J. HWANG;
R&D, EMD Millipore, Saint Charles, MO

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that is the most common cause of dementia among the elderly. There are approximately 44 million people worldwide with dementia and AD, and it is the sixth leading cause of death in the U.S. Patients with AD suffer from memory loss and cognitive decline, which increases in severity as the disease progresses. Two key neuropathological features that exemplify AD are extracellular Amyloid β (Aβ) plaques and intracellular neurofibrillary tangles, which are composed of the abnormally hyperphosphorylated protein Tau. Biochemical changes in Aβ and tau reflect AD pathologic processes in the brain. Monitoring altered levels of these biomarkers in patient cerebrospinal fluid (CSF) may be highly beneficial to understanding disease progression. Using a MILLIPLEX®MAP multiplex immunoassay kit, simultaneous detection of Aβ1-40, Aβ1-42, total Tau, and phosphorylated Tau Thr181 in age-matched AD and non-AD human CSF samples was performed, thereby minimizing the use of valuable CSF samples (12.5 ul/well). Phosphorylated Tau and Aβ1-42 were significantly correlated to AD (p-value < 0.01 and p-value< 0.05, respectively). Neither total Tau nor Aβ1-40 showed a significant correlation in the CSF samples used in this study. The ratio of phospho-Tau Thr181 over Aβ1-42 improved the p-

value < 0.001. In addition, the specificity of this kit was tested and showed no cross-reactivity nor any significant difference in analyte concentrations regardless of whether each analyte was measured in a single-plex or multiplex (full 4-analyte kit) format. Furthermore, sensitivity, intra- and inter-assay precision, linearity of dilution and spike recovery exhibited excellent analytical performance. The MILLIPLEX® MAP Human Amyloid Beta and Tau panel provides a powerful tool for examining the pathogenesis of AD in both nonclinical and clinical research studies.

Title: The effect of chronic neuroinflammation on cognition and the cholinergic system

Authors: *E. GYENGESI[1], A. RANGEL[1], O. KEKESI[1], P. YOON[1], K. V. K. GADALA[1], Y. BUSKILA[2], G. MUENCH[1];
[1]Univ. of Western Sydney, Penrith, Australia; [2]MARCS Inst. Univ. of Western Sydney, Penrith, Australia

Abstract: Inflammation in the central nervous system and disruption of its immune privilege are major contributors to the pathogenesis of multiple neurodegenerative disorders, including Alzheimer's (AD), Parkinson's disease (PD), Creutzfeldt-Jakob disease (CJD), multiple sclerosis (MS), traumatic brain injury and more. Neuroinflammation and the loss cholinergic input from the basal forebrain to the hippocampus and the cortex have both been intensely associated with the development of dementia, and particularly AD, however the specific link between neuroinflammation and cholinergic cell death, and the interaction of cholinergic neurons and activated glia cells, is still an unexposed area. Interleukin-6 (IL6), among other proinflammatory cytokines such as IL-1 and TNF-α, is a common early inflammatory marker in AD and PD. Over the past decade, it has been shown that neuroinflammation plays a role in the development of neuronal degeneration, and as such, is a promising therapeutic target. In this study we used

heterozygous transgenic mouse GFAP-IL6, which express pro-inflammatory IL-6 in astrocytes under the control of the glial fibrillary acidic protein promoter; causing low level, chronic inflammation in the brain. In this study, we have used heterozygous GFAP-IL6 mice to study motor-coordination, anxiety and cognitive performance together with immunohistochemistry. At 3 months of age, GFAP-IL6 mice showed decreased performance on rotarod, elevated narrow beam walk, hind limb clasping and ledge tests as well as in novel object recognition memory, indicating deficits in fine motor coordination that continued to deteriorate with age, reaching significant decline at 22 months of age. The behavioral changes were accompanied by increased microglia and astrocytes numbers and activation throughout the brain, and decreased cholinergic cell numbers in the basal forebrain at 22 months of age. These results confirm that the GFAP-IL6 transgenic mouse displays subtle deficits in fine coordination and memory already at 3 months of age that gradually worsens throughout the life span. Our results suggest that chronic neuroinflammation could potentially be a significant distributor to motor and cognitive function decline throughout the aging process. This mouse model may suitable to test anti-inflammatory medications for the treatment of AD and PD.

Title: Development of novel Alzheimer's disease plasma biomarkers: oligomeric Aβ and apoE/Aβ complex

Authors: ***N. C. COLLINS**, S. GHURA, K. P. KOSTER, M. LADU;
Anat. and Cell Biol., Univ. of Illinois At Chicago, Chicago, IL

Abstract: Alzheimer’s disease (AD) is a rapidly growing epidemic with a conservative predicted incidence of 14 million Americans by 2050, at a cost of $1 trillion. Despite these alarming statistics and the emotional devastation caused by AD. There are no biological biomarkers for

AD that are predictive or reliably diagnostic, or based on the underlying causes of AD. Clinical trials amplify this issue, as without mechanistic biomarkers, it is virtually impossible to identify novel preventative drugs, or track drugs designed for treatment of AD. Amyloid-beta (Aβ) peptide is a major cause of cognitive decline in AD. Aβ self-aggregates to form oligomeric Aβ (oAβ), considered a proximal neurotoxin in AD. The gene encoding apolipoprotein E4 (APOE4) is the greatest genetic risk factor for AD. APOE4 increases risk up to 15-fold, compared to the more common APOE3 genotype, while APOE2 reduces risk 4- fold compared to APOE3. Evidence suggests that one mechanism by which the apoE isoforms modulate AD risk is through the modulation of Aβ levels, an effect potentially mediated by physical interactions between apoE and Aβ (apoE/Aβ complex). Through an intensive research program, we developed a unique monoclonal antibody, MOAB-2, that enabled development of assays that detect oAβ and apoE/Aβ complex. Previous studies demonstrated that in both human brain and CSF, the levels of oAβ are higher with AD compared to control, and in patients with AD, higher with APOE4 compared to APOE3. Importantly, levels of apoE/Aβ complex are lower in AD patients compared to control, and within AD patients, apoE4/Aβ levels are lower than apoE3/Aβ levels. Thus, our hypothesis is that oAβ and apoE/Aβ complex levels are mechanistic biomarkers that track AD progression based on APOE genotype. A major obstacle for measurement of CSF biomarkers are CSF draws, which are highly invasive and do not allow for the repeated measures necessary for both diagnosis and theragnosis. Thus, an ideal biomarker would be both highly sensitive and selective allowing for measures in human plasma. Therefore, we measured oAβ and apoE/Aβ levels in human plasma. Our data in human plasma demonstrates that oAβ levels are higher and apoE/Aβ complex levels are lower in AD compared to control and with APOE4 compared to APOE3. Collectively, our results support the hypothesis that APOE modulated changes in apoE/Aβ and oAβ levels underlie the APOE4-induced risk for AD. Further, plasma levels of apoE/Aβ and oAβ may represent mechanistic biomarkers for the prediction and diagnosis of AD.

Ctr., Madison, WI; [3]Waisman Ctr., Madison, WI; [4]Wisconsin Alzheimer's Inst., Madison, WI; [5]Oxford Ctr. for Functional Magnetic Resonance Imaging of the Brain, Oxford, United Kingdom; [6]Geriatric Res. Educ. and Clin. Ctr., Madison, WI

Abstract: Background: Recent analyses suggest that insulin resistance (IR) is associated with several brain changes including lower regional volumes, lower glucose uptake, lower cerebral blood flow, and Alzheimer's disease (AD) pathology as measured in cerebrospinal fluid, as early as midlife. Still, little is known about the impact of insulin and IR on cerebral white matter. **Objective:** The aim of this study was to determine the effect of IR on myelin in healthy late-middle-aged adults. Given the role of insulin in cholesterol synthesis, we hypothesized that IR would be associated with a negative effect on myelin as shown on a novel brain imaging marker of myelin content. **Methods:** Asymptomatic adults enriched for risk factors for AD (N=127, mean age = 61.8 years) from the Wisconsin Registry for Alzheimer's Prevention study (WRAP) underwent Multi-component Driven Equilibrium Single-Pulse Observation of T1 and T2 (mcDESPOT) imaging on a GE MR750 3T scanner. Fasting blood draw was used to determine IR using the Homeostatic Model Assessment for IR (HOMA-IR). A linear regression analysis tested the effect of IR, APOE ε4 status, and the potential interaction between APOE ε4 and IR on myelin water fraction (MWF) maps using SPM12 software. **Results:** HOMA-IR was associated with altered myelin, shown by a main effect of HOMA-IR on MWF. This main effect was explained by a significant interaction between APOE ε4 and HOMA-IR. Higher HOMA-IR was associated with lower MWF, but only among APOE ε4 carriers. **Conclusion:** The results suggest that IR is associated with myelin content, and the effect is moderated by APOE ε4 genotype. Interestingly, higher IR was associated with lower MWF, but only among APOE ε4 carriers. Given that APOE ε4 and IR are risk factors for AD and their physiology converges on lipid processing, the current results suggest that negative effects on myelin may play a role in vulnerability to AD.

Title: CSF biomarkers of the neurovascular unit and the impact of APOE4 genetic risk in mild Alzheimer's disease

Authors: *M. D. SWEENEY[1], A. P. SAGARE[1], D. A. NATION[1], M. R. HALLIDAY[1], A. M. FAGAN[2], J. C. MORRIS[2], B. V. ZLOKOVIC[1];
[1]USC, Los Angeles, CA; [2]Dept. of Neurol., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Vascular dysfunction is increasingly recognized in the etiology of Alzheimer's disease (AD). Established biomarkers, amyloid-β (Aβ) and tau, do not predict the onset of cognitive decline and thus have limited clinical use. A clinical need exists to identify reliable biomarkers for early AD diagnosis, identifying novel treatment targets, and evaluating the effectiveness of clinical trials. Thus, we quantified novel cerebrospinal fluid (CSF) biomarkers of responses/injury to the neurovascular unit (NVU) - comprising vascular cells, glia, and neurons - using antibody-based single/multiplex assays. CSF biomarkers of the NVU in human subjects were analyzed by the degree of cognitive impairment, assessed via the Clinical Dementia Rating (CDR) scale, and the influence of apolipoprotein E-ε4 (*APOE4)*, the major genetic risk factor for late-onset AD. We observed that CSF biomarkers of blood-brain barrier (BBB)/vascular injury were altered during early stages of cognitive impairment prior to inflammatory, neuronal, and Aβ biomarkers. *APOE4* carriers but not non-carriers exhibited an age-dependent increase in albumin CSF/plasma ratio. Also, albumin ratio increased 55% in CDR 0.5 compared to CDR 0 in *APOE4* carriers, and correlated significantly with CSF fibrinogen levels in *APOE4* carriers with CDR 0.5. CSF levels of soluble platelet-derived growth factor receptor-β (sPDGFRβ), a marker of pericyte injury, increased by 60% and 27% in *APOE4* carriers and non-carriers, respectively, between CDR 0 and CDR 0.5 groups. Additionally, CSF biomarkers of endothelial cells (i.e., adhesion molecules) correlated with BBB breakdown only in *APOE4* carriers. CSF levels of

inflammatory cytokines and neuronal injury markers (i.e., total and phosphorylated tau and neuron specific enolase) were not altered in subjects with CDR 0, 0.5, or 1, regardless of *APOE* genotype. Finally, CSF Aβ42 levels were 28% lower in *APOE4* carriers compared to non-carriers at CDR 0.5 and decreased by 60% in *APOE4* carriers from CDR 0.5 to 1. These data reveal that CSF biomarkers of the NVU are differentially altered in early cognitive impairment and influenced by *APOE4*, beginning with changes in BBB/vascular injury biomarkers. Overall, this suggests that a molecular algorithm may define stages of cognitive impairment and AD development and could importantly aid in AD-specific diagnostic and treatment efforts.

Title: The role of ApoE-4 in hippocampal hyperactivity in amnestic mild cognitive impairment

Authors: *T. TRAN[1], C. SPECK[2], A. PISUPATI[2], M. GALLAGHER[1], A. BAKKER[2]; [1]Psychological & Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Increased fMRI activation in the hippocampus is recognized as a signature characteristic in the aMCI stage of Alzheimer’s disease (AD) and a predictor of cognitive decline and progression to AD dementia. Recent studies have localized this increased activation to the dentate gyrus / CA3 subregion of the hippocampus and showed a correlation with memory impairments in those patients, as predicted by a rodent model of aging. Increased hippocampal activation has also been reported in carriers of the ApoE-4 allelic variation independently of mild cognitive impairment although these findings were not localized to a hippocampal sub region.

Animal models of ApoE-4 predict that this increased activation would be similarly localized to the dentate gyrus / CA3 region. To assess whether ApoE-4 contributes to increased hippocampal fMRI activation, 62 patients with aMCI genotyped for ApoE-4 status and 30 healthy age-matched control participants completed a high-resolution fMRI scan while performing a memory task designed to tax hippocampal sub region specific functions as well a neuropsychological assessment. Consistent with previous reports, patients with aMCI showed increased hippocampal activation in the left dentate gyrus / CA3 sub region of the hippocampus as well as memory task errors attributable to this subregion of the hippocampus. However, this increased fMRI activation in the hippocampus did not differ between ApoE-4 carriers (N = 25) and ApoE-4 non-carriers (N = 37) and the proportion of memory errors attributable to dentate gyrus / CA3 function did not differ between ApoE-4 carrier and ApoE-4 non-carriers. These results indicate that increased fMRI activation of the hippocampus observed in patients with aMCI is independent of ApoE-4 status and that ApoE-4 does not contribute to the dysfunctional hippocampal activation or the memory errors attributable to this sub region in these patients.

Title: Effect of MMSE and ApoE4 allele on the LymPro Test®, a cell cycle based blood test for Alzheimer's disease

Authors: L. KIRBY[1], P. JORGENSEN[1], *D. A. LOWE[2], C. BIER[1], M. SABBAGH[3]; [1]Amarantus Diagnostics, San Francisco, CA; [2]Neuroassets Sarl, Vevey, Switzerland; [3]Banner Sun Hlth. Res. Inst., Sun City, AZ

Abstract: Background: A blood biomarker would be advantageous for early identification or screening for Alzheimer’s disease (AD). Multiple reports have identified Cell Cycle Dysregulation as a key pathology in AD. Furthermore, it appears likely that this dysfunction is systemic, affecting peripheral blood lymphocytes as well as neurons. The LymPro Test measures

differential lymphocyte proliferation in response to mitogenic stimulus. Multivariate algorithms have shown that the LymPro Test can distinguish AD from HN in clinically diagnosed cohorts with 80% accuracy or greater. This study reports the effect of ApoE4 and MMSE score on the LymPro Test. The LymPro Test potentially represents a useful blood-based biomarker for AD. Methods: 140 blood samples were obtained and 125 of the results passed analytical review (59 AD and 66 controls). Samples were analyzed (Becton Dickinson) for CD69 frequency (a surface marker of cell cycle activity) on peripheral T, B, and monocyte cells by flow cytometry with and without mitogenic stimulation. Each subject had ApoE allele determination (Quest labs) and AUC point estimates were determined for all LymPro flow variables with ApoE4+ AD compared to ApoE4- HN. MMSE scores were also compared on a univariate and multivariate basis with results compared within and between cohorts. Results: Multiple univariate measures were significantly ($p<0.05$) different in AD subjects compared with HN subjects. ApoE4 allele generally had little effect on univariate measures. A multivariate algorithm AUC score slightly declined when ApoE4- AD subjects were excluded from the analysis population. LymPro multivariate result showed no significant change when AD subjects were compared within cohort. Mild, moderate and severe AD cohorts were not statistically different on a key univariate measure. Conclusions: ApoE4 allele presence did not appreciably affect the LymPro results, indicating likely independence from this genotype. AD severity as measured by MMSE had little effect on the LymPro results suggesting insensitivity to dementia severity. This indicates that LymPro Test likely will show a signal in prodromal AD. Further research is planned.

Abstract: We aim to develop allopregnanolone (Allo) as the first regenerative therapeutic for Alzheimer's disease. Dose escalation and range finding studies were performed prior to selection of doses for chronic exposure. Allo formulated in cyclodextrin at 1:6 complexation resulted in optimal rate and efficacy of Allo delivery to brain by intramuscular route of administration and advanced to chronic exposure studies. Safety studies were conducted to identify target organs of toxicity and to estimate the no observed adverse effect level (NOAEL) of Allo after 24 weeks of once-per-week dosing to adult male and female Sprague Dawley rats. Rats were bolus administered Allo 0, 1, 4, and 8mg/kg intramuscularly once-per-week for 24 weeks. Necropsies were on Day163 (Main group) and on Day191 (Recovery group). Endpoints were clinical observations, body weight, food consumption, functional observational battery (FOB), ophthalmologic examination, plasma drug levels and toxicokinetics, clinical pathology, urinalysis, organ weight, and macroscopic and microscopic tissue examination. No toxicologically relevant changes were found in body weight, food consumption, ophthalmology, gross necropsy, organ weight, urinalysis parameters, or clinical pathology. Acute sedative effects were observed in high-dose groups determined by FOB parameters (home cage, handling, and reflex and physiology measurements) primarily in high-dose males and females on Day1 and 162. Sedative effects for high-dose groups were enhanced in males vs females. The incidence of epithelial hyperplasia in the non-glandular stomach was increased in highest dose Main group males but was not found in Recovery group. Allo blood levels were similar between males and females on Day1 at all doses, and trended higher in males compared to females on Day162 in the mid- and high-dose groups. Day162 exposures trended higher than Day1 at all doses. Terminal phase half-life values were less than 1hr in all groups except high-dose males on Day162. All animals survived to the end of the study. At 4 and 8mg/kg dose levels, threshold of sedation was achieved based on behavioral observations related to sedation. The high-dose group males exhibited histopathological changes to the nonglandular stomach, an anatomical feature not present in humans. Based on these findings, the MTD for Allo is ~4mg/kg, and the NOAEL is ~1mg/kg. NOAEL of 1mg/kg intramuscular injection is equivalent to 0.19 mg/kg in humans. Clinical dose-escalating studies with Allo (ClinicalTrials.gov Identifier: NCT02221622) are

warranted to determine safety and tolerability. Research supported by NIA U01AG031115; NIA U01AG047222; and UF1AG046148 to RDB

Title: The role of perimenopause, inflammation and apoe4 in the pathogenesis of Alzheimer's disease

Authors: ***A. MISHRA**[1], F. YIN[2], A. CHRISTENSEN[3], C. J. PIKE[3], E. CADENAS[2], R. D. BRINTON[2];

Abstract: Alzheimer's disease (AD) is known to have a long latent prodromal stage, before the symptoms and the pathology actually manifest. The etiology of the disease, obscured by its multifactorial nature, poses a challenge in isolating the effects of each risk factor and studying the mechanism involved in the development of Late Onset Alzheimer's disease (LOAD). The perimenopausal transition in women, characterized by symptoms of hot flashes, insomnia, fatigue, marks the beginning of reproductive senescence causing a reduction in the levels of female reproductive hormones- estrogen and progesterone. The perimenopausal transition is considered a "tipping point" in the prodromal stage of AD. NSAIDs (Non steroidal anti inflammatory drugs) on the other hand have been known to delay the onset of LOAD, and are shown to be most effective in their preventive action when taken during the ages of 40-50 years. The overlap in the age group undergoing the perimenopausal transition and the age group more susceptible to the preventive action of NSAIDs, indicates a correlation between the two factors and how they would be affecting the AD pathogenesis in the prodromal stage. Estrogen is a potent anti-inflammatory agent, and perimenopause causes a depletion of this hormone leading to a consequent increase inflammation both peripherally and centrally. In our preliminary study in the perimenopausal rat model which isolates endocrine aging from chronological aging, the

gene expression profiling of hippocampus and cortex indicated an upregulation of genes involved in the TLR4/MyD88/NFkB pathway in the irregular cycling and acyclic rats in comparison to regular cycling rats of the same age. Serum cytokine profiling in the same rats indicated a significant increase of IL-12 and IL-1A in acyclic rats as compared to regular cycling rats of the same age. This increase in proinflammatory cytokines correlated inversely with the levels of 17-B estradiol in plasma. On the basis of these preliminary analyses, we aim to characterize the inflammatory phenotype with respect to the perimenopausal transition and how both these factors together affect the pathogenesis of LOAD. Another key aspect of our analyses will include a focus on the effect of APOE4 allele on the inflammatory phenotype exhibited in the perimenopausal transition. Using the humanized ApoE4 KI rats and mice as our model, we aim to isolate the effect of this allele on the perimenopausal transition and how inflammation would be supplementing its effect in the progression of AD. This work was supported by NIA 5P01AG026572 to RDB; Project 1 to RDB & EC.

Title: APOE4 impairs cognitive performance in female APOE targeted-replacement and EFAD mice

Authors: *A. CHRISTENSEN[1], C. J. PIKE[2];
[1]Dept. of Gerontology, [2]Gerontology, USC, Los Angeles, CA

Abstract: Alzheimer’s disease (AD) is more prevalent in women than men. The reasons for this are still unclear, but are not simply due to the longer mean lifespan of women. One contributing factor may be the depletion of estrogens and progesterone at menopause. Estrogens in particular have been shown to exert several neuroprotective actions relevant to AD in multiple rodent paradigms. For example, estrogens decrease inflammation and reduce the incidence of metabolic disorders, both of which have been linked to greater AD risk. Another AD risk factor that exhibits sex differences is the ε4 allele of apolipoprotein E (ApoE4), the major genetic risk factor

for non-familial AD. ApoE4 confers significantly greater AD risk in women than in men. Thus, the combination of estrogen loss and ApoE4 status may contribute to the vulnerability of women to AD. To investigate this issue, we studied the independent and combined effects of ApoE4 and estrogen on cognitive and AD-like neuropathology in female mice with and without depletion of endogenous estrogen. We employed female mice with targeted replacement of humanized ApoE3 and ApoE4 (TRE3, TRE4; P. Sullivan) as well as targeted replacement ApoE mice that were crossed with the 5xFAD transgenic model (EFAD; M.J. LaDu). Targeted replacement (TRE3, TRE4) and EFAD (E3FAD, E4FAD) female mice were ovariectomized (OVX) or sham OVX at three months of age. OVX removes the peripheral source of sex steroid hormones. Sixteen weeks after surgery, mice were evaluated for behavioral performance then euthanized and assessed for AD-related neuropathology. Female TRE4 mice performed more poorly than TRE3 mice on both the novel object recognition (NOR) and novel object placement (NOP) tasks. OVX was associated with poorer performance on NOP but not NOR. EFAD mice showed similar behavioral trends: E4FAD females performed worse than E3FAD females on NOP and NOR but only NOP showed worsening performance with OVX. β-Amyloid (Aβ) plaques are a hallmark of AD neuropathology and are present in the EFAD mice. We observed an increase in Aβ burden in E4FAD females compared to E3FAD females, but no further increase by OVX. Thus, ApoE4 is associated with poorer cognition in both the presence and absence of AD-related neuropathology. Depletion of endogenous estrogens does not yield worsened Aβ burden but has mixed effects on behavioral outcomes. The modest effects of estrogen depletion on deleterious outcomes of ApoE4 suggest that the increased AD risk in women associated with ApoE4 is likely independent of estrogen's activational effects, suggesting an important hormone independent action.

Title: Sex and APOE in the amyloid burden and microbleeds of EFAD mice and humans

Authors: ***M. CACCIOTTOLO**[1], A. CHRISTENSEN[1], A. ALEXANDRA MOSER[1], J. LUI[1], C. J. PIKE[1], T. E. MORGAN[1], E. BACON[1,2], G.-Y. CHIANG[3], C. E. FINCH[1,2];

[1]USC Davis Sch. of Gerontology, Los Angeles, CA; [2]Biol. Sciences, Dornsife Col., USC, Los Angeles, CA; [3]Radiology, Weill Cornell Med. Col., New York, NY

Abstract: Women APOE4 carriers have the highest risk for Alzheimer's disease (AD), but sex-APOE allele interactions are unclear for AD neuropathology. To further resolve APOE-sex interactions, we examined EFAD mice transgenic for familial AD genes together with targeted replacement (APOE-TR) human APOE3 and -E4 alleles (Youmas et al, 2012) for endpoints of Aβ burden, cerebral amyloid angiopathy (CAA) and microbleeds. In EFAD mice at age 7 months, female sex and APOE genotype independently increased oligomeric Aβ42 and total PBS extracted Aβ (2- to 8-fold, F>M, ELISA). Female EFAD also had 2-fold larger Aβ plaques (with modest increase by apoE4). Cerebrovascular pathology followed these trends of female excess and APOE4: for CAA, the number of Aβ-positive microvessels differed 2-fold by APOE allele, which was increased 50% in females of both alleles. The microbleeds (microhemorrhages) were in >5-fold female excess with non-significant differences by APOE. The background APOE-TR mice had 20-fold fewer microbleeds than EFAD, with 2-fold female excess. Microbleeds may be precursors of gross lobar hemorrhages in APOE-TR mice by 18 months (Sullivan et al, 2008). Because aging wildtype mice do not develop microbleeds or lobar hemorrhages, these findings suggest that the introduction of human APOE3- or 4 interacts with endogenous murine Aβ to cause cerebrovascular pathology which is underappreciated. Sequence differences between human and mouse APOE and APP may underlie these vascular phenotypes. Human APOE-sex interactions were further explored in the Alzheimer's Disease Neuroimaging Initiative (ADNI), which showed the opposite sex bias, with male APOE4 carriers having more microbleeds, again with APOE4 dose effect. These findings suggest species differences in the neurobiology of APOE-sex interactions, relevant to AD as a uniquely human condition (Finch and Austad, 2015).

Title: APOE and sex influence glial density and cytokines in EFAD mice

Authors: *T. E. MORGAN, C. E. FINCH, M. CACCIOTTOLO;
Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: APOE4 carriers, particularly women, have the highest risk for Alzheimer's disease (AD), but sex-APOE allele interactions are unresolved. Because of the importance of inflammatory processes during AD, APOE-sex interactions for glial density and cytokines were analyzed in the EFAD mouse model. EFAD mice are transgenic for familial AD genes together with targeted replacement (APOE-TR) human APOE3 and -E4 alleles (1). At age 7 months, EFAD mice show independent effects of female sex and APOE4 for oligomeric Aβ and as plaques in cerebral cortex (2). We further show that female EFAD mice have 20-50% higher glial density, for microglia (Iba-1) and astrocytes (GFAP), with stronger APOE4 effects for microglia in females. Cytokine levels showed a range of associations with APOE alleles and sex. Of ten cytokines, only IL-6 and TNFa differed by APOE (E4>E3, 50-100%), while these and others were higher in females (IL1β, IL4, IL6, IL10; KC/GRO and TNFα). No sex or APOE allele differences were found for IFNγ, IL2, IL5, or IL12p70. The absence of APOE effect for most of the analyzed cytokines in EFAD male mice confirms findings on male APOE-TR (3). The EFAD mouse model suggests that APOE-sex interactions are restricted to subset of inflammatory cytokines that includes IL6 and TNFa. Both IL-6 and TNFa are recognized in AD inflammatory processes mediated by microglia, which also showed the strongest sex-APOE interaction. We hypothesize that the greater AD risk of women APOE4 carriers involves their higher microglial load and levels of a subset of cytokines including IL-6 and TNFa. We suggest human responses to anti-inflammatory drugs might be informed by sex-APOE interactions.

Title: Preclinical safety and efficacy of allopregnanolone in a mouse model for Alzheimer's disease

Authors: *C. C. CALDWELL[1], R. W. IRWIN[2], A. ROMANI[3], C. SOLINSKY[1], S. CHEN[2], R. D. BRINTON[2,4];
[1]Clin. and Exptl. Therapeut., [2]Pharmacol. and Pharmaceut. Sci., USC Sch. of Pharm., Los Angeles, CA; [3]Dept. of Biomed. and Specialist Surgical Sci., Univ. of Ferrara, Ferrara, Italy; [4]Neurol., Keck Sch. of Medicine, USC, Los Angeles, CA

Abstract: Allopregnanolone (Allo) promotes regeneration, associative learning and memory, and reduces β-amyloid burden in triple transgenic Alzheimer's disease (3xTgAD) mice. To further develop allopregnanolone as a therapeutic for Alzheimer's disease, we investigated once per week administration in male and female 3xTgAD animal model. Adverse outcomes of clinical trials with immunotherapeutic agents that target β-amyloid led FDA to institute the precaution to investigate risk potential for cerebral microhemorrhage in a preclinical model. Although Allo is not an immunotherapy against β-amyloid, Allo does decrease β-amyloid load in brain. 19-23 month-old 3xTgAD mice were given once weekly subcutaneous injection of vehicle or allopregnanolone (6 mg/kg) or intraperitoneal injections of 3D6 (antibody dosed at 50 mg/kg) for a period of 6 weeks. Each treatment group was composed of 10-12 females and 5-7 males 3xTgAD transgenic mice. In male and female 3xTgAD mice, formulations were tested at maximally tolerated doses by subcutaneous route assessed by Perls stain to detect cerebral amyloid angiopathy-associated microhemorrhage. Quantitative analyses indicated no elevation in microhemorrhages in Allo treated mice when compared to vehicle. Our previous data demonstrated that neuro-regeneration, maintenance of cholesterol homeostasis, and reduction of AD pathology were achieved with once per week Allo treatment. Histology and cytochemistry of brain sections from aged 3xTgAD mice dosed with either Allo or vehicle control were immunolabeled for the following pathology markers: β-amyloid, PHF-Tau; Iba-1 activated microglia; ABAD amyloid peptide binding protein on mitochondria; and CNPase, a oligodendrocyte marker for labeling myelin structure of white matter in brain. Images were analyzed both by qualitative pathology structure and location and by quantitative stain intensity. Analyses indicated that Allo treated mice exhibited a reduction in β-amyloid plaque size and prevalence. Iba-1 staining showed a strong association of activated microglia surrounding β-amyloid deposits and tau tangles. Additional trends of decreased Tau, ABAD, and increased white matter were associated with Allo treatment. These data support the development of Allo as a therapeutic candidate for Alzheimer's disease. Further analyses are in progress. This study has been supported by NIH National Institute on Aging NIA U01 AG031115 and NIA U01 AG047222 to RDB.

Title: Allopregnanolone and its analogues differentially potentiate mitochondrial function and gene expression in human neural stem cells

Authors: ***M. DESAI**[1], R. W. IRWIN[2], K. GEE[3], R. D. BRINTON[1,2,4];
[1]Clin. Pharm. and Pharmaceut. Econ. & Policy, [2]Pharmacol. and Pharmaceut. Sci., USC, Los Angeles, CA; [3]Pharmacol., USC, Irvine, CA; [4]Neurology, Keck Sch. of Med., USC, Los Angeles, CA

Abstract: Allopregnanolone (Allo) is in clinical development as the first regenerative therapeutic for Alzheimer's disease and other neurological disorders. In this study we sought to determine the action of Allo and analogues thereof on mitochondrial function of human neural stem cells (hNSCs) and then examine the gene expression profile responsible for differential mitochondrial potentiation. These *in vitro* hNSC studies were designed to assess potential biomarkers of Allo efficacy that can be translated to studies on patient derived stem cells. Mitochondrial function was tested using the Extracellular Flux Analyzer manufactured by Seahorse Biosciences. First we determined the optimum cell density and Allo concentration to be used. Treatment of hNSCs with Allo resulted in an inverted U-shaped dose response curve with the peak response observed at 100nM that was consistent with earlier published reports. Maximal respiration and spare respiratory capacity of hNSCs were increased by 39% and 53% respectively after treatment with Allo for 24h, compared to vehicle. Additionally, we conducted a pulse-based experiment to determine activation time requirement of hNSCs. The cells were treated with a 30 min pulse of Allo and mitochondrial function of hNSCs determined at multiple time points post-treatment. The pulse treatments were compared to a 24-hour continuous Allo treatment. We determined that 30 min. pulse Allo administered 8 hours or 4 hours prior to measurement potentiated the mitochondrial function of hNSCs to a level equivalent to 24-hour continuous Allo treatment. This further strengthens our translational research-based decision to administer Allo intravenously over 30 min. for Phase I clinical trial for MCI and early AD

Deleted: in vitro

(ClinicalTrials.gov Identifier: NCT02221622). We are currently evaluating mitochondrial gene expression levels in hNSCs in response to Allo treatment and expect to find that all 13 mitochondrial genes are upregulated by Allo. Title: Developing mitochondrial function and regenerative potential as biomarkers of patient response to allopregnanolone treatment

Authors: ***C. M. SOLINSKY**[1], M. K. DESAI[1], V. HENNES[2], H. C. CHUI[3], J. K. ICHIDA[2], R. D. BRINTON[1];
[1]Clin. Pharm. and Pharmaceut. Econ. & Policy, [2]Stem Cell Biol. & Regenerative Med., [3]Neurol., USC, Los Angeles, CA

Abstract: Alzheimer’s disease (AD) is a national and global epidemic with complex pathoetiology including compromised brain metabolic activity and decreased regenerative capacity. Allopregnanolone (Allo) is an investigational neuroregenerative therapeutic, currently in Phase 1b clinical trial for AD (NCT02221622,

https://clinicaltrials.gov/ct2/show/NCT02221622?term=NCT02221622&rank=1). In rodent preclinical models, Allo promotes neural stem cell (NSC) proliferation and neural differentiation and improves mitochondrial function. To develop biomarkers to predict regenerative response to Allo, we have initiated proof of concept analyses to determine the impact of Allo on human lymphocyte derived induced pluripotent stem cells (iPSCs) and iPSC-derived neural cells. T-cells from a patient with familial AD due to the A431E presenilin-1 (PSEN1) point mutation were reprogrammed to iPSCs. Using dual inhibition of SMAD signaling A431E iPSCs were differentiated to NSCs. Mitochondrial respiration and regenerative capacity were determined using metabolic analyzer, High Content Screening imaging, and FACS. Mitochondrial respiration analyses demonstrated that in PSEN1 mutation containing iPSC-derived NSCs treated with Allo 100nM, ATP turnover increased by 120% and maximal mitochondrial respiratory capacity by 100%. Concurrently, analyses were conducted to determine the regenerative effect of Allo on primary human NSCs. In human NSCs, Allo increased basal mitochondrial respiration by 25% and maximal mitochondrial respiratory capacity by 37.5%. FACS analysis indicated that Allo increased the number of Ki67 positive cells by 12% and, within that population, a rise in expression by 52%. Initial data demonstrate that iPSCs derived from PSEN1 lymphocytes can be generated, differentiated to NSCs, and their metabolic phenotype determined. Data indicate that Allo can increase mitochondrial respiration and promote regeneration of human-derived NSCs. Going forward the effect of Allo on the regenerative capacity and metabolic phenotype of PSEN1 mutation containing and sporadic iPS-derived NSCs will be evaluated. These data will form the foundation for developing the first regenerative biomarker to determine and monitor response to therapeutics. Title: Fine-mapping of the MAPT gene variation in progressive supranuclear palsy

Authors: *C. LABBE[1], M. G. HECKMAN[1], S. BAHETI[2], D. J. SERIE[1], M. ALLEN[1], O. LORENZO BETANCOR[1], A. I. ORTOLAZA[1], R. L. WALTON[1], Z. K. WSZOLEK[1], D. W. DICKSON[1], O. A. ROSS[1];
[1]Neurosci., Mayo Clin., Jacksonville, FL; [2]Mayo Clin., Rochester, MN

Abstract: Multiple association studies, including genome-wide association studies, have shown that *MAPT* H1 haplotype is associated with risk of developing progressive supranuclear palsy (PSP), more specifically; *MAPT* subhaplotype H1C is highly associated to PSP. However, the precise causal variants at the *MAPT* locus are still unknown. We performed a comprehensive association study of the locus to fine-map the association signal and identify causal variants in PSP. First, we used *MAPT* tag SNPs (rs1467967, rs242557, rs3785883, rs2471738, rs8070723, rs7521) to identify the associated H1 subhaplotypes in our large pathologically-confirmed series of 917 PSP cases and 974 healthy controls. We confirmed the association to H1C and report new PSP associated H1 subhaplotypes (H1G, H1D, H1O and H1I). We followed this step by a targeted re-sequencing of the entire *MAPT* gene including 10kb upstream and downstream using genome capture and next generation sequencing. This screening stage was performed on 280 PSP samples and 280 controls. After, quality control we completed association tests on common SNPs (Minor allele frequency>1%) and identified 30 variants ($P<0.05$) for follow-up. We validated and genotyped these variants in our PSP cases/controls total series (~2000 subjects). We identified three intronic variants associated to PSP: one located in intron 1, one in intron 10 and one downstream *MAPT*. The intron 1 and downstream variants sit on the H1C subhaplotype and the intron 10 variant sits on the H1D subhaplotype. Interestingly, alternative splicing of exon 10 leads to 3R or 4R versions of *MAPT* encoded protein tau, with 4R being the prominent form in PSP. Additional studies will be needed to fully assess the functional impact of the *MAPT* intronic variants identified.

Title: Age-related changes in [18F]GE-180 uptake in the rTg4510 mouse model of tauopathy

Authors: *J. GARTLON[1], S. KRAUSE[2], Z.-Z. LI[2], P. MCCRACKEN[2], A. GIBSON[3], W. TRIGG[3], A. KOYAMA[1];
[1]Neurosci. and Gen. Med. Product Creation Unit, [2]Biomarkers and Personalized Med. Core Function Unit, Eisai Inc., Andover, MA; [3]GE Healthcare Ltd., Amersham, United Kingdom

Abstract: Translocator protein (18 kDa) (TSPO) is expressed in the outer mitochondrial membrane of steroid-synthesising cells and may serve as a marker of microglial activation in neurodegenerative diseases (Rupprecht et al., Nature Reviews Drug Discovery, 9, 971-988, 2010). [18F]GE-180 is a TSPO-specific radiotracer developed by GE Healthcare (UK) for use in positron emission tomography (PET) imaging. The aim of this study was to measure age-related changes in [18F]GE-180 uptake in the rTg4510 transgenic mouse model of tauopathy using ex-vivo autoradiography and in-vivo PET imaging. [18F]GE-180 was synthesised on a microfluidic platform using a modified method. Autoradiography was performed on coronal sections prepared from brains of female rTg4510 mice aged 2, 8 and 14 months (m) and wild-type mice aged 2 m, using 5 MBq [18F]GE-180. For PET imaging, 15 min static scans were acquired 20 min post-injection of 10-15 MBq [18F]GE-180 to evaluate tracer uptake in the frontal, occipital and temporal cortex, hippocampus, striatum and cerebellum in 4, 9 and 12 m female rTg4510 (n = 8-9) and wild-type mice (n = 5). Regions of interest (ROI) were defined using a mouse atlas realigned to the CT image. Activity in each ROI was reported as standard uptake volume (SUV). Ex-vivo autoradiography revealed a progressive, age-related increase in signal in the cortex and hippocampus of rTg4510 mice (aged 2 - 14 m) which was blocked by 36 µM of unlabelled GE-180. PET imaging with [18F]GE-180 revealed similar age-related increases in [18F]GE-180 uptake in the cortex, striatum and hippocampus in rTg4510 mice compared to wild-type mice of the same age. For example, in the frontal cortex the SUV was increased in transgenic vs wild-type mice by 39 % at 4 m ($P<0.01$) and by 69 % at 12 m ($P<0.01$). A trend towards age-related increases in SUV in wild-type mice was also observed. For example, in the frontal cortex the SUV increased by 42 % in wild-type mice aged 12 m vs 4 m ($P<0.05$). Studies are ongoing in our laboratory to measure age-related regional volume changes in rTg4510 and wild-type mice using magnetic resonance imaging (MRI). These data will be used to check for any under-estimation of SUV due to discrepancies in regional volume in transgenics vs wild-types. In summary, the TSPO-specific radiotracer [18F]GE-180 was used successfully to detect an age-related increase in TSPO binding sites in wild-type mice and to a much greater extent in rTg4510 mice, suggesting that microglial activation increases as a result of both tauopathy and, to a lesser extent, natural ageing.

Title: Sigma-1 receptor regulates Tau phosphorylation by shaping p35 turnover via myristic acid

Authors: ***S.-Y. A. TSAI**[1], M. POKRASS[2], N. KLAUER[3], H. NOHARA[4], T.-P. SU[1];
[1]Cell. Pathobiology Sec Integrative Neurosci. Br,, NIDA-IRP, NIH, Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD; [3]Univ. of Minnesota Med. Sch., Minneapolis, MN; [4]Psychiatry, Komagino Hosp., Tokyo, Japan

Abstract: Dysregulation of cyclin-dependent kinase 5 (cdk5) per relative concentrations of its activators p35 and p25 is implicated in neurodegenerative diseases. P35 has a short half-life and undergoes rapid proteasomal degradation5 in its membrane-bound myristoylated form. p35 is converted by calpain to p25 which, along with an extended half-life, promotes aberrant activation of cdk5 and causes abnormal hyperphosphorylation of tau, leading to the formation of neurofibrillary tangles. One challenge in treating “tauopathy” is to effectively reduce the available p35 to circumvent the formation of over-reactive ckd5/p25. The sigma-1 receptor (Sig-1R) is an endoplasmic reticulum chaperone that is implicated in neuronal survival. However, the specific role of the Sig-1R in neurodegeneration is unclear. Here we found that Sig-1Rs regulate proper tau phosphorylation and axon extension by promoting p35 turnover through the receptor’s interaction with myristic acid. In Sig-1R knockout neurons, a greater accumulation of p35 is seen, which is neither due to elevated transcription of p35 nor to disrupted calpain activity, but rather to the slower degradation of p35. In contrast, Sig-1R overexpression causes a decrease of p35. Sig-1R knockout neurons exhibit shorter axons with lower densities. Myristic acid is found here to bind Sig-1R as a nanomolar affinity agonist that causes the dissociation of Sig-1R from its cognate partner BiP. Remarkably, treatment of Sig-1R knockout neurons with exogenous myristic acid mitigates p35 accumulation, diminishes tau phosphorylation, and restores axon elongation. Our results define the involvement of Sig-1Rs in neurodegeneration and provide a mechanistic explanation that Sig-1Rs help maintain proper tau phosphorylation by potentially carrying and providing myristic acid to p35 for enhanced p35 degradation to circumvent the formation of over-reactive cdk5/p25. Our results also identify the myristic acid as an endogenous Sig-1R ligand that may represent a naturally–occurring substance for shaping neuronal systems against neurodegenerative diseases.

Title: Aβ Amyloidosis stimulates development of tau pathologies in a new Alzheimer's mouse model

Authors: *K. E. BRAUNSTEIN, P. C. WONG, T. LI;
Div. Neuropathology, Dept. of Pathology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Effective therapy for Alzheimer's disease (AD), the most common form of dementia and a devastating illness of the elderly, remains a great-unmet need. Genetic studies of early onset familial AD have fueled the notion that abnormal accumulation of A in the brain would trigger the aggregation of tau, leading to synaptic dysfunction, neurodegeneration and dementia. However, the molecular mechanism underlying such an "amyloid cascade" hypothesis remains ill defined. To determine whether the amyloid burden could accelerate tauopathy-dependent neurodegeneration, we now develop a new mouse model that express the human tau fragment containing the four repeat microtubule binding domain of tau. Consistent with the finding that expression of wild type human full-length tau in mice did not develop tau tangle, neither tau tangle nor neuronal loss is observed in these tau mice. However, when our tau mice are crossbred with a model of Aβ amyloidosis (*APP^{swe};PS1E9* mice) to generate mice (*Tau312-AP mice*) that develop Aβ amyloidosis in the presence of this tau fragment, AD-like tau pathologies and tauopathy-dependent loss of neurons are observed. Furthermore, we show that the human tau fragment converts endogenous tau to form neurofibrillary tangles. These results strongly support the idea that Aβ amyloidosis plays a central role in stimulating the tauopathy-dependent neuronal loss in the pathogenesis of AD. Importantly, such a model of AD will be instrumental for further clarifying the molecular mechanism whereby Aβ impacts on tauopathy-dependent neurodegeneration and for evaluation of Aβ- and tauopathy-dependent loss of neurons as the principal outcome measure in preclinical testing of mechanism-based therapies.

Title: The distinctive TDP-43 pathology of CTE is accelerated in areas of traumatic axonal injury and co-aggregates with tau

Authors: ***A. C. MCKEE**[1,3], V. E. ALVAREZ[2,3], B. HUBER[2,3], A. DEDEOGLU[2], L. GOLDSTEIN[2], N. W. KOWALL[2,3], T. STEIN[2,3];

Abstract: CTE is a tauopathy associated with brain trauma, characterized by the widespread distribution of neurofibrillary tangle (NFTs), thorn-shaped astrocytes and other hyperphosphorylated tau deposits in the brain. The pathological severity of CTE can be divided into 4 stages (McKee et al 2013). Abnormal TDP-43 pathology is found in most cases of CTE and increases in parallel with tau pathology. TDP-43 pathology consists of abnormally rounded, dotlike structures in neuronal and glial processes and inclusions in astrocytes and neurons that partially co-localize with p-tau deposits. We examined over 150 cases of CTE in the VA-BU-SLI brain bank and found TDP-43 immunopositive neurites in the subcortical white matter and fornix, areas prone to traumatic axonal injury, in CTE Stage I. In CTE Stage II, TDP-43 dotlike, rounded structures and glial inclusions were found in the subcortical white matter, brainstem, medial temporal lobe, and retina often in a subpial, periventricular or perivascular distribution. Stage III CTE cases contained TDP-43 immunoreactive deposits in neurons and astrocytes in the cerebral cortex, medial temporal lobe, brainstem, retina and white matter, and Stage IV cases displayed TDP-43 positive rounded and threadlike neurites and glial structures, astrocytic and neuronal inclusions in cerebral cortex, medial temporal lobe, diencephalon, basal ganglia, brainstem, retina, spinal cord and white matter. In cases with the most severe TDP-43 deposition, dense accumulations of TDP-43 were found in layers II and III of the neocortex and in the

dentate fascia of the hippocampus, a distribution pattern that overlaps with the distribution of TDP-43 found in frontotemporal lobar degeneration with TDP-43 (FTLD-TDP), although the morphology of the deposits was distinctive. The morphology and distribution of TDP-43 appears to be unique in CTE, and can be distinguished from the TDP-43 pathology of Alzheimer's disease, normal aging and FTLD-TDP. TDP-43 accumulation in CTE appears to be accelerated in regions of traumatic axonal injury and in regions of p-tau deposition. Future studies will help determine whether the distinctive rounded neuritic and astrocytic TDP-43 pathology can be used as a tool in the pathological diagnosis of CTE.

Title: Sleep disturbance progression in P301S tau transgenic mice

Authors: ***J. HOLTH**, G. ROBINSON, D. M. HOLTZMAN;
Dept. of Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Tauopathies are a class of neurodegenerative disorders associated with abnormal, pathological aggregation of tau protein. This classification includes diseases such as Progressive supranuclear palsy (PSP), Corticobasal degeneration (CBD), some forms of Frontotemporal Dementia (FTD), and Alzheimer's disease (AD). In addition to neurodegeneration, tauopathies are associated with an increased prevalence of sleep disturbances including insomnia, excessive daytime sleepiness, and rapid eye movement (REM) sleep behavior disorder. Up to 76% of FTD and 66% of AD patients exhibit sleep disturbances of some kind and a high percentage of CBD and PSP patients suffer from insomnia. These sleep disorders are also a major cause of

institutionalization. Sleep is an important biological process that facilitates learning and memory as well as metabolic homeostasis of proteins within the brain. Despite the importance of sleep and the high prevalence of sleep disturbances in tauopathies, little is known about the role of tau pathology in sleep disruption. Studies in a mouse model of AD expressing both tau and amyloid pathology have shown that sleep deficits occur when tau pathology is present but before amyloid pathology is abundant. In this study we utilized P301S human tau transgenic mice to analyze if tau pathology development and progression alone is sufficient to alter sleep. P301S mice develop progressive tau pathology with the onset of tau aggregation around 5 months of age and neuronal loss at 8 months. Using EEG/EMG sleep analysis at 6, 9 and 11 months of age, we show that P301S mice with significant tau aggregation and pathology have sleep deficits that worsen with age. Compared to wild type, P301S mice have decreased REM sleep at 9 months of age and decreased REM and NREM sleep as well as increased wakefulness at 11 months. No changes are observed at 6 months of age. Furthermore, compared to wild type, P301S mice have increased cortical EEG power in delta and theta frequencies at 9 months of age but significantly decreased EEG power at 11 months. The REM sleep EEG power distribution at 11 months of age is also altered. These results suggest that tau pathology disease progression is sufficient to alter sleep in P301S mice. Understanding this interaction between sleep disturbances and tau pathology could lead to better diagnostics and treatments for tauopathy-associated sleep disorders, decreases in institutionalization, and possibly provide a strategy for slowing disease progression itself.

Title: Vascular β-amyloid and tau: bidirectional influence in APP and MAPT bigenic mice

Authors: ***S. SAITO**[1,2], M. IHARA[3], Y. OKAMOTO[4], Y. HATTORI[3], Y. YAMAMOTO[2], A. KITAMURA[1], R. TAKAHASHI[1];

Abstract: Alzheimer's disease (AD) is characterized by parenchymal β-amyloid (Aβ) plaques, cerebral amyloid angiopathy (CAA), and neurofibrillary tau tangles. Several studies using amyloid precursor protein (APP) and microtubule-associated protein tau (MAPT) bigenic mice showed enhanced neurofibrillary degeneration without any alterations in Aβ plaques, indicating that tau is downstream of Aβ. One report has shown greater Aβ deposition in double transgenic APP/tau mice than in single APP transgenic mice although interaction between Aβ and tau *in vivo* remains to be clarified. AD is attributed to both excess production and impaired clearance of Aβ but the latter may be more crucial in sporadic AD. Mice overexpressing the human APP gene with Swedish-Dutch-Iowa mutations (Tg-SwDI mice) model CAA in that Aβ clearance is impaired. Here, we have developed a double transgenic mouse by crossing Tg-SwDI mice with Tg-P301S mice carrying the human MAPT gene with P301S mutation to investigate the role of CAA in tau metabolism. Immunohistochemical staining showed that the amount of total tau, 4 repeat tau, and hyperphosphorylated tau was more abundant in the double Tg mice than Tg-P301S mice. The double Tg mice showed most prominent tau accumulation in the subiculum where Aβ deposits first appear in Tg-SwDI mice, while they exhibited significantly increased Aβ deposition in the dentate gyrus where tau accumulation is marked in Tg-P301S mice. The Aβ deposits were mainly observed in the capillaries and composed of $A\beta_{40}$. The double Tg mice showed more pronounced astrogliosis, microgliosis, and neuronal loss than wild type mice and single Tg mice, the greatest reduction of cerebral blood flow in the cortex as estimated with laser speckle flowmetry, and significantly impaired spatial reference memory as evaluated in the Barnes maze test. These findings indicate bidirectional influence between vascular Aβ and tau, suggesting a positive feedforward loop of toxic protein accumulation. Such vicious cycle may explain one of the pathomechanisms of sporadic AD.

Title: BRI3 allelic variants are associated with cerebrospinal fluid levels of phosphorylated-tau in Alzheimer's disease

Authors: *K. D. DETERS[1], K. NHO[2], S. L. RISACHER[2], S. KIM[2], R. VIDAL[3], A. J. SAYKIN[2];
[2]Radiology and Imaging Sci., [3]Pathology and Lab. Med., [1]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Background: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized neuropathologically by amyloid-beta (Aβ) plaques and neurofibrillary tangles comprised of hyperphosphorylated tau protein. Aβ is formed after the sequential cleavage of the amyloid precursor protein (APP) by β- and γ-secretase. BRI3 is predominantly expressed in brain and is able to binds APP and inhibit Aβ production by blocking the α- and β-secretase binding sites. Because of this interaction, we hypothesized that BRI3 may be involved in AD pathogenesis. Therefore, we aimed to identify novel genetic associations between BRI3 and cerebrospinal fluid (CSF) analytes (Aβ, total-tau, phosphorylated-tau (p-tau)) in participants from the Alzheimer's Disease Neuroimaging Initiative (ADNI). Methods: Whole-genome sequencing data of 584 white, non-Hispanic participants from the ADNI cohort were analyzed to identify common variants (minor allele frequency > 5%) within BRI3, resulting in 160 single nucleotide polymorphisms (SNPs) after standard quality control steps. To investigate the association of BRI3 variants with CSF analytes, both gene- and SNP-based linear regression methods were utilized. For the gene-based test, an empirical p-value was calculated using permutation testing. To correct for multiple comparisons for the SNP-based tests, a Bonferroni correction (correction factor derived from the number of linkage disequilibrium (LD) blocks in BRI3) was applied. Independent and significant SNPs were analyzed simultaneously as a multi-marker test using linear regression methods. Age, gender, and APOE ε4 status were used as covariates for all analyses. Results: Gene-based analysis of BRI3 was only significantly associated with CSF p-tau ($p = 0.013$). After SNP-based analysis and Bonferroni correction ($p = 0.05 / 15$ LD blocks $= 0.0033$), the minor allele of four SNPs within the BRI3 gene were significantly associated with decreased levels of CSF p-tau (rs1561324, $p = 0.0012$; rs934820, $p = 0.00132$; rs73992921, $p = 0.00136$; rs3806537, $p = 0.00236$). rs934820 was in LD with other

SNPs and was excluded from the subsequent multi-marker test. Using the remaining three independent SNPs for multi-marker analysis, a strong association with CSF p-tau was observed (GGC, p = 0.0001). Conclusions: The BRI3 gene is a member of the BRI gene family, with mutations in BRI2 causing diseases similar to AD. To our knowledge, this is the first study to investigate BRI3 with AD endophenotypes reflecting tau and Aβ. These results show that BRI3 is associated with CSF p-tau, a well-established biomarker of AD. Further study and replication is needed to fully understand the role of BRI3 in AD.

Abstract: [Background] Emerging evidence suggests that diabetes affects cognitive function and increases the incidence of dementia. We previously reported APP+ob/ob mice showed cognitive dysfunction. However, the mechanisms by which diabetes modifies cognitive function still remains unclear. In comparison with the characteristics of AD brain structure and cognition, diabetes seems to affect cognitive function through not only simple AD pathological feature-dependent mechanisms, but also independent mechanisms (Sato et al. Frontiers in

Endocrinology. doi: 10.3389/fendo.2014.00143). The aim of this study is to explore the mechanisms by which diabetes modifies AD using AD mice models with diabetes. [Methods] We previously reported that APP+ob/ob mice showed more severe cognitive dysfunction than APP transgenic mice (Takeda, Sato et al. PNAS, 13, 107, 7036-41, 2010). We performed western blotting using antibodies for tau phosphorylated in various sites. We isolated RNA from brains of APP mice with high fat diet (HFD) and APP+ob/ob mice and performed microarray analysis and validation by real-time PCR. [Results] APP+ob/ob mice showed aberrant tau phosphorylation at T181, T205, T212 and S422. APP+ob/ob mice also showed altered expressions of the genes involved in inflammation, insulin signaling, glucose-energy metabolism and protein quality control. Tgfbr2, a receptor of an anti-inflammatory cytokine, TGFβ, was up-regulated in HFD-fed APP mice and APP+ob/ob mice. Interleukine-1β (IL1β), a pro-inflammatory cytokine, was up-regulated in APP+ob/ob mice. The expression of insulin receptor substrate 2 (Irs2) was increased significantly in the APP+ob/ob mice. Prkab1, non-catalytic subunit of AMP-activated protein kinase (AMPK), was up-regulated in HFD-fed APP mice and in APP+ob/ob mice. Ubiquitin ligase-encoding Ube3A was increased in HFD-fed APP mice and in APP+ob/ob mice. [Conclusions] Tau phosphorylation increases in Alzheimer disease mice model with diabetes associated with altered expressions of the genes involved in inflammation, insulin signaling, glucose-energy metabolism and protein quality control. Further studies are required to determine the precise contribution of these genes in the pathogenesis in AD and diabetes. And taking together, this aberrant phosphorylation of tau in brain degeneration during AD and diabetes might be induced via cell autonomous and non-cell autonomous mechanisms.

Title: Increasing bioavailable copper targets Tau pathology via the phosphatase PP2A in a mouse model of Alzheimer’s disease

Authors: *S. MCKENZIE-NICKSON[1,2], P. S. DONNELLY[3], L. W. HUNG[2], K. J. BARNHAM[2];
[1]Pharmacol., Bio21 Inst., Melbourne University, Australia; [2]Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia; [3]Chem., Univ. of Melbourne, Melbourne, Australia

Abstract: Alzheimer's disease is the worldwide leading cause of dementia and affects up to 50% of the ageing population above 85. The pathogenesis of the disease remains to be fully elucidated and the current lack of therapies reflects this. Recently, intense research suggests that metals may play crucial roles in the pathogenic process. Indeed, treatment with copper delivery compounds has yielded therapeutic benefits. However, the precise mechanism of action is still being investigated. In this study, AD transgenic (APP/PS1) mice were treated with the intracellular copper-delivery compound, CuII(GTSM). Treatment rescued spatial memory deficits in the Morris water maze. Protein analysis indicated that treatment reduced the levels of phosphorylated forms of tau, consistent with previous reports. There was also a reduction in the levels of pathological aggregated Tau. Treatment additionally increased the level of all subunits of the serine/threonine phosphatase protein phosphatase 2A (PP2A), responsible for dephosphorylating Tau. These studies suggest that increasing bioavailable intracellular copper can increase levels of PP2A, which result in a reduction in pathological aggregated Tau, possibly via a reduction on phosphorylated Tau. As it has been shown that PP2A levels and activity are reduced in AD brains, this study shows that targeting this pathway is crucial in reversing pathology and further validates increasing bioavailable intracellular copper as an effective therapy for AD. Furthermore, the treatment did not alter amyloid-β levels effectively placing amyloid-β above Tau in the toxicity cascade and validates Tau as a potential therapeutic target.

Title: α-Synuclein modulates amyloid-β oligomer toxicity, tau phosphorylation, and ectopic cell cycle re-entry in neurons

Authors: *S. S. THOMAS, G. S. BLOOM;
Univ. of Virginia, Charlottesville, VA

Abstract: α-Synuclein aggregates, in the form of Lewy body inclusions, and tau neurofibrillary tangles, are often co-detected post-mortem in a spectrum of neurodegenerative diseases, including Alzheimer's and Parkinson's. A large body of evidence supports the hypothesis that α-synuclein and tau share a synergistic and deleterious relationship. However it is unknown why, or if, expression of both proteins is required to initiate disease progression and death in neurons. Importantly, no studies conducted in Alzheimer's models have carefully investigated the role of endogenous α-synuclein in disease progression. Using mouse-derived cortical neuron cultures treated with toxic amyloid-β oligomers (AβOs) to model Alzheimer's we tested whether tau-dependent disease phenotypes are affected by α-synuclein reduction or overexpression. We found that AβOs increase the expression of α-synuclein, but only in the presence of endogenous tau. Furthermore, α-synuclein expression is necessary for the AβO-stimulated ectopic neuronal cell cycle re-entry (CCR) that accounts for substantial neuron death in Alzheimer's. Phosphorylation of tau at serine 409, an indicator of Alzheimer's pathogenesis and a requirement for CCR, is also attenuated by reduction of α-synuclein. Interestingly, overexpression of mutant, but not wild type (WT) α-synuclein in WT neurons is sufficient to increase neuronal CCR and elevate tau phosphorylation at sites required for CCR independently of AβOs. In contrast, overexpression of mutant α-synuclein does not induce CCR in neurons derived from tau knockout mice, even in the presence of extracellular AβOs. Taken together, these results support the hypothesis that α-synuclein and tau interdependently promote neuronal dysfunction, particularly CCR. Targeting this interaction potentially represents a novel therapeutic approach for the treatment of Alzheimer's, Parkinson's, and other neurodegenerative diseases that involve synergism between α-synuclein and tau.

Abstract: Cholinergic nucleus basalis (NB) neurons provide the major cholinergic innervation to the cortical mantle and are exquisitely prone to tau pathology and neurofibrillary tangle (NFT) formation during the progression of Alzheimer's disease (AD). However, the molecular and cellular relationships between the evolution of tau pathological processes and NB cell survival remain unknown. NB neurons require the neurotrophin nerve growth factor (NGF) and its receptors, TrkA and p75(NTR), for their maintenance and survival. Therefore, we profiled NGF pathway genes in NB neurons immunostained for the pS422 tau epitope, which identifies an early phosphorylation event preceding tau C-terminal truncation at D421, or dual-labeled for pS422 and TauC3, a later stage tau neo-epitope revealed by the C-terminal truncation event. These phenotypically distinct NB neurons (n = 40-80/phenotype) were individually microaspirated from tissue sections harvested postmortem from Rush Religious Orders Study participants who died with an antemortem clinical diagnosis of no cognitive impairment (NCI), mild cognitive impairment (MCI, a putative prodromal AD stage), or mild/moderate AD (n = 8-10/group). Each neuron was processed for RNA amplification and custom-designed microarray analysis. Quantitative evaluation revealed a significant ~50% downregulation in mRNA encoding the cognate NGF receptor TrkA in pS422-labeled compared to pS422-negative NB neurons. In addition, the cognate brain-derived neurotrophic factor and neurotrophin-3 receptors TrkB and TrkC, as well as the Trk-mediated downstream pro-survival kinase Akt, were downregulated ~40-60% in pS422+ cells. These transcripts were not further downregulated in pS422/TauC3 dual-labeled NB neurons. By contrast, levels of the pan-neurotrophin receptor p75(NTR) were downregulated by ~35% in dual-labeled neurons. Transcripts encoding choline acetyltransferase (the synthetic enzyme for acetylcholine), β-amyloid precursor protein (APP), APP family members, and regulators of APP metabolism were not differentially regulated across the tau phenotypic cell groups. Notably, we found that gene expression patterns for each cell phenotype did not differ with clinical diagnosis, suggesting that differential gene regulation

within NB neurons is related to their pathological status and not the cognitive status of the individual. Taken together, these cell-type specific microarray data suggest that a dysregulation of neurotrophic cell survival signaling is an early pathogenic mechanism associated with NFT formation in vulnerable cholinergic NB neurons in AD, which may be amenable to therapeutic intervention.

Title: Disruption of 3R/4R tau ratio impairs APP axonal transport in human Embryonic Stem Cells (hESC) derived neurons

Authors: *V. LACOVICH[1], M. ALLOATTI[2], T. FALZONE[2], S. ESPINDOLA[3], M. E. AVALE[3], M. ČARNA[1], G. FORTE[1], G. B. STOKIN[1];

Abstract: Alzheimer’s disease is characterized by the abnormal abundance of two hallmark proteins, APP and tau. In the last two decades several studies have tried to propose a molecular cascade of events leading to the pathology. One of the approaches to study the mechanisms leading to disease is to use transgenic mice bearing mutations that have been described in familiar cases of AD. The triple-transgenic model (3xTg-AD; PS1M146V, APPSWE and tauP301L) developed an age-related and progressive neuropathological phenotype that included both plaques and tangles, providing evidence of amyloid cascade hypothesis, by which Aβ

deposits precede tau alterations. However it was later shown that if tau is knocked out, there are no amyloid related changes, thus leaving an open question about how APP and tau are interlinked. To test this hypothesis further we have produced changes in the tau isoforms by using a spliceosome-mediated RNA trans-splicing system (SMaRT). We induced tau imbalance in mature hESCs derived neurons using pseudolentiviral particles, leading the expression of tau with 3 or 4 microtubule-binding repeats, thus disrupting the normal 3R/4R tau ratio. A cherry pseudolentiviral control was used to assess the transduction rate. Five days after transduction, transfections with APP-YFP were performed 24 hours prior to imaging. After identifying the neuron's axons, we recorded the axonal transport of APP-YFP in 30s movies. Kymographs generated from the recordings were analysed and mobility parameters of single particle trajectories such as run-length, average and segmental velocities were calculated. We confirmed the 3R/4R tau imbalance by measuring tau RNA and protein levels. Cell cultures with predominant 3R or 4R tau expression exhibited impaired axonal transport of APP-YFP compared with control. More specifically, there was a significant reduction of average velocity and segmental velocity distribution. Intriguingly analyses of all parameters of axonal transport indicated consistently significant impairments in anterograde axonal transport with milder effect on retrograde axonal transport. Our findings indicate that changes in tau isoforms play a role in regulating APP axonal transport. Further experiments will be needed to fully characterize the relation between tau and APP.

Title: Motor speech phenotypes of frontotemporal dementia and primary progressive aphasia: a review of behavioral and brain imaging findings

Authors: *M. L. POOLE[1,2], A. BRODMANN[2,3], D. DARBY[2,3], A. P. VOGEL[1,2];
[1]Audiol. and Speech Pathology, Univ. of Melbourne, Parkville, Australia; [2]Eastern Cognitive Disorders Clin., Melbourne, Australia; [3]Dept. of Behavioural Neurosci., Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia

Abstract: Objectives: To review the behavioral and neurological profile of motor speech impairments in frontotemporal dementia and primary progressive aphasia syndromes. Background: Frontotemporal dementia (FTD) and primary progressive aphasia (PPA) are terms used to group a number of related neurodegenerative disorders. They are united by overlapping pathologies and significant impairment to communication. They include the clinical presentations of behavioural variant FTD (bvFTD), nonfluent variant FTD (nfvFTD or nfvPPA) and semantic variant FTD (svFTD or svPPA). An atypical onset of Alzheimer's disease, logopenic PPA (lvPPA) constitutes a further PPA variant, and many authors consider primary progressive apraxia of speech (PPAOS) to be a distinct syndrome. Motor speech impairments are common, either directly, as part of the symptom profile, or associated with concomitant motor neuron disease or parkinsonism. Method: 589 studies were identified from a search of the MEDLINE database. Abstracts were reviewed and studies included if they reported speech outcomes using quantitative or validated scales. Neuroimaging data were collated when imaging was compared to speech measures. Results: Forty-two articles were included in the review. Subjective (listener based) measures of speech were reported in 24 studies and objective (acoustic) assessments were reported in 19 studies which included participants diagnosed with bvFTD, nfvPPA, svPPA, lvPPA and PPAOS. Six studies correlated speech measures with neuroimaging findings. A range of brain/behaviour associations were reported. Speech production in people with nfvPPA was correlated with atrophy of the supplementary motor area (SMA), precentral gyrus and inferior frontal gyrus. White matter tract abnormalities connecting the SMA, pars opercularis, primary motor cortex and caudate were also linked to deficits in speech production in nfvPPA. Conclusions: Quantitative measures of speech correlate with the clinical diagnostic criteria for FTD and PPA. Motor speech impairments are common in nfvPPA, but are rare in svPPA and lvPPA, and inadequately documented in bvFTD. Several neuroanatomical regions which can be affected by these disorders are highlighted for their importance in speech production. Further, the review indicates the utility of quantifiable measures of speech as a useful clinical tool in classifying PPA subtype.

Title: Temperature is involved in tau exon 10 alternative splicing regulation

Authors: *F. PETRY;
CHUL Reserach Ctr., Quebec, QC, Canada

Abstract: Tau is a microtubule-associated protein abundant in neurons. Its main function, bind and stabilize MTs, is mediated by the MT binding domain consisting of 3 or 4 repeated regions. Alternative splicing of tau exon 10 results in the presence or the absence of a MT-binding repeat, leading to the expression of tau with either four (4R-tau) or three (3R-tau) MT-binding repeats. In human brain development, 3R-tau are expressed from the embryonic stages while 4R-tau expression begins after birth. An equal amount of 3R-tau and 4R-tau is expressed in adult human brain. Alteration of the ratio is thought to be causing several neurodegenerative diseases, called tauopathies. Interestingly, a different pattern of tau isoforms during mice development was reported. Indeed, 3R-tau are only expressed during the first developmental stages and their expression disappeared in adulthood. Preliminary data on body pups temperature show that pups are hypothermic during the first developmental stages, correlating with the expression of 3R-tau isoforms expression. The purpose of this study is to analyze the regulation of exon 10 splicing and the mechanisms involved in the differential expression of 3R and 4R-tau in mice development. In a new way, we also investigate the impact of the temperature in the regulation of exon 10 splicing. We have analyzed tau and splicing factors during mouse brain development. To analyze the impact of temperature in adulthood, we starved adult mice to induce hypothermia. Finally, we used N2a cells, a cell line known to express both 3R-tau and 4R-tau, and exposed them to direct hypothermia. Our results show an increase of SR proteins promoting the inclusion of exon 10 and a decrease of those promoting exclusion during mice development, which is consistent with the profile of tau isoforms. We also observed re-expression of 3R-tau mRNA in starved mice, confirming the hypothesis that temperature regulate tau exon 10 splicing. We have also seen an increase of splicing factor promoting exon 10 exclusion. N2a cells at 32°C showed an increase of 3R-tau at mRNA and protein levels, followed by an increase of splicing factors promoting exon 10 exclusion. All together, these result indicate that temperature is involved in the regulation of the alternative splicing of tau exon 10, by changing splicing factors expression. During development, tau exon 10 splicing well correlate with splicing factor expression and hypothermia seen in the first post-natal developmental stages may also contribute to the expression of 3R-tau and its decline in adulthood. Here, we are the first to propose temperature as a key regulator of exon 10 splicing.

Title: Comparative distribution of early and late appearing epitopes of tau in tauopathies

Authors: *O. MELÉNDEZ-FERÁNDEZ, E. Y. KAO, S. WEINTRAUB, E. BIGIO, M.-M. MESULAM, C. GEULA;
Cognitive Neurol. and Alzheimer's Dis. Ctr., Northwestern Univ., Chicago, IL

Abstract: Tauopathies are characterized by aggregation of hyperphosphorylated tau in glial cells and/or neurons. Differential accumulation and distribution of abnormal tau protein, along with specific morphologic characteristics of tau inclusions, contribute to the distinct pathology observed in each tauopathy. In Alzheimer's disease (AD), different phosphorylated and truncated epitopes of tau appear early, intermediate or late in the process of tangle formation. In this study we aimed to compare the presence and distribution of early versus late tau epitopes across AD, progressive supranuclear palsy (PSP), corticobasal degeneration (CBD) and Pick's disease (PiD). We employed the novel antibody tau oligomeric complex 1 (TOC1), which identifies oligomeric non-fibrillar forms of tau and appears early in the process of tangle formation, and MN423, a truncated epitope of tau which appears late in the process of tangle formation in AD. The AT8 antibody, which recognizes tau phosphorylated at Ser202/Thr205 and is routinely used for pathologic diagnosis of tauopathies, was employed to select the brain regions most affected in each tauopathy for analysis. TOC1 immunoreactivity was robustly distributed in neurites and intracellular inclusions across all tauopathies. TOC1 positivity was detected in pre-tangles, some tangles, dystrophic neurites and a dense population of neuropil threads in AD; in neuronal and glial cytoplasm, neuropil threads and astrocytic plaques in CBD; in neuronal and glial cytoplasm, tangles, and neurites in PSP, and in Pick bodies, neurites and glial cells in PiD. The TOC1 antibody revealed tau pathology distribution similar to AT8 stained structures, but with more neurites stained. MN423 was present in a large population of tangles and neurites in AD, and in a scattered population of glial cells and neurites in PiD. Only sparsely distributed neurites and occasional intracytoplasmic staining of cells with glial morphology were MN423 immunoreactive in PSP and CBD. These findings are consistent with previous reports pointing to both similarities and distinctions between tauopathies in relation to epitopes of tau present in each. Specifically, while the initial stages of tau abnormalities appear to be similar in all tauopathies, the progression of pathology seems to follow distinct paths. Distinguishing the

specific epitopes found in each tauopathy can contribute to a better understanding of pathology progression, allowing imaging probes to be tailored to identify *in vivo* tau accumulation specific to each tauopathy. This is likely to lead to therapeutic approaches targeting distinct pathways identified in the progression of tau pathology.

Title: Association of tau with the stress granule RNA-binding protein TIA1 regulates tau pathology and neurodegeneration

Authors: ***D. APICCO**, T. VANDERWEYDE, P. ASH, K. YOUMANS-KIDDER, A. FRAME, B. WOLOZIN;
Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

Abstract: Increasing evidence links neurological disease processes to dysfunction of RNA binding proteins (RBPs). RBPs regulate all facets of RNA metabolism and have particularly crucial roles in neuronal cells that require extensive splicing, transport, and local translation of specialized transcripts. RBPs also possess conserved hydrophobic, prion-like domains that facilitate their reversible aggregation in stress granules (SGs), which are RNA-protein complexes that form transiently in response to stress-induced translational arrest. Disease-linked mutations in RBPs increase the tendency of these proteins to aggregate in SGs, leading to the formation of stable, pathological SGs. Primary nucleating SG proteins, such as T-cell intracellular antigen 1 (TIA1), co-localize with neuropathology in brain tissue of subjects with Amytrophic Lateral Sclerosis (ALS), Alzheimer’s Disease (AD), and frontotemporal dementia (FTD). Here, we

report a novel role for microtubule associated protein tau in SG biology, and demonstrate that the interaction of tau with TIA1 promotes tau pathology and neurodegeneration. Tau and TIA1 co-immunoprecipitate and progressively co-aggregate in various mouse models of tauopathy. Overexpression of tau accelerates SG formation and increases SG size. Conversely, genetic deletion of tau reduces SG formation and abrogates the binding of TIA1 to various proteins in its core proteome. Further, the association of tau with TIA1 regulates the pathophysiology of tau. Overexpression of TIA1 stabilizes tau in granules, induces tau misfolding, and stimulates neurodegeneration. Importantly, TIA1 is required for the neurotoxic effect of the disease-linked P301L tau mutation since TIA1 knockout rescues dendritic shortening and caspase activation induced by P301L tau. Pharmacological agents that increase SG formation (i.e. puromycin or salubrinal) potentiate TIA1-induced neurotoxicity while compounds that inhibit SG formation (i.e. cycloheximide) attenuate tau pathology and neurodegeneration. These results point to the translational stress response as a novel tau regulatory pathway and highlight new therapeutic strategies for the treatment of tauopathies such as AD and FTD.

Title: The increase of L-type calcium channel density produced by overexpression of human tau might underlie augmentation of the afterhyperpolarization in rat hippocampal neurons

Authors: *T. W. CHURCH[1], E. M. RANDALL[1], J. R. MONTOMERY[2], J. T. BROWN[3], N. V. MARRION[1];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Takeda Cambridge Ltd, Cambridge, United Kingdom; [3]Univ. of Exeter, Exeter, United Kingdom

Abstract: Tauopathies, including Alzheimer’s disease and frontotemporal dementia, are neurodegenerative diseases characterised by cognitive impairment. Reduced action potential firing, arising from augmented afterhyperpolarizations (AHPs) has been postulated to contribute to these intellectual impairments. A large component of AHPs in hippocampal neurons is

calcium (Ca^{2+}) dependent, with L-type channels implicated in being the source of Ca^{2+}. Overexpression of human tau isoform 4R0N augmented the currents underlying AHPs in rat CA1 hippocampal pyramidal neurons within an organotypic slice preparation. The current underlying the medium AHP (ImAHP) increased by 111%, while the current underlying the slow AHP (IsAHP) was augmented by 71%, when compared with currents recorded from CA1 neurons expressing eGFP alone. Expression of L-type CaV1.2 or CaV1.3 with α1δ1 and β2A or 3 subunits in tSA201 cells, resulted in voltage-dependent macroscopic currents recorded under whole-cell voltage-clamp conditions. Coexpression of human tau isoforms 4R0N or 4R2N resulted in larger macroscopic currents only when Ca^{2+} channel subunits were expressed with β3. CaV1.2-mediated current was increased 68% by coexpression of 4R0N, and 54% by coexpression of 4R2N. CaV1.3-mediated current was increased 23% by coexpression of human tau 4R2N. Neither human tau isoform had effect on macroscopic CaV1.2 or 1.3 current when expressed with β2A. Conversely, coexpression of human tau isoform 4R1N had no effect on expressed L-type Ca current regardless of the pore-forming or β subunits. Increased macroscopic current did not result from a shift of voltage dependence or sensitivity to voltage. The sensitivity of the ImAHP and IsAHP to L-type Ca channel inhibitors was investigated. The dihydropyridine antagonist nimodipine (10 μM) inhibited the ImAHP by 51% and the IsAHP by 53% in cells expressing eGFP alone. Augmented ImAHP and IsAHP in cells overexpressing human tau 4R0N were inhibited by 69% and 68% respectively by nimodipine. The increase in the amount of current in both AHP components sensitive to inhibition by nimodipine was mirrored by isradipine. These data suggest that two isoforms of human tau (4R0N and 4R2N) can increase the number of functional L-type Ca^{2+} channels, in a β subunit-dependent manner. The increase in L-type Ca^{2+} channel number augmented the amplitude of the Ca^{2+}-dependent components of the medium and slow AHPs in CA1 hippocampal neurons. The enhanced AHP increased spike accommodation, which may contribute to cognitive impairment in certain tauopathies.

Title: Mouse strain differences and tau pathology status contribute to variability in adeno-associated viral vector-mediated shRNA knockdown

Authors: *T. A. DAY[1], Z. YANG[1], D. L. CZILLI[1], J. M. WOLAK[2], Z. AHMED[2], S. BOSE[2], M. J. O'NEILL[2], P. C. MAY[1];
[1]Neurosci Discov Res., Eli Lilly & Co./Llc, Indianapolis, IN; [2]Neurosci Discov Res., Eli Lilly & Co./Llc, Windlesham, Surrey, United Kingdom

Abstract: Background: Adeno-associated viral (AAV) vector gene delivery is a popular choice for CNS research due to its reported safety, efficacy, specificity and stability. Pilot studies in male C57BL/6 mice showed robust and reproducible AAV9 transduction of either GSK3β shRNA or caspase-6 cDNA in the hippocampus. In contrast, two separate studies in rTg4510 mice showed reduced expression and significant variability in AAV9-GSK3β shRNA knockdown and AAV9-Caspase-6 expression. A head-to-head comparison study in male C57BL/6 mice and female rTg4510 homozygotes and wild-type littermates was conducted to identify a potential strain-related AAV9-shRNA transduction difference. Methods: AAV9-GSK3β shRNA-eGFP or AAV9-scrambled shRNA-eGFP was delivered unilaterally to four month old male C57BL/6 mice and three month old female rTg4510 homozygotes and wild-type littermates via a single stereotaxic CA1 hippocampal injection (1.1×10^{10} GCs). Six weeks post-transduction, animals were euthanized and hippocampal brain tissue was processed for quantitation of GSK3β gene knockdown and eGFP spread via qRT-PCR. Results: At six weeks post-transduction, GFP expression was present within the hippocampus of all AAV9-transduced mice and correlated with GSK3β gene knockdown. GSK3β gene knockdown variability was observed in all groups, but was most pronounced in female rTg4510 mice. The greatest amount of GSK3β gene knockdown (~60%) was observed in male C57BL/6 mice, while the lowest amount of GSK3β gene knockdown (~15%) was observed in female rTg4510 homozygote transgenic mice. The female rTg4510 wild-type littermates showed intermediate gene knockdown. Conclusions: Robust GFP expression correlated with gene-targeted knockdown in male C57BL/6 mice at six weeks post-transduction with AAV9-GSK3β shRNA-eGFP. However, AAV9-shRNA gene-targeted knockdown and eGFP expression was reduced and more variable in the rTg4510 tau transgenic mouse model, indicating a strain-related AAV9-shRNA transduction difference that was exacerbated by tau pathology status.

Title: Effects of thyroid hormone upon insulin signaling pathway and tau protein in the hippocampus of diabetic rats

Authors: *F. P. ALMEIDA, A. PANVELOSKI-COSTA, S. S. TEIXEIRA, M. NUNES, A. S. TORRAO;
Inst. of Biomed. Sci., Sao Paulo, Brazil

Abstract: Many studies have shown that insulin affects several brain functions including cognition and memory and have pointed out that insulin deficiency and/or resistance of the brain may be related to Alzheimer's disease (AD), suggesting a relationship between AD and diabetes mellitus (DM). In addition, several studies also suggest a modulation of thyroid hormones (TH) on insulin signaling and in the function of nervous system, showing that its deficiency or excess are involved in neurological symptoms. However, little is known about the effects of TH in the adult nervous system. The aim of this study was to evaluate the effects of TH (triiodothyronine-T3) treatment upon proteins related to insulin signaling pathway and neurodegeneration markers in the brain of diabetic rats. Adult male Wistar rats (300-350 g body weight) received a single intraperitoneal injection of saline (Control group, CTL) or 150 mg/kg alloxan monohydrate (Diabetic group, DM). After 15 days the animals were treated as follows: 1) CTL treated with

saline (C), 2) CTL treated with T3 (T3, 1.5 microg/100 g of body weight/day), 3) DM treated with saline (D), and 4) DM treated with T3 (DT3, 1.5 microgg/100 g of body weight/day). After 4 weeks of treatment the animals were sacrificed by decapitation and the hippocampus region subjected to immunobloting technique to evaluate the levels of insulin signaling pathway proteins (IR, Akt and p-Akt, GSK3 and p-GSK3) and neurodegenerative markers (p-Tau and Beta-amyloid peptide). The data were analyzed by ANOVA (two-way) and significance adopted $p < 0.05$. (Protocol CEUA 148/2014). T3 treatment produced a decrease of 33.24% in the IR levels compared to C group. D and T3 groups exhibited a decrease of 38.38% ($P<0.05$) and 45.27% ($P<0.05$), respectively, in p-Akt levels compared to C group, while DT3 group showed an increase of 31.32% ($P<0.05$) and 38.17% ($P<0.05$) in relation to D and T3 groups, respectively. Increases of 65.26% ($P<0.01$) in p-GSK3 were observed in T3 group, when compared to C group, while a decrease of 51.51% ($P<0.01$) was observed in DT3 group in relation to T3 group. Finally, the D group exhibited increases of 94.62% ($P<0.01$) in p-Tau levels, when compared to C group. In addition, we observed a decrease of 78.92% ($P<005$) in DT3 group when compared to D group. No significant differences were observed in Beta-amyloid levels. Our results suggest that diabetes or increased levels of HT conditions are able to produce an insulin resistance and degenerative states of the rat hippocampus, which may be reversed, at least partially, when both conditions are present.

Authors: *C. VOLLERT, L. MARTINEZ, M. TEJADA-SIMON, J. ERIKSEN; Pharmacol. and Pharmaceut. Sci., Univ. of Houston, Houston, TX

Abstract: Alzheimer’s Disease (AD) is the most common cause of neurodegeneration in patients over the age of 65. Pathological hallmarks of AD include the formation of plaques and neurofibrillary tangles in the brain that lead to gross loss of brain function. Mutations in the human GRN gene are associated with frontotemporal lobar dementia with ubiquitinated TDP-43 inclusions. Current studies suggest a reduction in progranulin (PGRN) has a broad importance for neurodegenerative disease and may be a risk factor for AD. Recently, PGRN was shown to be neuroprotective in an AD mouse model and modulates amyloid plaque load. However, despite a growing interest in the role of PGRN in dementia, there are no studies characterizing the behavioral and neuropathological effects of PGRN haploinsufficiency in an AD transgenic mouse model. In this study, we carry out a series of behavioral tests assessing motor control, emotion and memory in an AD mouse model. In addition we examined the effect of PGRN haploinsufficiency on neural correlates of learning and memory and amyloid-associated pathology using immunohistochemistry and western blot techniques. We report that PGRN haploinsufficiency in an AD transgenic mouse model results in significant behavioral impairments.

Title: Progranulin over expression in a mouse model of tauopathy

Authors: D. J. FINNERAN[1], *M. N. GORDON[2], D. MORGAN[1], K. R. NASH[1]; [1]Mol. Pharmacol. & Physiol., USF Hlth. Byrd Alzheimer Inst., Tampa, FL; [2]USF Hlth. Byrd Alzheimer's Inst., Tampa, FL

Abstract: Alzheimer’s disease is a progressive neurodegenerative disorder and the most common form of dementia. Microglial activation and inflammation have been suggested to be significant contributing factors to the neurodegeneration. It has been demonstrated that increasing inflammation exacerbates tau pathology while reducing inflammation ameliorates it. Progranulin is an endogenous growth factor secreted by both neurons and microglia that

attenuates microglial activation. Furthermore, mutations in the *GRN* gene are associated with Alzheimer's disease and frontotemporal lobar dementia. Experiments have shown that knockout of *GRN* exacerbates amyloid-beta deposition and worsens cognitive deficits in a mouse model of APP over expression. Furthermore, haploinsufficiency of *GRN* in P301L tau transgenic mice increases phosphorylation of tau. Conversely, over expression of progranulin suppresses amyloid-beta deposition in APP mice. The aim of this study was to examine the effects of over expressing progranulin in the Tg4510 mouse model of tauopathy. Four month-old Tg4510 mice were injected bilaterally into the hippocampus and anterior cortex with recombinant adeno-associated virus (rAAV) expressing progranulin or empty capsid as a control virus. Three months later, the animals were assessed behaviorally. We observed no improvement in cognitive performance of the animals injected with rAAV-progranulin as measured by radial arm water maze. Furthermore, the animals injected with rAAV-progranulin ran a significantly greater distance in the open field test than did non-transgenic animals. We are currently examining the levels of neurodegeneration and tau pathology but would predict no improvement or potentially worsening of disease pathology. The lack of behavioral and pathological rescue may be explained by the dual role of progranulin. Progranulin can be cleaved by matrix metalloproteases into one of seven granulins (A through E). Despite progranulin's anti-inflammatory effects, the granulins act as pro-inflammatory signals. Thus, the over expressed progranulin may have been cleaved to the pro-inflammatory granulins and exacerbated the tau pathology. We are currently examining the levels of progranulin versus granulins in our injected animals. These results indicate that, while progranulin over expression may ameliorate amyloid pathology, over expression does not alleviate tau behavioral deficits in the Tg4510 model of tauopathy.

Title: Metabotropic glutamate receptor 5 couples brain cellular prion protein physically and genetically to intracellular signaling

Authors: *L. T. HAAS, S. V. SALAZAR, S. M. STRITTMATTER;
Yale Univ., New Haven, CT

Abstract: We recently proposed that metabotropic glutamate receptor 5 (mGluR5) propagates neurotoxic signals from extracellular soluble Aβ oligomers (Aβo) bound to cellular prion protein (PrP) onto intracellular substrates. Here we report the novel finding that GPI-anchored PrP interacts physically with intracellular signaling mediators selectively when mGluR5 is present. The physical association between PrP and intracellular proteins can be modified by extracellular soluble Aβ oligomers (Aβo), the key mediators of Alzheimer's disease (AD) pathophysiology. Genetic coupling between *prnp* and *grm5* mediates acute Aβo-triggered alterations in activation states of intracellular proteins and Aβo-dependent impairment of synaptic plasticity *in vitro*. Interestingly, we can recapitulate alterations in activation states of intracellular mediators in a chronic *in vivo* model using APP/PS1 AD transgenic mice. Our data further verifies genetic coupling between *prnp* and *grm5* in mediating changes in protein phosphorylation states selectively in mouse hippocampus and cortex. Importantly, genetic coupling between *prnp* and *grm5* is also responsible for synapse loss and survival deficits in APP/PS1 AD transgenic model mice. Notably, phenotypes in *prnp* and *grm5* double heterozygote transgenic mice are recovered without altered gliosis, β-amyloid plaque load or Aβo levels. This suggests that the recovery is fully dependent on targeting signaling pathways responsible for Aβo-induced aberrations in AD transgenic mice. Thus, this study is of highest significance for the development of AD therapeutics.

Title: Prnp and Grm5 double heterozygous state rescues Aβo-dependent inhibition of long-term potentiation in hippocampal slices

Authors: *S. V. SALAZAR, L. T. HAAS, S. M. STRITTMATTER;
Program in Cell. Neuroscience, Neurodegeneration, and Repair, Yale Univ., New Haven, CT

Abstract: Alzheimer's disease (AD) is the most common form of dementia, and synaptic dysfunction and loss are central to symptoms of the disease. A growing amount of genetic and biochemical evidence exists for Amyloid-beta (Aß) as the cause of AD, and it is a soluble aggregated form, oligomeric Aß (Aßo), as the key toxic species. Our laboratory has identified the cellular prion protein (PrP^C) as a high-affinity binding partner to Aßo in an unbiased genome-wide screen. Subsequent work in our lab has identified Aßo-PrP^c coupling leads to activation of the intracellular tyrosine kinase Fyn through the transmembrane receptor mGluR5. Further, we have shown that *Prnp*$^{-/-}$ mice rescue Aßo-dependent deficits in long-term potentiation (LTP). My aim here was to investigate whether haploinsufficiency of Aßo-PrP-mGluR5-Fyn signaling components would ameliorate the inhibitory effects of LTP by Aßo. I used single heterozygous animals, *Prnp*$^{+/-}$ or *Grm5*$^{+/-}$, or transheterozygote *Prnp*$^{+/-}$ and *Grm5*$^{+/-}$ animals to determine their effect on LTP in the presence or absence of Aßo. Single heterozygous animals do not rescue Aßo-dependent LTP deficits, while transheterozygote *Prnp*$^{+/-}$ and *Grm5*$^{+/-}$ animals rescue these deficits. My work here establishes a genetic interaction between *Prnp* and *Grm5* in the Aßo-dependent inhibition of LTP. These results underscore the importance of mGluR5 and PrP^c in developing therapeutics for the treatment of Alzheimer's disease.

Title: Impact of crfr1 ablation on amyloid-β production and accumulation in a mouse model of Alzheimer's disease

Authors: *S. N. CAMPBELL, C. ZHANG, A. D. ROE, N. LEE, K. U. LAO, L. MONTE, M. C. DONOHUE, R. A. RISSMAN;

Abstract: Stress exposure and the corticotropin-releasing factor (CRF) system have been implicated as mechanistically involved in both Alzheimer's disease (AD) and associated rodent models. In particular, the major stress receptor, CRF receptor type 1 (CRFR1), modulates cellular activity in many AD-relevant brain areas, and has been demonstrated to impact both tau phosphorylation and amyloid-β (Aβ) pathways. The overarching goal of our laboratory is to develop and characterize agents that impact the CRF signaling system as disease-modifying treatments for AD. In the present study, we developed a novel transgenic mouse to determine whether partial or complete ablation of CRFR1 was feasible in an AD transgenic model and whether this type of treatment could impact Aβ pathology. Double transgenic AD mice (PSAPP) were crossed to mice null for CRFR1; resultant CRFR1 heterozygous (PSAPP-R1+/-) and homozygous (PSAPP-R1-/-) female offspring were used at 12 months of age to examine the impact of CRFR1 disruption on the severity of AD Aβ levels and pathology. We found that both PSAPP-R1+/- and PSAPP-R1-/- had significantly reduced Aβ burden in the hippocampus, insular, rhinal, and retrosplenial cortices. Accordingly, we observed dramatic reductions in Aβ peptides and AβPP-CTFs, providing support for a direct relationship between CRFR1 and Aβ

production pathways. In summary, our results suggest that interference of CRFR1 in an AD model is tolerable and is efficacious in impacting Aβ neuropathology.

Title: Pramlintide antagonizes beta amyloid (Aβ)- and human amylin-induced depression of hippocampal long-term potentiation

Authors: ***R. KIMURA**[1], D. MACTAVISH[2], J. YANG[2,3], D. WESTAWAY[2,3], J. JHAMANDAS[2];

Abstract: Alzheimer's disease (AD) is characterized by accumulation of amyloid-β peptide (Aβ) in the brain regions that subserve memory and cognition. We have previously demonstrated that electrophysiological and neurotoxic effects of human amylin and Aβ are expressed via the amylin receptor. Furthermore, the effects of $A\beta_{1-42}$ and human amylin on hippocampal long-term potentiation (LTP) are blocked by the amylin receptor antagonist, AC253. Recently pramlintide, a synthetic analog of amylin, has been reported to improve cognitive function in transgenic AD mouse models. In this study, we examined the effects of pramlintide on $A\beta_{1-42}$ and human amylin-evoked depression of LTP at Schaeffer collateral-CA1 hippocampal synapses. In mouse hippocampal brain slices, field excitatory postsynaptic potentials (fEPSPs) were recorded from the stratum radiatum layer of the CA1 area in response to electrical stimulation of Schaeffer collateral afferents. LTP was induced by either high frequency (HFS) or 3-theta burst stimulation (TBS) protocols. $A\beta_{1-42}$ (50 nM) and human amylin (50 nM), but not $A\beta_{42-1}$ (50 nM), depressed LTP evoked using both stimulation protocols. Pre-application of pramlintide (250 nM) blocked Aβ- and human amylin-induced reduction of LTP without affecting baseline transmission or LTP on its own. We also examined the effects of pramlintide on LTP in transgenic mice (TgCRND8) that over-express amyloid precursor protein. In contrast to wild-type controls, where robust LTP was observed, 6-12-month old TgCRND8 mice show blunted LTP. In TgCRND8 mice, basal

LTP is enhanced by application of pramlintide. Our data suggest that pramlintide, like AC253, acts as an amylin receptor antagonist to reverse the effects of $A\beta_{1-42}$ and human amylin on LTP and also increases LTP in transgenic mice that demonstrate increased ambient brain amyloid levels. Amylin receptor antagonists may thus serve as potentially useful therapeutic agents in treatment of AD.

Abstract: Alzheimer's disease (AD) is associated with peripheral metabolic disorders. Clinical/epidemiological data indicate increased risk of diabetes in AD patients. Here, we show that intracerebroventricular infusion of AD-associated Aβ oligomers (AβOs) in mice triggered peripheral glucose intolerance, a phenomenon further verified in two transgenic mouse models of AD. Systemically injected AβOs failed to induce glucose intolerance, suggesting AβOs target brain regions involved in peripheral metabolic control. Accordingly, we show that AβOs affected hypothalamic neurons in culture, inducing eukaryotic translation initiation factor 2α phosphorylation (eIF2α-P). AβOs further induced eIF2α-P and activated proinflammatory IKKβ/NF-κB signaling in the hypothalamus of mice and macaques. AβOs failed to trigger peripheral glucose intolerance in tumor necrosis factor-α (TNF-α) receptor 1 knockout mice. Pharmacological inhibition of brain inflammation and endoplasmic reticulum stress prevented glucose intolerance in mice, indicating that AβOs act via a central route to affect peripheral glucose homeostasis. While the hypothalamus has been largely ignored in the AD field, our findings indicate that AβOs affect this brain region and reveal novel shared molecular mechanisms between hypothalamic dysfunction in metabolic disorders and AD.

Title: Pyroglutamate-amyloid-11-42 peptide induces antibodies recognizing main pathological forms of amyloid present in human brain and protection without activation of autoreactive T cells

Authors: ***G. GEVORKIAN**, R. PEREZ GARMENDIA, G. ACERO, A. POMMER, E. GONZALEZ AVILA;
UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, DISTRITO FEDERAL, Mexico

Abstract: Objectives: N-truncated/modified forms of amyloid beta (Abeta) peptide are found in diffused and dense core plaques in Alzheimer's disease (AD) and Down's syndrome patients as well as animal models of AD, and represent highly desirable therapeutic targets. An important requirement for safe immunotherapy for AD is prevention of activation of autoreactive T cells since they may increase the incidence of adverse events in the elderly population as observed in early clinical trials. In this study we evaluated antibody production, T cell response and protection in mice and in cholesterol-fed rabbits after immunization with pyroglutamate-amyloid-11-42 (AbetaN11(pE)) in the presence of saponin. Methods: C57BL/6J wild type and 3XTg-AD mice were immunized with AbetaN11(pE) using saponin as an adjuvant. ELISA and cell proliferation assay followed by flow cytometric analysis and supernatant cytokine measurement were performed using standard protocols. Reduction of Abeta in the brains of AbetaN11(pE)-immunized 3xTg-AD mice as well as cholesterol-fed rabbits was evaluated by ELISA and dot blot. Results: We have demonstrated that AbetaN11(pE) induced antibodies binding to different pathological amyloid species present in human brain: Abeta1-42, AbetaN3(pE) and AbetaN11(pE). Interestingly, we did not observe proliferation of AbetaN11(pE) immunized mouse T cells *in vitro* in the presence of any Abeta peptide/epitope probably because of the loss of the known T cell epitope mapped to the central region of Abeta 1-42 in previous studies. We did not detect microhemorrhages in the brains of immunized wild-type and 3xTg-AD mice. Total Abeta load was reduced in the brains of 3xTg-AD mice and cholesterol-fed rabbits after immunization with AbetaN11(pE). Conclusions: Our results may have implication in future design of new immunotherapeutic protocols for AD targeting different Abeta species with reduced risk of side effects related with activation of autoreactive T cells.

Title: Effects of unsaturated fatty acids on Aβ fibrillization

Authors: ***M. ETO**[1,2], T. HASHIMOTO[1], T. SHIMIZU[2], T. IWATSUBO[1];
[1]Fac. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]Natl. Ctr. for Global Hlth. and Med., Tokyo, Japan

Abstract: Amyloid β peptide (Aβ) is the major component of amyloid fibrils in the senile plaques found in the brains of patients with Alzheimer disease (AD). Aβ aggregation and accumulation cause neuronal cell death, leading to cognitive impairment in patients. The course of Aβ fibril formation starts from a lag phase (nucleation phase), followed by a rapid elongation phase. In this study, we focused on the effects of lipids on Aβ fibrillization *in vitro*. First we incubated synthetic Aβ1-40 or Aβ1-42 peptides (11 μM) with phospholipid liposomes (PC, PE, PA or PG) or free fatty acids (palmitic acid (16:0), oleic acid (18:1), arachidonic acid (20:4), or docosahexaenoic acid (22:6, DHA)) at 37 °C for 4 h. The level of Aβ fibrillization was quantified using thioflavin T (ThT). Aβ peptides incubated with unsaturated free fatty acids showed higher ThT fluorescence compared to vehicle treated Aβ. Saturated fatty acids and phospholipid liposomes showed no effects. We next incubated Aβ1-40 with vehicle, palmitic acid (saturated) or DHA (unsaturated) for different time periods. DHA treated Aβ showed high ThT fluorescence at 1 h, while vehicle and palmitic acid treated Aβ started the fibrillization at 24 h. This suggests that DHA might shorten the nucleation phase of Aβ fibrillization. Treatment with different concentrations of DHA showed that the effect of DHA was concentration-dependent. Next, we studied whether DHA treated Aβ1-40 had higher seeding effects. We incubated vehicle or DHA treated Aβ1-40 for 24 h, diluted the samples in a new Aβ1-40 mixture at 1/100, and incubated them for a further 4, 8, and 24 h. Surprisingly, DHA treated Aβ1-40 had lower seeding effects compared to vehicle treated samples. To study the morphology of Aβ1-40 fibrils treated with unsaturated fatty acids, Aβ1-40 was incubated with vehicle or DHA for 4, 8, and 24 h, and the ultrastructure was observed by negative stain electron microscopy. DHA treated Aβ1-40 showed short (< 200 nm) and curved fibrils at all time points examined, whereas vehicle treated Aβ formed long (> 200 nm) and straight fibrils at 24 h. In this study, we newly found that unsaturated free fatty acids shorten the nucleation phase of Aβ aggregation, and form Aβ1-40 fibrils with short and curved morphology. These fibrils showed lower seeding effects compared to vehicle treated Aβ1-40. These results suggest that unsaturated fatty acids rapidly convert Aβ peptides into off-pathway intermediates in the Aβ amyloid fibril formation. Further *in vitro* and *in vivo* studies are needed to know whether unsaturated fatty acids alleviate or exacerbate the Aβ pathology in the brain.

Title: Neprilysin: neurogenesis and ß-amyloid toxicity

Authors: S. KRAFT[1], B. HEIMRICH[1], C. KLEIN[3], M. MAITRE[3], H.-D. HOFMANN[1], A. G. MENSAH-NYAGAN[3], *M. KIRSCH[2];
[1]Anat. & Cell Biol., Neuroanat., [2]Univ. Freiburg, D-79104 Freiburg, Germany; [3]Biopathologie de la Myéline, Neuroprotection et Stratégies Thérapeutiques, INSERM U1119, Univ. de Strasbourg, Strasbourg, France

Abstract: Alzheimer Disease is the leading cause of dementia and affects up to 36 Million people. In over 95% of the cases neuronal degeneration is accompanied by pathological accumulation of ß-amyloid resulting from proteolytic processing of APP. There is also evidence, that the decline in cognitive function is exacerbated by impaired neurogenesis. Previous reports relate increased Aß levels to decreased numbers of stem/progenitor cells in the subgranular zone of the dentate gyrus (SGZ) and the subventricular zone of the lateral ventricle (SVZ). The metalloproteinase Neprilysin (NEP) is the key Aß degradating enzyme and by reducing amyloid may also protect neural stem/progenitor cells from its toxic effects. We examined NEP expression in the two major neurogenic areas of the adult mouse brain, SVZ and SGZ, in neural stem cell cultures and in organotypic hippocampal slice cultures (OHSC). Immunofluorescence staining of brain sections shows that NEP is expressed in both neurogenic areas, mainly by immature neurons, identified by staining for doublecortin and PSA-NCAM. *In vitro*, proliferating neural stem cells express NEP at low levels. However, NEP-expression and activity strongly increased during differentiation. A similar increase of expression during maturation was also observed in OHSCs. By comparing toxicity of exogenous Aß in proliferating and differentiating neural stem cells, we could show that toxicity is inversely correlated with NEP-expression and activity levels. Addition of recombinant NEP completely protects proliferating neural stem cells from Aß-toxicity. In OHSCs exogenous Aß initially induces NEP expression. However, prolonged treatment with Aß, NEP-expression is reduced and plaque like structures develop. In summary, our data suggest that proliferating neural stem cells are particularly vulnerable when exposed to Aß due to their low NEP-expression. Their progeny on the other hand, by upregulating NEP expression become more resistant. Stimulating expression of NEP may therefore help to protect the sensitive stem cell population.

Title: Circadian system influence on beta-amyloid diurnal oscillation

Authors: ***G. J. KRESS**, F. LIAO, D. M. HOLTZMAN, E. S. MUSIEK;
Dept of Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Alzheimer's Disease (AD) is the most common neurodegenerative disease associated with age-related cognitive decline. The accumulation of pathogenic β-amyloid (Aβ) plaques during AD progression appears to precede the onset of cognitive impairments. Thus, it is important to identify mechanisms that influence Aβ accumulation which may be useful for the prevention of cognitive decline in AD. Recently, several studies in both humans and rodents, show acute changes in the sleep/wake cycle influence soluble Aβ levels, while chronic sleep/wake disturbances contribute to increased Aβ plaque formation. Additionally, it has been shown that brain Aβ aggregation leads to the disruption of sleep and circadian rhythms in mice. These findings implicate circadian clock dysfunction as either a cause or a consequence of the disease process. Therefore, we sought to investigate the role of circadian clock function in the diurnal oscillation of Aβ levels in a mouse model of AD. Our overall study aim is to disrupt circadian clock function without perturbing the sleep/wake cycle in order to isolate roles of the circadian system impacting brain Aβ levels. We therefore genetically distributed hippocampal circadian clock function via viral mediated deletion of a core clock gene, Bmal1 within the hippocampus of ~1.5 month old AD mice. This AD model has both presenilin 1 (L166P) and the amyloid precursor protein mutations (KM670/671NL), with Aβ plaque deposition at around 2 months of age and rapidly accumulates. Using *in vivo* microdialysis in awake behaving mice, in 12:12 light:dark conditions, we collected hourly interstitial fluid from the ipsilateral virally injected hippocampus. We found no change in the diurnal Aβ oscillation when hippocampal clock function was disrupted, supporting the idea that local clock function within the

Deleted: in vivo

hippocampus does not acutely mediate Aβ levels. Next we asked if disrupting circadian clock function within the whole brain, while sparing the suprachiasmatic nucleus (SCN) and leaving the sleep/wake cycle intact, would influence Aβ levels. To our surprise, we found no change in the diurnal oscillation of Aβ levels in the hippocampus. Currently, we are collecting samples to investigate if global Bmal1 gene excision resulting in fragmented sleep patterns impacts the diurnal oscillation of Aβ levels. In summary, our present study shows that acute Aβ levels are not influenced by circadian clock function outside of the SCN, implicating the SCN and sleep/wake dynamics as key regulators of Aβ oscillation. The insight gained from this work should create a cellular framework within which the dynamics of Aβ levels can be better understood and therapeutically modulated.

Abstract: Alzheimer disease (AD), the most prevalent type of dementia, has been associated with the accumulation of amyloid beta oligomers (AbetaOs) in the brain. Reported AbetaO species vary widely in size, ranging from dimers to larger than 100 kDa. Evidence indicates that not all oligomers are toxic, and there is yet no consensus on the size of the actual toxic oligomer. To address this question, we have made use of conformational antibodies to detect and isolate particular Abeta species from both *in vitro* and *in vivo* sources. In one of these approaches, we have used NU4, a well characterized anti-AbetaO monoclonal antibody, to investigate size and shape of a toxic AbetaO assembly. By using a combination of size-exclusion chromatography and immuno-based detection we isolated an AbetaO-NU4 complex ameanable for biochemical and morphological studies. The apparent molecular mass of the NU4-targeted oligomer was 80 kDa. Atomic force microscopy imaging of the AbetaO-NU4 complex showed a size distribution centered at 5.37 nm, an increment of 1.5 nm compared to the size of AbetaOs (3.85 nm). This increment was compatible with the size of NU4 (1.3 nm), suggesting a 1:1 oligomer to NU4 ratio. NU4-reactive oligomers extracted from AD human brain concentrated in a molecular mass range similar to that found for *in vitro*-prepared oligomers, supporting the relevance of the species herein studied. These results, along with data obatnied using conformational antibodies targeting distinct Abeta oligomers, represent an important step towards understanding the connection between AbetaO size and toxicity, and may guide the search for novel anti-AD therapeutics aimed to neutralize toxic oligomers.

Title: The deleterious impact of soluble amyloid-beta oligomers on memory and sleep in Alzheimer's disease

Authors: A. SAJADI, C. PROVOST, G. FERLAND, V. MONGRAIN, R. GODBOUT, *J. BROUILLETTE;
Hôpital du Sacré-Coeur de Montréal, Univ. de Montréal, Montreal, QC, Canada

Abstract: Alzheimer's disease (AD) is the leading cause of dementia among people over 65-years old, and affects approximately one in three individuals over 85-years. Thirty five million people are affected by AD worldwide, and it is expected to reach 114 million by 2050 if new therapies do not emerge. Currently, there is no treatment to cure or halt this devastating age-related neurodegenerative disorder. Decline in hippocampal-dependent explicit memory (memory for facts and events) is the earliest clinical symptom of AD. It is well established that synapse loss and ensuing neurodegeneration are the best predictors for memory impairments in AD. Latest studies have emphasized the neurotoxic role of soluble amyloid-beta oligomers (Aβo) that begin to accumulate in the human brain approximately 10 to 15 years before the clinical symptoms become apparent. Many reports indicate that soluble Aβo correlate with memory deficits in AD models and humans. In addition, cognitive decline in mild cognitive impairment (MCI) and early AD was shown to be accompanied by poor sleep quality, difficulty initiating sleep, insomnia, and early morning wakening. Although recent ground-breaking discoveries have shown the critical impact of sleep on the regulation of Aβo level in the brain, the interaction existing between soluble Aβo and sleep loss to induce memory impairments at the onset of AD still need to be determined. To achieve our goal, we took advantage of our novel AD animal model in which repeated Aβo injections mimic the synaptic and neuronal loss observed in early AD. We observed that hippocampal accumulation of Aβo was associated with marked cell death, and memory deficits in the passive avoidance task. Electroencephalography (EEG) and electromyography (EMG) measurements were also done on these animals to analyze various oscillatory activities (delta, theta, sigma, alpha, and gamma waves) during rapid eye movement (REM) sleep and non-REM (NREM) sleep as well as in wake AD animals. The results obtained so far support the notion that soluble Aβo might have a deleterious effect on memory and sleep hallmarks affected in AD.

Title: Expression of Calbindin is suppressed by Aβ peptide

Authors: *H. CHOI, E. JUNG, Y. KIM, I. MOOK-JUNG;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD) is an age-related neurological disorder and β-amyloid (Aβ) is one of the major causative factors. Calcium is an important ion to regulate neuronal homeostasis and Calbindin D28k (Calbindin), a calcium-binding buffering protein, has critical roles in the calcium homeostasis and neuroprotection in central nervous system (CNS). It has been reported that Calbindin expression is reduced in the hippocampus of AD mouse models and patients. Moreover, crucial roles of Calbindin in the pathogenesis of AD using Calbindin D28k KO X 5XFAD (CBKOTg) mice were confirmed in our previous study. Since Aβ positive neurons are not able to detect Calbindin expression and Calbindin protein level was reduced by exogenously added Aβ42 in primary cultured hippocampal neurons, we hypothesize that Ab suppresses Calbindin expression indirectly as Ab cannot enter the nucleus. In this study, promoter assay system with Calbindin promoter was set up to identify transcription factors that regulate Ab-induced Calbindin expression. Several possible transcription factors are underway to examine the role of modulation in Calbindin expression. It will provide important clues to figure out the mechanism of Calbindin expression in AD pathogenesis.

Title: Amyloid-β binds to cerebral proteins

Authors: *D. M. RIDGLEY[1], G. SUN[2], T. TENG[3], J. LEE[3];
[2]Biochem., [3]Bioengineering, [1]Univ. of Missouri, Columbia, MO

Abstract: Alzheimer's disease (AD) is the most common form of dementia which affected an estimated 5.2 million Americans in 2014 and is characterized by neurofibrillary tangles and the accumulation of Amyloid-β (Aβ) forming insoluble aggregates and plaques. Aβ is cleaved from the amyloid precursor protein (APP) by the sequential cleavage of β- and γ-secretases. Both of

the most common forms of Aβ (Aβ42 and Aβ40) are capable of aggregating into oligomers, fibrils and plaques, although Aβ42 is the better aggregator due to two additional aliphatic amino acids on its c-terminus. Increasing evidence demonstrated oligomeric Aβ is the most toxic form of Aβ in AD and this form can lead to oxidative stress and inflammation, two hallmarks of AD. It is this principle that led to the hypothesis that Aβ can bind to or aggregate with natively stable cerebral proteins to form small Aβ-protein complexes that may contribute to AD pathogenesis. Here we introduce the Amyloid-β Binding Affinity Score (AβBAS) which is calculated based on a protein's secondary structure, hydrophobic amino acid content and disulfide bonds. Over 70 natively stable proteins known to exist within the cerebrospinal fluid were ranked according to AβBAS. Interestingly, some of the highest ranking proteins, such as ApoE and S-100B, are associated with AD pathogenesis. Other high ranking proteins, such as α- and β-hemoglobin, may contribute to AD pathology due to interaction with blood brain barrier (BBB). Finally, new proteins can be hypothesized for their possible involvement in the AD pathology due to their high AβBAS ranking. This study utilizes AβBAS to identify cerebral proteins with a high propensity to bind to Aβ. Furthermore, the affinity for Aβ42 to bind to and/or aggregate with some of the aforementioned proteins is characterized and quantified using spectroscopy and microscopy. Cytotoxic and biochemical assays are also employed to characterize what affect (if any) these Aβ-protein complexes may have on cerebral cellular functions. This study utilizes AβBAS to identify and characterize Aβ42 binding propensity to natively stable proteins providing useful information to understand proteins that are already implicated in AD pathology as well as to unveil new proteins that may interact with Aβ42 and play an unknown role in AD etiology. This work has the potential to introduce new proteins, therapeutic targets and mechanisms that contribute to neurodegeneration in AD.

Title: Role of ABCA7 in clearance of amyloid-beta peptides

Authors: *W. S. KIM;
Neurosci. Res. Australia, Randwick, Australia

Abstract: Genome-wide association studies indicate that ATP-binding cassette transporter A7 (ABCA7) is a strong risk factor for late-onset Alzheimer's disease (AD). We have previously demonstrated that deletion of ABCA7 in the J20 amyloidogenic mouse causes significant increases in insoluble amyloid-beta levels with concomitant increases in the number of amyloid-beta plaques in the hippocampus. ABCA7 has also been implicated in the role of phagocytosis. However, the mechanism by which ABCA7 reduces amyloid-beta load in the brain is unknown. In this study we investigated the role of ABCA7 in clearance of amyloid-beta (Aβ) peptides. We isolated the brain from ABCA7 knockout mice and wild type littermates following thorough perfusion with Hank's buffer. The whole brains were homogenized, filtered through cell strainer and cultured in flasks using L929 media. Following shaking the floating microglia were harvested and seeded onto chamber slides. They were then treated with FITC-labelled Aβ40 and Aβ42 oligomers, separately, and the uptake of Aβ oligomers was analysed using fluorescence microscopy. The clearance of both Aβ40 and Aβ42 oligomers was significantly reduced in microglia from ABCA7 knockout mice compared to those from wild type mice. We conclude that ABCA7 mediates microglial clearance of Aβ oligomers, providing a pathogenic mechanism by which ABCA7 is implicated in AD neuropathology.

Title: Dependently concentration effects of Amyloid-beta (25-35) peptide on oxidative stress in septal-hippocampal pathway of rats

Authors: *I. LIMON PEREZ DE LEON[1], F. SÁNCHEZ-CANO[1], A. BÁEZ-CORDERO[1], A. PATRICIIO[1], L. MENDIETA[2];
[1]Benemerita Univ. Autonoma De Puebla FCQ Lab. Neurofarma, Puebla, Mexico; [2]Inst. Cajal, Ctr. de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas, Consejo Superior de Investigaciones Científicas (CSIC), Madrid, Spain

Abstract: The amyloid-beta (25-35) fraction (Aβ(25-35)) impairs short and long-term memory in rats, similarly to full length amyloid-beta peptide. Moreover, Aβ(25-35) causes a loss of the

cholinergic phenotype of septal neurons without neuronal cell death in medial septum (MS). Therefore the functionality of the septal-hippocampal regions may be crucial for memory process. In this study, we have investigated the effects of three different Aβ25-35 concentrations administered into the medial septum (MS) of rats on spatial memory and nitrosative stress in MS, hippocampus (Hp) and frontal cortex (FCx). For this purpose, male Wistar rats were administered unilaterally with Aβ25-35 at one of the following concentrations [100 μM], [500 μM] and [1 mM] by stereotaxic surgery. Fourteen days after spatial learning was tested in Water maze for 5 consecutive days, and one week later spatial memory was tested during one day of evaluation. At the end of behavioral testing, animals were sacrificed to get the brain and dissect MS, Hp and FCx. In these areas of the brain the following oxidative markers was investigated: Nitric oxide (NO), lipoperoxidation (LPO) by colorimetric methods and nitration of proteins (3-NT) by immunohistochemistry. We found that spatial memory impairments in Aβ25-35- treated group was concentration dependent, where the higher concentration of Aβ25-35 [1mM] causes a significant deficit in the spatial memory respect to control group. Meanwhile [100μM] Aβ25-35 did not impairs the spatial memory of rats. These effect could be due to of that Aβ25-35 [1mM] increases NO and LPO levels, accompanied of higher 3-NT immunorreactivity in MS and Hp respect to animals that received lower doses of Aβ25-35 or control group. These results indicate that Aβ25-35 causes nitrosative stress and impairs spatial memory of rats in a concentration-dependent manner.

Title: Aggregation states of amyloid-β affect apolipoprotein E secretion and lipidation

Authors: *D. S. CHERNICK[1], L. LI[2];
[1]Pharmacol., [2]Exptl. and Clin. Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Alzheimer's disease (AD) is an age-related debilitating neurodegenerative disease that afflicts approximately five million individuals in the U.S. alone. Although the pathogenesis of AD is not fully understood, it is widely accepted that accumulation of amyloid-β protein (Aβ) in the brain initiates the pathogenic cascade, ultimately leading to neurodegeneration and dementia. Apolipoprotein E (apoE) in the brain is produced primarily by astrocytes and microglia. Once secreted, apoE binds lipids and forms high-density lipoprotein (HDL)-like particles in the interstitial and cerebrospinal fluid. Human apoE has three common isoforms, designated E2, E3, and E4. The apoE4 allele is the major genetic risk factor for late-onset AD, increasing an individual's risk for AD up to 15-fold. As such, apoE has been extensively studied in AD. It has been shown that apoE directly interacts with Aβ, and that the level and lipidation state of apoE affects Aβ aggregation and clearance. ApoE may also play a role in AD via effects on cholesterol/lipid metabolism, synaptic plasticity, cell signaling, and inflammation. However, the effects of AD pathology on apoE have not been as deeply explored. It has been shown that apoE levels are reduced in AD patients, and that astrocytes surrounding Aβ plaques do not express apoE. Compelling evidence indicates that aggregated states of Aβ play differential roles in AD. However, the effects of different forms of Aβ on apoE have not been thoroughly examined. Therefore, this study was designed to test the hypothesis that different aggregation states of Aβ (monomeric, oligomeric, and fibrilar) will have differential effects on apoE expression, secretion and lipidation in glial cells. Preliminary results show that oligomeric and fibrilar forms of Aβ significantly reduce apoE secretion and lipidation from primary mouse astrocytes and microglia as well as microglial-BV2 cells. Future studies will determine if Aβ has differential effects on the three human apoE isoforms by utilizing primary astrocytes and microglia cultured from targeted replacement mice. Studies of mRNA, apoE-regulating transcription factors, as well as the members of the exocytic pathway will allow us to determine if Aβ's effect on apoE is through direct effects on expression, or due to indirect effects on the secretory pathway. In addition, both astrocytes and microglia treated with an apoA-I mimetic peptide showed increased secretion and lipidation of apoE. Experiments are underway to determine if treatment with the apoA-I mimetic peptide mitigates Aβ-induced changes in apoE secretion and lipidation.

Title: Amyloid beta oligomers alter sensitivity of hippocampal neurons to optogenetic stimulation

Authors: ***G. J. PAGANDIAZ**[1], M. WANG[2], A. JOSE[3], P. SENGUPTA[1,4];
[1]Dept. of Bioengineering, [2]Dept. of Animal Sci., [3]Dept. of Mol. and Cell. Biol., [4]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Alzheimer's disease (AD) is an irreversible, progressive brain disease that slowly destroys thinking skills and memory, and eventually the ability to carry out the simplest everyday tasks. Extra-cellular deposition of insoluble amyloid-β (Aβ) plaques and intra-cellular neurofibrillary tangles in the brains are hallmarks of this disease. The monomers of Aβ peptide are soluble and are thought to be harmless until toxic soluble intermediates, Aβ oligomers (AβOs), concentration is elevated. At relatively lower concentrations, AβOs do not cause apparent neurodegeneration or cell death. But it is postulated that they cause subtle, often un-detectable, changes to the neural network dynamics. In this study, we set out to delineate this subtle effects of very low concentrations of AβOs on neuronal network dynamics and its sensitivity to external stimulation. For our investigation, we have developed a hybrid technology based on optogenetics and multi-electrode array (MEA) electrophysiology. This combinatorial approach can be used to induce, detect and track short- and long-term changes in spontaneous and evoked neuronal network activity in response to optical stimuli, using a 470 nm LED, under various types of AβO exposure. We used disassociated cultures of primary mouse hippocampal neurons for detecting any changes in spontaneous network activity. For optogenetic stimulation experiments, mouse hippocampal neurons expressing channelrhodopsin-2 (ChR2) were used. Spike and burst analyses were performed using MC-Rack software (Multichannel Systems), and sensitivity to stimulation was determined using codes developed in-house. Our results demonstrate that even though sub-nanomolar AβOs did not generate any lasting changes to spontaneous network activity, it altered its response to optogenetic stimulation. AβO-treated networks were hyper-sensitive, but they showed larger quiescence time post-stimulation. These observations indicate a subtle, but significant, change in network equilibrium dynamics in cultured networks. A more comprehensive study aiming to link this phenomena to network plasticity, and its potential use as an assay for testing new drug candidates are currently underway.

Title: Oligomeric Aβ42 toxicity induce ER calcium release in subicular pyramidal neurons

Authors: *S. ANGULO[1], H. MORENO[2];
[1]Pharmacol. and Physiol., [2]Pharmacol. and Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Subicular pyramidal neurons are vulnerable to the pathophysiology of Alzheimer's Disease (AD) in its early stages. There is mounting evidence of calcium dyshomeosthasis in AD, but the mechanism of such alterations remains unclear. In familial AD (PS1 mutation), the calcium release from the Endoplasmic Reticulum (ER) is increased through the activation of IP3 receptors (IP3R) and Ryanodine receptor (RyR). It is still unknown if (or how) the oligomeric Aβ42 (oAβ42) affects the function of these receptors in subicular pyramidal neurons. Our preliminary data showed that the acute treatment with oAβ42 increased the peak calcium transients in the apical dendrites of subicular neurons, and we hypothesized that the possible mechanism underlying this process is the increase of calcium release from the ER. We performed calcium imaging in combination with patch-clamp in whole-cell recording in subicular pyramidal neurons from mice (1 month-old) acute brain slices. We used Oregon Green-1 BAPTA (50μM) as a calcium indicator, and studied the calcium transients induced by 3 rapid depolarization steps in voltage-clamp. Calcium signals from the apical dendrite compartment were initially characterized, and pharmacologically dissected. A specific blocker of RyR (Dantrolene 10μM) decreased the peak of the calcium transients by 36%, but the transients remained unchanged in the presence of specific blockers of IP3R (Xestospongin C 1μM, 2-APB 30μM). Treatment with Caffeine (10mM) decreased the peak calcium transient by 46%, possibly through calcium store depletion of the ER. oAβ42 increased the peak calcium transient by 34%, but the combination of oAβ42 and caffeine reduced the peak calcium transient by 40%. Calcium transients were unaltered by the treatment with the control peptide (Aβ scrambled), and were decreased if caffeine was also present in the bath. To verify that caffeine affected the calcium release from the ER in the apical dendrites of subicular pyramidal neurons, we induced calcium transients with rapid and local extracellular application of caffeine (20mM) that were dependent

of the calcium release from ER through RyR. We conclude that the calcium release from the ER (specially the RyR) contribute to the calcium transients evoked by rapid depolarization of subicular neurons. Calcium transients were increased with oAβ42, and this is in part mediated through calcium release from the ER. oAβ42 toxicity in the ER can lead to a molecular cascade of cellular damage that can be part of the early pathophysiology of AD. Presently we are conducting IP3 uncaging experiments in subicular neurons from amyloidogenic mouse model (J20) and control.

Title: Aβ1-42 oligomers block the inward rectifier potassium currents from rat pyramidal neurons

Authors: M. CUAXOSPA[1], *J. M. ARIAS[2], U. GARCÍA[1];
[1]Physiology, Biophysics and Neurosciences, CINVESTAV, Mexico City, Mexico; [2]FES Iztacala -UNAM, Tlalnepantla de Baz, Mexico

Abstract: A seminal event in the pathogenesis of Alzheimer's disease (AD) is the abnormal proteolytic processing of amyloid precursor protein (APP), resulting in increased production of a self-aggregating form of β amyloid (Aβ). A portion of Aβ peptides can oligomerize, initially intravesicularly, and be released into the interstitial fluid of brain, where soluble oligomers may diffuse into synaptic clefts and interfere with synaptic function by unknown mechanisms. Aβ oligomers can further polymerize into insoluble amyloid fibrils that aggregate into spherical plaques, resulting in tortuosity and dysfunction of adjacent axons and dendrites in the entorhinal cortex of the brain (Selkoe, 2004). Aβ oligomers are known to be the neurotoxins responsible for neuronal death, the underlying mechanisms remain largely elusive. Here we report the interaction between Aβ1-42 oligomers and inward rectifier potassium channels from pyramidal neurons of the rat entorhinal cortex. Aβ1-42 oligomers were prepared by incubating aqueous solutions of peptide monomer for up to 48 h. Atomic force microscopy showed a wide range of oligomeric species with molecular diameters ranging between ∼15 and 30 nm, corresponding to

roughly 5-40 peptide multimers, which were recognized by 6E10 and OC, sequence- and fibrillar-specific Aβ antibodies, respectively (Kayed et al., 2010). Aβ1-42 oligomers were assayed at 1 μg/ml on the isolated inward rectifier potassium currents (Kir) using both whole-cell and cell-attached voltage-clamp recordings on pyramidal neurons in culture as well as HEK-293T cells that transient expressed Kir2.1 channels. Aβ1-42 oligomers induced a reversible blockade about 40% of the macroscopic current in pyramidal neurons before 5 min application; in HEK cells, we observed a comparable reduction in both open probability and unitary conductance. Finally, we compared the blockade exerted by micromolar concentrations of barium (25 μM) on the Kir currents, and we conclude that Aβ1-42 oligomers and barium have the same molecular target.

Title: ROS recovery by HDAC6 inhibition rescues impaired axonal transport by amyloid beta

Authors: ***H. CHOI**, J. KIM, H. KIM, H. CHOI, J. YANG, I. MOOK-JUNG;
Seoul Natl. Univ., Chongro-Gu, Seoul, Korea, Republic of

Abstract: The major pathological feature of Alzheimer’s disease (AD) is extracellular accumulation of beta-amyloid protein (Aβ). Excessive Aβ have harmful effects to axonal transport in neuronal cells and increase production of reactive oxygen species (ROS), which are responsible for AD. Decreased axonal transport can be recovered through HDAC6 inhibition. In this study, we revealed that anti-oxidant protein peroxiredoxin, one of HDAC6’s substrates, is malfunctioning in AD condition. To further clarify the role of peroxiredoxin in impaired axonal transport by Aβ, we treated Aβ and HDAC6 inhibitor Tubastatin A (TBA) to HT22 and primary neuronal cells. We observed decreased ROS level, followed by reduced Ca2+ level which is increased by Aβ. Moreover, by using live cell imaging method, axonal transport is recovered by TBA and ROS inhibitor. These results indicate that not only α-tubulin, which is a major substrate of HDAC6, but also peroxiredoxin takes part in axonal transport dysfunction. Taken together, we demonstrated malfunctioned peroxiredoxin by Aβ also affects impairment of axonal transport and HDAC6 inhibitor can restore the function of peroxiredoxin which results in rescue of axonal transport.

Abstract: Alzheimer's disease (AD) is the most prevalent age-associated neurodegenerative disorder worldwide for which there is no resolving cure available. Although AD is clinically well characterized, the molecular mechanisms responsible for onset and progression of AD remain poorly understood. Understanding such mechanisms is important to reveal new targets for the development of an effective treatment strategy. Among these, the aberrant cleavage of the Amyloid Precursor Protein (APP) by beta and gamma secretase that leads to the formation of the neurotoxic amyloid beta peptide (Aβ) is well documented. In particular, small oligomeric aggregates of Aβ have been shown to be the most toxic contributing, among others, to the induction of mitochondrial dysfunction and neuronal death. Further evidence suggests that age related impairments of such protective mechanisms as chaperones may also contribute to AD progression. Indeed, chaperones like Hsp60, Hsp70 and Hsp90 have been shown to target intracellular amyloid oligomers, thus preventing neuronal damage. Particularly, the mitochondrial Hsp60 seems to play a crucial role in the prevention of Aβ dependent mitochondria dysfunction although the biological mechanisms of Aβ-Hsp60 interaction are poorly understood. Our preliminary data using a cell free model suggest that Hsp60 effectively inhibits Aβ misfolding by directly and irreversibly blocking of its aggregation. On these bases, in the present work we investigated the effect of overexpression of Hsp60 on production and sub-cellular distribution of Aβ and formation of the toxic Aβ oligomeric species in a more biological relevant system using an established cellular model expressing human APP. For this model,

Chinese hamster ovary (CHO) cells overexpressing human APP751 (7PA2 cells) containing the V717F mutation, that induces the overproduction of Aβ oligomers, were modified to stably overexpress human Hsp60. Western blotting, immunocytochemistry and immunoprecipitation were used to determine Hsp60 and Aβ presence/levels in the whole cell extracts as well as in subcellular fractions and extracellular environments. Our results indicate that overexpression of Hsp60 in 7PA2 cells reduces the intracellular formation of Aβ oligomers without significantly affecting their subcellular localization. Collectively, our data support the hypothesis that Hsp60 reduces levels of the toxic Aβ oligomers and might, therefore, be an effective inhibitor of Aβ neurotoxicity. Further understanding of this biological mechanism could reveal novel targets to develop effective treatment strategies for AD.

Title: Recurrent herpes simplex type-1 (HSV-1) infections alter adult hippocampal neurogenesis in mice via amyloid-β protein (Aβ) production and accumulation

Authors: *D. D. LI PUMA[1], R. PIACENTINI[1], A. CAMPANELLI[1], A. MASTRODONATO[1], L. LEONE[1], G. DE CHIARA[2], A. PALAMARA[3,4], C. GRASSI[1];

Hlth. and Infectious Diseases, Pasteur Institute-Fondazione Cenci-Bolognetti, Sapienza Univ. of Rome, Rome, Italy; [4]IRCCS San Raffaele Pisana, Rome, Italy

Abstract: Altered neurogenesis in the dentate gyrus (DG) of hippocampus has been suggested to be an early event in Alzheimer's disease (AD). Though conflicting data have been reported, amyloid-β protein (Aβ) seems to inhibit proliferation and neuronal differentiation of hippocampal neural stem cells (hNSCs). Several studies, including ours, linked recurrent herpes simplex type-1 (HSV-1) infections in the brain to AD based on evidence that HSV-1 triggered APP processing and intracellular Aβ accumulation. Here we checked whether recurrent HSV-1 infections impairs adult hippocampal neurogenesis through Aβ production and accumulation. First, we established a mouse model of recurrent HSV-1 infections in the brain obtained by

inoculating HSV-1 (F strain, 1×10^6 PFU) in 1 month-old C57BL/6 mice via snout abrasion, and periodically reactivating latent virus in the brain by exposing mice to hyperthermia at one month intervals. To study neurogenesis brain sections were immunolabelled for the cell proliferation marker 5-bromo-2'-deoxyuridine (BrdU) and the neuroblasts marker doublecortin (DCX). Infected mice exhibited: i) a significant decrease in the number of DCX^+, $BrdU^+$ and double-labelled $DCX^+/BrdU^+$ cells (-43%, -40%, and -60%, respectively; $P<0.05$) compared to mock-infected mice; ii) large intraneuronal Aβ accumulation in the DG; iii) memory alterations, documented by a decrease of preference index (from 69±3% to 55±4%; n=5; $P<0.05$) in the novel object recognition test. To get insights on the mechanisms by which HSV-1 impairs hippocampal neurogenesis, we studied *in vitro* differentiation of hNSCs isolated from C57BL/6 mice. hNSCs were infected with HSV-1 (0.5 MOI) immediately before starting the differentiation protocol lasting 3, 6 and 9 days (referred as D3, D6 and D9, respectively). The percentages of hNSCs displaying immunoreactivity for the neuronal marker MAP-2 were reduced from 17.5%±1.6% of total cells in mock-infected cultures to 13±1.2% in HSV-1-infected cells at D3, from 24%±2.0% to 12.2±2.3% at D6 and from 34.9%±1.6% to 21.1±2.4% at D9 ($P<0.05$). Similar reductions were found when hNSCs were exposed to 200 nM Aβ42 during the differentiation protocol, and this effect was independent of apoptotic cell death. The effects of HSV-1 were reversed by adding to the culture medium either 4G8, that is a neutralizing antibody against Aβ, or β- and γ-secretase inhibitors, thus suggesting their dependence on Aβ production and accumulation in hNSCs. Our findings suggest that HSV-1 infection causes intracellular accumulation of Aβ42 in hippocampal NSCs thereby significantly reducing their proliferation and differentiation towards the neuronal phenotype.

Abstract: The pathology of Alzheimer's disease (AD) is characterized by the extracellular accumulation of amyroid-β (Aβ) peptide and the intraneuronal aggregation of hyperphosphorylated tau protein. In the " β-Amyloid Hypothesis", the extracellular deposit of Aβ peptide plays the central role in the pathogenesis of AD. However, recent studies have suggested that the intraneuronal Aβ peptide is more toxic than extracellular form of it. Because APP is cleaved into several physiologically active protein fragments including Aβ peptide *in vivo*, they are not rigorous models corresponding to the amyloidosis. Alternatively, direct observation of the process of deposition and disaggregation of Aβ peptide *in vivo* is quite important for the evaluation of candidate molecules in drug discovery research. With the aim of drug screening by analyzing the intracellular dynamics of Aβ peptide and toxicity *in vivo*, we have developed the new animal models of AD, an Aβ-GFP mouse and Aβ-GFP *C. elegans*, which express an Aβ42 peptide fused with GFP in neuronal cells. Observation of Aβ dynamics as GFP fused protein is not easy because the aggregation of Aβ inhibits the fluorescence of fused GFP. However, we succeeded to visualize the Aβ dynamics by arranging the linker sequence between Aβ and GFP. The intracellular Aβ42 was clearly observed as various sized aggregates in the cultured COS7 cells transfected with long linker Aβ-GFP, and brain tissues from Aβ-GFP mouse. Using a fusion protein with the short linker, we could monitor the status of Aβ dynamic in Aβ-GFP *C. elegans* *in vivo*. To observe the state of molecule, we compared the aggregate conditions of Aβ-GFP with mutated Aβ-GFP that suppresses the aggregation of Aβ *in vitro*, using electron microscope and NMR. As results of those, we revealed that the Aβ-GFP is not able to compose fibril but exists in the oligomer state. We compared the intracellular dynamics of these proteins using Fluorescence Correlation Spectroscopy, and revealed that Aβ-GFP composed oligomer *in vivo*, too. These visualization methods can be applied to analyze the physiological functions of intracellular Aβ, by directly observing the aggregation state and its toxicity in the living animals.

Title: A topological analysis in APP/PS1 mice reveals that astrocytes do not migrate to amyloid-beta plaques

Authors: *E. GALEA[1,2], W. MORRISON[3], E. HUDRY[4], M. ARBEL-ORNATH[4], B. J. BACSKAI[4], T. GÓMEZ-ISLA[4], H. E. STANLEY[3], B. T. HYMAN[4];

Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: Problem: Although the clustering of GFAP immunopositive astrocytes around amyloid-beta plaques in Alzheimer's disease has led to the widespread assumption that plaques attract astrocytes, recent studies show that astrocytes stay put in injury. Here we re-examine whether astrocytes migrate to plaques by analyzing with mathematical functions, and computer modeling, the topology of astrocytes in 3D images obtained by 2-photon microscopy of living APPSwe/PS1dE9 bitransgenic mice and wild type littermates. Methods: Cranial windows were installed on 5-9-month-old wild type and APPSwe/PS1dE9 mice. Astrocytes were labeled with sulforhodamine, plaques with methoxy-XO4, and vessels with FITC-dextran, and images were obtained by a 2-photon microscope (Olympus Fluoview 1000MPE). Stacks of images were collected 0-200 microns below the pial surface at a 4 micron-step and 1x zoom. Image processing: Astrocytes, plaques and vessels were extracted from 3D reconstructions of such images with algorithms implemented through a combination of the Fiji image processing package and custom Python code. Astrocyte and plaque interactions were then examined with two mathematical functions: the pair-correlation g(r) and the characteristic length (LC) of Voronoi cells. These methods combine global and plaque-centered perspectives, and allow for quantitative comparisons to be made. We used the g(r) function to assess astrocyte topology, and we examined the effect of plaques on several tiers of astrocytes using Lc, a very sensitive approach that reveals changes in object position from the redistribution of object-associated domains approximated by Voronoi tessellation. Results: In wild type mice, cortical astrocyte topology fits a model akin to a liquid of hard spheres that exclude each other in a confined space.

Plaques do not disturb this arrangement except at very large plaque loads, but, locally, they cause subtle outward shifts (1-4 microns) of the astrocytes located in three tiers around plaques. Conclusions: The implications of these findings are: (i) that a tight balance of repulsive factors maintains the highly territorial astrocyte organization, and (ii) that, contrary to a belief widely-held by Alzheimer's researchers, astrocytes do not break this order, migrate to plaques, and phagocytose them. We thus conclude that astrocytes respond to plaque-induced neuropil injury mostly by changing phenotype, and hence function, rather than location.

Title: Quantifying amyloid-β pathology in an Alzheimer's disease mouse model: an evaluation of supervised machine learning compared to thresholding

Authors: ***M. T. KIRKCALDIE**[1], A. R. O'MARA[2], A. E. KING[2], J. C. VICKERS[2]; [2]Wicking Dementia Res. and Educ. Ctr., [1]Univ. of Tasmania, Hobart, Australia

Abstract: Measuring the load of amyloid plaques in stained or immunolabelled brain tissue images is a technique used in many studies of Alzheimer's disease. Although thresholding is widely used, it is sensitive to small variations in stain intensity, imaging, and viewing conditions. We studied rater variability in manually thresholding plaque images, selecting 10 subregions from large 8-bit confocal images of 12 month old APP/PS1 mouse cortex, six stained with thioflavin S (thioS) and six immunolabelled with MOAB2 (amyloid β 1-4 epitope, Novus Biologicals). Raters chose thresholds for each subimage three times, in a randomly shuffled order, with no feedback other than the thresholded image. Thresholds chosen for each subimage varied considerably. The average range per subimage, for each rater, was 12.0 levels (SD 9.5) for MOAB2, and 14.9 (SD 10.6) for thioS. Because plaque edges are diffuse, this variation caused large differences in measured plaque load: for subimages with > 0.02% pathology, the ratio of maximum to minimum plaque area for each subimage averaged 1.77 (SD 0.77) for MOAB2, and 1.86 (SD 1.30) for thioS - nearly a twofold difference using thresholds chosen by the same raters.

This variability could be addressed by averaging thresholds, or using an algorithm to choose the threshold. However, no single threshold applied to the large images agreed closely with the raters' assessment of the subimages taken from it. We applied all possible thresholds (0-255); the best gave an average discrepancy from subimage ratings of 29.6% (SD 27.5) for MOAB2, and 28.3% (SD 28.8) for thioS. A single global threshold, even in the best case, cannot closely reproduce the way human raters judge subregions of the same image. As an alternative, we trained a machine learning algorithm, the random forest classifier (RFC), to identify plaques using the same thresholded subimages as examples, and including image criteria other than pixel intensity. The RFC was then used to segment the large images, and its accuracy was assessed in the same way that global thresholds were evaluated. The RFC segmentations agreed more closely with raters' thresholded subimages, with discrepancies averaging 13.9% (SD 15.3) for MOAB2, and 22.2% (SD 22.7) for thioS. Similar scores were found when random subsets of raters' subimages were used for training, implying that RFC segmentation is not as sensitive to which part of the main image is rated in order to train the algorithm. The RFC is available as a free ImageJ plugin, and can be trained using any thresholded or annotated image set. By offering these tools we hope to increase the consistency and comparability of pathology quantification in Alzheimer's disease research.

Title: Suppression of hSlo1.1 BK channel current by different Aβ42 conformations

Authors: B. E. ZUCHELKOWSKI[1], *L. B. FRENCH[2];
[1]Neurosci., [2]Allegheny Col., Meadville, PA

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by profound memory loss in afflicted individuals. The disease was classically characterized by widespread deposition of insoluble amyloid-beta (Aβ) plaques throughout the cortex, leading to synaptic dysfunction and neuronal loss. Big-conductance potassium (BK) channels are involved in action potential repolarization and calcium-induced apoptosis and have been shown to be affected by Aβ. Recent research has implicated the toxicity of intraneuronal Aβ, particularly soluble oligomers and immature fibrils that have become sequestered in the cell, interfering with synaptic transmission. The current study investigated the effects of different conformations of intracellular and extracellular Aβ on hSlo1.1, a BK channel, in a *Xenopus laevis* oocyte model. Oocytes expressing hSlo1.1 channels were exposed to intracellular Aβ via dissolution of the peptide in the electrode-filling solution or extracellular Aβ via application to the recording bath solution. BK current was measured by two-electrode voltage clamp. Intracellular fibrils and monomers suppressed BK current without cross-interaction with endogenous oocyte channels, while extracellular fibrils suppressed BK and endogenous current. These results are important for designing an oocyte model in which to study the effects of various Aβ conformations on ion channels.

Title: Protective roles of neuronal autophagy induction in an adult-onset *Drosophila* model of amyloid-β accumulation

Deleted: *Drosophila*

Authors: ***N. S. WOODLING**, J. CASTILLO-QUAN, S. MASON, L. PARTRIDGE;
Univ. Col. London, London, United Kingdom

Abstract: A common thread among the most prevalent neurodegenerative diseases of ageing is the accumulation of toxic peptide species that fail to be properly cleared from the nervous system. In Alzheimer's disease (AD), the accumulation of amyloid-β (Aβ) peptides leads to synaptic and neuronal damage resulting in cognitive decline. Understanding the processes by which cells clear protein aggregates is thus central to strategies aimed at reducing Aβ load to

ameliorate AD. In this study, we have focused on the role of macroautophagy as one cellular clearance pathway that could play a protective role in AD. To model Aβ toxicity *in vivo*, we have developed an inducible adult-onset *Drosophila* model of Aβ accumulation with phenotypes including increased mortality and accelerated decline of nervous system function. Here we use genetic over-expression of autophagy-related genes to investigate the effects of neuronal autophagy induction on Aβ accumulation and nervous system decline.

Title: Amyloid β-induced inhibition of protein prenylation causes autophagy dysfunction

Authors: *K. T. SMITH[1,2,3], E. M. GARCIA[1,2], A. MOHAMED[1,2], E. I. POSSE DE CHAVES[1,2,3];
[2]Pharmacol., [3]Neurosci. and Mental Hlth. Inst., [1]Univ. of Alberta, Edmonton, AB, Canada

Abstract: There is ample evidence that autophagy is affected in Alzheimer's disease (AD) but the causes, the nature of the dysfunction and the mechanisms of autophagy impairment are unclear. Autophagy depends on vesicular trafficking and membrane fusion, events that rely on several protein complexes and small GTPases. Previously our lab demonstrated that a neurotoxic mechanism of amyloid-β oligomers (Aβ) is inhibition of protein prenylation. Reduced protein prenylation results in impairment of intracellular and axonal trafficking. The Rab family of small GTPases are prenylated proteins required for normal trafficking, membrane fusion and autophagy. We hypothesize that defective autophagy in AD is due to inhibited protein prenylation and restoring protein prenylation will normalize the autophagic pathway and prevent neuronal death. We are performing *in vitro* and *in vivo* experiments to determine the nature of autophagy dysfunction. A biomarker of autophagy is the microtubule-associated protein light

chain 3-II (LC3-II), which associates with the autophagosome membrane. Neurons challenged with Aβ accumulated LC3-II when analyzed by western blot. LC3-II increase is ambiguous, since it could represent induced autophagy or blocked lysosomal degradation of LC3-II. To differentiate between these possibilities we directly examined autophagic flux by expressing mCherry-GFP-LC3, in cultured cells and the mouse CNS. Autophagic flux was decreased in cultured cells treated with Aβ, and was recovered by rescuing protein prenylation with geranylgeranylpyrophosphate. Similarly, simvastatin and psoromic acid, two agents that inhibit protein prenylation, also blocked autophagic flux in a prenylation-dependent manner. Among prenylated proteins we focus on Rab7, which is essential in autophagy progression and lysosomal biogenesis, and is altered in brains of AD patients. During autophagy, Rab7 localizes to autophagosomes together with LC3. Treatment with Aβ reduced Rab7 co-localization with LC3. Normalization of protein prenylation restored colocalization of Rab7 and LC3. Significantly, reversing autophagy dysfunction has been validated as an innovative therapeutic strategy in AD. Yet, the lack of knowledge on the nature and cause(s) of autophagy dysfunction prevents the development of selective autophagy-targeted strategies with disease-modifying value. Our work will provide an essential evidence base for potential therapeutic developments that target autophagy flux in the CNS.

Title: Degradation of the mdmx/mdm4 cell cycle regulatory protein as a mechanism of amyloid-β-induced neuronal damage

Authors: ***C. AKAY**, D. J. COLACURCIO, J. W. ZYSKIND, K. L. JORDAN-SCIUTTO; Pathology, Univ. Pennsylvania, Philadelphia, PA

Abstract: Alzheimer Disease (AD) is characterized by the presence of extracellular senile plaques composed predominantly of amyloid-β (Aβ), intracellular neurofibrillary tangles (NFTs) composed of hyperphosphorylated tau protein, and progressive synaptic loss / neuronal death in

the cortex and hippocampus. While the precise mechanisms linking Aβ accumulation to neuronal loss is not completely understood, *in vitro* and *in vivo* studies demonstrate Ab-mediated activation of the cyclin-dependent kinase 5 (CDK5) plays a role in neuronal death. Intriguingly, aberrant expression of CDK5 as well as several other cell cycle proteins, such as E2F1 and p53 has been reported in several neurodegenerative diseases, including AD. CDK5 activation through activation of the cellular cysteine proteases, calpains is a mechanism of neuronal death. We have recently shown that calpain-mediated degradation of MDMX/MDM4, a cell cycle protein regulating p53 in dividing cells, led to excitotoxic neuronal death. We determined the role of MDMX in *in vitro* and *in vivo* models of Aβ-associated neuronal death. *In vivo* experiments utilized cortical tissue obtained from 14 month-old Tg2576 mice (APPSWE) and age-matched wild-type (w.t.) mice for to assess MDMX protein expression by immunoblotting and immunostaining. *In vitro* experiments utilized 14-21 days *in vitro* primary rat cortical neurons. Aβ-mediated neuronal loss were assessed by MAP2-positive cell counting, and mitochondrial membrane depolarization was determined by ELISA. Small molecule inhibitors to MDMX, and p53, SJ-172550 and pifithrin-α, respectively, were used to dissect the roles of these cell cycle proteins in Aβ-mediated neuronal death *in vitro*. Cortical tissue from 14 month-old APPSWE mice displayed reduced MDMX protein levels relative to w.t. mice, and progressive death of MDMX-expressing cholinergic neurons occurred following the time course of amyloid pathology in these mice. *In vitro*, both Aβ treatment and SJ-172550 led to MDMX loss and neuronal death via calpain and CDK5 activation. Our initial studies also suggest that SJ-172550 induced mitochondrial membrane depolarization independent of p53. These results suggest that MDMX loss may lead to mitochondrial depolarization, calpain and CDK5 activation, contributing to neuronal damage during the progression of AD.

Title: Characterization of key regions for the aggregation process that determine the cytotoxic properties of the amyloid beta peptide

Authors: *V. ZOMOSA[1], A. TREVIÑO[1], R. VIDALTAMAYO[2];
[1]UANL, Monterrey, Mexico; [2]Basic Sci., Univ. de Monterrey, San Pedro Graza García, Mexico

Abstract: Alzheimer's disease is a neurodegenerative disorder and the most common form of senile dementia. Formation of amyloid beta peptide (Aβ) plaques is thought to lead to cell death and loss of cognitive functions. It is known that Aβ aggregation depends on its aminoacid sequence. So by the creation of mutants that can inhibit the conformational change and give rise to stable structures unable to aggregate as an amyloid plaque, it may be possible to identify key residues that affect these processes and use them as therapeutic targets. We decided to study the aggregation process and cytotoxicity of wild type Aβ and different sequence mutants. We studied the aggregation and cytotoxicity of wild type peptides Aβ (25-35) and Aβ (1-40), as well as of the mutants Aβ (1-40) K28A, Aβ (1-40) A30W, Aβ (1-40) M35C, Aβ (25-35) K28A, Aβ (25-35) A30W and Aβ (25-35) M35C using thioflavin T assays, characterization of the aggregates in western blot, and *in vitro* studies of the effects of the aggregates on cell viability, apoptosis and necrosis of the C6 rat glioblastoma cell line. All mutants showed different aggregation kinetics and cytotoxicity profiles, compared to the wild type peptides. Remarkably, Aβ (1-40) (M35C) mutant showed faster aggregation kinetics, formed more stable aggregates and increased cytotoxicity compared to the Aβ (1-40) wt peptide. We demonstrate the effects of the change on one single aminoacid on cytotoxicity and the aggregation kinetics, showing hot spots in the aggregation process and plaque formation.

Title: Re-acidification of Alzheimer's-associated presenilin 1 A246E fibroblasts by cAMP requires protein kinase A and exerts downstream effects on both mechanistic target of rapamycin (mTOR) and transcription factor EB (TFEB)

Authors: *E. E. COFFEY, C. H. MITCHELL;
Anat. and Cell Biol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: A primary cause of familial Alzheimer's disease (fAD) is mutation of the transmembrane protein presenilin 1 (PS1); recent work has demonstrated a link between the PS1-fAD mutation A246E and lysosomal alkalization. The present study found that cAMP treatment re-acidifies compromised lysosomes in PS1-fAD fibroblasts, and identified a critical role for protein kinase A (PKA) in cAMP-induced re-acidification. When PKA activity was blocked, re-acidification did not occur. Blocking PKA also blocked restoration of cathepsin D active site availability after cAMP treatment, as measured by the reduced binding of boron-dipyrromethene (BODIPY) FL-pepstatin A to the cathepsin D active site. cAMP treatment increased mechanistic target of rapamycin (mTOR) phosphorylation at S2448, a site linked to increased mTOR activity. This mTOR phosphorylation event appears to be an effect, rather than a cause, of lysosomal re-acidification. cAMP treatment reduced mRNA expression of transcription factor EB (TFEB), a critical transcription factor for both lysosomal biogenesis and autophagic regulation; treatment also reduced mRNA expression of one of TFEB's targets, the v-(H+)ATPase subunit B2. mTOR phosphorylation in response to cAMP was found to depend on PKA activity, as would be expected if mTOR phosphorylation first required successful pH restoration. These data stress the importance of PKA activity to achieve lysosomal re-acidification in PS1-fAD fibroblasts, and suggest that further therapeutic approaches may do well to consider engaging the downstream targets of PKA-dependent re-acidification: mTOR and TFEB. Importantly, cAMP restored lysosomal pH in rat primary cortical cultures following pharmacological pH elevation with tamoxifen; cAMP treatment also blunted the effect of tamoxifen exposure on cathepsin D active site availability in these cultures. Together, these data support a more general role for cAMP in lysosomal re-acidification across multiple cell types, and suggest novel treatment avenues for future work.

Title: ADAM10 endocytosis and Alzheimer's disease: looking for new therapeutic strategies

Authors: S. MUSARDO[1], S. PELUCCHI[1], D. DI MARINO[3], A. TRAMONTANO[3], V. GRIECO[2], C. GIUDICE[2], F. GARDONI[1], E. MARCELLO[1], *M. DILUCA[4,1];

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder characterized by progressive loss of synapses and neurons and accumulation of insoluble deposits of amyloid beta-peptide (Aβ). Although AD is emerging as the most prevalent and socially disruptive illness of aging populations, it is currently incurable. Aβ derives from the amyloid precursor protein (APP), which can undergo 2 mutually exclusive pathways in the cell. The amyloidogenic pathway involves BACE and gamma secretase activities and leads to Aβ formation. On the other hand, the main protagonist of the non-amyloidogenic pathway is ADAM10, a disintegrin and metalloproteinase 10, which cleaves APP in the domain corresponding to Aβ, thus precluding Aβ production. Since the modulation of ADAM10 synaptic localization through ADAM10 membrane insertion/removal could constitute an innovative therapeutic strategy to finely tune its shedding activity, we have investigated the ADAM10 endocytosis mechanisms. We show that ADAM10 removal from the plasma membrane is mediated by clathrin-dependent endocytosis and we describe the clathrin adaptor AP2, which initiates the endocytosis process, as new interacting partner of ADAM10 C-terminal domain. In particular, we identify an atypical binding motif for AP2 complex in ADAM10 cytoplasmic tail, which is relevant for ADAM10 endocytosis and the modulation of its plasma membrane levels. Moreover, we describe a pathological alteration of ADAM10/AP2 association in AD patients. On the basis of these findings, we designed four cell permeable peptides (CPPs) able to interfere with ADAM10/AP2 association and, thereby, to reduce ADAM10 endocytosis. We demonstrate, both with *in vitro* and *in vivo* experiments, that two of four CPPs are able to disrupt ADAM10/AP2 interaction and to increase the levels of ADAM10 at synaptic membrane. Several studies highlighted the key role of ADAM10 in health and disease, due to its shedding activity toward a number of functional membrane proteins such as APP and N-cadherin. Through its shedding activity, ADAM10 has been shown to regulate key cellular functions including cell growth, adhesion, and migration and spine stabilization in excitatory neuron. A finely balanced membrane level of ADAM10 is an essential prerequisite to control enzyme activity and its functions. We designed a powerful tool able to interfere with mechanisms regulating intracellular trafficking of ADAM10 and to modulate its membrane availability, and thereby to shift APP

Deleted: in vitro

Deleted: in vivo

metabolism toward the non amyloidogenic pathway. In light of the above, the use of CPPs is a key starting point to develop new therapeutic strategy for AD.

Title: Presenilin-dependent modulation of axodendritic outgrowth requires APP function

Authors: C. DEYTS, M. CLUTTER, S. HERRERA, N. JOVANOVIC, A. GODDI, *A. PARENT;
Univ. Chicago, Chicago, IL

Abstract: Presenilin 1 (PS1) is an essential component of the γ-secretase complex, the enzyme responsible for intramembraneous cleavage of amyloid precursor protein (APP) that generates β-amyloid peptides (Aβ) and APP intracellular domain (AICD). Mutations in PS1 lead to dominant inheritance of early onset familial Alzheimer's disease (FAD). Although there is a consensus that FAD-linked PS1 mutations affect toxic Aβ production, the importance of APP per se and other PS1-dependent substrates in the etiology of the disease has not been confirmed. Recently, we have observed that primary cortical neurons generated from PS1 knock-out (PS1KO) and PS1 knock-in (PS1KI) mice harboring FAD-linked PS1-M146V variant exhibit an increase of axodendritic outgrowth. These outcomes parallel a large and moderate increases of APP-CTF and DCC-CTF in brain lysates prepared from either PS1KO or PS1KI mice, respectively. Accordingly, these results are in support of a partial lost of function of γ-secretase activity in PS1 mutant. Strikingly, lack of APP expression in cortical neurons expressing PS1-M146V variant led to a decrease in both axonal and dendritic outgrowth; an effect that was not seen in neurons lacking DCC expression. These results indicate that APP is required for PS1-dependent change in neurite outgrowth associated with PS1 mutation. Treatment with γ-secretase inhibitor does not

induce additional morphological change in APPKOPS1KI supporting again the importance of APP in PS1-induced neurite outgrowth. Moreover, we observed that accumulation of APP-CTF through concomitant overexpression of APP full-length and γ-secretase inhibition or overexpression of membrane-tethered APP intracellular domain (mAICD) rescue axodendritic outgrowth in PS1KI neurons lacking APP expression. Taken together, our findings provide the first demonstration that a pathological loss of PS1 function lead to a gain of APP function. Our results also identify APP-CTF accumulation as a key player in axodendritic outgrowth. Because accumulation of APP-CTF at the membrane is an invariable outcome of therapeutic inhibition of γ-secretase aimed at reducing cerebral amyloid burden, our findings could have important implications in Alzheimer's disease treatment. Abstract: Mutations in the genes encoding presenilin 1 (*PSEN1*), presenilin 2 (*PSEN2*), and the amyloid precursor protein (*APP*) are associated with autosomal dominant, early onset familial AD (EOFAD). The *PSEN2*^{N141I} mutation causes EOFAD in the Volga German kindred. We have optimized an *in vitro* protocol to generate human basal forebrain cholinergic neurons (BFCNs) from iPSCs of AD patients and controls. BFCNs are one of the cell types most affected in Alzheimer's disease patients (AD). We introduced innovations to other published BFCNs protocols including the purification of an intermediate CD271^{+} forebrain progenitor population by Flow Activated Cell Sorting (FACS) to generate 3D neural embryoid bodies (NEBs). NEBs showed enrichment in BCFNs as compared to unsorted monolayer cultures, demonstrated by higher % of Tuj1+/FOXG1+/ChAT+ neurons. Our immediate goal was to characterize BFCNs and intermediate neural progenitors (NPCs) differentiated from the skin cells of 3 subjects, two affected by *PSEN2* ^{N141I} mutation, one an unaffected family member control. Skin fibroblasts from these three subjects were reprogrammed, using modified RNA mediated transfer of the reprogramming factors, followed by selection and expansion. All iPSCs were tested to ensure normal karyotypes, robust self-renewal, pluripotency, and expression of stem cell markers including NANOG, TRA-160. After induction of BFCN differentiation in these cell lines, we have analyzed: (1) rates of cell death either at baseline or in response to apoptotic stimuli; (2) capacity to generate Tuj1+/FOXG1+/ChAT+ neurons *in vitro*; (3) expression of genes/proteins of interest related to neuronal differentiation or inflammation; and (4) generation of soluble and oligomeric Aβ40 and 42. Our ultimate goal is to employ the molecular, transcriptomic, and electrophysiological properties of these cells in the development of novel diagnostics and/or therapeutics for AD. MOV is a New York Stem Cell Foundation-Druckenmiller Fellow. Title: A mutation in presenilin1 promotes Alzheimer-associated phenotype without affecting Notch signaling

Authors: ***F. CAI**[1], S. ZHANG[2], Y. WU[2], W. SONG[2];
[1]Univ. of British Colu, Vancouver, BC, Canada; [2]Univ. of British Columbia, vancouver, BC, Canada

Abstract: Neuritic plaques, the unique neuropathological hallmark of Alzheimer's disease (AD), mainly consist of amyloid-beta protein (Aβ) . Aβ is derived from amyloid-beta precursor protein (APP) through sequential cleavages by β- and γ-secretase. Pathogenic mutations in presenilin 1 (PSEN1), the catalytic subunit of the γ-secretase complex, are the major cause of familial AD (FAD). PS1 mutations not only impair APP processing and Aβ generation, but also reduce the cleavage of Notch, one of the most prominent substrates of γ-secretase, leading to Notch signaling disruption. In this study, we found that a novel PSEN1 mutation significantly impairs APP processing and Aβ generation *in vitro* and *in vivo*. Moreover, this PSEN1 mutation promotes neuritic plaque formation, and learning and memory deficits in AD transgenic mice. However, the mutant PSEN1 undergoes normal endoproteolysis, and displays normal functions on Notch cleavage and Notch signaling *in vitro* and *in vivo*, sparing the impairment of Notch signaling. Taken together, we first demonstrate that a novel mutant PSEN1 functions separately on APP processing and Notch signaling pathway. Furthermore, our study provides a novel insight into developing γ-secretase modulators for AD treatment by specifically modulating APP processing, not affecting Notch cleavage to avoid the severe side effects of γ-secretase inhibitors on Notch signaling.

Title: Presenilin1 mutations impair neovascularization and increase vulnerability of brain to ischemia

Authors: ***A. GEORGAKOPOULOS**[1], Y. YOON[2], L. CHEN[2], N. K. ROBAKIS[2];
[2]Psychiatry, [1]Icahn Sch. Med. At Mount Sinai, New York, NY

Abstract: A large amount of evidence has linked brain vascular disorders to the onset of Alzheimer's Disease (AD). A strong association between cognitive decline and cerebrovascular abnormalities is supported by data that AD brains show impaired brain vasculature (1,2) with changes in the microvasculature preceding neurodegenerative changes and cognitive decline (3,4,5). Insufficient angiogenesis and vascular regression in the AD brain may thus represent an important pathogenic mechanism of disease progression affecting repair of the vasculature and ultimately neuronal health and function. We have observed that Presenilin1 (PS1) a protein involved in the pathogenesis of familial AD (FAD) regulates the angiogenic response of endothelial cells *in vitro* (6). We want to examine whether PS1 affects vasculature *in vivo* and whether mutations in PS1 found in FAD impair vascular integrity. To examine the role of PS1 FAD mutations in brain neovascularisation after ischemic insult we induce ischemia using middle cerebral artery occlusion (MCAO) in wild type (WT) and knock in mice carrying PS1 FAD mutations. Lesion size is measured using T2 MRI and restoration of blood volume in the lesion area, which is an indication of neovascularisation, is detected and quantified using perfusion MRI (T7). To identify molecular mechanisms via which PS1 FAD mutations affect brain angiogenesis we perform co-immunoprecipitation experiments in brain extracts of PS1 FAD and WT mice measuring complex formation of angiogenic proteins including VE-cadherin, Rock2 and Raf1 which we have found to depend on PS1 (6). We show that ischemia-induced lesions are larger in brains of PS1 FAD mice compared to WT controls and the edema induced by MCAO remains significantly longer time in the lesion area of the FAD brains compared to WT. GFAP staining shows that accumulation of astrocytes in the lesion area lasts much longer in the PS1 FAD brains indicating a prolonged tissue scar formation compared to WT. Blood volume restoration in the lesion area is also significantly decreased in the brains of PS1 FAD mice compared to WT. Our data show that PS1 mutant mice are more vulnerable to ischemic insult in the brain and that they have reduced ability to recover from this insult compared to WT mice. Interestingly, angiogenic complexes involving VE-cadherin, Rock2 and Raf1 decrease in brains of PS1 knockout (KO) embryos suggesting a role of PS1 in regulation of these complexes *in vivo* affecting angiogenesis in the brain. Together our data indicate that in FAD, brain vasculature may be compromised due to defective angiogenesis, rendering the brain more vulnerable to toxic insults leading to cell death and neurodegeneration.

Title: Gamma-secretase activating protein (GSAP) alterations in the frontal cortex during the progression of AD

Authors: *M. NADEEM[1], S. PEREZ[2], E. J. MUFSON[3];
[1]Dept Neurol, St Josephs Hospital, Barrow Neurolog. Inst., Phoenix, AZ; [2]Dept Neurol, Rush Univ. Med. Ctr., Chicago, IL; [3]NEUROBIOLOGY, BARROW NEUROLOGICAL INST., PHOENIX, AZ

Abstract: Beta-amyloid (Aβ), a pathological hallmark of Alzheimer's disease (AD), is the product of the concerted cleavage of the amyloid precursor protein (APP) by β- and γ-secretases. However, the molecular mechanism(s) that regulate this process remain unclear. Recent studies suggest that a novel molecule, γ-secretase activating protein (GSAP, 16 kDa), which is derived from a larger 98 kDa precursor protein, regulates γ-secretase activity and Aβ production. However, limited information is available regarding the association between GSAP and the onset of AD. Here we performed quantitative western blotting to determine whether GSAP precursor (GSAPp, 98 kDa) and GSAP (16 kDa) protein levels in frontal cortex, are dysregulated during the progression of AD using tissue obtained from subjects who died with a premortem clinical diagnosis of non-cognitive impairment (NCI), mild cognitive impairment (MCI), mild to moderate AD (mAD) and severe AD (sAD). Our analysis revealed that levels of 98 kDa GSAPp were significantly increased in the frontal cortex in sAD compared to NCI ($p=0.004$), whereas the levels of 16 kDa GSAP were significantly reduced in sAD compared to MCI ($p=0.003$) and mAD ($p=0.006$). Protein levels for 16 kDa GSAP were not associated with mini-mental state examination (MMSE), CERAD, NIA-Reagan and Braak neurofibrillary tangle neuropathology criteria during AD progression. Interestingly, there was a significant negative correlation between GSAPp and MMSE score across the four clinical groups ($r=-0.41$, $p=0.006$), but not other clinicopathological variables examined. In summary, our findings indicate that the frontal cortex displays different patterns of GSAPp and GSAP 16 kDa dysregulation late in the disease process. In addition, the association between 98 kDa GSAP levels and MMSE suggest that GSAPp, but not GSAP 16 kDa, plays a role in cognitive decline preferentially late in AD.

Title: Analysis of Presenilin-1 Asp385 knockin mice

Authors: Y. TAN[1], D. XIA[1], R. KELLEHER[2], *J. SHEN[3];
[1]Neurol., Brigham and Women's Hosp., Boston, MA; [2]Neurol., Massachusetts Gen. Hosp., Boston, MA; [3]Dept Neurol, Harvard Med. Sch., Boston, MA

Abstract: Presenilin-1 (PS1) is the major causative gene of early onset familial Alzheimer's disease (FAD). Presenilin is the catalytic subunit of the γ-secretase complex that cleaves type I transmembrane proteins including APP and Notch. Two conserved aspartate residues (Asp257 and Asp385) in PS1 are thought to constitute the active site of γ-secretase. Overexpression of PS1 with the aspartate to alanine alteration at either site (D257A or D385A) in CHO cells resulted in the failure of mutant PS1 endoproteolysis and abolishment of γ-secretase cleavage of APP. To determine the role of these Asp residues in PS1 *in vivo*, we generated *Psen1* KI mice, in which an Asp385Ala (D385A) alteration was introduced in the genomic *Psen1* locus. Interestingly, homozygous D385A KI mice display severe developmental deficits, including perinatal lethality, cerebral hemorrhages, shortened rostro-caudal body axis, and kinked tails; these phenotypes are identical to those of *Psen1*-null mice. Levels of the *Psen1* mRNA are normal in homozygous D385A KI mice, but the N- and C-terminal fragments of PS1 are absent, and PS1 holoprotein accumulates at ~18-fold in homozygous D385A KI mice relative to the wild-type control. Similar to the *Psen1*-null mutation, the D385A mutation causes severe brain hemorrhages as early as embryonic day 12.5. Biochemical assays of γ-secretase activity in the brain of D385A KI/KI mice revealed abolished γ-secretase-mediated processing of APP, Notch and N-Cadherin. Moreover, histological analysis showed strikingly impaired neurogenesis in D385A KI/KI brains. Collectively, these results demonstrate that the Aspartate 385 of PS1 is indispensable for its function in maintaining normal development and γ-secretase activity. Title: Attenuation of capacitative calcium entry in familial Alzheimer's disease by gamma-secretase cleavage of stromal interaction molecule 1

Authors: ***C. TONG**[1], C. S. K. LEE[2], C. W. H. CHENG[2], K.-H. CHEUNG[2];
[2]Dept. of Physiol., [1]The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Abnormal γ-secretase cleavage of amyloid precursor protein (APP) to amyloid beta (Aβ) is believed to link with the pathogenesis of Alzheimer's disease (AD). γ-secretase is a multimeric intramembranous protease that cleaves various type-I transmembrane proteins and mounting evidence has demonstrated the proteolytic activity of γ-secretase is presenilin-1 (PS1) dependent. Enhanced γ-secretase activities were observed in many familial AD-linked PS1 mutations and thus leading to disproportionated production of amyloidogenic $A\beta_{42}$. In addition, these mutations have been demonstrated to disrupt cellular calcium homeostasis by attenuating extracellular calcium (Ca^{2+}) influx through the capacitative Ca^{2+} entry (CCE) pathway. However, the correlation between CCE attenuation and exaggerated γ-secretase activity is yet to be determined. Using human neuroblastoma SH-SY5Y and single cell imaging techniques, we demonstrated that CCE attenuation was associated with exaggerated γ-secretase activity as application of γ-secretase inhibitor DAPT can restore the attenuated CCE in PS1 mutant expressing cells. Apart from this, we found that DAPT can potentiate CCE in PS1WT expressing and control cell lines, suggesting a negative regulatory role of γ-secretase on CCE. Since stromal interaction molecule 1 (STIM1) is a type-I transmembrane protein and is the ER Ca^{2+} sensor that participates in the CCE pathway, we hypothesized that STIM1 is a putative substrate for γ-secretase cleavage. Using protein sequence analysis, we found the transmembrane domains of STIM1 and APP were highly conserved, suggesting that STIM1 may be a substrate of γ-secretase. We further validated our hypothesis by *in vitro* fluorogenic peptide cleavage assay and found that FAD-linked PS1 mutation enhanced not only the γ-secretase cleavage of APP, but also the cleavage of STIM1 that leading to the attenuation of CCE. Furthermore, we demonstrated the neuronal spine maturation in cultured hippocampal neurons were impaired by

Deleted: *in vitro*

FAD-linked PS1 and this impairment can be rescued by γ-secretase inhibitor, DAPT. The result indicated that exaggerated γ-secretase associated with PS1 mutation destabilized mature spine which leading memory loss in AD. In summary, the identification of the γ-secretase cleavage of STIM1 suggests a pathogenic mechanism of FAD, and provides a novel target for therapeutic intervention to treat the disease.

Title: Nicastrin and Pen-2 are required while Aph-1 is dispensable for gamma secretase catalyzed turnover of the C-terminal fragment of APP

Authors: ***C. HU**[1], T. LI[2], L. ZENG[2], M. CUI[2], X. XU[2];
[1]Comparative and Exptl. Med., [2]The Univ. of Tennessee, Knoxville, TN

Abstract: Based on the "amyloid cascade hypothesis", the ratio of Aβ42 verses Aβ40 plays a key role in Alzheimer's disease (AD). The ratio of Aβ42/Aβ40 is controlled by gamma secretase, which cleaves APP (Aβ precursor protein) at C terminal and release Aβ in different length: Aβ38, Aβ40, Aβ42, Aβ43, Aβ46, Aβ49 and so on. Hence, dissecting the biological and biochemical nature of gamma secretase is important in understanding the mechanism of Aβ formation. Gamma secretase is a complex composed of four components: presenilins (PS1 or PS2), nicastrin (NCT), anterior pharynx-defective 1 (Aph-1), and presenilin enhancer 2 (pen-2). The roles of these components remain unclear. Previous studies have suggested that PS functions as the catalytic subunit; NCT may serve as a receptor for the substrate; Aph-1 is assumed to stabilize the other three components; and pen-2 was reported to be essential for the endoproteolysis of PS. However, our recent study revealed that pen-2 is dispensable for the

endoproteolysis of PS, but is required for gamma secretase activity. Our data also demonstrated that NCT is also required for gamma secretase activity. Interestingly, we found that APP is processed by gamma secretase activity in the absence of Aph-1, indicating that Aph-1 is not absolutely required for gamma secretase activity. Furthermore, our data revealed that NCT and pen2 are necessary for a novel post-translational modification of PS1 while Aph-1 is not required. However, the effect of this modification on gamma secretase activity needs to be further investigated.

Title: Neuronal overexpresssion of GGA3 reduces BACE1 levels and BACE1-mediated APP processing in 5XFAD mice

Authors: ***W. KIM**, G. TESCO;
Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: One of the major pathological hallmarks of Alzheimer’s disease (AD) brains is extracellular amyloid plaques which are mainly composed of the amyloid beta peptide (Aβ). The Aβ is derived by sequential proteolytic cleavage of amyloid precursor protein (APP) via β-site amyloid precursor protein cleaving enzyime1 (BACE1) and γ-secretase. Initial cleavage of APP by BACE1 releases soluble APP (sAPPβ) and generate membrane bound C-terminal fragment (C99). Subsequently, C99 is cleaved by γ-secretase within membrane domain of APP to generate AB. Therefore, BACE1, which is upregulated in AD, is a prime therapeutic target for the treatment of AD patients. It has been shown that BACE1 is normally bound to the trafficking molecules, Golgi-localized gamma-ear-containing ARF binding protein 3 (GGA3) and sorted to the endosomes and lysosomes to be degraded. We had previously shown that levels of BACE1 in AD brains are increased and inversely correlated with GGA3 levels. We had also reported that BACE1 levels are increased in the brain of GGA3 null mice compared with age-matched GGA3

wild type littermates. However, it is unclear whether mice overexpressing GGA3 have any significant effect on BACE1 levels and activity *in vivo*. To address this question, we generated transgenic mice overexpressing N-terminal hemagglutinin tagged human long isoform of GGA3 under transcriptional control of the neuronal-specific mouse Thy1 promoter (GGA3tg+). In this study, we found that BACE1 levels are significantly reduced by the overexpression of GGA3 protein *in vivo* compared with age-matched non-transgenic littermates. Furthermore, in order to examine the effect of reduced BACE1 levels on APP processing in the brain of AD model, we crossed GGA3tg+ mice with mice overexpressing FAD-linked mutation in APP and PS1 under the control of Thy1 promoter (5XFAD). We found that the levels of total APP C-terminal fragments are significantly decreased in the brain of 5XFAD mice overexpressing GGA3 proteins (GGA3tg+:5XFAD). Interestingly, the relative ratio of phosphorylated C99 compared to full-length APP is significantly reduced when compared to the other APP-CTFs in GGA3tg+:5XFAD mice. Our results suggest that the regulation of GGA3 protein could be a potential target to modulate BACE1-mediated APP processing, which is a critical step in Aβ formation in AD.

Abstract: In Alzheimer's disease both amyloid and tau pathology accumulates in the brain and causes dementia and cognitive impairment mainly in aged people. Previously we have shown that the non-amyloidogenic APP processing fragment sAPPalpha is neurotrophic and also reduce amyloid pathology from mice brain. In addition,to investigate whether sAPPalpha also reduce tau phosphorylation, we found that inhibition of tau phosphorylation by sAPPalpha is independent of amyloid mediated toxicity. Data from primary cortical neurons and SH-SY5Y cell lines showed that, sAPPalpha increase inhibitory GSK3-beta (Ser9) phosphorylation, which decreased GSK-3-beta activity. In addition, SH-SY5Y cells overexpressing BACE1 (SH-SY5Y/BACE1), as well as HeLa cells overexpressing human tau (HeLa/tau), sAPPalpha increase GSK-3-beta (Ser9) phosphorylation while reducing tau phosphorylation, as indicated by phospho-tau (Thr231) and PHF1 immunoreactivity. These results suggest that sAPPalpha indeed reduces GSK3-beta activity and thereby reduces tau phosphorylation, even in the context of enhanced BACE1 activity. sAPPalpha mediated reduction of tau phosphorylation was not altered by gamma-secretase inhibition. AD mice overexpressing sAPPalpha (PSAPP/TgsAPPalpha) display greater GSK3-beta (Ser9) phosphorylation and less tau phosphorylation than littermate controls (PSAPP).Therefore, sAPPalpha appears to reduce GSK-3-beta activity and thereby reduce tau phosphorylation *in vivo* as well as *in vitro*.

Abstract: Elevated β-secretase (β-site amyloid precursor protein-cleaving enzyme1,BACE1) is a major catalytic component of the amyloidogenic cascade. We, as well as two other research group, discovered that higher levels of BACE activity and protein expression in brains from cases of sporadic AD. Moreover, we recently found that BACE1 activity precedes the clinical diagnosis of AD and could be an early indicator of neuronal dysfunction or pathology in AD. All these results lie in the fact that the population from which our autopsy program was drawn from is overwhelmingly Caucasian. Due to different life style and diet habits between Western and Asian countries, which could be risk factors, in this study, we examined BACE expression and activity in rapidly autopsied brains from Caucasian and Asian patients. We found that not only significantly increased BACE1 activity and protein level occur in Asian AD patients, but also we discovered distinct expression patterns of BACE expression in the AD brains between Caucasian and Asian populations. Moreover, increased BACE1 activity is correlated with plaque numbers and cognition status. Our international and cross-cultural comparative studies of AD offer significant advantages in elucidating risk factors for the disease by providing a wilder diversity of environmental exposures as well as greater genetic diversity than do studies confined to a single ethnic group.

Abstract: β-site amyloid precursor protein (APP) cleaving enzyme 1 (BACE1) initiates amyloid-β (Aβ) generation and the resultant cerebral amyloidosis as the characteristic of Alzheimer's disease (AD). Thus, inhibition of this enzyme has been the focus of a large body of both pre-clinical and clinical research. The most recent clinical trials highlight the difficultly involved in this type of anti-AD therapy as evidenced by side effects that are likely due to the ubiquitous nature of BACE1 which cleave multiple substrates. The human Swedish mutant form of APP (APPswe) has been shown to possess a higher affinity for BACE1 compared to human wild-type APP (APPwt). We pursued a new approach wherein we harness this greater affinity of the substrate to modulate BACE1 APP processing activity. We found that one specific peptide derived from APPswe, containing APPswe β-cleavage sites, strongly inhibits BACE1 activity and thereby reduces Aβ production. This peptide, termed APPswe BACE1 binding site peptide, was further conjugated to the fusion domain of the HIV-1 Tat protein (TAT-APPsweBBP) at the C-terminus to facilitate blood-brain barrier- and neuronal cell-penetration. APPwt and APPswe over-expressing CHO cells treated with this peptide resulted in a marked reduction of Aβ and a significant increase of soluble APPα. Intraperitoneal administration of TAT-APPsweBBP to 5XFAD mice markedly reduced amyloidogenic APP processing and β-amyloid deposits as well as improved hippocampal-dependent learning and memory. These findings provide evidence for a novel strategy for alternative design of BACE1 inhibitors and suggest that TAT-APPsweBBP may be a novel, safe and effective APP substrate-based BACE1 inhibitor for the treatment of AD.

Title: Brain-specific hBACE1 knock-in induces systemic diabetes via hypothalamic pathology in mice

Authors: *K. PLUCINSKA, R. DEKERYTE, D. KOSS, K. SHEARER, N. MODY, G. RIEDEL, M. DELIBEGOVIC, B. PLATT;
Univ. of Aberdeen, Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Neuronal β-secretase 1 (BACE1) is associated with pathogenesis of Alzheimer's disease (AD) due to its role in amyloid production exerted via amyloid precursor protein (APP) cleavage. However, growing evidence suggests that BACE1 has multiple substrates other than APP, and its diverse actions may be involved in maintenance of glucose and insulin homeostasis. We here investigated whether introduction of neuronal BACE1 induced changes in central and/or peripheral glucose homeostasis and insulin sensitivity *in vivo*, using our brain-specific human (h) BACE1 knock-in mouse (PLB4). We conducted extensive physiological, biochemical and molecular analyses of systemic and central alterations in glucose metabolism, insulin signalling, lipid and hormonal composition in PLB4 mice using Western blotting, qPCR, immunoassays and LC-MS. Despite a leaner phenotype (~20% body mass loss), PLB4 mice exhibited hyperglycaemic blood (>8mM), severe impairments in glucose clearance from 4 months of age compared to WT counterparts, indicating major metabolic complications and loss of glycaemic control. Hyperinsulinaemia was only detected in 4 and 5-month hBACE1 mice, while low levels of serum insulin in 8-month old transgenics resembled advanced stage of insulin deficiency. The metabolic disturbance in PLB4 mice was associated with advanced hypothalamic endoplasmatic reticulum (ER) stress (elevated expression p-eIF2α and CHOP) and dysregulation of melanocortin system (POMC and MC4R). Brain hBACE1 knock-in promoted defective central insulin signalling and sensitivity (increased expression of PTP1B and insulin resistance-associated RBP4 cytokine). Further, both brain and plasma lipid composition was altered in PLB4 mice, with up-regulation in several classes of lipid species (i.e. phospholipids, triglycerides and ceramides). These hBACE1-induced central alterations paired with initial hyperinsulinaemia promoted impairments in hepatic glycogen storage, fatty liver phenotypes and hepatic insulin resistance. Our data uncover for the first time that neuronal BACE1 regulates

Deleted: in vivo

global metabolic homeostasis and promotes systemic diabetes via induction of hypothalamic ER stress and decreased neuronal insulin sensitivity *in vivo*.

Title: Transmembrane interactions in APP structure, folding, and processing by γ-secretase

Authors: ***P. KIENLEN-CAMPARD**[1], C. MARINANGELI[1], M. DECOCK[1], B. TASIAUX[1], J.-N. OCTAVE[1], I. DEWACHTER[1], S. O. SMITH[2], S. N. CONSTANTINESCU[1];

Abstract: Objective Understanding the molecular mechanisms controlling APP processing by γ-secretase represents a challenging task in AD research. Transmembrane (TM) interactions appear to have a central role here, both by driving the assembly and activation of the γ-secretase, and the docking/fitting of the substrate prior to cleavage. We identified key structural determinants (GxxxG and GxxxG-like motifs) in APP/Presenilins TM domains (TMDs) and analyzed their role in APP amyloidogenic processing and γ-secretase activity. Methods APP/PS1/PS2 constructs (including FAD mutants) were generated by site-directed mutagenesis. Assembly and activation of γ-secretase was studied by non-denaturating electrophoresis, co-immunoprecipitations, and combined to results of *in vitro* γ-secretase assays. APP transmembrane/juxtamembrane regions were analyzed by structural approaches (FTIR/NMR spectroscopy). APP processing was monitored by electrochemiluminescence assays (ECLIA). Results GxxxG motifs in APP TMD were initially found to control the association and orientation of APP homodimers. We showed here they control the αhelix/βsheet structure of inhibitory and cholesterol-binding regions, impacting on γ-cleavage and Aβ release. Mutation of PS1 and PS2 TMD8 motifs either abolishes PS endoproteolysis and γ secretase activity, or

Deleted: in vitro

increase it in the case of FAD mutant. Non-denaturating conditions indicated that GxxxG-like motifs in PS TMD8 are key determinants for the geometry of the mature γ-secretase controlling the switch between physiological and pathological conformations. Conclusion Our data suggest that GxxxG-like motifs in APP and PS are crucial structural determinants for the physiological and pathological processing of APP. They control both the fitness of APP for γ-cleavage and the conformation of the active γ-secretase complex.

Title: Extracellular mechanisms of tfeb-mediated clearance of ptau in tauopathies

Authors: *H. MARTINI-STOICA[1], H. ZHENG[2];
[2]Mol. and Human Genet., [1]Baylor Col. of Med., Houston, TX

Abstract: Tauopathies affect over thirty million individuals worldwide and the prevalence of Alzheimer's disease (AD), the most common tauopathy, is expected to quadruple by 2050. Clinically, tauopathies are characterized by progressive cognitive decline and behavioral changes, resulting in total caregiver dependence and death. Pathologically, the disease is marked by intracellular neurofibrillary tangles (NFTs) composed of aggregates of hyper-phosphorylated tau (pTau) protein and extensive neurodegeneration. Unfortunately, current AD therapies addressing tau pathology are limited, lacking in efficacy and/or safety. With studies demonstrating the existence of extracellular tau and cell-to-cell tau spreading, targeting extracellular tau will likely prove crucial to halting disease progression. Our objective is to determine the multiple roles of transcription factor EB (TFEB), a critical regulator of lysosomal biogenesis, in clearing pTau. In addition to neuronal TFEB's known cell-autonomous effect in

enhancing the autophagy-lysosomal pathway, we hypothesize that astroglial TFEB expression enhances uptake and clearance of aberrant extracellular tau, preventing the neuronal spreading of tau pathology. Upregulation of TFEB in the CNS by adeno-associated virus results in the clearance of aberrant tau and rescue of neurodegeneration in tauopathy mice. Furthermore, TFEB expression in astrocytes plays a functional role in extracellular amyloid-β uptake and clearance. We plan to demonstrate that TFEB upregulation in astrocytes enhances uptake and clearance of pTau *in vitro* and *in vivo*, in addition to halting the propagation of tau pathology in an *in vivo* tau spreading assay. Through this study, we expect to reveal potential therapeutic targets that will have a substantial impact on AD prevention and treatment.

Title: Chronic treadmill exercise prevents tau pathology and behavioral deficits in P301S tau transgenic mice

Authors: ***J. L. ERIKSEN**, O. OHIA-NWOKO;
Pharmacol. and Pharmaceut. Sci., Univ. of Houston, Houston, TX

Abstract: Alzheimer’s disease (AD) and some frontotemporal dementias are classified as tauopathies. All tauopathies are characterized by intraneuronal or glial accumulation of fibrillar deposits, which are comprised of hyperphosphorylated and aggregated tau protein. These pathological changes result in significant neurodegeneration in the brain, that results in a progressive decline in cognitive and motor abilities.Based on recent clinical evidence in patients with neurodegenerative tauopathy, it is possible that introducing physical exercise can be instrumental in delaying the onset of behavioral impairments. In this study, 4-month old P301S tau transgenic mice were subjected to 6 months of forced treadmill exercise and evaluated for effects on tau pathology and behavior. Exercise prevented deficits in muscular strength, anxiety-like behavior, sensorimotor gating and cued fear conditioning. Significant reductions in tau

hyperphosphorylation were observed in the brain, and sarkosyl-insoluble tau was altered in the spinal cord and brain. The effects of exercise on neurodegeneration in the spinal cord and brain were also assessed. We believe this research contributes to a more comprehensive understating of how treadmill exercise may prevent or mitigate the onset of neurodegenerative disease.

Title: Entorhinal tau pathology affects motor behavior but not spatial working memory

Authors: ***S. E. TANNINEN**[1], X. JI[2], A. D. SOKO[2], R. L. KLEIN[3], K. TAKEHARA-NISHIUCHI[1], P. J. FLETCHER[2];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [3]Hlth. Sci. Ctr. Shreveport, Louisiana State Univ., Shreveport, LA

Abstract: Alzheimer’s disease is a progressive neurodegenerative disease characterized by cognitive deficits such as long-term and working memory impairments and non-cognitive abnormalities such as aberrant motor behavior, apathy, and disinhibition. Pathophysiological symptoms of AD are thought to occur years or even decades before the onset of cognitive deficits; however, there is not a consensus for preclinical biomarkers to aid the detection of preclinical AD and the prevention of AD. Post-mortem analyses revealed that the accumulation of hyper-phosphorylated tau in the entorhinal cortex (EC) is one of the first pathophysiological symptoms of preclinical AD. We previously generated a rat model that accurately mimics this site-specific pathology by using a viral vector approach and confirmed that entorhinal tau pathology did not impair the acquisition of a hippocampus-dependent associative memory. The present study aims to identify other potential behavioral deficits that precede the impairment in

long-term memory by examining the behavior of the rat model during an operant delayed non-match to place (DNMTP) task. Adult male Long-Evans rats were trained in DNMTP over 16 weeks. Then, to emulate the site-specific, adult onset pathology observed in human patients with preclinical AD, we transduced with a viral vector, an excess of mutated human tau with the P301L mutation (Tau rats) or green fluorescent protein (GFP rats) into the EC of adult rats. Afterwards, we continued training the rats in DNMTP for 9 weeks during which their working memory and patterns of movement were examined. Tau and GFP rats had similar accuracy in DNMTP at 1, 2, 4, 8, and 16s delays. However, Tau rats, in comparison to GFP rats, showed signs of repetitive or disinhibited motor behaviour: they had more head entries into the food magazine during the inter-trial interval; Tau rats tended to repeatedly nose poke the choice hole after they had chosen the correct choice; and Tau rats moved around more in a novel environment. Thus, tau pathology confined to the EC does not affect spatial working memory but can produce aberrant motor behavior. Non-cognitive symptoms such as repetitive behavior or disinhibition may therefore be a sensitive behavioral measure of preclinical AD.

Title: Active immunization with highly immunogenic tau epitope induced a strong immune response together with improvement in short memory but failed to significantly reduce tau pathology in a mouse model of tauopathy

Authors: *A. JOLY AMADO[1], H. DAVTYAN[2], K. SERRANEAU[1], K. ZAGORSKI[2], M. N. GORDON[1], D. H. CRIBBS[3], A. GHOCHIKYAN[2], N. PETROVSKY[4], M. G. AGADJANYAN[2], D. MORGAN[1];

Abstract: Abnormal tau hyperphosphorylation and its accumulation into neurofibrillary tangles are a hallmark of tauopathies, which are neurodegenerative disorders that include Alzheimer’s

disease (AD). Tau immunotherapy has therefore been proposed as a new therapeutic approach to AD. The aim of this study was to test if active immunotherapy with highly immunogenic tau epitope in a mouse model of tau deposition was capable of reducing levels of tau pathology in the brain and improving cognition. Tg4510r mice, carrying the human four-repeat tau with the P301L mutation (4R0N tauP301L) and the CamK-II tetracycline-controlled transactivator protein were used. Male and female transgenic rTg4510 mice (3 months old; n = 36) subdivided into 3 groups (n=12 per group) received intramuscular injections of tau vaccine, Aβ vaccine or adjuvant only. Non-transgenic and tet only littermates (tetracycline-controlled transactivator protein expressing mice) were used as control groups for behavioral testing and anatomy comparisons. All groups received three injections in alternating weeks and were boosted an additional three times (4 weeks apart) for a total of 7 injections. Mice were subjected to behavioral testing including open field, Y maze, radial arm water maze and novel object recognition by an observer blind to the treatment/genotype of the mice in order to evaluate learning, memory and general activity. Sera were collected at different time points to measure anti-tau and anti-Aβ antibodies responses and tissue was collected at 8 months of age. Active immunization induced strong humoral immune response in both non-transgenic and transgenic mice (1.76 ± 0.17 mg/ml and 1.93 ± 0.27 mg/ml for tau vaccinated mice and Aβ vaccinated mice, respectively). Mice vaccinated with tau epitope displayed an improvement in short-term memory when compared to adjuvant and Aβ treated mice during novel object recognition test. Tau vaccination failed to significantly reduce pathology; however we observed some trend of reduction of total tau and pS396 tau in our study. Altogether, these data indicate that active immunotherapy with tau epitope was effective in improving cognition but had no significant effect on tau pathology in a mouse model of tau deposition. Nonetheless, it is possible that immunotherapy should be initiated very early to be effective in significant reduction of tau pathology. Further analysis and our ongoing studies in different tau transgenic mouse models may result in more comprehensive assessment of vaccine efficacy, and to the understanding of the mechanisms involved in cognition improvement.

Title: Examining the intracellular breakdown of toxic tau fragments

Authors: A. SHEPARD[1], B. STEVENS[1], E. COOKSEY[1], *M. L. STEINHILB[2];
[1]Biol., Central Michigan Univ., Mount Pleasant, MI; [2]Central Michigan Univ., Mt Pleasant, MI

Abstract: Alzheimer's disease and other tauopathies are characterized by the accumulation of abnormally phosphorylated and aggregated forms of the microtubule-associated protein tau. Several independent laboratories have reported the appearance of a soluble, 17kD fragment of tau in dying neurons that is the product of calpain cleavage. Results from our lab using *Drosophila* as a genetic model organism for tauopathy show that calpain cleavage of tau has profound impact on neurotoxicity *in vivo*. Many researchers now support the idea that the toxic tau species is a soluble, highly phosphorylated, aggregated form of tau. What remains unknown is the mechanism controlling how the toxic tau moiety causes neuronal dysfunction. The two major degradation pathways for both physiological and pathological forms of tau are the ubiquitin-proteasome system and the autophagy-lysosome system. Other labs have shown that full-length tau is degraded by the proteasome, but that truncated fragments and soluble oligomers are cleared by autophagy. Accumulating evidence suggests that there is significant cross talk between the autophagic and proteasomal systems and that phosphorylation and truncation may play an important role in targeting proteins to the appropriate degradation pathway. Since others have noted that tau assembly into oligomers inversely correlates with proteasomal degradation (suggesting that soluble oligomers may be degraded via autophagy), we are particularly interested in studying the degradation fate of 17kD tau. We are using primary neuronal cultures from *Drosophila* to study how wild-type and mutant forms of tau are eliminated by neurons. In this study, *Drosophila* neurons expressing either human wild-type tau (tau^{WT}), calpain-resistant tau (tau^{CR}), or amino acids 44-230 of human tau comprising the 17kD fragment (tau^{17kD}), were treated with pharmacological agents to manipulate the autophagic and proteasomal systems. Confocal microscopy and live-cell imaging were used to visualize autophagic/proteasomal modulation and assess the toxicity of our tau constructs. Given the importance of soluble tau oligomers and the 17kD fragment, these experiments are important for defining the pathways involved in clearance of the 17kD fragment in order to understand the molecular mechanisms underlying tau toxicity.

Title: Enhanced tau phosphorylation in cold-exposed old mice: linking thermoregulation deficit with Alzheimer's disease

Authors: *M. TOURNISSAC[1,2], M. VANDAL[1,2], A. FRANCOIS[1,2], E. PLANEL[1,3], F. CALON[1,2];
[1]Axe neurosciences, Ctr. De Recherche Du CHU De Québec, Quebec, QC, Canada; [2]Faculté de pharmacie, [3]Dept. de psychiatrie et neurosciences, Univ. Laval, Quebec, QC, Canada

Abstract: Thermoregulatory deficits coincide with a rise in the incidence of Alzheimer's disease (AD) in old age. Lower body temperature increases tau phosphorylation, a neuropathological hallmark of AD. To determine whether old age potentiates cold-induced tau phosphorylation, we compared the effects of cold exposure (4°C, 24 hours) in 18-month-old versus 6-month-old mice. Although reduction of body temperature was similar in young (-4.3%) and old mice (-4.5%), the effect of cold exposure on cortical tau phosphorylation was more pronounced in older mice. Although exposition to 4°C increased tau pSer202 in both 18 and 6-month-old mice (+128%, $p<0.03$ and +73%, $p<0.01$, respectively), only old mice displayed a rise in tau pThr181 (+38%, $p<0.02$) following cold exposure. Furthermore, while tau pSer202 correlated with body temperature in old ($r^2=0.43$) and young mice ($r^2=0.16$), tau pThr181 and pThr231 correlated with temperature in old ($r^2= 0.47$ and $r^2=0.28$, respectively) but not in young mice ($r^2=0.02$ and $r^2=0.11$, respectively). Interestingly, an increase in pGSK3βSer9 (+49%) was observed only in cold-exposed young mice, suggesting a protective mechanism against cold-induced tau phosphorylation. These results suggest that old age may be associated with a higher susceptibility to a change in environmental temperature, which could contribute to enhance the risk of developing AD.

Title: Neuroprotective effects of a novel Hsp90 C-terminal modulator in Abeta-treated neurons and mutant tau mice

Authors: ***M. L. MICHAELIS**[1], H. MENCHEN[1], R. PAL[1], H. ZHAO[2], R. H. SWERDLOW[3], E. K. MICHAELIS[4], B. S. J. BLAGG[2];
[1]Dept Pharmacol, [2]Dept Medicinal Chem, Univ. Kansas, Lawrence, KS; [3]Dept Neurol., Univ. Kansas, Kansas City, KS; [4]Dept Pharmacol., Univ. Kansas, Lawrence, KS

Abstract: Most neurodegenerative diseases are characterized by 'mis-folded proteins' in aggregates or fibrils, suggesting suboptimal activity of brain molecular chaperones. Heat shock protein 90 (Hsp90) is the master regulator of cell responses to 'proteotoxic' stresses, and some Hsp90 modulators can activate transcriptional and/or metabolic cascades leading to protein re-folding or degradation. Such modulators have been reported to reduce the amyloid peptide aggregates (Aβ) and hyper-phosphorylated Tau fibrils (P-Tau) induced in animal models of Alzheimer's (AD). However, most of the Hsp90 modulators were designed to target the N-terminal domain of the protein where they inhibited the ATPase activity and led to *in vivo* toxicity. We previously described a novel, non-toxic C-terminal Hsp90 modulator, A4, that markedly protected neurons against amyloid peptide (Aβ) - induced toxicity. More recently, we identified a derivative, designated 'KU-32', that appears to be even more potent than A4 in protecting neurons against Aβ. The goals of these studies were to test (1) the *in vitro* and *in vivo* toxicity of KU-32, (2) the pharmacokinetics, brain permeation, and oral bioavailability of the compound, and (3) the *in vivo* efficacy of chronic KU-32 treatment in slowing progression of neuritic dystrophy, synaptic abnormalities, levels of P-Tau oligomers, and neuronal cell death in brains of a mouse model with targeted forebrain over-expression of a tet-regulatable P301L Tau mutation, the rTg4510 mice. Our results indicated that KU-32 showed no *in vivo* toxicity, it readily crossed into the brain, and it was orally bioavailable. Most significantly, chronic administration of KU-32 slowed the accumulation of P-Tau oligomers, reduced the synaptic markers of Tau pathology, and decreased progression of neuronal cell death. In addition, the treatment enhanced retention of a learned task. The data thus far support the potential value of further studies with this C-terminal Hsp90 modulator to assess fully the efficacy of KU-32 in slowing development of the pathology normally resulting from high expression of mis-folded Tau oligomers.

Title: Bone loss as a predictor for brain disease? Decreased bone mineral density and osteoporosis early in the lifespan of htau Alzheimer's disease mice may be associated with pathology in the dorsal raphe

Authors: ***M. A. SMITH**[1], D. MARGEVICIUS[2], C. M. DENGLER-CRISH[2];
[2]Pharmaceut. Sci., [1]Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Low bone mineral density (BMD) and its sequelae, osteoporosis, occur disproportionately in Alzheimer's disease (AD) patients compared to the age-matched healthy population. Bone loss and fragility present a significant clinical comorbidity that affects quality of life and mortality in AD patients. Of note, low BMD and bone fractures have been reported very early in the progression of AD, when cognitive decline is minimal and mobility has not yet been compromised. In fact, bone loss may predict AD years before any evidence of dementia is apparent and may be part of a constellation of symptoms that comprise a prodromal phase of AD. AD pathological markers have been linked to bone loss and some transgenic strains of amyloid-beta (Aß) overexpressing mice have an osteoporotic phenotype early in life before the large-scale accumulation of classic transentorhinal AD pathologies are shown. However, it is unclear whether this pathology is due to degenerative changes in central bone regulatory mechanisms or Aß acting peripherally on the bone itself. We report here, for the first time, early bone loss in an AD model characterized by hyperphosphorylation of tau (ptau). As tau is a cytoskeletal protein primarily expressed in and associated with the nervous system, skeletal deficiencies in these models would be consistent with central pathologies in bone regulatory brain regions. We investigated whether components of this bone regulatory circuitry that include the dorsal raphe nuclei (DRN) and ventral medial hypothalamus (VMH) were affected by ptau pathology early in the *htau* AD mouse model, and whether this was associated with a skeletal phenotype. Using dual x-ray absorptiometry, we found that at 2-3 months of age, *htau* mice have significantly lower BMD measured at the lumbar spine, femur, and overall skeleton compared to age-matched wild-type controls. Intriguingly, bone loss was greater in male *htau* mice as they

met criteria for osteoporosis (BMD more than two standard deviations below control age-matched animal peak bone mass) at the lumbar spine and whole body whereas the female *htau* mice did not. Additionally, immunohistochemical studies revealed increased staining for ptau-231 and astrogliosis (GFAP) in the DRN of 2-3 month old *htau* mice compared to wild-type controls. Our results suggest that skeletal deficits in AD may be due to pathologies in central bone regulatory regions of the brain. These findings may be useful for identifying early pathological mechanisms common to bone loss and AD as well as opening new therapeutic windows for delaying or preventing AD.

Title: Behavioral tests identify early phenotypic changes in P301S tauopathy mice

Authors: *L. VER DONCK, M. MAHIEU, K. VAN KOLEN, R. WILLEMS;
Janssen Res. & Development, A Div. of Jans, Beerse, Belgium

Abstract: Tau is a highly soluble cytosolic microtubule binding protein, but under pathological conditions it aggregates into neurofibrillary tangles (NFT) containing hyperphosphorylated tau. Intracellular accumulation of these NFTs is believed to lead to synaptic loss and neuronal cell death, e.g. in Alzheimer’s disease or frontotemporal dementia. Attenuation of tau aggregation therefore holds promise for the treatment of such neurodegenerative diseases. To evaluate the efficacy of potential treatments, animal models are needed where tau aggregation can be correlated to a sensitive behavioral phenotype. The P301S mutant mouse is a commonly used tauopathy model that develops tau aggregation in the CNS along with muscle weakness, tremor and severe paralysis by 3-6 months of age. In this study, we evaluated age-dependent motor dysfunction in female P301S and C57BL6 control (WT) mice using a battery of tests: clasping behavior and paralysis was scored as an indicator of functional loss of hind paws; muscle strength of fore paws was measured as grip strength; the animal’s ability to climb on the top of an inverted grid was used as a measure of muscle strength and motor coordination function; balance was monitored using the beam walking test, measuring the time to reach a platform at the end of either side of a horizontal bar; limb coordination was evaluated on a rotarod by measuring time of first turnaround or when falling off. The mice were evaluated once a month

between 2 and 5 months of age: mice were naïve to the tests at each time point, while one group was re-tested every month. Analysis of data revealed main effects for age, genotype and an interaction effect for age x genotype, except for the grip strength test where only an interaction effect was found. Performance of naïve mutant animals was impaired vs WT in all tests at 4 or 5 months of age, while impairments were already seen in repeatedly tested animals at 3 months in clasping and inverted grid task. Impairment in mutant mice was more pronounced in repeatedly tested mice in grip strength and rotarod. While tau pathology in P301S mice develops at 3 months of age, functional impairments were observed after a short delay suggesting a causative relationship between tau aggregation and the phenotypic changes. More work needs be done to confirm this relationship.

Title: Physiological tissue distributions of tau and MAP2 in mice brains

Authors: ***A. KUBO**[1], H. MISONOU[2], M. MATSUYAMA[4], Y. IHARA[3], M. TOMOHIRO[1]; [1]Dept. of Neuropathology, [2]Lab. for Ion Channel Pathophysiology, Doshisha Univ., Kyotanabe-shi / Kyoto-fu, Japan; [3]Lab. for Cognition, Memory and Aging, Doshisha Univ., Kyotanabe-Shi / Kyoto-Fu, Japan; [4]Div. of Mol. Genet., Shigei Med. Res. Inst., Okayama-City, Japan

Abstract: Tau and Microtubule-Associated Protein (MAP)-2, are major MAPs in neurons and are known to stabilize neuronal microtubules (MT). In healthy neurons, it is believed that tau is mainly localized in axons in sharp contrast to MAP2, which localizes in the somatodendritic

compartment. In fact, tau and MAP2 are routinely used as markers of the axon and dendrite, respectively, especially in *in vitro* studies. However, in contrast to MAP2, as well as to neurofibrially tangles, the tissue distribution of physiological normal tau in healthy brains is yet inadequately demonstrated because of its poor detectability in immunohistochemistry. To determine the tissue distribution of physiological normal tau, we developed high-sensitive immunohistochemical technique, which allowed us to visualize physiological or pre-pathological tau in the brain tissue. First, we examined the distribution of physiological mouse tau (m-Tau) in the brains of wild-type mice. m-Tau is globally expressed, but abundant in non-myelinated nerve fibers rather than in myelinated nerve fibers in the white matter. The distribution of tau and MAP2 are clearly segregated into axonal and somatodendritic regions, respectively. High-resolution imaging further demonstrated that m-Tau is distributed as punctate along axonal MT. Next, we compared the distributions of endogenous m-Tau and exogenous human tau (h-Tau) in the brains of tau-transgenic (tau-Tg) or tau-knock in (tau-KI) mice. In tau-Tg mice brains, exogenous h-Tau was localized not only in the axonal component but also in the somatodendritic compartments. This was already apparent at a neonatal stage, and further indicates the pre-pathological mislocalization of exogenous tau. In contrast, exogenous h-Tau in tau-KI mice did not show any abnormal sorting. We further found that the MT-binding of h-Tau in tau-Tg mice, but not in tau-KI mice, was affected. Endogenous m-Tau in both of tau-Tg and tau-KI (heterozygous) mice brains behaved as normal throughout their lifetime. Our results indicate the presence of specific machinisms that somehow regulate the axonal localization and MT-binding of tau, whose expression is driven by the tau promoter but not by ectopic promoter. Tau is hyperphosphorylated and accumulated in cell bodies and dendrites, and forms NFTs in affected neurons of tauopathy brains. In rodent models, similar tauopathy-like pathologies have been reproduced only in the brains of tau-transgenic mice Pathogenesis of exogenous-tau in these model mice may be due, at least in part, to the expression of tau using ectopic promoters.

Title: Emergence of early alterations of functional EEG oscillations and network connectivity in a Tau seeding mouse model of Alzheimer’s disease

Authors: *A. AHNAOU, D. MOECHARS, L. RAEYMAEKES, R. BIERMANS, E. PEERAER, N. MANYAKOV, T. VAN DE CASTEELE, J. KEMP, W. DRINKENBURG; Dept. of Neurosci. Discovery, Janssen Res., Beerse, Belgium

Abstract: OBJECTIVE: Neuronal network connectivity and oscillations are critical for cognitive functions that are altered in neurodegenerative disorders such as Alzheimer's disease (AD). Early indicators of AD are crucial for implementing therapeutic interventions when brain systems are still adequately functioning. Here, using a tau seed injection model, the early and late effects of induction and spread of tau aggregation pathology on neurophysiological and functional connectivity networks were investigated. METHODS: First, sleep-wake and related physiological variables were monitored over 24 weeks in mice equipped with bipolar epidural EEG electrodes. Second, multichannel EEG epidural and intra-hippocampal oscillations were used to assess 1) coherent activity-based synchrony between frontal cortex and CA1-CA3 networks; 2) phase-amplitude cross frequency coupling (CFC) in slow theta and higher gamma EEG frequencies, which are known to be instrumental in cognition, i.e. episodic memory formation; 3) information processing as assessed via auditory evoked potentials (AEP) and evoked oscillations in the passive oddball, mismatch negativity (MMN) paradigm. RESULTS: Sleep-wake cycle, body temperature and locomotor activity were generally preserved over 24 weeks after the injection of preformed Tau fibrils into the dorsal CA1 region of the hippocampus. In contrast, consistent enhancement of EEG cortical theta oscillations occurred as from week 8 onwards, which coincides with the first signs of neuronal loss, while developing seeded Tau pathology is already at maximal level at 4 weeks. Interestingly, network dynamics analysis revealed weakened functional connectivity between the neocortex and CA1 and drastic impairments in theta-gamma CFC from week 2 onwards, i.e. preceding detectable Tau spread and cell loss. Moreover, the Tau pathology disrupted the P1/N1/P2 AEP complex and evoked oscillations to standard stimuli isuggesting a decreased sensory information processing. DISCUSSION: The present results provide strong preclinical evidence that network alterations indicate very early functional disruptions due to Tau seeding, well in advance of any detectable cognitive or histopathological features. The increase in theta power may disrupt the ability of the brain to dynamically adjust the amplitude of higher frequency oscillations. The strong theta-gamma uncoupling can be exploited as an early cognitive neurophysiological signature of hippocampal network dysfunction. Consequently, network connectivity, theta-gamma CFC and the uncoupling phenomenon described here, might serve as an early, functional biomarker of Tauopathy and AD.

Abstract: Frontotemporal dementia (FTD) is a neurodegenerative disorder that is as common as Alzheimer's disease (AD) in the population under age 65 but progresses to death more rapidly than AD. Frontotemporal lobar degeneration that features prominent intracellular aggregates composed of microtubule-associated protein tau is termed FTLD-tau. Aggregated tau can be toxic to neurons, reducing synaptic transmission, promoting synapse loss, and driving cell death. It is proposed that activating intracellular protein degradation pathways may be a rational therapeutic avenue to reduce tau aggregation in FTD. Previous studies indicated that pharmacologic inhibition of Rho-associated coiled-coil containing protein kinases (ROCK) 1 and ROCK2 can enhance protein degradation pathways in mammalian cells. In neurons, we show that treatment with SR3677, a selective drug inhibitor of ROCK2, depletes endogenous tau protein level in a dose-dependent manner. Fasudil, a pan-ROCK inhibitor, had more modest effects. Exposure to SR3677 decreased p62, phospho-mTOR, and phospho-S6 Kinase levels in neurons, suggesting that ROCK2 inhibition promotes autophagy-mediated degradation of tau. Importantly, ROCK2 depletion by shRNA mimicked effects of SR3677 on tau levels as well as autophagy markers in human neuroblastoma cells. ROCK2-shRNA rescue experiments revealed that ROCK2 mutants with amino acid substitutions in the ATP-binding site could not restore tau levels, indicating that ROCK2 kinase activity is required for these effects. Immunoblot analysis of postmortem human frontal cortex tissue samples from FTLD-tau cases, including corticobasal degeneration and progressive supranuclear palsy, revealed changes in autophagy markers as well as ROCK1 and ROCK2 compared to age-matched, pathology-free control cases. Finally, we demonstrate that treatment with Fasudil reduces tau protein level in transgenic *drosophila* expressing human tau. Our findings highlight ROCK2 as a potentially new and exciting therapeutic target to reduce tau protein level in FTD.

Title: The effects of caffeine on *Drosophila* expressing tau pathology

Authors: ***A. M. BOOTH**, A. H. JALALI, D. I. LAMBRECHT, D. D. LENT;
Biol., California State University, Fresno, Fresno, CA

Abstract: Tau pathology commonly occurs in the regions of the brain affected by Alzheimer's disease (AD). Current research indicates that caffeine administration in mammalian model organisms such as mice or rabbits that are expressing tau pathology leads to a reduction in both learning and memory deficits and neuronal damage. Additionally, it has been noted that there is a negative correlation of the expression of AD in aging patients with increasing caffeine consumption from beverages such as coffee. The effects of caffeine on tau pathology has not been studied extensively in the more basic model organism *Drosophila melanogaster*. Studies in *Drosophila* could be useful in developing models to study the basic mechanisms of how caffeine could have an effect on the cognitive deficits and associated neuronal pathology. Genetic tools available in *Drosophila* such as the GAL4-UAS system permits for controlled expression of proteins associated with AD disease. Experiments can be conducted with a large number of flies simultaneously, providing a high throughput model system. Here we examine associative and spatial learning and memory, as well as longevity in *Drosophila melanogaster* expressing human tau protein in the mushroom bodies and ellipsoid body exposed to caffeine post-eclosion in the diet. The mushroom bodies and the ellipsoid body are distinct neuropils in the brain of *Drosophila* that have been implicated in associative and spatial learning and memory and multimodal integration and sensory perception. Additionally, the mushroom bodies and ellipsoid body have been suggested to have homologies to regions of the vertebrate brain attacked during AD (the hippocampus and striatum, respectively). Our approach thus far has focused on analyzing the improvements in the health and lifespan and on the performance in olfactory-shock associative learning and visual place learning assays. Our data suggests that similar to mammalian models of caffeine and AD, caffeine exposure has a positive effect on the behavior and longevity in *Drosophila* expressing tau pathology. By exploring different benefits of caffeine

on health, spatial cognition and learning, we can better understand the broad deficits caused by tau pathology. Our effort is aimed at further developing new ways to use *Drosophila* as a high-throughput system to study declines in complex behaviors and the underlying neural deficits associated with AD and other neurodegenerative diseases.

Title: Tau pathology-induced memory impairments: a role for T-cell infiltration ?

Authors: ***D. BLUM**[1], C. LAURENT[1], G. DOROTHÉE[2], Y. MONNET[3], M. DUCHAMP[2], A. LEBOUCHER[1], S. BURNOUF[1], R. CAILLIEREZ[1], N. ZOMMER[1], D. DEMYER[1], N. JOUY[1], S. SCHRAEN-MASCHKE[1], S. HUNOT[3], L. BUÉE[1];

Abstract: Tau pathology is central to cognitive decline in Alzheimer's Disease. Notably, Tau pathology has been shown to promote synaptic deficits underlying memory impairments in Tau transgenic mice. To which extent immune responses contribute to Tau-induced cognitive decline in AD remains poorly understood. To address this question, we took advantage of the THY-Tau22 mouse model -that progressively develops brain Tau pathology in parallel of cognitive

deficits- and reappraised the relationships between central immune response and Tau lesions. Using conventional immunohistochemical approaches as well as transcriptomics, we observed, as expected, astro/microglial hippocampal activations spatially and temporally correlated with Tau pathology. More surprisingly, we also observed that several markers of adaptive immune responses were upregulated in Tau transgenic mice. We identified, for the first time, CD8+ T-cell infiltration in the brain of Tau mice, without any major impairment of the blood brain barrier integrity. T-cell infiltration was associated with upregulation of chemokine production (Ccl3, Ccl4, Ccl5) as observed by a combination of transcriptional, biochemical and immunohistochemical approaches. In order to get insights into the potential implication of T-cell infiltration in the pathophysiological development in THY-Tau22 transgenic mice, we chronically depleted T-cells using anti-CD3 antibodies. Such treatment totally prevented CD8+ T-cell infiltration in the brain of Tau mice and restored normal spatial memory as measured using the Y-maze task. Overall, our study highlights the involvement of chemokines and adaptive cellular immunity in the development of memory deficits in Tau pathologies.

Abstract: [Background]FUS is a causative gene for familial ALS and FTLD. FUS aggregates are recognized as a pathological hall mark of both familial and sporadic ALS/FTLD. In ALS/FTLD, distinct atrophies are the major characteristics in the lesion with FUS pathology. [Aim] To determine whether FUS knock-down causes neuronal loss and brain atrophy by using a FUS knock-down mouse model established by injecting adeno-associated virus (AAV) encoding shRNA against FUS into the bilateral hippocampus, which exhibited FTLD-like behavioral impairments [Methods]We injected AAV encoding shRNA against FUS (shFUS) and control (shCont) to the bilateral hippocampus of C57/BL6J mice at the age of 6 weeks. The size of hippocampus was measured at 6-month, 12-month and 18-month of post-injection by 3.0T MRI. Immunohistochemical analysis was also performed to validate the results of imaging study. [Results]We observed a significant decrease in hippocampal volume in shFUS mice at 18 months of post-injection compared to shCont, whereas no apparent difference was observed until 12 months of post-injection. Marked hippocampal atrophy accompanied with neuronal loss and subsequent enlargement of the lateral ventricles were observed in shFUS mice at 18 months of post-injection, whereas histology was almost intact at 12 months of post-injection. [Conclusion]The loss of FUS leads to brain atrophy accompanied with neuronal loss in an age-dependent manner. Taken together with their behavioral impairments, our FUS knock-down animals mimic the phenotypes of FTLD.

Title: Targeting the mapt locus by TALEN to study the trafficking of endogenous tau

Authors: ***D. XIA**, J. GOTZ;
The Univ. of Queensland, Queensland Brain Inst., Brisbane, Australia

Abstract: Neurofibrillary tangles (NFTs) are a major histopathological hallmark of neurodegenerative disorders such as Alzheimer's disease (AD) and frontotemporal dementia. Their major proteinaceous constituent is tau, a microtubule-associated protein tau (MAPT). Tau is enriched in neurons, where under normal conditions, it is mainly localized to the axon, while expression in the dendrites is weak. In contrast, when Tau is overexpressed in cultured neurons it distributes uniformly in all processes. It has been hypothesized that in AD, Tau relocalizes from the axonal to the somato-dendritic domain and that this process is facilitated by another AD hallmark, amyloid-β. Studying tau however is compromised by classical over-expression approaches, because the Tau-encoding mRNA is translated in the soma whereas in the case of endogenous Tau, its mRNA is transported to the axonal shaft for local translation. Also, tau exists in several isoforms. To overcome the drawback of overexpression system, we established a transgenic mouse line targeting a photo-convertible mEOS2 tag to the carboxy-terminus of the MAPT gene, using the genome-editing tool TALEN. Live cell imaging techniques will allow monitoring the trafficking of endogenous Tau in neurons under both physiological and pathological conditions.

Abstract: Background Alzheimer’s Disease (AD) pathology is characterized by β-amyloid (Aβ) deposits and neurofibrillary tangles (NFT). The pathology progresses from the entorhinal cortex to hippocampal sub-regions and the cortical area via anatomical connections. It is

hypothesized that progression occurs via a cell to cell transmission and tau is secreted into the extracellular space. Therefore, progression of the pathology can be evaluated using a microdialysis approach. The present study monitors the different forms of β-amyloid, tau protein, monoamines, acetylcholine (ACh) and kynurenate (KYN) levels in the interstitial fluid (ISF) of three different brain structures of a transgenic mice strain exhibiting Aβ and tau pathology. **Methods** Male TauPS2APP ($APP^{695\ (K670N-M671L)}$/$PS2^{N141I}$/Tau^{P301L}(3xtg)**)** were evaluated at 8 months in comparison to C57Bl6 mice. A ~300kDa cut off membrane, (Brainlink, Netherland) was stereotaxically implanted in the frontal cortex (2 mm long, Lat, -0.4, AP, +2.0, DV, -3.0), the ventral hippocampus (2mm long, Lat, +2.9, AP, -3.1, DV, -4.5) or the amygdala region (1 mm long, Lat, +2.5, AP, -1.5, DV, -5.5) under ketamine/xylasine anaesthesia. Two days later, freely-moving mice were perfused (0.5µl/min) with Ringer solution and samples collected during 7 hours. Simultaneous ELISA quantification of $Aβ_{1-40,}$ $Aβ_{1-42}$ and total tau was performed using MesoScale Discovery technology. Neurotransmitters were evaluated by HPLC coupled to electrochemical, fluorimetric detection or mass spectroscopy. **Results** ISF levels of total tau were significantly increased in the ventral hippocampus of the 3xtg mice compared to controls. The similar increase was observed in the frontal cortex and the amygdala region. ISF levels of $Aβ_{1-40}$ and $Aβ_{1-42}$ were similarly increased in the 3xtg mice. In contrast, levels of noradrenaline were significantly reduced in the ventral hippocampus, frontal cortex and the amygdala region of the 3xtg mice. No significant differences were observed in serotonin, ACh and KYN levels. **Conclusions** Monitoring tau, β-amyloid, monoamine, KYN and ACh levels in different brain regions using microdialysis provides a useful tool to assess the spreading of the AD pathology and neuronal dysfunction *in vivo*. The present research was part of the PharmaCog consortium funded by the European Community's Seventh Framework Programme for the Innovative Medicine Initiative under Grant Agreement n°115009. All procedures using these animals conformed to international European ethical standards (86/609-EEC) and the French National Committee (décret 87/848) for the care and use of laboratory animals.

Title: Electrical and network neuronal properties are preferentially disrupted in dorsal, but not ventral, medial entorhinal cortex in a mouse model of tauopathy

Authors: ***T. RIDLER**[1], C. BOOTH[3], T. K. MURRAY[4], M. A. WARD[4], M. GOODFELLOW[2], K. G. PHILLIPS[4], A. D. RANDALL[1,3], J. T. BROWN[1,3];

Abstract: The entorhinal cortex provides the main interface between the hippocampus and the cortex and is one of the first areas to be affected in dementia. Neurones in the medial entorhinal cortex (mEC) display a dorsal-ventral gradient in a number of neurophysiological properties ranging from intrinsic excitability of stellate cells to grid cell firing field spacing, the functional output by which certain mEC cells respond in specific spatial locations within an environment. Here we explore the cellular and network properties of neurones in dorsal and ventral layer II/III mEC in rTg4510 mice, a transgenic model of tauopathy. Electrophysiological recordings were performed both *in vitro* and *in vivo* from 7-9 month old, male Tg4510 and wild-type (Wt) littermate control mice. Dorso-ventral gradients in certain intrinsic membrane properties such as membrane capacitance and after-hyperpolarizations are flattened in rTg4510 mEC stellate cells (SCs). Specifically, the intrinsic properties of rTg4510 mEC-SCs in dorsal aspects of the mEC are preferentially affected, such that action potential firing patterns in dorsal mEC-SCs are altered, whilst those in ventral mEC-SCs are unaffected. We also found that gamma frequency band (30-80 Hz) neuronal oscillations *in vitro* induced by low concentrations of kainic acid (500 nM) are preferentially disrupted in the dorsal mEC of rTg4510 slices, whilst those in ventral regions are comparatively preserved. We next determined whether these deficits were present in an intact system by chronically implanting 16-channel linear silicon probes along the dorsal-ventral axis of the mEC of Tg4510 and Wt control mice. The extent of theta-modulation of gamma frequency local field potential oscillations varied along the dorso-ventral axis of the

Deleted: in vitro

Deleted: in vivo

Deleted: in vitro

mEC in Wt mice, such that cross-frequency coupling was higher in dorsal vs ventral electrodes. In rTg4510 mice, however, this clear gradient in theta-gamma coupling was abolished. Deficits in mEC activity may have functional implications for grid cell firing field geometry and may contribute to the impairment in spatial information processing observed in this mouse model and clinical dementia.

Title: Early stage alterations to prefrontal cortex neurophysiology in the rTg4510 transgenic mouse model of tauopathy

Authors: ***L. E. STANIASZEK**[1], J. T. BROWN[2];
[2]Inst. of Biomed. and Clin. Sci., [1]Univ. of Exeter, Exeter, United Kingdom

Abstract: The prefrontal cortex (PFC) is critical for higher-order cognitive processes, such as the association of particular actions and locations with reward. Neurodegenerative diseases affecting the PFC, such as frontotemporal dementia can present pathologically with neurofibrillary tangles (NFTs) of the tau protein in later stages of disease progression. However, neurophysiological changes within the PFC and the timeline of these changes, remains unknown. The rTg4510 transgenic mouse expresses a mutant form of tau clinically associated with fronto-temporal dementia with Parkinsonism. These mice develop age-related neuropathology (NFTs, neurodegeneration) correlated with deficits in spatial- and recognition-memory tasks. However, the effect of this form of tauopathy on cognitive tasks commonly associated with the PFC (such as working memory) is not known. In this study we sought to determine if working memory deficits could be detected at an early-stage, prior to significant neuropathology. We also used *in vivo* electrophysiology to explore global- and task-related effects of tau overexpression on PFC neurophysiology. To achieve this, we examined working memory in a delayed non-matched-to-

Deleted: in vivo

sample alternating T-maze task in 10 rTg4510 (TG) and 10 wildtype (WT) littermate control female mice (aged 4-5 months), over seven days. Simultaneously, we recorded PFC pre-limbic cortex (PrL) single unit action potentials (AP) and local field potentials (LFP) from the same cohort of mice. Analysis of single unit AP characteristics and the degree to which their firing was phase-locked to the LFP was undertaken to elucidate alterations at the cellular and network level in these mice. At this age point, TG and WT mice performed equally well on the behavioural task, with no statistically significant differences between the two groups at any stage of the task. Nevertheless, analysis of PrL neurophysiology illustrated that APs recorded from TG mice had a significantly wider peak-to-trough interval. Furthermore, TG neurons were less likely to fire high frequency (>67 Hz) bursts of APs than equivalent WT cells. Analysis of network characteristics revealed a trend towards increased phase-locking of action potentials to the local field-potential on correct choice trials vs force or incorrect choice trials on the first day of testing, in WT but not TG mice. These analyses suggest that in this model of dementia, changes to cellular neurophysiology in the PrL precede network and behavioural deficits.

Title: Correlating the expression of tau and ptau with behavioral dysfunction in *Drosophila* melanogaster

Deleted: *Drosophila*

Authors: ***J. APARICIO VALENZUELA**, A. C. OLVERA, K. HWANG, D. D. LENT; CSU Fresno, Fresno, CA

Abstract: The fruit fly, *Drosophila* melanogaster, has proven to be a useful model organism in the study of many human disease processes and they are commonly used in both genetic experiments and neurological experiments. Our previous experiments quantified the behavior of flies in a place learning/spatial memory assays in order to elucidate cognitive traits associated with expression of human tau protein in specific brain regions associated with learning and memory. The ellipsoid body and the mushroom bodies were found to be individually important in certain elements of perception and learning. However, only when both regions were functionally intact was more complex spatial cognition revealed. Here we look to better understand how the expression levels of tau and the phosphorylation of tau impact spatial

Deleted: Drosophila

cognition. We used GAL4-UAS to express the human tau protein, which is associated with neurodegenerative diseases such as Alzheimer's disease, in circumscribed brain regions of the fruit fly. Adult females were tested in a place learning assay at multiple time points post-eclosion. Following learning trials and memory tests, flies were sacrificed and the brains were removed and the expression of tau and ptau were analyzed using immunoblot and SDS-PAGE. Flies show a decrease in learning and memory as well as a shortened lifespan and this correlates with the expression of tau in the nervous system in a time dependent manner. The phosphorylation of tau appears to also increase with time. However, the specific impact that the levels of tau vs. ptau are having on spatial cognition is unknown. It has been suggested that ptau leads to cytosolic toxicity in *Drosophila*, so this may be having an impact on spatial cognition. The results have allowed us to start looking at how the expression of the human tau protein in the fruit fly model is impacting learning and memory. By examining the limitations of the fruit fly model and investigating the molecular pathways and the quantitative expression levels of the disease associated protein tau in the nervous tissue of fruit flies and correlating that with a quantitative measure of spatial cognition, we can further enhance our understanding of neurodegenerative diseases in humans.

Title: Pioglitazone and memantine effects on memory impairment and tau hyperphosphorylation in intracerebroventricular-streptozotocin injected rats

Authors: *T. PONCE-LOPEZ[1,2], M. ABASCAL-DÍAZ[2], G. LIY-SALMERÓN[2], A. MENESES[1];

Abstract: The intracerebroventricular (icv) administration of the streptozotocin (STZ) has been found to induce an insulin resistance brain state (IRBS), a new, no-transgenic, animal model that has been proposed as a representative model of Alzheimer disease sporadic. Insulin could be regulating tau phosphorylation in neurons. Hyperphosphorylation of tau is considered as one of the typical pathological changes in Alzheimer Disease. During the development of AD tau is

phosphorylated at multiple sites as a result of the imbalance of numerous Ser/Thr kinases like glycogen synthase kinase 3β (GSK3β) and protein phosphatase 2A (PP2A), and integrates paired helical filament to lead to intraneuronal neurofibrillary tangles, losing their physiological functions. Previously, we demonstrated that memory deficit has been associated to increased abnormal hyperphosphorylation of tau protein, GSK3β activation and inhibition of PP2A in the hippocampus and prefrontal cortex (PFC) induced by icv administration of STZ in rats. Indicating that probably such kinase and phosphatase contribute to regulation of phosphorylation of tau. This study aims to investigate the effect of chronic treatment of pioglitazone and memantine on memory impairments, disruption insulin receptor (IR), phosphatidylinositol-3-kinase/protein kinase B/GSK3β (PI3K-Akt/PKB-GSK3β) signaling cascade, PP2A and abnormal phosphorylation of tau induced by STZ-icv. Wistar rats were bilaterally injected with STZ-icv (3 mg/kg). Memory was assessed by autoshaping, an associative learning task. The rats were administrated orally with memantine (5 mg/kg), pioglitazone (30 mg/kg) or vehicle fifty days before the last autoshaping testing test. Animals were sacrificed three months after of STZ-icv treatment, the brain were removed and dissected hippocampus and PFC. We are quantifying IR, PI3K, PKB/Akt, GSK3β, PP2A, and tau protein by Western blot. Results showed that STZ-icv treated rats had deficits in short- (1.5 h) and long-term (24 and 48 h) memory after one month and progressive memory impairment following three months of icv STZ injection relative to control rats. Pioglitazone and memantine was effective in reversing memory deficits. This data will be discussed with changes associated to hyperphosphorylation of tau, IR, key proteins downstream signaling cascade insulin and PP2A. This evidence will provide insight about the role IRBS and the therapeutic benefits of insulin sensitizer (pioglitazone) and NMDA antagonist (memantine) on abnormal phosphorylation tau and memory dysfunction.

Title: Examining the role of the polyamine system in animal models of tauopathy

Authors: *L. A. SANDUSKY[1], W. J. D. FRASER[1], H. SHAIR[1], A. M. BARAKAT[1], N. M. SLOUHA[1], K. RATNASAMY[1], J. B. HUNT[1], K. NASH[2], D. C. LEE[1];
[1]Pharmaceut. Sci., [2]Mol. Pharmacol. and Physiol., USF Hlth. Byrd Alzheimer's Inst., Tampa, FL

Abstract: In a non-diseased brain, the protein tau is responsible for stabilizing microtubules; however, this protein becomes hyperphosphorylated, aggregates, and promotes microtubule dysfunction eventually resulting in neuronal death in tauopathies. Polyamine dysfunction has been observed in numerous disease states, and may contribute to pathology and cognitive impairment seen in tauopathies. Our lab has recently identified polyamine dysregulation, specifically changes in spermidine/spermine N1-acetyltransferase (SAT1), spermine oxidase (SMOX) and spermine synthase (SMS), in P301L tau transgenic (rTg4510) mice. Conversely, we have shown that increasing polyamines by arginase 1 (Arg1) overexpression decreases tau neuropathology *in vivo*, suggesting that Arg1 and polyamines may impact tau pathology. However, a question that remains is whether these effects on tau pathology are due to the depletion of L-arginine or the production of polyamines. To answer this question and further elucidate the relationship between the polyamine system and tau biology, we examined the role of polyamine catabolic enzymes (SAT1), polyamine producing enzymes (arginine decarboxylase (ADC) and Arg1), and arginine depleting enzymes (arginine deiminase (ADI), and the impact on tau neuropathology and cognitive processing in transgenic or knockout mice. The first model examined the effect of increased polyamine production, through decreased polyamine catabolism (SAT1+/-+and SAT1-/-), using viral-mediated tau (AAV9-tauD421; C-terminally -truncated at D421). The second model examined the effect of viral-mediated polyamine production and L-arginine depletion, through overexpression (AAV9-Arg1 and AAV9-ADC, or AAV9-ADI, respectively), in tau transgenic mice (MAPT P301S; PS19 model). All injections were given bilaterally to the hippocampus and anterior cortex while behavioral testing included measures of both affect and cognition. While both models produced tau-mediated cognitive impairment, the effect of arginine metabolism and/ or potentially polyamine modulation was significant both in the presence of and independent of tau. Taken together, our results identify polyamine enzymes and arginine depleting enzymes as not only being necessary for normal cognitive and affective function, but that their interaction with tau produces significant alterations in cognitive and affective processing, identifying this system as playing a key role in tauopathies. Immunohistochemical and western blotting neuropathological data will examine effects of genotype and treatments as well as correlations with behavioral performance to support and extend our findings.

Title: Tau-induced down-regulation of BDNF in transgenic mouse models of tauopathy

Authors: E. ROSA[1], S. MAHENDRAM[1], Y. KE[2], L. ITTNER[2], S. D. GINSBERG[3], *M. FAHNESTOCK[1];
[1]Dept Psychiatry & Behavioural Neurosciences, McMaster Univ., Hamilton, ON, Canada; [2]Dementia Res. Unit, The Univ. of New South Wales, Sydney, Australia; [3]Ctr. for Dementia Research, Nathan Kline Institute, Depts of Psychiatry, Neurosci. & Physiol, New York Univ. Sch. of Med., Orangeburg, NY

Abstract: In Alzheimer's disease (AD), soluble tau is hyperphosphorylated, and some of this population presumably aggregates and precipitates as neurofibrillary tangles and/or neuropil threads. Although many theories exist, a precise toxic mechanism of tau is not well understood. We hypothesized that soluble tau-induced neurotoxicity is due to its ability to decrease trophic support for affected neurons. Specifically, our goal was to determine if over-expression of wild-type tau can down-regulate brain-derived neurotrophic factor (BDNF), a pro-survival marker that shows pathway deficits in AD and in animal and cellular models of AD. Mouse models of normal, not mutated, tau over-expression (8c-het and hTau transgenic mouse models) were used to examine the effect of excess tau on BDNF expression. 8c-het mice over-express wild-type human tau on a heterozygous mouse tau background, and while they exhibit increased tau phosphorylation and altered tau isoform expression compared to wild-type mice, they do not develop neurofibrillary tangles. On the other hand, hTau mice, which over-express wild-type human tau on a null mouse tau background, exhibit neurofibrillary tangle pathology similar to that found in human AD and tauopathies. Cortical tissue from both of these tau over-expressing models shows significantly down-regulated BDNF mRNA compared to wild-type animals, as quantified by qRT-PCR. Similarly, APP23 mice, which over-express soluble Aβ, also have significantly reduced BDNF expression. When crossed with Tau knockout (KO) mice, cortical tissue from the resulting APP23xTauKO animals exhibits BDNF expression levels intermediate between APP23 and wild-type animals and not statistically different from wild-type animals. Our

results demonstrate that excess wild-type, soluble tau can down-regulate BDNF, and that neither a mutation in tau nor neurofibrillary tangles are required for toxicity as measured by BDNF expression. Furthermore, the partial rescue of BDNF levels by tau knockout suggests that tau contributes to Aβ-induced BDNF down-regulation. Thus, loss of BDNF may mediate tau neurotoxicity, which has profound implications for therapeutic intervention in AD and tauopathies.

Title: Chronic *in vivo* imaging of tau aggregation and toxicity in the rtg4510 mouse model

Deleted: *in vivo*

Authors: *R. E. BENNETT, S. L. DEVOS, B. T. HYMAN;
Neurol., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Neurofibrillary tangles (NFTs) containing tau protein aggregates are a key feature of Alzheimer's disease. The development of NFTS is closely correlated with both the severity and duration of dementia (Arriagada 1992, Bierer 1995) as well as the amount of neuronal loss (Gomez-Isla 1997). However, NFTs are also present in cognitively normal individuals (Price and Morris 1998, Braak and Tredici 2014) and the precise relationship between the development of NFTs and toxicity is unclear. *In vivo* two-photon imaging via cranial windows has been used by our group and others to visualize protein aggregation, but longitudinal imaging has been restricted to the use of dyes and compounds that can be delivered intravenously or peripherally. Here we adapted a method for creating re-sealing silicon ports in cranial window coverglass (Roome 2014) which allows repeated topical application of dyes. We used this technique in rTg4510 mice which express mutant human tau P301L (SantaCruz 2005) to repeatedly image tau aggregation with either thioflavin S or thiazine red in tandem with Hoechst 33342 nuclear labeling to identify cell loss. Additional indicators of cellular degeneration were tested through cranial window port application including Sytox, the caspase indicating reagents NucView and FLICA, and propidium iodide. Altogether, this method allows further investigation of tau

Title: Suppression of mutant P301L tau in young neurons slows the course of tauopathy in the rTg4510 mouse model

Authors: ***C. VOLBRACHT**, P. JUL, L. HELBOE;
H. Lundbeck A/S, Valby, Denmark

Abstract: In Alzheimer's disease (AD), the microtubule associated protein tau dissociates from microtubules and forms aggregates of hyperphosphorylated tau termed neurofibrillary tangles (NFTs), which are neuropathological hallmarks of the disease. We characterized the neuropathological and behavioural consequences of a tauopathy in the rTg4510 mouse, overexpressing an inducible human mutant tau (Tau_{P301L}) selectively in the forebrain (SantaCruz *et al.*, 2005). We observed an age-dependent progression of tau pathology including tau hyperphosphorylation and NFTs followed by late neurodegeneration in cortex and hippocampus. However, rTg4510 mice displayed early deficits in cognitive performance in the Morris water maze (MWM) already at 6 weeks of age preceding tau pathology. Continuous tau transgene suppression with doxycycline from conception was sufficient to fully prevent tau pathology, neurodegeneration and cognitive deficits. Initiation of tau suppression in adult rTg4510 mice was able to reduce tau pathology and neurodegeneration depending on the time points of intervention. Tau suppression in adult rTg4510 mice initiated at 6 weeks significantly improved learning and memory in 16-20 weeks old rTg4510 mice, but not to the levels of non-transgenic littermates. Interestingly, short term tau suppression from conception to 1 week or 3 weeks of age in young rTg4510 mice dramatically delayed appearance of tau pathology and cognitive impairment by more than 6 months. In rTg4510 mice which underwent this transient short tau suppression during development, manifestation of tau pathology and cognitive impairment coincided. These findings indicate that a critical time frame during brain development exists in the rTg4510 mouse model, which contributes essentially to the mnemonic behaviour and progression of tauopathy.

Title: Metallothionein-3 modulates Aβ endocytosis in astrocytes through its effect on actin polymerization

Authors: *B.-R. SEO[1], S.-J. LEE[1], J.-Y. KOH[1,2];
[1]Neural Injury Res. Center, Asan Inst. For, Seoul, Korea, Republic of; [2]Dept. of Neurol., Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: Whereas neurons are the main cell type that is afflicted in Alzheimer's disease (AD), astrocytes may also play important roles in amyloid beta (Aβ) metabolism such as endocytosis. Recently, we have shown that metallothionein 3 (Mt3) contributes to actin polymerization and the related signaling cascades in astrocytes. Since actin cytoskeleton is likely involved in endocytosis of Aβ, in the present study, we investigated the possible role of Mt3 in Aβ endocytosis by cortical astrocytes. Cultured cortical astrocytes were exposed to FITC-conjugated Aβ, and its endocytosis was observed under confocal fluorescence microscope. Whereas Aβ endocytosis was almost completely blocked by chloropromazine, an inhibitor of clathrin-dependent endocytosis, no change was resulted with addition of MβCD, an inhibitor of caveolin-dependent endocytosis. Clathrin-mediated endocytosis was almost completely blocked by actin disruption with CytD or LatB. Likewise, Mt3 null cells that showed defective actin polymerization, exhibited markedly reduced the clathrin-dependent CtxB uptake as well as FITC-Aβ endocytosis as compared with WT cells. In addition, Western blots showed that intracellular levels of Aβ, both monomers and oligomers, were reduced in Mt3 null astrocytes. Finally, we tested whether actin disruption or Mt3 null state changed the expression and distribution patterns of clathrin itself and the associated protein PICALM. CytD, LatB, and Mt3 null strate all increased overall levels of clathrin and PICALM in astrocytes. Consistently,

immunocytochemistry showed that these conditions increased clathrin and PICALM immunoreactivities in these cells. Taken together, our results indicate that the absence of Mt3 may reduce Aβ uptake in astrocytes through the abnormality in actin polymerization. In light of evidence that Mt3 is downregulated in AD, this mechanism may contribute to the extracellular accumulation of Aβ in this disease.

Title: Identification of a novel regulatory mode for Alzheimer's disease-associated DSCR1 protein stability through USP22-mediated de-ubiquitination

Authors: A. HONG[1], D. KIM[1], *H. RHIM[2], K. C. CHUNG[1];
[1]Dept. of Systems Biology, Col. f Life Sci. and Biotech., Yonsei Univ., Seoul 120-749, Korea, Republic of; [2]Korea Inst. Sci. Tech. (KIST), Seoul, Korea, Republic of

Abstract: Protein ubiquitination can be reversed by de-ubiquitinating enzymes (DUBs). DUBs, which include ubiquitin-specific proteases (USPs) and ubiquitin C-terminal hydrolases, target several key proteins involved in regulation of tumorigenesis, apoptosis, senescence, and autophagy. DSCR1 (also known as RCAN1 or MCIP1) functions as an endogenous inhibitor of calcineurin signaling. In addition, DSCR1 modulates the balance of cell survival and cell death, and the aberrant expression of DSCR1 might be closely related to the pathogenesis of Alzheimer disease. In the present study, we have identified a novel interaction between USP22 and DSCR1 (DSCR1-1S) in the mammalian cells. In addition, the overexpression of USP22 caused the increase of DSCR1 protein stability. USP22 antagonized the actions of FBW7, NEDD4-2, and β-TrCP E3 ligase on DSCR1 and promoted DSCR1 de-ubiquitination. Moreover, we found that DSCR1 was bound to USP22 in basal conditions, and IFN-α treatment caused the dissociation of DSCR1 from USP22, which subsequently triggered DSCR1 ubiquitination and proteasome degradation. Taken together, these results suggest that USP22 positively regulates DSCR1 levels, which would consequently affect diverse DSCR1-linked cellular processes, such as the inflammatory process involving the release of IFN-α.

Title: Epigenetic and endosomal-lysosomal dysfunction in the basal forebrain during the progression of Alzheimer's disease

Authors: *L. MAHADY;
Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Epigenetic and endosomal-lysosomal dysfunction in the basal forebrain during the progression of Alzheimer's disease [*]L. Mahady[1,2], M. Nadeem[1], B. He[1], S.E. Perez[1], E.J. Mufson[1] [1] Dept. of Neurobiology, Barrow Neurological Institute, Phoenix, AZ 85013, [2] Dept. Neurological Sci., Rush University, Chicago, IL and [3]Arizona State University Interdisciplinary Graduate Program in Neuroscience, Tempe, AZ Basal forebrain neuronal degeneration occurs during the progression of Alzheimer's disease (AD). However, the factors underlying the onset of basal forebrain cellular dysfunction remains unclear. Recent findings indicate that endosomal-lysosomal (E-L)/autophagic dysregulation occur prior to β-amyloid (Aβ) plaque and tau tangle pathology and may play a role in neuronal selective vulnerability during the progression of AD. However, E-L alterations likely act in concert with other factors to drive neuronal degeneration. In fact, epigenetic factors regulate E-L gene transcription and function. For example, histone deacetylases (HDAC6 and HDAC2) and methylated histone H3 lysine 9 (H3K9) are implicated in the pathogenesis of AD. Whether E-L/autophagic and epigenetic changes co-occur in the basal forebrain during the onset of AD remains unknown. Here we quantified changes in the E-L/autophagic proteins cathepsin D (Cat D), rab5, respectively, and the epigenetic markers HDAC2, HDAC6, and H3K9 using frozen basal forebrain tissue obtained from subjects who died with a premortem clinical diagnosis of NCI (n=7; mean age=87; mean MMSE=28), MCI (n=7; mean age=91; mean MMSE=24), mild/moderate AD (n=8; mean age=90; mean

MMSE=20) and severe AD (n=8; mean age=75; mean MMSE=6.7) from the Rush Religious Orders Study (RROS) and the Rush RADC, respectively. Groups were matched by age and postmortem interval (PMI=5 hr) and underwent detailed postmortem neuropathologic evaluations. Western blot analysis of tissue homogenates revealed stable levels of HDAC2 and HDAC6 across the four clinical groups examined. Increased levels of dimethylated H3K9, Cat D, and rab5 were found in severe AD compared to NCI, MCI and mild/moderate AD. We also observed a strong positive correlation between both H3K9 and Cat D (r=0.73), and H3K9 and rab5 (r=0.65), suggesting that epigenetic factors play a role in the regulation of E-L systems in AD. In summary, these results indicate that the basal forebrain is resilient to E-L disturbances early in the disease process. Since, E-L and epigenetic dysregulation occur late in the disease process, this molecular interaction may exacerbate neuronal degeneration in severe AD.

Title: Alzheimer´s disease-related vascular pathology in human and transgenic mouse brain

Authors: M. TEMMEL[1], *J. NEDDENS[1], D. HAVAS[1], C. SCHWEINZER[1], J. ATTEMS[2], H. HUTTER[3], B. HUTTER-PAIER[1];

Abstract: During recent years evidence for a connection between neurovascular dysfunction and the pathogenesis of Alzheimer's disease (AD) has accumulated. A vascular factor, specifically the ε4 allele of APOE, is so far the only common accepted genetic risk factor for AD beside the imperative effects of APP and Presenilin mutations. Alterations in the brain vasculature, such as microvascular atrophy, decreased clearance of amyloid β (Aβ), and loss of astrocytic water channels, come more and more into focus as probable upstream events. The current study was therefore designed to investigate whether vascular changes associated with human AD may be replicated in the transgenic APPSL mouse model. Using indirect immunofluorescence and

quantitative image analysis, AD-associated vascular changes in cortical areas of healthy and diseased human brain sections and in both transgenic APPSL mice and non-transgenic controls were investigated. We found that the occurrence and progression of cerebral amyloid angiopathy (CAA) is associated with age in APPSL mice, whereas a positive correlation of CAA and Braak stage was less obvious in human AD. The approach was then extended to test AD-related hypotheses on collagen IV, and the data show total intensity of collagen IV immunofluorescence increases similarly in the hippocampus of transgenic mice and in AD individuals. Detailed analysis revealed that in mice this is due to enlargement of existing blood vessels, whereas in human subjects it is associated with an increasing numerical density of blood vessels. Astrocytes express aquaporin 4 (AQP4), a water channel enabling active water transport. The evaluation suggests that AQP4 is expressed following complex spatio-temporal patterns in humans and transgenic mice. An abnormally low amount and a delocalization of hippocampal AQP4 were detected at early Braak stage. If confirmed by additional investigations, this could be potentially useful as an early marker for AD. In conclusion, the present study supports the notion that the brain vasculature is affected in AD and that APPSL mice represent a useful model for studying different aspects of blood vessel-associated AD-related histopathology.

Title: Shankopathis in Alzheimer’s disease

Authors: ***Y. GONG**[1,2], F. E. CHOW[2], R. M. TSAI[2], C. F. LIPPA[2];
[1]Nanjing Univ. Chinese Med., Jingsu, China; [2]Dept. of Neurol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder characterized by synaptic loss and cognitive degeneration. Synaptic loss correlates strongly with disease severity but the underlying mechanism remains elusive. During the pathological progression of AD, Aβ oligomers induce the disruption of glutamate receptors in the macromolecules of the

Shank-network located in the postsynaptic density (PSD). Shank proteins show distinct pathological changes which contribute to N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor loss at the PSD in AD. The oligomers of Aβ can induce hyperphosphorylation in tau and neurofilament (NF) proteins in AD, which may cause the same pathological changes in the Shank proteins. Dephosphorylation in hyperphosphorylated tau proteins is dependent on the activity of peptidyl-prolyl cis/trans-isomerase Pin1 and protein phosphatases. During this investigation, we found the Pin1 colocalized with Shank3 and the loss of Pin1 activity altered the macromolecules of the Shank-network by ubiquitin proteasome system at the PSD, thus contributing to the synaptic dysfunction and loss in the early stages of AD. This suggest that the loss of Pin1 activity may be the common initial pathological change leading to the extreme modifications in synaptic proteins as observed in amyloid precursor protein (APP) and Tau in preclinical AD. Shank proteins could play a pathological role in the cognitive deficiency in AD.

Title: Hippocampal cathepsin D and p62 association with APP/Aβ processing and tau pathology during the progression of AD

Authors: ***S. E. PEREZ**[1], H. CHOUDARY[1], E. J. MUFSON[2];
[1]Dept Neurolog Sci., Rush Univ. Med. Ctr., Chicago, IL; [2]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Hippocampal endosomal-lysosomal (E-L) and autophagy dysregulation may underlie neuronal selective vulnerability during the progression of Alzheimer's disease (AD). Our previous western-blot finding demonstrated an up-regulation of the lysosomal hydrolase cathepsin D (Cat D) in the hippocampus of people who died with a clinical diagnosis of mild cognitive impairment (MCI) compared to mild/moderate AD, but not changes occurred in autophagy markers. Since E-L pathways and autophagy are major routes of amyloid precursor protein (APP) processing and tau dysregulation, we examined whether hippocampal intraneuronal Cat D was associated with intraneuronal APP/Aβ and neurofibrillary tangle (NFT)

(phosphorylated AT8 tau) pathology, endosomal (rab5 and rabaptin5) and the autophagy marker (p62), a mTOR upstream signaling protein involved in cargo recognition and autophagosome formation that plays a critical role in autophagy failure and is associated to NFT formation early in AD. Hippocampal neuronal Cat D and intraneuronal APP/Aβ levels were quantified using immunohistochemistry and densitometry in paraffin sections from subjects who died with a premortem clinical diagnosis of non-cognitive impairment (NCI), MCI or mild to moderate AD obtained from the Rush Religious Study (ROS) cohort. Adjacent hippocampal sections were immunolabeled with antibodies against p62. Optical density (OD) analysis revealed no changes in neuronal Cat D- and APP/Aβ (6E10)-immunoreactive (-ir) levels within the different hippocampal subfields. In addition, the density p62-ir neurons were unchanged in the different hippocampal layers across the clinical groups examined. Hippocampal neuronal Cat D OD values correlate positively with intraneuronal APP/Aβ OD values in CA1 pyramidal neurons during AD progression ($r=0.660$, $p=0.001$). Conversely, OD measurements of Cat D-ir neurons were not associated with rab 5, rabaptin5 or neurofibrillary AT8 and p62 neuronal density. Interestingly, p62 and AT8-ir neuronal density showed a strong relationship within all hippocampal subfields across the groups examined ($p<0.0001$). These data reinforce and extend our previous observations that Cat D alterations in hippocampal neurons occur late in AD and may be associated to APP/Aβ processing rather than tau pathology, while the association between hippocampal AT8 and p62 neuronal density indicates a major role of autophagy in NFT formation.

Title: An Alzheimer’s disease-linked mutant T835M-UNC5C causes neuronal cell death by activating an intracellular death signal cascade

Authors: *Y. HASHIMOTO, M. MATSUOKA;
Tokyo Med. Univ., Tokyo, Japan

Abstract: A previous study showed that a missense mutation (T835M) in the UNC5C gene appears to cause autosomal-dominant late-onset Alzheimer's disease in two families and that various insults lead to increased death in neurons expressing T835M-UNC5C. In this study, we found that overexpression of T835M-UNC5C itself causes prominent death while overexpression of wild-type UNC5C causes minimal death in F11 neurohybrid cells and SH-SY5Y cells. Netrin inhibits this death. T835M-UNC5C-induced neuronal cell death is mediated by an intracellular death signal pathway consisting of DAPK1/PKD/ASK1/JNK/caspases. These results may provide a new insight on the pathomechanism of Alzheimer's disease.

Title: Transcriptomics profiling of Alzheimer's disease reveal neurovascular defects, altered amyloid β homeostasis and deregulated expression of long noncoding RNAs

Authors: *M. MAGISTRI, D. VELMESHEV, M. MAKHMUTOVA, M. FAGHIHI; Psychiatry, Univ. of Miami, Miami, FL

Abstract: Background: The underlying genetic variations of late onset Alzheimer's Disease (LOAD) cases remain largely unknown. A combination of genetic variations with variable penetrance and lifetime epigenetic factors may converge on transcriptomics alterations that drive LOAD pathological process. Transcriptome profiling using deep sequencing technology offers insight into common altered pathways regardless of underpinning genetic or epigenetic factors and thus represents an ideal tool to investigate molecular mechanisms related to the pathophysiology of LOAD. Results: We performed directional RNA sequencing on high quality RNA samples extracted from hippocampi of 4 LOAD and 4 age-matched controls and we further validated our data using qRT-PCR on a larger set of post-mortem brain tissues. Pathway analysis indicates dysregulation in neural communication, cerebral vasculature and Amyloid β clearance. Beside protein coding genes, we identified several annotated and non-annotated long noncoding RNAs that are differentially expressed in LOAD brain tissues, three of them are activity-dependent regulated and one is induced by Aβ1-42 exposure of human neural cells. Conclusions:

Our data provide a comprehensive list of transcriptomics alterations in LOAD hippocampi and warrant holistic approach including both coding and non-coding RNAs in functional studies aimed to understand the pathophysiology of LOAD.

Title: Role of the RCAN1 isoforms on calcineurin activity and mitochondrial morphology

Authors: *C. A. ZAMBRANO[1], H. WONG[3], S. KIM[4], E. ZIFF[4], C. HOEFFER[1,2,4,5]; [1]Inst. for Behavioral Genet., [2]Dept. of Integrated Physiol., Univ. of Colorado, Boulder, CO; [3]Ctr. for Neural Sci., [4]Sch. of Med., New York Univ., New York, NY; [5]Linda Crnic Inst., Denver, CO

Abstract: Regulator of calcineurin 1 (RCAN1) protein is an important modulator of Ser/Thr phosphatase, calcineurin (CaN). Three isoforms of RCAN1 are produced in the brain, RCAN 1.1L, RCAN 1.1S and RCAN 1.4. RCAN1 overexpression has been linked to oxidative stress and mitochondrial dysfunction and is also elevated in sporadic Alzheimer's disease (AD). RCAN1 overexpression may be involved in the progression of Alzheimer's disease by regulating CaN activity related to mitochondrial function. One potential substrate for RCAN1/CaN regulation activity related to AD-associated mitochondrial dysfunction is dynamin-related protein 1 (DRP1). We have recently shown that, DRP1 phosphorylation is modulated by overexpression of the RCAN1.1S isoform during aging. In this study, we show that all RCAN1

isoforms modulate CaN activity using a fluorescence resonance energy transfer (FRET) based CaN activity reporter 1(CANAR1) approach. To do this, RCAN1 isoforms were transfected in both HEK393 human cell lines and mouse primary hippocampal neuronal cultures. CANAR1 was co-expressed with RCAN isoforms to measure CaN activity. RCAN1.1S and RCAN1.4 isoforms were able to modulate calcineurin activity in a cell specific fashion, observing and increase in activity in primary neurons but the opposite effect in HEK cells. This result highlight the importance of the context of where RCAN1 is being study. In genetically modified cre-dependent mouse primary neurons that overexpress RCAN1.1S isoform (RCANtg) it was possible to confirm the positive regulation of that particular isoform on CaN activity. RCANtg neurons display smaller mitochondria than control neurons, suggesting a role of RCAN1.1S on mitochondrial morphology. Moreover, RCANtg neurons have elevated oxidative stress relative to control cre(-) neurons determined with CellROX® fluorescence assay. These results reinforce the idea of RCAN1.1S isoform as a key component of the neurodegenerative process observed in Alzheimer's pathology.

Title: Bri2, a gene mutated in Alzheimer-like dementias, is a functional partner of irisin

Authors: *C. D. WRANN[1,2], K. GERBER[1,2], M. JEDRYCHOWSKI[2], L. YANG[2,3], V. MOOTHA[2,3], M. SCHUMACHER[4], L. D'ADAMIO[5], H. TU[6], S. GYGI[2], B. SPIEGELMAN[1,2]; [1]Dana-Farber Cancer Inst., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Massachusetts Gen. Hosp., Boston, MA; [4]Duke Med. Sch., Boston, MA; [5]Albert Einstein Col. of Med., New York, NY; [6]Lakepharma Inc., Belmont, CA

Abstract: Exercise can improve cognitive function and the outcome of neurodegenerative diseases, like Alzheimer's disease. Recently, we have reported a FNDC5/irisin pathway which is activated by exercise in the hippocampus in mice and induces a neuroprotective gene program. Affinity-purification of irisin complexes from the media of primary cortical neurons followed mass spectrometry identifies the transmembrane protein ITM2b as a binding partner of irisin. ITM2b, also known as Bri2, is the causal gene mutated in two forms of Alzheimer-like dementias in humans, British Familial Dementia and Danish Familial Dementia. Co-immunoprecipitation experiments with recombinant proteins confirmed the interaction. Bioinformatical analysis using the CLIME algorithm indicates that FNDC5 and ITM2B are members of same strongly evolutionary conserved cluster. Bri2 positively regulates the protein levels of FNDC5 and its secreted form irisin, without changing Fndc5 mRNA expression. Interestingly, in primary cortical neurons from Bri2-/- mice overexpression of FNDC5 full-length protein or stimulation with irisin recombinant protein fails to induce the neuroprotective gene program compared to neurons from Bri2+/+ mice. Taken together, this indicates a functional relationship between irisin and Bri2, a gene mutated in Alzheimer-like dementias.

Title: Intraneuronal Abeta accumulation increases vulnerability to oxygen-glucose deprivation and excitotoxicity

Authors: *L. CALZA[1,2], V. A. BALDASSARRO[1], A. MARCHESINI[2], M. FERNÁNDEZ[1], L. GIARDINO[1,2];
[1]CIRI-SDV, Univ. of Bologna, Ozzano Emilia, Italy; [2]IRET Fndn., Ozzano Emlia (BO), Italy

Abstract: Microvascular dysfunction is considered an integral part of Alzheimer disease (AD) pathogenesis. Several working hypothesis attempt to clarify the possible relationship between

amyloid pathology, microvascular dysfunction and cell death. In fact, Abeta fragments inhibit angiogenesis, interact with VEGF receptors and alter glutamatergic transmission, interacting with NMDA receptors and glutamate uptake and release. Moreover, APP expression is increased following ischemic or hypoxic conditions, stimulating the production and deposition of Abeta peptide in the brain. In order to investigate the influence of intraneuronal Abeta accumulation on vulnerability to glutamate excitotoxicity and Oxygen Glucose Deprivation (OGD), primary cortical neurons isolated from Tg2576 (carriyng the hSwAPP-mutation) and WT new-born mice were used as *in vitro* model, and exposed to glutamate (42µM; 10 minutes) or OGD (3 hours, followed by 24 hours reoxigenation). Cell death (nuclear morphology) and human APP levels (immunocytochemistry using the 6E10 antibody) were analysed using cell-based High Content Screening. VEGF and VEGF receptors (Flt1 and Kdr) mRNA expression was analysed by using real time PCR. Neurons isolated from Tg2576 new-born mice showed an increase in VEGF mRNA expression (2,47 times, $p<0,05$) and a decrease in the expression of the two VEGF receptors (Flt1: 0,56 times, $p<0,001$; Kdr: 0,31 times $p<0,001$), compared to WT cells. Tg2576 primary neurons displayed higher spontaneous cell death (WT: 13,93%; Tg2576: 26,24% $p<0,001$) and the percentage of pyknotic/fragmented nuclei is higher in Tg2576 cells (60,02%) compared to WT (54,16%; $p<0,001$) when cultures were exposed to glutamate. When exposed to OGD, Tg2576 neurons show higher cell death in terms of percentage of pyknotic/fragmented nuclei (WT: 22,40%; Tg2576: 29,37% $p<0,05$) and mitochondrial depolarization (percentage of cells showing low intensity of the mitochondrial dye MitoTracker; WT: 31,53%; Tg2576: 44,49%, $p<0,001$). When exposed to OGD Tg2576 primary neurons show an increase in the 6E10 immunoreactivity intensity (Tg2576 OGD 14,6% of increase $p<0,0001$). This study showed that the presence of the mutated human APP gene, leading to the intracellular accumulation of APP and Abeta fragments, alters the sensitivity of cortical neurons to glutamate excitotoxicity and OGD. In a mutual correlation, the expression pattern of genes related to OGD response is modified in cells carrying the transgene, and the APP accumulation is worsened by OGD.

Title: ADAM10-mediated shedding significantly impacts on prion disease

Authors: ***M. GLATZEL**[1], B. PUIG[2], P. SAFTIG[3], H. C. ALTMEPPEN[2];
[2]Inst. of Neuropathology, [1]Univ. of Hamburg, Hamburg, Germany; [3]Christian Albrechts Universit, Christian Albrechts University, Kiel, Germany

Abstract: Proteolysis of of adhesion molecules, growth factors and receptors play key roles in neurological diseases. In neurodegenerative diseases such as prion disease or Alzheimer`s disease, proteolytic processing of proteins critically influences disease initiation and propagation. For prion diseases, α-cleavage of the cellular prion protein (PrPC) impairs misfolding into the pathogenic isoform (PrPSc) and is thus protective. The role of PrP-shedding (a physiological cleavage event occurring in close proximity to the GPI-anchor of PrPC) remained largely unknown. We and others have identified ADAM10 as the physiologically relevant sheddase of PrPC regulating its membrane homeostasis. Here we show that depletion of ADAM10 in forebrain neurons leads to posttranslational increase of PrPC levels. When infected with prions, these mice present with drastically shortened incubation times, increased PrPSc formation and upregulation of calpain. Our spatiotemporal analyses also suggest that absence of shedding impairs spread of prion pathology within the brain. Taken together, ADAM10-mediated shedding seems to have a dual role in prion diseases thus emphasizing the relevance of proteolytic processing in prion disease. Given the suggested role of PrPC as a receptor for toxic protein oligomers in more common proteinopathies our findings might impact on these devastating conditions as well.

Abstract: Fused in Sarcoma / Translocated in Sarcoma (FUS/TLS, or FUS) is a multifunctional DNA/RNA binding protein known to be involved in diverse processes of gene regulation, including DNA repair, transcription, pre-mRNA splicing, RNA transport, RNA stability and translation. Since 2009, it has been known that intracellular inclusion bodies containing FUS are the pathological hallmark of a subset of cases of Amyotrophic Lateral Sclerosis (ALS) and Frontotemporal Lobar Degeneration (FTLD). These cases have since been reclassified as FUS proteinopathy. Despite much recent efforts to elucidate the pathogenesis of FUS proteinopathy, much remains unknown about the biological function of FUS in the nervous system and the role(s) of FUS in disease pathogenesis. Emerging evidence from our data and others suggests a previously unknown role of FUS in microRNA biogenesis. MicroRNAs play important roles in a wide range of biological processes. Aberrant regulation of microRNA genes contributes to human diseases, including various aging related disorders such as neurodegeneration and cancer. Here, we systematically examined miRNAs whose expression levels are regulated by FUS using paired expression profiles of miRNAs and mRNAs using small-RNA-Seq and mRNA-Seq, respectively. We compared the brains of control and FUS-deficient mice. We have also begun to examine and compare the post-mortem brain tissue from well-characterized FTLD-FUS proteinopathy patients and control subjects. Using these paired expression profiles, we developed a computational pipeline to identify candidate microRNAs regulated by FUS, examine the sets of genes targeted by each candidate miRNA, and predict which microRNA-mRNA gene networks are altered in the FUS-deficient brain samples. Specifically, we used miRExpress and eXpress to map the reads to the genome, Probabilistic miRNA-mRNA Interaction Signature (ProMISe) to predict miRNA-mRNA interactions for each sample, and a combination of DESeq and Fatiscan to examine the sets of genes for each candidate miRNA and their associated processes. At the time of submission, we completed the computational analysis, with several microRNAs identified as candidates and major signaling pathways identified related to synaptic signaling and mitochondrial function. We have begun to validate these computational predictions using molecular cellular, biochemical and cell biological approaches. The computational pipeline, previously unknown miRNA-target gene pairs that may play important roles in FUS

proteinopathy, and new contributions to our understanding of the role of FUS in pathogenesis of neurodegenerative disorders will be discussed.

Title: Aav-mediated overexpression of progranulin corrects social behavior deficits in grn+/- mice

Authors: ***A. E. ARRANT**, E. D. ROBERSON;
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Loss-of-function mutations in progranulin (GRN), a secreted glycoprotein with neurotrophic and anti-inflammatory effects in the brain, are a major cause of frontotemporal dementia (FTD), accounting for 5-10% of all FTD cases. Boosting progranulin levels is therefore a promising strategy for preventing or treating FTD-GRN. This approach is supported by data from cultured neurons, but has not been tested in an animal model. In this study, we tested the benefits of increasing progranulin levels with an AAV vector in Grn+/- mice, a mouse model of FTD due to GRN mutations. Grn+/- mice develop reduced social dominance in the tube test and reduced sociability in the three-chamber sociability test around 9 months of age. We injected an AAV 2/1 virus expressing progranulin with a C-terminal myc tag (AAV-Grn) or a control AAV-Gfp virus into the medial prefrontal cortex (mPFC) of 10-13 month-old wild-type and Grn+/- mice to determine if AAV-Grn could correct these social phenotypes. AAV-Grn treatment boosted progranulin levels to approximately 7-fold over wild-type levels in the mPFC, and significantly increased progranulin levels in the septum and medial areas of the dorsal and ventral striatum. Four to six weeks after AAV injection, AAV-Grn-treated Grn+/- mice were more dominant in the tube test and spent more time interacting with a novel mouse in the three-

chamber sociability test than did AAV-Gfp-treated Grn+/- mice. These data support progranulin-boosting therapies for FTD-GRN by providing, to our knowledge, the first data showing that increasing progranulin levels corrects an FTD-like phenotype in a mouse model of FTD-GRN.

Title: Endosomal pathway deficiencies in fibroblasts from FTD-3 patients

Authors: ***N. ROSTGAARD**[1], J. E. NIELSEN[2], T. T. NIELSEN[2];
[2]6991, [1]Danish Dementia Res. Centre, Univ. Hospit, Copenhagen OE, Denmark

Abstract: Frontotemporal dementia constitutes one third of dementia cases and a small percentage of these are caused by autosomal dominant mutations in a few identified genes. Frontotemporal dementia linked to chromosome 3 (FTD-3) is a rare familial dementia, described in a large Danish family, caused by a single base mutation in the *CHMP2B* gene leading to early-onset dementia. *CHMP2B* encodes a component of the ESCRTIII-complex which is located in the membrane of endosomes. The complex is necessary for the formation of multivesicular bodies (MVBs) - a late endosomal compartment. Previous studies have shown an enlarged endosomal phenotype in patient brains, recapitulated in patient fibroblasts and transgenic mice. Furthermore deficiencies in endosomal trafficking and autophagy have been shown in FTD-3 fibroblasts and several cell models transfected with the CHMP2B mutation. Autophagy and lysosomal membrane permeabilization (LMP) contributes to degenerative diseases but the role of LMP in neurodegeneration is poorly understood but could contribute to disease pathogenesis in diseases were the endocytic pathway is either disrupted or malfunctioning as in FTD-3. Here we investigate the cellular disease pathology and assess endosomal pathway, autophagy deficiencies and LMP in fibroblasts from symptomatic and presymptomatic mutation carriers using immune staining and confocal microscopy. Further we evaluate the gene expression of several genes with key roles in the pathways affected by the *CHMP2B* mutation by Q-PCR such as vesicular transport, autophagy and Ca^{2+} signaling.

Title: Time-dependent formation and disappearance of TDP-43 inclusions in a conditional transgenic mouse model of FTLD

Authors: ***L. KUKREJA**[1], G. KIM[1], K. SADLEIR[2], L. WANG[3], H. DONG[3], J. CSERNANSKY[3], M.-M. MESULAM[1], R. VASSAR[2], C. GEULA[1];

Abstract: Dementias caused by Frontotemporal lobar degeneration (FTLD) constitute the third most prevalent dementia, after those caused by Alzheimer’s disease and Lewy bodies, and are among the most prevalent dementias of early-onset. The vast majority of these cases contain abnormal precipitates of a phosphorylated and mislocalized form of the Tar DNA/RNA-binding protein-43 (TDP-43). Moreover, overexpressing wild-type or mutant human TDP-43 gene in transgenic animals results in the formation of inclusions and neuronal loss, which have led to the conclusion that TDP-43 pathology leads to FTLD. To directly investigate the temporal sequence of the appearance of TDP-43 inclusions and its relationship to pathology, we employed a conditional transgenic mouse line in which expression of wild-type human TDP-43 is under the control of tetracycline operator sequences. In this study, transgene expression was switched off from birth until weaning age by doxycycline treatment in the mouse diet in order to avoid previously reported complex phenotypes of early neuronal development. In accordance with previous findings, the induction of human TDP-43 recapitulated features of FTLD-TDP, including the formation of phospho-TDP-43 neuronal cytoplasmic inclusions and progressive neurodegeneration. Our immunohistochemical analyses using an antibody that recognizes TDP-

43 phosphorylated at Ser-403/404 revealed that inclusions appear as early as 5 days following TDP43 transgene expression. Mice which express the transgene for 10 days show a moderate density of inclusions. The inclusions appear to peak by 14 to 19 days post-transgene expression and decline rapidly thereafter. At these early days of TDP-43 transgene expression, the inclusions are present across frontal, parietal, and temporal cortical areas, and the hippocampus. While inclusions were absent at 8 weeks and 24 weeks of TDP-43 transgene expression, qualitative analysis showed severe neuronal loss in the dentate gyrus. However, the dentate gyrus contained among the lowest densities of inclusions. Thus, the density of TDP-43 inclusions does not directly correlate with neuronal loss in this animal model. It is likely that intracytoplasmic accumulation of TDP-43 oligomers plays a more direct role in neuronal loss and perhaps explains neurodegeneration in the absence of inclusions. Our findings suggest that this TDP-43 mouse model might provide critical information towards understanding how TDP-43 aggregation is linked to neurodegeneration and behavioral deficits in FTLD.

Abstract: Inflammaging in the elderly is a risk factor for age-related diseases that share an inflammatory component, including neurodegenerative diseases. Moreover, the resultant chronic low grade neuroinflammation is increasingly considered a significant actor in the triggering and progression of Alzheimer's disease (AD). The senescence accelerated prone mouse P8 (SAMP8) is a model of pathological aging and AD, showing a maximum lifespan of shortly 18 months, cognitive loss, increased levels of amyloid and hyperphosphorylated tau, oxidative stress and neuroinflammation. We aimed to study the progression of brain inflammatory derangement in SAMP8 by testing basal status and response to an injection of lipopolysaccharide (LPS) at the early age of 6 months and at the advanced stage of pathological changes of 12 months. The level of the proinflammatory cytokines IL6, IL1β and TNFα was determined by ELISA in blood and cerebral cortex, whereas their gene expression was determined by quantitative RT-PCR in cerebral cortex and hippocampus. Brain tissue of 6-month old SAMP8 showed higher inflammatory markers than control mice SAMR1. Moreover, LPS induced an inflammatory response in both strains, although SAMP8 showed a potentiation of the response as compared to SAMR1. Strikingly, 12-month-old SAMP8 showed lower inflammatory markers and lack of activation by LPS, whereas the response was preserved in SAMR1 mice. Therefore, SAMP8 cerebral inflammatory mechanisms were overreactive at 6 months of age and nearly nonresponsive to stimulation at 12 months of age. Studies in mixed glial culture and in pure microglia obtained from newborn SAMP8 and SAMR1 strains, showed higher levels of cytokine release to the culture medium in response to LPS/interferon γ (IFN) in SAMP8 than SAMR1 cultures. Furthermore, the measure of nitrites accumulated in the culture medium indicated higher activation of NO production in both SAMP8 cell type cultures after LPS/INF stimulation, but also in SAMP8 microglia in basal conditions. Therefore, chronic inflammation in the brain of SAMP8 mice relays in early hyperactivated glia. Chronic inflammation would let to an impaired response to external proinflammatory stimulus in the aged SAMP8 brain. Therefore, neuroinflammaging greatly contributes to disruption of neural defense mechanisms against homeostatic disturbances. This loss of brain physiological reserve will pave the way to frailty and AD. Title: Asymmetric distribution of activated microglia in a left-handed patient with primary progressive aphasia, TDP-43 pathology and right hemisphere language dominance

Authors: G. KIM[1], S. VAHEDI[1], S. WEINTRAUB[1], *C.-K. WU[2], E. BIGIO[1], M.-M. MESULAM[1], C. GEULA[1];
[1]Cognitive Neurol. and Alzheimer's Dis. Ctr., Northwestern University, Feinberg Sch. of Med., Chicago, IL; [2]Neurol., Texas Tech. Univ. Sch. of Med., Lubbock, TX

Abstract: Primary progressive aphasia (PPA) is a neurodegenerative clinical dementia syndrome characterized by language deficits as the most salient clinical feature and atrophy in the perisylvian language network in the dominant hemisphere (usually the left). The asymmetric nature of the language network and focal atrophy render PPA an excellent model for investigation of the relationships between the regional distribution of pathologic markers, cortical atrophy and clinical phenotype. The subject in this study was a left-handed patient with PPA in whom the language network was lateralized to the right hemisphere as indicated by functional MRI before death. In a preliminary stereological analysis we had observed significantly high densities of TDP-43 inclusions in the superior temporal gyrus (STG) and the inferior temporal gyrus (ITG), with asymmetry favoring the right hemisphere, matching the patterns of atrophy as seen by structural MRI. The next highest density of TDP-43 inclusions was observed in other language-related cortical areas such as inferior frontal gyrus (IFG), inferior parietal lobule (IPL) and middle frontal gyrus (MFG, area 9), but without hemispheric asymmetry. The lowest density of TDP-43 inclusions was detected in the memory related area entorhinal cortex (ERC). In this study, an antibody to HLA-DR was used to obtain measures of activated microglia bilaterally, and to determine concordance with TDP-43 inclusion density and cortical atrophy. Unbiased stereological techniques were used to quantify activated microglia in IFG, MFG, IPL, STG, ITG, and ERC. Activated microglia were found in relatively high density in all cortical areas, with slightly lower density in ERC. Significantly, microglial density displayed substantial asymmetry favoring the right hemisphere in all cortical areas. However, this asymmetry was greatest in STG and ITG, matching the asymmetry in TDP-43 inclusions. These findings suggest that microglial activation does not share a linear relationship with the density of TDP-43 inclusions. However, the two pathological markers share a pattern of greatest asymmetric distribution in the same cortical areas and display concordance with the PPA clinical phenotype and patterns of atrophy.

Title: Determining the role of TDP-43 in Alzheimer's disease-related neurodegeneration

Authors: ***K. D. LACLAIR**[1], P. C. WONG[2];
[1]Cell. and Mol. Med., [2]Pathology, Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: The development of disease modifying treatments for Alzheimer's disease (AD) has been severely limited by poor understanding of its molecular determinants and under-appreciation for its underlying mechanistic diversity. Indeed, recent studies show that most AD cases exhibit various additional pathologies other than the canonical amyloid-β and tau aggregates. One of these non-canonical pathologies is TDP-43 proteinopathy occurring in 30-50% of cases, characterized by cytoplasmic aggregation of TDP-43 accompanied by its nuclear clearance. Independent studies also showed that TDP-43 proteinopathy in AD correlates strongly with worse cognition, greater neurodegeneration, and increased severity of tau pathology. Tdp-43 depletion in mice leads to age-dependent neurodegeneration, supporting the view that loss of nuclear TDP-43 could contribute to disease pathogenesis. However, it is unclear whether TDP-43 depletion and β-amyloidosis have distinct or interconnected roles in neurodegeneration, and whether loss of function in TDP-43 affects β-amyloid production or deposition. To address these critical questions, we created a mouse line with age-dependent β-amyloidosis and conditional loss of Tdp-43 in mature forebrain neurons. We assess β-amyloid production and pathology, neurodegeneration, and frank neuron loss in these mice compared to those with only β-amyloidosis or forebrain depletion of Tdp-43. These studies begin to clarify how TDP-43 proteinopathy affects neurodegeneration in the context of β-amyloidosis, and may lead to the identification of therapeutic targets for the treatment of this large sub-population of AD patients.

Abstract: TDP-43 is a multi-functional DNA/RNA-binding protein that has been identified as the major component of the cytoplasmic inclusions in the diseased cells of frontotemporal lobar dementia (FTLD) and amyotrophic lateral sclerosis (ALS). Unfortunately, effective drugs for these neurodegenerative diseases are yet to be developed. We have tested the therapeutic potential of rapamycin, an inhibitor of the mammalian target of rapamycin (mTOR), in a FTLD-U mouse model with TDP-43 proteinopathies as well as ALS-TDP fly model. We showed that rapamycin administration at the early pathological stage of a mouse model with FTLD characterized with cytoplasmic TARDBP/TDP-43(+) inclusions in the diseased neurons could rescue the learning/memory deficiency and the abnormal motor function disorder of the mice. Moreover, autophagy activation at a late pathological stage also could improve motor function, which was accompanied by a reduction of the TARDBP(+) inclusions. In ALS-TDP flies, autophagy activation also could rescue partially locomotor activity and lifespan. These studies have set the principal for therapy of neurodegenerative diseases with the TARDBP protein, i.e., ALS-TDP and FTLD-TDP, with the use of autophagy activators. **Key word:** TDP-43 proteinopathies, ALS, FTLD, rapamycin, autophagy

Title: Deep Brain Stimulation in Parkinson's disease reduces cortico-subthalamic oscillatory synchrony

Authors: *V. LITVAK[1], A. OSWAL[1], M. BEUDEL[1,2], A. JHA[1], T. FOLTYNIE[1], P. LIMOUSIN[1], L. ZRINZO[1], M. I. HARIZ[1], P. BROWN[2];

Abstract: Deep Brain Stimulation of the subthalamic nucleus (STN) is an effective treatment for Parkinson's Disease (PD), yet its mechanisms of action and influences on cortico-STN networks are unknown. It has previously been shown that two spatially and spectrally distinct resting STN-cortical networks exist in PD: 1) An STN-temporo-parietal alpha band (7-12 Hz) network and 2) An STN - premotor/motor beta (13-30 Hz) band network. We sought to examine the effects of DBS on these networks. We performed simultaneous magnetoencephalography (MEG) and bilateral STN local field potential recordings (LFPs) in 15 post-operative PD patients, whose DBS electrodes had been temporarily externalised. Using a purpose built amplifier we were able to stimulate the STN and record its activity during concurrent MEG recording. Cortical sources coherent with the STN were reconstructed using beamforming. Monopolar DBS in the MEG scanner generated severe artefacts rendering some MEG channels unusable. However, we used a phantom recording to show that physiological brain activity could still be recovered under these conditions. Analysis of patient data showed that unilateral monopolar DBS at 130 Hz suppressed low beta power (11-14 Hz) locally within the STN ($p< 0.05$) in addition to suppressing coupling between the STN and mesial premotor areas (including supplementary motor area, SMA) across the entire beta (15-30 Hz) frequency range ($p <0.01$). In contrast, alpha band coupling with the

temporal cortex was not significantly altered by DBS. DBS-related clinical motor improvements, assessed through part III of the unified PD rating scale score, correlated with reductions in local beta power in the STN across subjects ($r2 = 0.38$, $p < 0.01$), but not with the reductions in STN-mesial premotor coupling. We show that MEG can be used to study the effect of DBS on oscillatory cortico-subcortical networks. Our results confirm previous findings suggesting that DBS may exert therapeutic benefit through suppression of low beta activity locally within the STN. Furthermore, we found a suppression of broad beta band coupling between the STN and mesial premotor structures which could be indicative of exaggerated activity in the hyperdirect pathway in PD.

Title: Amplified movement-related cortical desynchronization and decoupling allow normal motor responses in patients with Parkinson's disease and essential tremor

Authors: ***E. D. KONDYLIS**, M. J. RANDAZZO, A. ALHOURANI, W. J. LIPSKI, T. A. WOZNY, A. S. GHUMAN, M. RICHARDSON, D. J. CRAMMOND;
Dept. of Neurosurg., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Alpha (8-12) and beta (12-35 Hz) rhythms are thought to function in sensorimotor cortices to maintain the motor status quo, since movement related desynchronization (MRD) in these frequency bands accompanies motor execution. In patients with Parkinson's disease (PD), synchronous cortical beta activity has been shown to be more widespread, more stable, and more tightly coupled with high frequency activity (phase-amplitude coupling, PAC), compared to subjects with dystonia or without a movement disorder. Importantly, these relationships are modulated by therapeutic deep brain stimulation of the subthalamic nucleus, suggesting that cortical beta activity is important in maintaining the hypokinetic symptoms of PD. The role of synchronous cortical activity in ET is less well studied, though modulation of alpha and beta band activity with therapeutic thalamic DBS has been documented. Significant gaps remain, however, in our understanding of how the timing and spatial distribution of MRD and PAC are altered in patients with movement disorders. The objective of this study was to examine the cortical dynamics of MRD in patients undergoing deep brain stimulation (DBS) for PD and ET, and in patients without a movement disorder undergoing intracranial monitoring for seizure mapping. We applied a monetarily incentivized bimanual grip force task to 27 subjects (12 PD, 9 ET, 6 epilepsy) while recording local field potentials (LFP) from subdural electrodes temporarily implanted over sensorimotor cortex, including hand primary motor cortex. Patients with PD and ET exhibited increased alpha and beta synchrony in sensorimotor cortex in the absence of movement, compared to patients without a movement disorder. We found that successful movement was accompanied by a greater extent of MRD, in both movement disorder groups. A reduction with movement in alpha and beta synchrony and beta-gamma PAC in hand sensorimotor and premotor cortices was common to all three groups. Beta MRD predominated in PD while alpha MRD predominated in ET, and both groups exhibited significantly greater MRD than subjects without a movement disorder ($p < 10\text{-}14$, $p < 10\text{-}7$). In addition, movement-related reductions in PAC also were significantly greater in PD and ET ($p < 10\text{-}2$, $p < 10\text{-}2$), with alpha-gamma decoupling predominating in ET and beta-gamma decoupling predominating in PD. These results demonstrate that patients with PD and ET can produce vigorous movement, but that they must overcome a larger burden of cortical synchrony and coupling. This is the first study to demonstrate a common neural mechanism through which patients with different movement disorders can achieve similar execution of motor actions.

Title: Phase-amplitude coupling between beta band and high-frequency oscillations as a marker for motor impairment in Parkinson's disease

Authors: *B. C. M. VAN WIJK[1], M. BEUDEL[2,3], A. JHA[2], A. OSWAL[1,3], T. FOLTYNIE[2], P. LIMOUSIN[2], L. ZRINZO[2], M. I. HARIZ[2], P. BROWN[3], V. LITVAK[1];
[1]Wellcome Trust Ctr. for Neuroimaging, [2]Inst. of Neurol., Univ. Col. London, London, United Kingdom; [3]Nuffield Dept. of Clin. Neurosci., Univ. of Oxford, Oxford, United Kingdom

Abstract: Exaggerated beta band oscillations within the subthalamic nucleus are a hallmark of Parkinson's disease. However, it remains unclear how this leads to motor impairment. We studied cross-frequency coupling between the phase of beta band activity and the amplitude of high-frequency oscillations (around 300Hz) known to increase in strength during movement. Local field potential recordings from 33 patients who underwent bilateral implantation of deep brain stimulation electrodes in the subthalamic nucleus were analyzed. Recordings took place both after overnight withdrawal of dopaminergic medication and following levodopa administration. There was a significant positive correlation between the strength of phase-amplitude coupling and clinical scores of contralateral hemibody bradykinesia and rigidity (r=.26, p=.01). In addition, more severe motor impairments were associated with lower beta band frequencies at which phase-amplitude coupling occurred (r=.42, p=<.001). Whereas phase-amplitude coupling within the subthalamic nucleus was strongest for low-beta frequencies (around 17Hz), beta band coherence with the motor cortex dominated at high-beta frequencies (around 25Hz), as determined via simultaneous magneto-encephalography. These findings support previous suggestions of a functional subdivision within the beta frequency band. Results suggest that exaggerated low beta band oscillations may hamper normal motor functioning by pathologically constraining the pro-kinetic high-frequency oscillations in the subthalamic nucleus.

Title: Homeostatic regulation of beta power with motor practice is present in normal subjects but not in patients with Parkinson's disease

Authors: *C. MOISELLO[1], A. B. NELSON[1], D. BLANCO[1], P. PANDAY[1], J. LIN[1], A. DI ROCCO[2], M. GHILARDI[1];

Abstract: Parkinson's disease (PD) is characterized by impairments in cortical plasticity, in beta power at rest and its modulation during movement. Recent results with protocols inducing long-term potentiation (LTP) in normal subjects further suggest the connection between cortical plasticity and changes of beta power recorded with EEG during rest. Here, we determined whether beta power at rest and its modulation during movement change in subjects with PD and controls with extended, repetitive practice in a simple motor task, and whether such changes are renormalized by a night of sleep. We recorded high-density EEG in 17 patients with PD and 15 age-matched controls before, during and after a 40-minute task requiring reaching movements to visual targets presented in an unpredictable order. The same task in the same conditions was

repeated the following day. For both days, we determined post-task changes of beta power at rest and assessed the progressive changes in beta modulation during the task over a frontal and two sensorimotor regions, which showed the strongest movement-related beta modulation. In controls, we found that, on day1, in electrodes over these three regions, a significant increase in beta power at rest was present in the spontaneous EEG at rest compared to baseline and that movement-related beta modulation increased significantly with practice. On day2, both beta power at rest and its modulation during movement returned to the baseline values of day1 and then increased similarly to the previous day. In patients with PD, on both day1 and 2, beta power at rest was higher than in controls and practice-induced changes at rest, like those during movements, were markedly reduced compared to the controls. In both groups, kinematic characteristics improved with practice. We conclude that, in normal subjects, prolonged practice in a motor task produces use-dependent modifications that are reflected in changes of beta power at rest and during movement and that renormalize with rest or sleep. In PD, such changes are significantly reduced; this might represent, at least partially, impairment of cortical plasticity. The significant post-task beta increase in controls can be interpreted as a reduction of cortical excitability resulting from protracted use, a phenomenon akin to the 'occlusion' of LTP-like plasticity, which can be overcome by rest or sleep that restore beta levels to the original levels. The failure in patients to display changes in beta power could be ascribed to an already 'over-inhibited' state or an occlusion of LTP-like plasticity, and thus to a failure of homeostatic mechanisms.

Title: Dyskinesia occurring with by dopaminergic medication or DBS are Associated with a narrowband high Frequency oscillation in human chronic cortical and subcortical recordings

Authors: *N. C. SWANN[1], C. DE HEMPTINNE[1], S. MIOCINOVIC[2], S. QASIM[1], S. WANG[2], N. ZIMAN[2], J. OSTREM[2], M. SAN LUCIANO[2], N. GALIFIANAKIS[2], P. STARR[1]; [1]Neurolog. Surgery, [2]Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Introduction: Parkinson's Disease (PD) is characterized by abnormal oscillatory activity throughout basal ganglia-thalamocortical motor loops, that is modulated by medication and deep brain stimulation (DBS). To study these patterns over time we utilized a novel, fully implantable, device, which records and stores field potentials, in addition to delivering therapeutic DBS. This method alleviates the challenges associated with an intraoperative environment and acute brain changes related to the surgical procedure. One goal of this study is to characterize electrophysiological signatures associated with adverse effects induced by medication or stimulation (such as involuntary hyperkinetic movements, known as dyskinesia.) **Methods:** Five advanced PD patients were implanted with the recording/stimulating device. Each of these patients were studied at multiple visits from the time of surgery up to a year post-operatively during periods on and off medication, on and off DBS, and with and without dyskinesia. Each patient has a unilateral 4 contact electrode implanted in the subthalamic nucleus (STN) which has the capability of either stimulating or recording, and a 4 contact electrocorticography (ECoG) strip over primary motor cortex (M1) for recording only. Recordings, sampled at 800 Hz, were initiated and downloaded by radiotelemetry. **Results:** We observed an increase in narrowband activity during periods of dyskinesias associated with the medication, DBS, or both. This activity is > 60 Hz and is characterized by a large increase in power in M1, and a smaller increase in STN power at the same frequency. There is also strong phase coherence between the two. The frequency at which the activity occurred was usually about 70-75 Hz when no DBS was delivered, and moved to half the stimulation frequency during DBS. This activity is generally not present during recordings without dyskinesia. **Discussion:** We characterized a reliable biomarker of dyskinesia in humans: a high frequency, narrowband increase in oscillatory activity, which is especially strong in the cortex. A similar observation has been made in a rodent model of dyskinesia. We propose that therapeutic high frequency STN DBS entrains neuronal populations at a sub-harmonic of the stimulation frequency, and that this sub-harmonic drives dyskinesia. These results suggest that monitoring for this narrowband increase in activity could improve DBS delivery, by serving as a signal for closed loop control of DBS. This finding also suggests changes in STN DBS stimulation protocols may help to avoid dyskinetic adverse effects.

Title: Physiology of cueing in Parkinson's disease: effects of rhythmic stimulus presentation on oscillatory brain activity

Authors: *E. S. TE WOERD[1,2], R. OOSTENVELD[2], B. R. BLOEM[1], F. P. DE LANGE[2], P. PRAAMSTRA[1,2];
[1]Neurol., Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [2]Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands

Abstract: Studies have shown that the basal ganglia play an important role in beat perception, and that patients with Parkinson's disease (PD) are impaired in the perception of beat-based rhythms. This contrasts with considerable evidence for a beneficial effect of rhythmic external cues in gait rehabilitation, and raises the question how rhythm can improve movement in PD. We addressed this question with analyses of slow oscillations and beta oscillatory activity (13-30 Hz), recorded using magnetoencephalography (MEG) during a choice response task with rhythmic and non-rhythmic modes of stimulus presentation. The study comprised 15 PD patients, of mild to moderate disease severity, and 15 control subjects. Analyses focussed on (i) entrainment of slow oscillations in the delta frequency-band, (ii) the depth of beta power modulation (defined as the difference in power between maximal beta synchronization and desynchronization), and (iii) whether a gain in modulation depth of beta power, due to rhythmicity, is of predictive or reactive nature. Replicating earlier work, the results show weaker entrainment of slow oscillations, and a relative shift from predictive to reactive movement-related beta suppression in PD patients. Nonetheless, rhythmic stimulus presentation increased the beta modulation depth to the same extent in PD patients and controls. Critically, in both groups, this gain selectively increased the predictive and not the reactive movement-related beta power suppression. Together, the results indicate that PD patients and controls exploit rhythmicity in the same way, providing no support for the popular view that rhythmic stimulation confers a special advantage to PD patients. The results provide converging evidence for a recent proposal that post-movement beta synchronisation constitutes a signal involved in trial-to-trial updating of an internal model guiding future movement.

Title: The subthalamic nucleus processes emotion: electrophysiological differences between Parkinson's disease and Obsessive-Compulsive Disorder patients

Authors: A. BUOT[1], *B. LAU[1], M.-L. WELTER[1,2], J. YELNIK[1], E. BARDINET[1,3], S. FERNANDEZ-VIDAL[1,3], C. KARACHI[1,2], L. MALLET[1,4];

Abstract: The subthalamic nucleus (STN) of the basal ganglia is divided into motor, associative and limbic territories based on anatomical connectivity. The posterior and dorsolateral (motor) territory is routinely targeted to treat Parkinson's Disease (PD) using deep brain stimulation (DBS), while the anterior and ventromedial (limbic) territory has been recently targeted to successfully treat severe refractory obsessive-compulsive disorder (OCD). To better understand how the STN processes emotional information, we recorded STN local field potentials (LFP) post-operatively in 7 PD and 4 OCD patients who underwent DBS implantation while they performed an emotional categorization task. The task consisted of the presentation of emotional stimuli (pleasant, unpleasant or neutral pictures from the IAPS), followed by a motor response in some trials. This allowed us to compare emotional and motor-related activity across two different STN territories. In all patients, stimulus presentation induced a synchronization of activity (ERS: event-related synchronization) in the theta band (3-8 Hz). This ERS was significantly stronger and lateralized (left>right hemisphere) in OCD compared to PD. The magnitude of the theta ERS varied according to stimulus valence. In PD, both ON and OFF dopaminergic medication, the theta ERS was significantly stronger for unpleasant compared to neutral stimuli, although we did not observe any effect for pleasant compared to neutral stimuli. By contrast, in OCD patients, we observed a change in theta activity for both valences, with a significantly stronger ERS for pleasant compared to unpleasant stimuli. During the motor response in PD patients, we observed a desynchronization (ERD) in the beta band (14-30 Hz) that commenced at stimulus presentation. The beta ERD magnitude depended on motor execution, dopaminergic treatment and reaction time. However, there was no significant dependence on emotional valence in the beta band. By contrast, the beta ERD was almost nonexistent in OCD patients. Our results show that STN activity varies according to location within the nucleus, with strong emotion-related

and weak motor-related modulations of oscillatory activity in the anterior and ventromedial compared to the posterior and dorsolateral STN. The striking difference in STN activity for pleasant stimuli between PD and OCD patients may be specific to the pathologies studied.

Hosp. and Julius-Maximilian-University, Würzburg, Germany; [3]Dept. of Physiology, Pharmacol. and Neurosci., CUNY Med. Sch., New York, NY

Abstract: Extensive work with electroencephalographic (EEG) scalp recordings has shown that power in the beta range (13-30 Hz) is modulated during passive, active, observed or imagined movement. Studies in patients with Parkinson's Disease (PD) with Deep Brain Stimulation (DBS) have further explored the oscillatory beta activity of the subthalamic nucleus (STN). Both at cortical and subcortical level, beta power starts decreasing before movement, reaches floor values during movement execution and finally increases again after movement end. However, despite the growing body of evidence, very few studies have determined whether the two hemispheres equally contribute to the production of movement performed with the dominant and non-dominant arm. Therefore, we recorded simultaneously high-density EEG and STN local field potentials in six right-handed patients with PD, who had undergone bilateral STN electrode implantation for DBS (Activa PC+S®, Medtronic Inc., Minneapolis, USA). The patients were tested in two successive days in meds-OFF state (overnight withdrawal of all dopaminergic

drugs). They performed a motor task requiring reaching movements to visual targets presented in an unpredictable order every three seconds. On each day, they performed 50 movements both with the right and left hand. We measured several characteristics of the motor performance, including reaction time, movement speed and spatial error. There was no difference in any of the kinematic indices between the movements performed with the right and left. We also found that the depth of beta modulation was similar in the electrodes over the left and right sensori-motor cortices independently of the execution side. On the other hand, subcortical activation showed an asymmetry of modulation depth: specifically, in the right STN, beta modulation was larger for contralateral movements (i.e. performed with the left hand, day 1: $p<0.0001$; day2: $p=0.0052$), while the left STN showed a similar activation for movements irrespective of active hand. This is the first evidence of a differential involvement of cortical and subcortical beta rhythms in the production of dominant and non-dominant upper limb movements.

Title: Cortical phase-amplitude coupling in Parkinson’s disease using magnetoencephalograpy

Authors: *E. PEÑA[1], L. ROSEDAHL[1], M. D. JOHNSON[1], J. BAJWA[2];
[1]Biomed. Engin., Univ. of Minnesota, Twin Cities, Saint Paul, MN; [2]King Fahad Med. City, Riyadh, Saudi Arabia

Abstract: Phase amplitude coupling (PAC) describes the degree to which the amplitude of oscillatory activity in a high frequency band phase-locks to oscillatory activity in a lower frequency band. Such coupling is thought to be indicative of information transfer between neuronal populations at different spatiotemporal scales, and has been shown to play a critical role in cognitive processes such as learning. In some cases this type of coupling may be pathological,

and recent intraoperative studies in Parkinson's Disease (PD) patients have noted strong coupling between gamma/high-frequency oscillatory activity and beta-band oscillations in primary motor cortex, subthalamic nucleus, and between both structures. Here, we investigate the heterogeneity of cortical PAC in human PD across a range of clinical severities, motor subtypes, and responsiveness to dopaminergic replacement therapy. In a cohort of 18 patients (5 females and 13 males; ages 55-70, disease duration of 2-9 years) and 10 age-matched healthy controls, we recorded resting-state magnetoencephalography (MEG, Elekta Neuromag) off and on medication. PAC comodulograms were constructed (phase frequency range: 1-30Hz, amplitude frequency range: 50-280Hz) based on source-space estimations of oscillatory activity in three gyri (precentral, postcentral, superior frontal) and two sulci (central, superior frontal) from both hemispheres. Significant beta-gamma PACs that were reduced by medication were found in 7 patients (2 female, 5 males). All seven patients who showed significant PAC also demonstrated symptoms of akinesia/rigidity, though two patients had predominantly tremor symptoms on one side. None of the 10 control subjects exhibited significant PAC over the sensorimotor cortex. These results demonstrate the utility of MEG to non-invasively assess cortical PACs in PD patients. In addition, the results support the multi-dimensional relationship between the clinical features of PD and cortical PACs.

Title: Thalamic oscillatory activity in patients with Parkinsonian tremor and essential tremor

Authors: ***P. ZHUANG**[1], M. HALLETT[2], T. LIU[1], Y. ZHANG[1], J. LI[1], Y. LI[1];
[1]Xuanwu Hosp, Capital Med. Uni, Beijing, China; [2]HMCS, NINDS, NIH, Bethesda, MD

Abstract: OBJECTIVE: To characterize oscillatory activity in the ventrolateral thalamus in patients with parkinsonian tremor and essential tremor (ET). BACKGROUND: The mechanisms

of parkinsonian tremor and ET remain unclear. Parkinsonian tremor has been supposed to be associated with the basal ganglia-thalamocortical circuit while ET has been predicted to be related to cerebellar-thalamocortical circuit. Stimulation or lesioning of the ventrolateral thalamus, in particular, the ventral intermediate nucleus (Vim) can effectively abolish both parkinsonian tremor and ET suggesting that the region is likely involved in the pathophysiology of tremor METHODS: 26 patients with PD and 14 patients with ET who underwent thalamic surgery were studied. Microelectrode recordings in the ventral oral posterior (Vop)/Vim and EMG of contralateral limbs were performed. Single unit analysis and interspike interval (ISI) histograms were performed to assess neuronal mean firing rate (MSFR) and pattern. Spectral characteristics were evaluated. Coherence analysis was used to explore the relationship between oscillatory activity and EMG. Results: Of 196 neurons obtained from PD patients, 63.7% neurons were oscillatory. Of these, 74.4% neurons (n=93) with tremor frequency band (TFB) oscillation at mean frequency of 4.5 ± 0.9 Hz were correlated with tremor; 25.6% neurons (n=32) with ß frequency band (ßFB) oscillation had mean firing rate of 19.6 ± 8.9 Hz. Of 70 neurons obtained from ET, 65.7% neurons were oscillatory. Of these, 89.1% (n=41) neurons had TFB oscillation at mean frequency of 6.8 ± 4.5 Hz frequently correlated with postural tremor; 10.9% neurons (n=5) had ßFB oscillation at mean of 22.2 ± 6.2 Hz. Further analysis found that the proportion of ßFB oscillatory neurons in PD were significantly higher than that of ßFB oscillatory neurons in ET ($p<0.05$). Moreover, MSFR of oscillatory neurons in PD were significantly lower than that of oscillatory neurons in ET (26.7 ±6.8 Hz vs. 42.3 ±15.6 Hz, $p<0.05$). There were no significant differences of proportion of TFB oscillatory neurons between PD and ET. CONCLUSIONS: The proportion of thalamic ßFB oscillatory neurons is higher in PD supporting that ßFB oscillatory neurons are associated with dopaminergic deficits in the basal ganglia circuit. Compared with normal MSFR (estimated to be 30 Hz from recordings in normal monkeys), the MSFR of oscillatory neurons in the VL are likely high in ET suggesting an etiologic role of the thalamus in ET.

Title: The modulation of subcortical beta oscillations during motor learning in essential tremor and Parkinson's disease

Authors: *D. BASHA[1,2], S. ELLIS[4,1], S. KALIA[4,3], M. HODAIE[4,3], A. M. LOZANO[4], W. D. HUTCHISON[2,1,4];
[1]Brain, Imaging and Behaviour, Toronto Western Res. Inst., Toronto, ON, Canada; [2]Physiol., [3]Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada; [4]Div. of Neurosurg., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Beta oscillations are commonly observed in the major motor structures of the brain, including the basal ganglia, motor cortex, thalamus and cerebellum. In healthy subjects, the power of beta oscillations is suppressed during movement execution but is high during rest and postural maintenance. Recent studies have shown that the degree of this movement-related beta suppression in the motor cortex correlates positively with improved performance during motor learning. We hypothesized that beta suppression in subcortical structures is also a marker for motor learning in Parkinson's disease (PD) patients. Beta power was measured from spike and local field potential recordings of the motor thalamus and subthalamic nucleus during microelectrode-guided deep brain stimulation surgery as patients learned a visuomotor adaptation task. Four patients performed a centre-out task (20 trials) which involved moving a cursor on a computer screen from a central starting point to equidistant targets to the left or right for the baseline condition. The display was then inverted so that leftward movements produced rightward deflections of the cursor on the screen and vice versa for the experimental condition (20 trials). In the baseline condition, mean centre-out response time improved from 6.68±4.64 seconds to 4.12±0.96 seconds (first 10 versus last 10 trials, t-test, p=0.001). In the inverted condition, mean response time improved from 7.09±4.35 seconds to 6.23±2.76 seconds (t-test, p=0.02). Trial by trial analysis revealed that movement-related beta suppression was highest in trials where response time was shortest. These preliminary findings suggest that beta oscillations correlate with improved motor performance during motor learning.

Universitario San Vicente de Paul, Rionegro-Medellin, Colombia; [7]Div. Neurosurg., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Tremor at rest affects approximately 75% of patients suffering from Parkinson's disease (PD) but is not a cardinal symptom of dystonia. Theories of tremorgenesis seem to fall into a "thalamocentric" view (Pare et al 1992) and a "pallidocentric" view (Helmich et al. 2011). Evidence for each theory is hampered by the lack of demonstration of pacemakers; cells or circuits that are capable of oscillating at the tremor frequency in the absence of sensory feedback, i.e. central pattern generators. Here we present evidence that neurons with the internal segment of the globus pallidus (GPi) of dystonia patients initiate a sustained tremor frequency oscillation following recovery from microstimulation-induced inhibition.Two independently driven microelectrodes were advanced through the GPi of PD and dystonia patients undergoing DBS implantation surgery. Upon isolation of single, stable recording units, 10s of baseline neuronal activity was recorded followed by a brief microstimulation (3/5/7.5µA, 1s duration, 0.3ms biphasic pulse width, 200Hz). Cells were then recorded for 10s following stimulation and traces were saved for offline analysis in Spike2 software. Traces were bandpass filtered (300-3000Hz) before being template matched to generate spike times. These times were then imported into MatLab for spike pattern and burst analysis with an in-house script. A total of 95 neurons from 9 PD (n =58) and 7 dystonia (n= 37) patients were analyzed of which, 19 were identified as border cells. For PD cells stimulated at 3 uA no overall change was seen, 73 Hz to 72 Hz (n= 23, NSD) 5 uA decreased from 80 Hz to 66 Hz ($n = 50$, $p < 0.05$) and at 7.5uA, 85Hz to 58 Hz (n= 15, $p< 0.05$). Burst indices at 3 uA did not change (2.03 to 2.01,) and at 5 uA increased (1.8 to 2.5) and 7.5 uA (1.7 to 2.5). Six neurons defined as border cells were induced into a tremor frequency oscillation post stimulation (4 - 6 Hz). Border cells have previously not been found to response to passive movement of limbs. Short trains of microstimulation appear to hyperpolarize GPi neurons and increase burstiness and in a subset of border cells this leads to pacemaker-like oscillations. These results suggest the GPi may be a tremorgenic site in the basal ganglia - thalamocortical loop.

Title: Apathy and depression networks in Parkinson's disease

Authors: H. MORGAN[1], *E. A. DISBROW[2], C. LEDBETTER[4], H. NAM[5], C. HIGGINSON[6], C. REYNOLDS[3];
[1]LSUHSC Sch. of Med. in Shreveport, Shreveport, LA; [2]Neurol., [3]Dept. of Neurol., LSU Hlth. Sci. Ctr., Shreveport, LA; [4]Dept. of Neurosurg., [5]Dept. of Pharmacology, Toxicology, and Neurosci., LSUHSC Shreveport, Shreveport, LA; [6]Dept. of Psychology, Loyola Univ. of Maryland, Baltimore, MD

Abstract: Psychiatric comorbidities such as depression, anxiety and apathy are common non-motor symptoms in PD, however they can be difficult to identify because of symptomatic overlap with the associated movement disorder. There is growing evidence that abnormal connectivity in the default mode network is linked both to PD and depression. We hypothesized that measures of depression and apathy would correlate with different DMN related networks that were disrupted in PD. We measured depression (Geriatric Depression Score) and apathy (Frontal Lobe Personality Score) in 18 right handed, right side dominant PD patients and 17 age-matched controls. For resting state MRI we used a 3T Siemens TIM Trio MR system to collect T1- weighted MP-RAGE and echo planar functional T2*- BOLD images. Image preprocessing and analysis was performed in SPM 8, and first-level functional connectivity analysis was performed with the CONN toolbox. Second-level analyses correlating cognitive test scores and connectivity of medial prefrontal and dorsal anterior cingulate cortex seeds were performed in AFNI using 3dRegAna. The PD group (mean=4.9, SD=4.3) reported significantly more depression than controls (mean=1.9, SD=1.5; $F(1, 33)=7.5$, $p<0.01$). There were no differences in apathy scores between the PD (mean= 25.6, SD=6.9) and control groups (mean=23.1, SD=6.3). For the MPFC seed in the PD group, depression scores were negatively correlated with connectivity between MPFC and striatum as well as right insula. In the PD group, apathy scores were negatively correlated with connectivity between MPFC and anterior cingulate as well as left insula. For the dACC seed in the PD group, bilateral insula was negatively correlated with

dACC connectivity and GDS. We also observed a positive correlation between dACC connectivity and GDS in the posterior cingulate. Bilateral insula, anterior cingulate and medial frontal gyrus were also negatively correlated with dACC connectivity and apathy score. In general, connectivity decreased as depression and apathy increased. Networks overlapped (cingulate and insula), while striatal involvement was unique to depression and medial frontal gyrus connectivity was unique to apathy. Our results represent a potential biomarker for depression in PD that could improve the assessment of disease progression and treatment efficacy, as well as the identification of disease subgroups.

Title: Cognitive and motor switching networks are disrupted in Parkinson’s disease

Authors: *A. M. PURI[1], C. LEDBETTER[2], K. RUSSO[4], K. SIGVARDT[5], E. DISBROW[3]; [1]Dept. of Psychology, Illinois State Univ., Normal, IL; [2]Dept. of Neurosurg., [3]Dept. of Neurol., LSU Hlth. Sci. Ctr., Shreveport, LA; [4]Dept. of Psychology, UC Berkeley, Berkeley, CA; [5]Dept. of Neurol., UC Davis, Davis, CA

Abstract: Set switching deficits are a well-described consequence of Parkinson’s Disease (PD). Here we sought to determine the degree to which activity in networks related to motor and cognitive task switching differs in PD compared to healthy controls. In an event-related fMRI experiment, 18 right handed, medicated, early stage, right side dominant PD patients and 19 age-matched controls performed a motor and cognitive switching task. Trials consisted of a colored (yellow or pink) shape (square or circle) presented beneath a word cue. Written cues indicated the stimulus attribute to be identified (“COLOR” or “SHAPE”; adapted from Shook et al., 2005). Participants used fingers on their right hand to press the left button on a button box to indicate “square” or “yellow” and the right button for “circle” or “pink”. On the subsequent trial, a new

randomly generated colored shape would appear. Thus, a given trial could involve no switch, a motor switch (different key press), and/or a cognitive switch (respond to different attribute) relative to the previous trial. Brain images were acquired on a 3T Siemens Trio MRI scanner using a gradient-echo echoplanar imaging pulse sequence and high-resolution, T1-weighted anatomical MP-RAGE sequence. Statistical analysis was performed using SPM8 and AFNI. Comparing fMRI activity during motor switch vs. non-switch trials in controls revealed activity in superior and middle frontal gyri (SFG/MFG), right inferior frontal gyrus (rIFG) and the caudate nucleus, consistent with previous findings. In contrast, the PD group exhibited reduced activity in the left insula, with greater relative activity in the rIFG and left premotor cortex compared to controls. Trials involving a cognitive switch were related to increased activity in SFG/MFG as well as the left insula, putamen, anterior cingulate (ACC), precuneus, and premotor cortex compared to non-switch trials in controls. In PD compared to controls, activity was decreased in the left insula as in the motor switch condition, and also in the ACC and caudate nucleus. Thus, motor and cognitive switching appeared to engage overlapping networks involving frontal (SFG/MFG and premotor cortex) and striatal regions. Motor switching additionally involved the IFG, whereas the insula, ACC and precuneus were selectively active for cognitive switching. The PD group showed relative underactivation in the insula for both types of switching, with additional underactivation in the ACC and caudate for cognitive switching. These patterns of underactivation in PD likely reflect functional deficits in cognitive control networks involved in task switching and response selection.

Title: Processing speed deficits have far reaching consequences in PD

Authors: ***B. HALL**[1], H. NGUYEN[2], C. HIGGENSON[4], K. SIGVARDT[5], L. ZHANG[5], N. MALHADO-CHANG[5], E. DISBROW[3];

[1]LSUHSC Shreveport, Shreveport, LA; [2]Dept. of Pharmacol., [3]LSU Shreveport Hlth. Sci. Ctr., Shreveport, LA; [4]Psychology, Loyola Univ. Maryland, Baltimore, MD; [5]Univ. of California Davis, Davis, CA

Abstract: Processing speed is a dopamine dependent measure of cognitive proficiency that has been shown to increase with age. Parkinson's disease (PD) is a dopaminergic neurodegenerative disorder that is associated with aging, possibly putting people with PD at higher risk for processing speed deficiency. Thus, we hypothesize that processing speed is increased in those with PD without dementia compared to controls. We studied a group of 68 participants with PD (35 males, 33 females) and 50 controls (26 males, 24 females) between the ages of 55 and 75. Groups were matched for age, years of education, and premorbid IQ. Subjects with PD were medicated and in relatively early stages of the disease. Subjects underwent a battery of neuropsychological tests, including measures of processing speed, attention, memory, cognitive flexibility, activities of daily living, and quality of life, as well as motor performance. Processing speed was evaluated using the Symbol Digit Modalities Test. Between groups comparisons were made using Multivariate Analysis of Variance (MANOVA), and age, daytime sleepiness and motor performance (functional Dexterity Test) were used as covariates in the analysis as possible confounding factors. Processing speed was significantly decreased in the PD group (Mean(SD) 44.3 (11.9) items completed in 90 sec.) compared to controls (Mean(SD) 52.4 (8.2) items completed in 90 sec.; $F(4, 113)=12.78$, $p<0.0001$). Additionally, maximum likelihood factor analysis revealed two factors in PD: cognitive and motor. The items that loaded heavily on the cognitive pattern were measures of trail-making, switching, inhibition, and processing speed. Those that loaded heavily on the motor pattern were manual dexterity, mobility, and processing speed. Interestingly, increased processing speed was also associated with increased difficulty with activities of daily living (UPDRS II; $R= -.426$, $p=0.001$) and instrumental activities of daily living ($R= -.653$, $p<0.0001$) as well as decreased self report quality of life ($R= -.279$, $p=0.024$). Our results indicate that processing speed is negatively affected in PD. This deficit has far reaching consequences, contributing to motor and cognitive deficits associated with the disease as well as every-day activities and quality of life.

Title: Differences in circle drawing rate in pd persons that show impairment in repetitive finger movement

Authors: ***A. F. ZAMAN**, E. STEGEMOLLER;
Kinesiology, Iowa State Univ., Ames, IA

Abstract: Repetitive finger movement is a clinical tool used to assess severity, progression, and treatment efficacy of Parkinson’s disease. Many persons with Parkinson’s disease (PD) demonstrate movement impairment in repetitive finger movement at rates greater than 2 Hz which is not improved with dopaminergic medication. Impaired finger movement can significantly impact the performance of daily living activities such as writing. The purpose of this study was to examine circle drawing at rates both above and below 2 Hz (120 beats per minute) in persons with PD with and without repetitive finger movement impairment. Sixteen persons diagnosed with mild to moderate PD completed a series of circle drawing tasks. Participants used their dominant hand to draw circles 1) at two different sizes (1, and 2cm), and 2) at three different speeds (self-selected pace, 70 beats per minute, and 140 beats per minute). The circle drawing tasks were presented in a random order. Participants were seated in a comfortable position and were allowed to change the angle of the paper to match their preferred writing position and wrote using a pen with an electromagnetic sensor attached to the tip. Based upon performance on the repetitive movement task (differences in movement rate and movement amplitude), participants were divided into groups of with and without impairment. The total area (width x height) of each circle and rate of circle drawing was calculated and averaged across conditions and participants. A two-tailed paired t-test ($\alpha = 0.05$) was used to compare the means. The results showed that there were significant differences between groups for circle drawing rate, but not for circle area. Future analysis examining the change in area is needed. These results suggest that those persons with PD that demonstrate greater impairment in repetitive finger movement performance may also show greater impairments in handwriting.

Title: Aberrant neural activity during cognitive control in association with Parkinson's disease

Authors: *P. MANZA[1], G. SCHWARTZ[1], S. ZHANG[2], C.-S. R. LI[2], H.-C. LEUNG[1]; [1]Stony Brook Univ., Stony Brook, NY; [2]Yale Univ., New Haven, CT

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by hallmark motor problems but also cognitive deficits. Individuals with PD experience problems with cognitive control of behavior, resulting in a detriment to their quality of life. Cognitive control is the ability to flexibly regulate behavior in the face of distraction, temptation, or surprise, in order to achieve behavioral goals. However, cognitive control deficits have been difficult to treat because the underlying neural mechanisms are unclear. To address this issue, we utilized functional magnetic resonance imaging while individuals performed the Stop-Signal Task. A visual stimulus (Go) is presented on every trial, to which subjects would make a speedy button press. However, a stop signal is presented on a minority (25%) of trials soon after the go signal at a variable delay, which requires withholding of the go response. Twelve individuals in earlier stages of PD (age 63+/- 9 years; 9 Male, UPDRS part III motor scores 23.7+/- 9.3, Hoehn & Yahr stage 1.9+/- 0.3, all drug naïve or "off" PD medications for 12 hours pre-study) and 12 age/sex-matched control subjects participated in the study. We found that stop-signal reaction time, the main measure of stopping ability, was significantly longer in the PD group than in the control group. This cognitive control deficit is not due to general motor slowing in the PD group as no significant differences were found in overall reaction time. Compared to controls, individuals with PD also showed reduced activation on stop trials in several prefrontal and posterior parietal areas and subcortical regions. Finally, we found that neural responses in dorsomedial frontal cortex during post-error go trials were significantly associated with stop-signal reaction time in the control group, but not in the PD group. These findings suggest that individuals with PD show reduced neural activity during stopping and impaired neural responses during error adaptation, which normally guide goal-directed behaviors in healthy adults.

Title: Characterization of essential tremor throughout the upper limb

Authors: ***A. PIGG**[1], D. W. GEIGER[1], S. K. CHARLES[1,2];
[1]Mechanical Engin., [2]Neurosci., Brigham Young Univ., Provo, UT

Abstract: Although Essential Tremor (ET), which primarily affects the upper limbs, is one of the most prevalent movement disorders, we do not currently know where in the upper limb the tremor tends to originate (mechanically), how it propagates throughout the upper limb, and where it manifests most severely. The long-term goal of this study is to characterize the distribution of ET patients' tremor from their shoulder to their wrist, simulate the propagation of their tremor across these degrees of freedom (DOF), and estimate the mechanical origin of their tremor (i.e. which DOF or muscle). Here we present a method for characterizing tremor throughout the upper limb and present a preliminary characterization in a small number of patients with mild ET. Ten subjects with mild ET participated in this study. Each subject was instrumented with electromagnetic motion capture sensors on their hand, distal forearm, distal upper arm, and scapula. Subjects were asked to place their upper limb in 16 different postures and hold each posture for 15 seconds. The set of 16 postures were repeated 4 times. We used inverse kinematics with compensation for soft-tissue artifacts to estimate the joint angles in each DOF. Joint angle data were analyzed in the frequency domain to calculate a number of tremor measures, including the power between 4 and 12 Hz (Narrow-band Area, NBA) and over the entire spectrum above 2 Hz (Wide-band Area, WBA), as well as any significant peaks. Mixed-model ANOVA tests were performed to investigate the effects of DOF, posture, repetition, gravitational torque, and subject characteristics on tremor measures. NBA and WBA varied significantly between DOF, being greatest in the elbow and forearm, intermediate in the shoulder, and lowest in the wrist. NBA and WBA also varied significantly with posture, although no pattern was discernable. Only 5% of observations had significant peaks, with 49% of peaks occurring in wrist flexion-extension and 39% occurring in wrist radial-ulnar deviation. Peak frequency was quite stereotyped (5.7 Hz ± 1.3Hz). Repetition had no significant effect, indicating that tremor measures were consistent over the duration of the experiment. Effects of gravity and demographic factors on measures were mixed and did not present discernible patterns. This preliminary characterization suggests that tremor may be focused in a subset of upper limb DOF, being greatest (in terms of power) in elbow flexion-extension and forearm pronation-supination, and most concentrated (with peaks at a stereotyped frequency) in wrist flexion-extension and radial-ulnar deviation. We are currently characterizing more ET patients and simulating tremor propagation.

Title: A one-year phase I trial to evaluate the safety and feasibility of implanting autologous peripheral nerve grafts into the substantia nigra in subjects with Parkinson’s disease undergoing Deep Brain Stimulation surgery and treatment

Authors: C. G. VAN HORNE[1,2,3], J. E. QUINTERO[1,3], J. T. SLEVIN[1,4,5], J. A. GURWELL[4], *G. A. GERHARDT[6,1,2];

Abstract: In Parkinson’s disease (PD), the substantia nigra undergoes a loss of dopaminergic cells and cell function that, in part, manifests into the outward symptoms of PD. We have an ongoing Phase I trial with the primary endpoint to examine the safety and feasibility of implanting an autologous peripheral nerve graft into the substantia nigra of PD patients undergoing deep brain stimulation (DBS) surgery. Schwann cells from the peripheral nervous system may serve as potential sources of neurotrophic factors including GDNF, NGF, BDNF, and NT-3, and peripheral nerve grafts to the CNS may provide an opportunity to directly deliver neurotrophic factors in areas affected by neurodegenerative diseases. Multi-stage, DBS surgery targeting the subthalamic nucleus was performed using standard procedures. After the DBS leads were implanted, a section of sural nerve (approximately 5mm in length) containing Schwann cells was excised and unilaterally delivered, using a custom-designed cannula, into the area of the substantia nigra. Adverse events were continuously monitored. Quality of life and Unified Parkinson’s Disease Rating Scale (UPDRS) evaluations were monitored preoperatively and at 1, 3, 6, 9, and 12 months after surgery. We have implanted 8 of 8 participants (average age: 62.9 ± 9.2 years; duration with the disease: 9.8 ± 9.2 years; Mean ± SD) with no significant adverse events. Immediate, postoperative magnetic resonance scans did not indicate evidence of abnormal tissue disruption. For the six participants who have completed the 12 month study,

UPDRS Part III (motor) scores off medication/off stimulation were 23.4 ± 12.4 points while at baseline they were 33.1 ± 7.6 points (moderate clinically important differences are defined as >5 points, Shulman et al. 2010). On medication/on stimulation scores were 13.3 ± 9.4 points at baseline and 9.0 ± 6.2 at 12 months. All the while, medication levels decreased from 863 ± 593 daily levodopa equivalents, preoperatively, to 37.5 ± 91.9 after 12 months. Based on our initial safety outcomes and early efficacy results, combining Schwann cell delivery with DBS therapy may provide a means of offering neuroregenerative therapy that augments the benefits of DBS in patients with PD.

Title: Using deep brain stimulation surgery as an avenue for providing neuroregenerative therapy to alter the progression of Parkinson’s disease

Authors: J. R. LAMM[1], J. E. QUINTERO[2,3], A. J. ANDERSON[4], J. T. SLEVIN[2,4,5], G. A. GERHARDT[1,2,3], *C. G. VAN HORNE[1,2,3];

Abstract: For over 10 years, deep brain stimulation (DBS) therapy has been used to ameliorate the symptoms of Parkinson’s disease (PD). However, many PD-related symptoms, especially non-motor symptoms, are not relieved through the use of DBS. In addition, DBS therapy has not been shown to halt or reverse the progression of the disease; therefore, new therapies need to be

developed to enhance the therapeutic benefits of DBS. One challenge in that development is finding a means to deliver biologic therapy (such as cell transplants or gene therapy). Based on our current results in a Phase I trial involving delivery of peripheral nerve tissue to the substantia nigra in conjunction with DBS, with think delivery of biological therapy at the time of DBS surgery will prove to be safe and feasible. Our approach was to deliver Schwann cells, a potential, alternative source of neurotrophic factors from the peripheral nervous system. We found that the wealth of results of previous non-clinical, pre-clinical, and early clinical trials showing that neurotrophic factors help restore dopaminergic cell function indicate that neurotrophic factors could serve the role of a therapy that complements DBS. After injury, Schwann cells release a host of growth factors including GDNF, NGF, BDNF, and NT-3. The added benefit of using Schwann cells is that patients can supply their own tissue thereby minimizing the risk for immune rejection. One of the possibilities of this type of surgery and therapy is that other brain areas, ones affected in patients with PD, could be targeted for receiving peripheral nerve grafts to potentially deliver neurotrophic factors and alter non-motor PD-related symptoms. An example of this is the basal forebrain where a loss of cholinergic cell function in PD is associated with cognitive impairment, gait disturbance, and increased incidence of falls. Based on an initial Phase I trial, DBS surgery may provide an avenue for the delivery of biologic therapy that augments the benefits of DBS in patients with PD.

Title: Two modalities of adaptive deep brain stimulation in Parkinson's disease patients implemented using the Activa® PC+S investigational neurostimulator and Nexus-D System Interface

Authors: *A. VELISAR[1], J. A. HERRON[3], Z. BLUMENFELD[2], E. J. QUINN[2], M. H. TRAGER[2], H. J. CHIZECK[3], H. BRONTE-STEWART[2];
[1]Neurol., Stanford Univ., Stanford, CA; [2]Neurol., Stanford Univ., Palo Alto, CA; [3]Dept. of Electrical Engin., Univ. of Washington, Seattle, WA

Abstract: Objective: Different control variables may be needed for adaptive deep brain stimulation (aDBS) for different phenotypes in Parkinson's disease (PD). We report the performance of aDBS driven by 1) a neural variable (local field potential (LFP) power) (naDBS) and 2) a kinematic variable (synchronized contralateral hand angular velocity (ang vel) using an inertial measurement unit (IMU) from a LG® Watch) (kaDBS). Methods: Two PD patients (akinetic rigid (AR) and tremor dominant (TD)) were implanted with the Activa ® PC+S (Medtronic, Inc.; IDE and IRB approved) neurostimulator. The Nexus-D System Interface communicated with a computer implementing stimulation. Patients were off medication and OFF DBS at baseline. LFP rest beta power (AR) or tremor (TD) was determined during a 60s rest period. naDBS (AR patient): Blocks of "stimulation ON" (2 min) were separated by periods of "stimulation OFF" (15s). The last 5s of a "stimulation OFF" period was used to sense neural activity and measure LFP power in low beta (12-20Hz). If LFP power > 55% of baseline, the next stimulation block voltage (Vstim) was increased; if < 22% of baseline, Vstim was decreased. Wrist flexion-extension (WFE) tasks were performed before, at mid-point, and at the end of naDBS. kaDBS (TD patient): Two kaDBS trials with different Vstim ramp rates (fast and slow) were performed. Hand tremor was monitored in real-time using the IMU. The hand ang vel magnitude in 3-7Hz band was measured at a 5Hz rate and compared to a threshold. If hand tremor > threshold, the Vstim was incremented towards 2V, and if under, Vstim was decreased to 0V. Results: naDBS: The sensed beta power was always > 55% baseline so all stimulation blocks had the max voltage (3V). The WFE ang vel was 254 deg/s before naDBS, 1928 deg/s at mid-point, and 2422 deg/s at the end. kaDBS. Less Vstim was delivered during fast ramp (FR) kaDBS (63%) and slow ramp (SR) kaDBS (67%) versus continuous DBS at 2V, which would amount to one year of extra battery life. During FR kaDBS, the Vstim range was 0-2V with many high-low oscillations; during SR kaDBS, Vstim rose slowly with fewer oscillations and tended to settle around 0.8V (range 0-1.4V). Tremor was present 52% time during SR kaDBS and 56% during FR kaDBS but was stronger during SR kaDBS than FR kaDBS (One way RM ANOVA, P=0.001) and reduced during each kaDBS vs baseline (both P=.001). Conclusions: These experiments demonstrate feasible applications of aDBS using an implanted sensing neurostimulator in PD patients with both neural and kinematic control variables. These results provide preliminary evidence of the potential efficacy of adaptive neuromodulation in clinical practice for different PD phenotypes.

Title: Subthalamic nucleus beta oscillations are attenuated for up to one hour OFF neurostimulation after six months of chronic deep brain stimulation

Authors: ***M. H. TRAGER**[1], E. J. QUINN[1], Z. BLUMENFELD[1], A. VELISAR[1], M. MILLER KOOP[1], L. SHREVE[1], C. KILBANE[3], J. M. HENDERSON[2], C. H. HALPERN[2], H. BRONTE-STEWART[1];
[1]Dept. of Neurol. and Neurolog. Sci., [2]Dept. of Neurosurg., Stanford Univ., Stanford, CA; [3]Dept. of Neurol., Case Western Reserve Univ., Cleveland, OH

Abstract: Background: Subthalamic nucleus (STN) local field potential (LFP) recordings demonstrate oscillatory neuronal activity and synchrony in the beta (13-30 Hz) band in the resting state in Parkinson's disease (PD). Beta synchrony may be attenuated for up to 40 seconds after 5 minute (min) periods of high frequency STN deep brain stimulation (DBS), but it is unknown whether and for how long attenuation persists after turning OFF chronic DBS. We examined whether resting state STN beta band synchrony in PD patients is attenuated after turning OFF chronic DBS and whether this persists for 60 min. Methods: Ten PD subjects underwent bilateral implantation of STN DBS leads connected to a sensing neurostimulator (Activa® PC+S, lead model 3389, Medtronic, Inc. FDA IDE-, IRB-approved). Subjects were tested in the resting state off medication/OFF DBS immediately prior to initial activation of DBS (baseline) and after 6 months (m) of continuous DBS. Five subjects were also tested after 12 m of continuous DBS. STN LFPs were recorded at baseline and immediately after DBS was turned off (0 min) and every 15 min thereafter for at least 60 min. A one-sample t-test (normal data) or one-sample signed rank test (non-normal data) was used to compare power at baseline to the 0 and 60 min 6 m recordings, and a Wilcoxon signed rank test was used to compare power between the 0 and 60 min recordings at 6 m. The Unified Parkinson's Disease Rating Scale

(UPDRS III) was performed pre-operatively (off medication) and at the 6 m visit after DBS was OFF for at least 60 min. Results: Synchronous recordings of kinematic and neural data were used to select periods of at least 10 seconds of data without movement; 4 sides were excluded (2 had intermittent tremor and 2 sides were not stimulated). Baseline beta band power was significantly attenuated immediately (0 min) and 60 min after DBS was turned off at 6 m ($P<0.05$ for both). There was no significant difference between beta band power at 0 min compared to 60 min after DBS was turned off. UPDRS scores were 42.4 ± 8.9 pre-operatively and 39.9 ± 15.2 after DBS was turned OFF for 185 ± 36.1 min. The interval between UPDRS assessments was 405.5 ± 75.2 days. Five subjects had data after 12 m of DBS: 4 of the 6 sides had lower beta power at 0 min than at baseline, and 3 had less beta power 60 min after DBS was turned off than at baseline. Conclusions: Resting state beta synchrony was attenuated immediately and 60 min after chronic DBS was turned OFF 6 m after initial activation of DBS. There was no increase in pre-operative UPDRS scores even after DBS had been OFF for > 3 hrs. Persistent attenuation of beta band power after chronic DBS suggests that chronic DBS exerts long term effects on neural synchrony in the STN.

Title: Characterization of resting state beta to high frequency oscillation phase amplitude coupling within the human subthalamic nucleus in Parkinson’s disease

Authors: ***M. MALEKMOHAMMADI**[1], L. SHREVE[1], Z. BLUMENFELD[1], A. VELISAR[1], B. C. HILL[1], J. M. HENDERSON[2], C. H. HALPERN[2], H. BRONTE-STEWART[1];

Abstract: Objective: Phase amplitude coupling (PAC) of beta (13-30 Hz) and high frequency oscillations (HFO: 200-400 Hz) in the subthalamic nucleus (STN) may be involved in Parkinson's disease (PD) pathophysiology. Investigation of PAC is necessary before it can be called a biomarker for PD. We explored beta-HFO PAC in the resting state in a large well-characterized dataset of PD subjects. Methods: Intra-operative STN local field potentials (LFP) were recorded after placement of deep brain stimulation (DBS) leads (Medtronic Inc, model 3389) in 30 PD subjects (50 STNs) (4 kHz sampling frequency, 400 Hz Low pass filtered). Rest periods without artifact, tremor, or voluntary movement, were selected. Power spectral density analysis was done using multi-taper method (1 second windows, 90% overlap, 1 Hz frequency resolution) and PAC was calculated by modulation index (MI) (phase: 5-35 Hz with 2 Hz bandwidth; amplitude: 50-400 Hz with 15 Hz bandwidth). 100 surrogate data sets were generated to assess the statistical significance of MI values at $P < 0.05$. Phase of coupling was calculated and its distribution was tested for non-uniformity (Rayleigh test, $P < 0.05$). The time variability of PAC was studied in 5 seconds non-overlapping time windows. Results: 42 STNs (84%) showed significant beta-HFO PAC ($P < 0.05$). The Rayleigh test showed deviation of phase distribution from uniform circular distribution ($P < 0.05$), confirming the presence of a preferred phase for the coupling. The more clinically affected side (MA) (defined by lateral UPDRS III/OFF stimulation and off medication) exhibited stronger PAC in 14 subjects (out of the 20 with bilateral recordings). PAC was spatially specific across the DBS lead and both its magnitude and preferred phase were variable over time across subjects. Conclusions: Resting state beta-HFO PAC exists in the STN in PD and is stronger on the MA side. Moreover PAC is dynamic over time exhibiting temporal correlation with beta power. These results provide additional support for potential pathophysiological role of aberrant PAC in PD and its application for adaptive DBS.

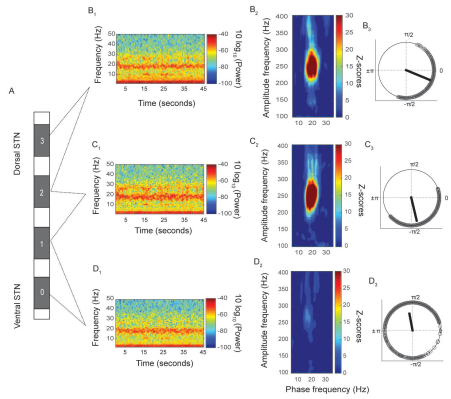

Figure Description: PAC exists between phase of beta (13-30 Hz) and amplitude of HFO (200-500 Hz) for bipolar recordings from DBS Lead (shown for a single subject). A: DBS lead, signals were recorded between bipolar contacts (2-3), (1-2) and (0-1) respectively. B1, C1 and D1: Power spectral density in time and frequency. B2, C2 and D2: PAC maps for pairs of phase and amplitude frequency (MI values converted to z-scores to reflect statistical significance). B3,C3 and D3: Circular histograms for phase of coupling between beta phase and HFO amplitude (each dot on the periphery of unit circle shows the phase of coupling for one of the frequency pairs and thick black line indicates the mean preferred phase).

Title: Aberrant nucleocytoplasmic transport in Huntington’s disease

Authors: ***I. AHMED**, J. C. GRIMA, C. J. DONNELLY, R. SATTLER, S. H. SNYDER, J. D. ROTHSTEIN;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Huntington’s disease (HD) is a hereditary and incurable neurodegenerative disorder caused by an expanded CAG repeat in the first exon of the huntingtin (htt) gene, resulting in progressive degeneration of striatal medium spiny neurons. Disease onset and severity are dependent on CAG repeat length with a longer expansion resulting in earlier onset and greater severity. However, the underlying mechanisms by which mutant htt causes the disease have not been fully elucidated. Nonetheless, some studies suggest that nucleocytoplasmic trafficking dysfunction could be a pathogenic contributor. The transport of transcription factors between the cytoplasm and the nucleus is a critical aspect of signal transduction and is especially arduous for neurons due to their highly polarized structure. Molecules smaller than 40 kDa are able to transit *passively* through the Nuclear Pore Complex (NPC), the only transport conduit between the nucleus and cytoplasm. Larger molecules are *actively* transported by nuclear transport receptors that recognize nuclear localization and export sequences. During nuclear import, cargo release occurs when the transport receptor interacts with RAN-GTP. During nuclear export, RAN-GTP

is required to form the transport receptor and cargo complex and cargo is released into the cytoplasm upon GTP hydrolysis of RAN-GTP. This irreversible event is induced by RANBP1 or RANBP2 and RANGAP, which are located at the cytoplasmic filaments of the NPC. As a result, a RAN-GTP gradient between the nucleus and cytoplasm is required for this process. Recent studies have shown that HD exhibits increased levels of the polyglutamine-expanded protein in the nucleus, potentially due to a reduction in nuclear export. More specifically, its been shown that expansion of the N-terminal htt fragment reduces its interaction with TPR, a component of the NPC involved with export. Also, live-cell imaging studies have shown that mutant htt demonstrates reduced dynamics and rates of nucleocytoplasmic transport. Finally, cell culture and transgenic animal models display distortions in nuclear envelope and increases in the clustering of NPCs. Our early studies suggest that mutant htt may disrupt nucleocytoplasmic transport. To this end, we assessed components of this pathway in HD immortalized striatal cell lines and a transgenic animal model of HD. Our preliminary data indicate that selected proteins involved in nucleocytoplasmic trafficking are affected in these disease models as evidenced by nuclear aggregation that co-localizes with mutant htt as well as a disruption in the RAN-GTP gradient. This study suggests a defect in nucleocytoplasmic transport in HD.

Abstract: Autophagy is an important degradative process that eliminates long-lived proteins, protein aggregates and damaged organelles. Autophagy is required for maintenance of neuronal homeostasis, and its dysregulation is involved in many neurodegenerative disorders. Autophagy is therefore a promising target for blunting neurodegeneration. We searched for novel autophagic pathways in primary neurons and identified the cytosolic sphingosine-1-phosphate (S1P) pathway as a regulator of neuronal autophagy. S1P is a cytoprotective lipid messenger generated by sphingosine kinase 1 (SK1) in the cytoplasm. We found that SK1 expression enhances the flux through autophagy and the S1P-metabolizing enzymes decrease the flux. When autophagy is stimulated, SK1 relocalizes to endosomes/autophagosomes in neurons. Expression of a dominant-negative form of SK1 inhibits autophagosome formation. In a neuron model of Huntington's disease, pharmacologically elevating the levels of S1P decreased the accumulation of a substrate of autophagy mutant huntingtin and protected neurons from mutant huntingtin-induced neurotoxicity. These results identify the S1P pathway as a novel regulator of neuronal autophagy and provide a new target for developing therapies for neurodegenerative disorders.

Title: Mutant Huntingtin mediated repression of antioxidant gene expression is associated with sequestration of Nrf2 in aggresomes

Authors: *R. C. CUMMING, L. TINDALE, C. LI;
Dept. of Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: Mitochondrial dysfunction and elevated reactive oxygen species (ROS) levels are strongly implicated in various neurodegenerative disorders, including Huntington's disease (HD). We previously demonstrated that overexpression of mutant Huntingtin (mHtt) in PC12 cells leads to elevated ROS production and a concomitant decrease in transcription of the gene encoding the antioxidant protein peroxiredoxin 1 (Prx1). Interestingly, treatment with the FDA-approved compound dimercaptopropanol (DMP) prevented mHtt-mediated inhibition of

antioxidant gene expression and neurotoxicity. Nrf2 is a transcription factor responsible for regulating expression of a diverse array of antioxidant genes including Prx1. Nrf2 is normally maintained at very low levels by its negative regulator Keap1, which facilitates the sequential ubiquitination and degradation of Nrf2 by the proteasome. Electrophiles and oxidants can disrupt the Keap1-Nrf2 interaction, resulting in the stabilization and nuclear translocation of Nrf2. Following induction of mHtt expression in PC12 cells, we observed a sequestration of both Nrf2 and Keap1 in mHtt containing aggresomes in the cytosol. However, DMP treatment attenuated the sequestration of Nrf2, but not Keap1, in aggresomes and also promoted increased nuclear localization of Nrf2. DMP treatment strongly increased expression of Nrf2 transcriptional targets. These observations suggest that mHtt either directly or indirectly promotes recruitment of Nrf2 to cytoplasmic aggresomes thereby preventing activation of the antioxidant response; an event countered by DMP exposure. DMP, also known as British anti-Lewisite (BAL), was shown to attenuate disease progression in a long term study of two HD patients conducted in 1955. The current study highlights a previously unknown intracellular target of DMP and indicates that this FDA approved compound may have relevance for the treatment of HD and other neurodegenerative disorders.

Title: Studying turnover of mutant huntingtin in neuronal and glial cells at subcellular level

Authors: ***T. ZHAO**[1], Y. HONG[3], S. LI[2], X.-J. LI[3];
[1]Human Genet., Emory Univ., Atlanta, GA; [2]Emory Univ., atlanta, GA; [3]emory Univ., Atlanta, GA

Abstract: Huntington’s disease (HD) is an autosomal dominant, neurodegenerative disease that affects one in every 10,000 Americans. About 200,000 Americans are at risk of inheriting the

disease from affected parents. HD patients are characterized by motor, cognitive and neuropsychiatric abnormalities. HD is caused by the expansion of the trinucleotide CAG (>37 units) encoding an expanded stretch of polyglutamine (PolyQ) in the N terminal region of mutant huntingtin (mhtt). Mhtt is neurotoxic and induces neuronal death by disturbing gene expression, axonal transport, and mitochondrial function. Mhtt is prone to forming insoluble aggregates. Appearance of mhtt aggregates is indicative of the accumulation of mhtt. In HD, progressive emergence of mhtt aggregates in neurons is observed. Compared to neurons, fewer and smaller mhtt aggregates are found in astrocytes. Furthermore, the mhtt aggregates preferentially form in neuronal neurites and nuclei, and few aggregates form in the cytosol of soma. This implicates that degradation rates of mhtt in different subcellular compartments are uneven. In order to study degradation rates of mhtt in subcellular compartments, we conjugate dendra2, a photoconvertible fluorescent protein, to the N-terminal fragmented mhtt (Htt230-130Q) and wild-type htt (Htt230-23Q) that is used as the control. Dendra2 is irreversibly photoconverted from a green to a red fluorescent state with 405nm light in the neuronal compartments. After photoconversion, decline of red signal over time is used to measure the degradation rates of Htt230(130/23Q)-dendra2 in the subcellular compartments. In the present study, we used brain slice and primary culture models and found that mhtt is degraded faster than wild-type htt in the cytosol of soma in neurons. However, expanded polyQ stabilizes mhtt in neurites. By contrast, mhtt is cleared faster than wild-type htt in both cytosol of soma and processes of astrocytes. Our data demonstrates differential clearance rates of mhtt in distinct subcellular compartments, and indicates that astrocytes and neurons cope with mhtt in different ways.

Title: Role of o linked beta n acetylglucosamine modification in Huntington’s disease

Authors: ***K. MAROSI**, R. WU, M. P. MATTSON;
NIH, Baltimore, MD

Abstract: Huntington Disease (HD) manifests with impaired motor and cognitive functions and psychiatric symptoms. HD is caused by a CAG repeat expansion in the huntingtin (Htt) gene that codes for polyglutamine in the huntingtin protein. The mutant huntingtin protein causes

abnormalities in cellular proteostasis and impairs cellular metabolism resulting in neuronal death. O-GlcNAcylation is a posttranslational modification by the O-linked ß-N-acetylglucosamine moiety at proteins. O-GlcNAc transferase (OGT) catalyzes the addition of the sugar moiety to the protein and O-GlcNAcase (OGA) catalyzes the sugar removal. O-GlcNAc acts as a nutrient sensor that couples metabolic status to cellular regulation of signal transduction, transcription, and protein degradation. Aberrant O-GlcNAcylation has been implicated in many diseases including neurodegenerative disorders. Here we performed studies aimed at advancing an understanding of the role of O-GlcNAc modification in the HD pathology. We used immortalized striatal precursor cells expressing normal Htt (Q7) or mutant Htt (Q111) as a model of HD. We found that Q111 cells exhibit slower proliferation rate compared to Q7 cells. Q111 cells showed altered metabolism including reduction in glycolitic capacity and mitochondrial respiration. The Q111 cells showed enhanced capsase 3 activation, ROS production and increased vulnerability to serum-deprivation induced stress compared to Q7 cells. This phenotype was associated with elevated p53 levels, which may play an important role in HD pathology. We found that supressing O-GlcNAc signalling by inhibiting OGT enzyme activity with BADGP rescues the stress - mediated cell death and improves glycolitic function in Q111 cells. In addition, enhancing the global O-GlcNAc signaling with glucosamine treatment resulted in the accelerated death of Q111 cells. We showed that p53 is modified by O-GlcNAc which can potentially regulate its activity and stability. Currently we are determining whether suppression of O-GlcNAc modification on p53 with either pharmacological (BADGP) or genetic tools can potentially enable its ubiquitination and subsequent degradation by the proteasome, which might lead to the prevention of p53-mediated cell death in HD. Since O-GlcNAc modification can fluctuate greatly in response to varying nutrient availability, it is important to understand how dietary interventions might be implemented to suppress pathogenic events involving O-GlcNAcylation in HD.

Title: Lycium barbarum polysaccharide attenuates the cell toxicity of mutant huntingtin through activation of AKT pathway

Authors: *F. FANG;
Dept. of Human Anat. and Embryology, Huazhong Univ. of Sci. & Technol., Wuhan, China

Abstract: Huntington's disease (HD) is an inherited neurodegenerative disease caused by abnormal expansion of CAG repeats in the first exon of *IT15* gene encoding huntingtin (Htt). Clinically, HD is characterized by motor dysfunction, psychiatric disturbance and cognitive deterioration to dementia. Reduction of AKT phosphorylation or inhibition of AKT activity has been found to be involved in cell death induced by mutant Htt. *Lycium barbarum* polysaccharide (LBP), the main bioactive component of *Lycium barbarum*, has been reported to play neuroprotective roles through enhancing phosphorylation of AKT in neural injuries including neurodegenerative diseases. Here we report that, treating with LBP can significantly improve motor behavior of HD transgenetic mice, B6C3-Tg(HD82Gln)81Dbo/J Tg mice, and increase cell viability of HEK293 cell stably expressing mutant Htt 160Q (HEK293-160Q cell). Nissl staining shows that there are more Nissl's bodies in the neurons in the cortex and hippocampus of Tg mice treated with LBP than in those of Tg mice without treatment. Furthermore, we found that treatment with LBP increases the phosphorylation of Thr 308 and Ser 473 in AKT and Ser 9 in GSK3β in the cortex, hippocampus and striatum of the TG mice. The upregulation of phosphorylation of Ser 2448 in mTOR is also detected in the hippocampus and striatum. In HEK293-160Q cells, the phosphorylation of Thr 308 and Ser 473 in AKT, Ser 9 in GSK3β and Ser 2448 in mTOR is also significantly increased. Our findings suggest that LBP could alleviate the cell toxicity of mutant huntingtin through activation of AKT pathway, indicating the potential of LBP in treating HD. Title: Regulation of endoplasmic reticulum stress and ribosome biogenesis in a yeast model of Huntington's disease

Authors: *Y. JIANG, P. LAJOIE;
Anat. and Cell Biol., The Univ. of Western Ontario, London, ON, Canada

Abstract: Huntington's disease (HD) is a neurodegenerative disorder caused by the expansion of polyglutamine (PolyQ) repeats in the huntingtin protein. The expansion results in increased mutant huntingtin protein aggregation, leading to various cellular dysfunctions and ultimately to neuronal cell death. Previous data have identified accumulation of misfolded proteins in the endoplasmic reticulum (termed ER stress) as a major contributor to polyQ toxicity in both mammalian and yeast models of HD. Upon ER stress, down regulation of ribosome biogenesis is a highly conserved coping mechanism by which cells can reduce the amount of nascent proteins to maintain homeostasis. However, the impact of toxic polyQ proteins on ribosome biogenesis and protein translation is unclear. In the well characterized yeast model of HD, this may involve the activation of cell wall integrity pathway (CWI), a signaling cascade homologous to the MAP kinase pathways in human cells. Interestingly, upon polyQ expression, yeast cells expressing an HD-associated polyQ length (72Q) have an obvious growth defect but growth arrest was not associated with cell death. We also showed that cells with expanded polyQ are more sensitive to ER, heat shock and cell wall stresses. Furthermore, we observed a re-localization of Sfp1, a regulator of ribosome biogenesis, from nucleus to cytoplasm in cells expressing expanded polyQ. Therefore we postulate that polyQ expression in yeast impairs translation and cell growth by repressing ribosome biogenesis through CWI activation. Understanding the mechanism of polyQ-induced cell growth arrest will lay a foundation for further research on the mechanisms involved in polyQ toxicity in mammalian systems.

Title: Molecular mechanism underlying defective BDNF secretion from astrocytes expressing mutant huntingtin

Authors: ***Y. HONG**[1], T. ZHAO[2], X.-J. LI[3], S. LI[2];
[1]Human Genet., [2]Emory Univ., Atlanta, GA; [3]Emory Univ., atlanta, GA

Abstract: Huntington's disease (HD) is a fatal, inherited, neurodegenerative disorder that affects one in every 10,000 Americans. However, there is no effective treatment for HD to date, in part because the pathogenic mechanism driving the disease is incompletely understood. A mutant form of the huntingtin protein (htt), in which a polyQ repeat region is greatly expanded, is a critical molecular feature of the disease. The huntingtin protein is necessary for multiple cellular functions, including gene transcription and vesicle trafficking. However, mutant htt is toxic to neurons. Most studies of neurodegenerative diseases have been focused on neurons because degeneration is observed mainly in neuronal cells. However, the survival of neuronal cells is also supported by glial cells such as astrocytes. One important role of astrocytes is to synthesize and release brain-derived neurotrophic factor (BDNF), which is vital for neuronal survival, development and function. Mutant htt is found in astrocytes both in the brains of HD patients and mouse models of the disease; however, little is known about the pathogenic role of mutant htt in astrocytes. We have found that mutant htt inhibits BDNF secretion from astrocytes. However, how mutant htt impairs BDNF secretion from astrocytes and contributes to the preferential loss of striatal neurons in HD remains unknown. In this study, we used a transgenic HD mouse model (GFAP-160Q) that specifically expresses N-terminal mhtt in astrocytes to study the effect of mutant htt on BDNF secretion. Western blot and real-time PCR results show no significant difference of BDNF level in astrocytes between WT and GFAP-160Q mice. However, ELISA results demonstrate that the secretion level of mature BDNF is decreased in the culture medium of astrocytes from GFAP-160Q mice compared with WT. These results indicate that mutant htt may impair secretion of BDNF from astrocytes, which might contribute to the neuronal dysfunction and degeneration in HD. The mechanism of decreased BDNF secretion is under investigation.

Title: Calcium dependent regulation of Drp1 expression in Huntington's disease

Authors: *J. JEON, H. SEO;
Hanyang Univ., Ansan, Gyeonggi, Korea, Republic of

Abstract: Huntington's disease (HD) is a neurodegenerative disorder with progressive degeneration of GABAergic neurons in the striatum. HD is characterized by involuntary movements, chorea, dystonia, changes in personality and cognitive decline. HD is caused by CAG repeat expansion in the huntingtin gene. Recent studies suggest that abnormal mitochondrial dynamics are involved in HD pathogenesis. In this study, we detected how resveratrol, an antioxidant, regulate mitochondrial dynamics in HD model mice. We observed improved mitochondrial function by ATP elevation and attenuation of cellular oxidative stress levels. Especially, Drp1, a mitochondrial fission protein, showed increased expression level in resveratrol administered YAC128 HD mice. We also detected increase in mitochondrial length by resveratrol. Our results demonstrated that the intracellular calcium level affected mitochondrial dynamics by regulating Drp1 expression. Furthermore, down regulation of Drp1 altered mitochondrial morphology. These results suggest that calcium dependent regulation of Drp1 expression not only improves mitochondria function, but aides in the recovery of HD through alteration of mitochondrial morphology.

Title: Cdk5-mediated mitochondrial fission: A key player in dopaminergic toxicity in Huntington´s disease

Authors: M. CHERUBINI, M. PUIGDELLIVOL, J. ALBERCH, *S. GINES-PADROS; Med. School, Univ. of Barcelona, Barcelona, Spain

Abstract: The molecular mechanisms underlying striatal vulnerability in Huntington's disease (HD) are still unknown. However, growing evidence suggest that mitochondrial dysfunction could play a major role. In searching for a potential link between striatal neurodegeneration and mitochondrial defects we focused on cyclin-dependent kinase 5 (Cdk5). Here, we demonstrate that increased mitochondrial fission in mutant huntingtin striatal cells can be a consequence of Cdk5-mediated alterations in Drp1 subcellular distribution and activity since pharmacological or genetic inhibition of Cdk5 normalizes Drp1 function ameliorating mitochondrial fragmentation. Interestingly, mitochondrial defects in mutant huntingtin striatal cells can be increased by D1 receptor activation a process also mediated by Cdk5 as down-regulation of Cdk5 activity abrogates the increase in mitochondrial fission, the translocation of Drp1 to the mitochondria and the raise of Drp1 activity induced by dopaminergic stimulation. In sum, we have demonstrated a new role for Cdk5 in HD pathology by mediating dopaminergic neurotoxicity through modulation of Drp1-induced mitochondrial fragmentation, which underscores the relevance for pharmacologic interference of Cdk5 signaling to prevent or ameliorate striatal neurodegeneration in HD.

Title: Neuroprotective effects of MicroNeurotrophins in Huntington's disease cellular models

Authors: *K. A. MUELLER[1], K. E. GLAJCH[1], V. PRABHAKAR[1], A. GRAVANIS[2], G. SADRI-VAKILI[1];

[1]Neurol., MassGeneral Inst. for Neurodegenerative Dis., Boston, MA; [2]Univ. of Crete, Crete, Greece

Abstract: Neurotrophic factors (NTFs) are a group of molecules that are important for the development, maintenance, and survival of neurons. NTFs exert their beneficial effects on neurons by binding to tyrosine kinase (Trk) receptors and activating pro-survival cascades. In Huntington's disease (HD), NTF signaling is dysfunctional and may underlie neuronal death in both animal models of HD and in people living with the disease. Therefore, Trk ligands have been proposed as therapeutic agents for the treatment of HD. Importantly, previous studies in cellular and animal models of HD have demonstrated that NTF treatment is neuroprotective. However, the key challenge in the field of NTF therapy is drug delivery to the central nervous system (CNS) since NTFs are large, charged proteins that do not to cross the blood-brain barrier (BBB). Despite the practical challenges of administration, the use of NTFs or NTF analogues remains a promising potential therapeutic given the significant potency of NTFs in preventing cell death and stimulating cell function in animal models of neurodegenerative disease. Currently we are investigating the effects of a novel class of compounds known as MicroNeurotrophins (MNTs) in cellular models of HD. These compounds are small agonists of NTF receptors that can penetrate the BBB. Thus MNTs have immense potential for the treatment of neurodegenerative disorders such as HD. Our results demonstrate that MNT treatment decreases caspase 3 activation, increases mRNA expression of downregulated genes, and enhances autophagy in mutant STHdh$^{111/111}$ cells compared to wild-type STHdh$^{7/7}$ cells. Furthermore, MNT treatment increases AKT levels as well as huntingtin phosphorylation. Together these findings demonstrate that MNTs confer neuroprotection by decreasing caspase activation, improving transcription and increasing autophagy in cellular models of HD.

Psychiatry, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington's disease (HD) is a progressive neurodegenerative disorder, which results from an expansion in the CAG repeat region of the Huntingtin (Htt) gene. Multiple studies suggest that mutant Htt (mHtt) expression leads to a deficiency in the major astroglial glutamate transporter and an elevation in extrasynaptic NMDA receptor (NMDAR) expression, especially those containing GluN2B subunit, in striatum. These changes may contribute to NMDAR overactivation and cell death. Uncoupling of PSD-95 from GluN2B with a disrupting peptide, NR2B9c, can rescue the increased vulnerability of HD striatal neurons to NMDA-induced apoptosis, suggesting the peptide has therapeutic potential in HD. However, little is known about the effects of this peptide on synaptic function. Here, we investigated whether TatNR2B9c treatment to weaken the PSD-95/GluN2B interaction can ameliorate synaptic signaling changes in striatal neurons in corticostriatal co-culture from the YAC128 HD mouse, a model that expresses human Htt of 128 repeats. Surprisingly, the peptide reduced rather than improved pro-survival signaling, as reflected in nuclear levels of phospho-cAMP Responsive Element Binding protein (pCREB). Moreover, 1-hour treatment with TatNR2B9c decreased synaptic GluN2B-NMDAR; effects on synaptic GluN2A-NMDAR are being assessed. Currently, we are using whole-cell patch clamp recording to test whether NR2B9c peptide reduces synaptic NMDAR function, which may contribute to impaired survival signaling. In addition, we will assess whether this peptide rescues other changes associated with mHtt expression in striatal neurons, such as enhanced extrasynaptic NMDAR. Together, these studies will lay the foundation for a preclinical trial of Tat-NR2B9c peptide in HD mice.

Title: Characterization of the role of N-type calcium channels in Huntington's disease

Authors: ***L. B. VIEIRA**[1], F. R. SILVA[2], R. P. M. SANTOS[3], E. M. L. BATISTA[2], F. M. RIBEIRO[2];
[2]Biochem., [3]Pharmacol., [1]Univ. Federal de Minas Gerais (UFMG), Belo Horizonte, Brazil

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder caused by a polyglutamine expansion in the amino-terminal region of the huntingtin protein (Htt). HD patients exhibit neurodegeneration on the caudate-putamen and neocortical regions of the brain, as well as symptoms including motor alterations, cognitive decline, psychiatric disturbances and inevitable death. Although neurodegeneration is pointed as the main cause of HD symptoms, cognitive decline can be observed even before detectable levels of neuronal cell loss. Several studies indicate that mutated Htt (mHtt) can promote Ca2+ signaling disturbances, which are closely related to the death of striatal neurons. It has been demonstrated that wild type Htt can interact with and also modulate N-type calcium channels (Cav2.2), which play an important role in pre-synaptic neurotransmitter release. Our main question is how N-type calcium channels are affected by full-length mHtt expression and whether it could account for altered neurotransmission in HD. Using synaptosomes from HD mouse model, BACHD, we observed an increase on glutamate release in the striatum. Applying to these synaptosomes, a potent and selective Cav2.2 blocker (w-CgTx GVIA), we noticed that the increase in glutamate release is abrogated by this N-type calcium blocker. Through immunoblotting and biotinylation, We analyzed the total expression as well the membrane expression of Cav2.2 in the cortex and striatum of BACHD mice. We observed that Cav2.2 total expression is decreased in older mice, but increased in the striatum membrane in younger mice. Co-immunoprecipitation was applied for measuring the interaction between Cav2.2 and mHtt, or Gβγ and Syntaxin 1A, that both have a binding site on this channel and also contribute to its regulation. Our results showed that Cav2.2 interacts less with mHtt in the striatum. On the other hand, Cav2.2 interacts more with Syntaxin 1A and less with Gβγ in BACHD mice. Taking together our results, we may suggest that the neuronal death that occurs in HD has a possible involvement of N-type calcium channel with mHtt, Gβγ and Syntaxin 1A proteins during the early phase of HD.

Abstract: White matter (WM) atrophy in Huntington disease (HD), an autosomal dominant neurodegenerative disorder, is well documented, with WM changes occurring many years before the onset of clinical manifestations. Despite these observations, the significance of WM changes towards the pathogenesis of HD has not been fully explored. To better understand the role of wild-type huntingtin (HTT) in WM biology and function, we performed microarray gene expression profiling of the immortalised human MO3.13 oligodendroglial cells with lentiviral-mediated shRNA knockdowns of wild-type HTT. Knockdown of wild-type HTT by more than 80% of its endogenous levels resulted in the differential expression of 1289 genes (734 up-regulated and 555 down-regulated) with a fold change of at least 1.5 and a false discovery rate corrected p-value of <0.05 in three independent biological samples (using two different HTT shRNA constructs). Gene Ontology (GO) term analysis revealed dysregulation in processes integral to normal oligodendroglia function such as chemotaxis, cell adhesion, metabolic processes and cell morphogenesis. A number of oligodendrocyte related genes were also dysregulated following knockdown of wild-type HTT. We verified the differential expression of a subset of genes involved in these processes using quantitative real time PCR analysis and also assessed how cell proliferation, survival and chemotaxis may be impaired following HTT knockdown. In all, this is the first study that specifically explores the potential roles of wild-type HTT in the context of oligodendrocytes.

(CRN), Lausanne Univ. Hosp. (CHUV), Lausanne, Switzerland

Abstract: Huntington's disease (HD) is an autosomal dominantly inherited disorder characterized by late onset psychiatric, cognitive and motor deficits. The main pathological hallmark of HD is the massive neuronal loss of GABAergic projection neurons (medium spiny neurons) of the striatum. As the disease progresses marked neuronal loss is as well observed in the cortex (in particular cortico-striatal and cortico-thalamic pyramidal neurons housed in the cortical layer V and layer VI, respectively) and other subcortical structures. HD is caused by a CAG repeat expansion in the exon 1 of the HTT gene from a normal range of usually 16-20 to more than 35. This gives rise to an expanded polyglutamine tract in HTT protein. The mutant protein (mut-HTT) is prone to aggregation and is associated with a gain of toxic function and a dominant negative activity on normal HTT function. As HTT is a scaffold protein involved in many pathways, mutation within HTT has an impact on several cell mechanisms. The signaling pathways linking the genetic cause of HD and mut-HTT to the cascades of cellular processes leading to the striatal and cortical neurons dysfunction and death are not fully understood. Here we explored the specific role of HTT and the impact of HD mutation in various derivatives of human pluripotent stem cells (hPSC). We used hPSC-derivatives featuring phenotype equivalent to that of cells in brain regions most affected by the disease such as telencephalic neuroepithelial progenitor cells, cortical and striatal neurons as well as control cells such as retinal pigmented epithelium cells (RPE) a highly polarized epithelial type of cells (not affected in HD patients). We designed DOX-inducible shRNA lentiviral vectors targeting single nucleotide polymorphisms present in the human HTT gene to selectively target the mut-HTT isoform (previously described in Drouet et al 2014) and DOX-inducible shRNA vectors targeting total HTT. We next used these inducible shHTT-viruses on WT and HD-hPSCs and on their derivatives to explore the specific impact of HTT loss of function and mut-HTT toxic or dominant negative effect on different cellular functions. Initial whole genome transcriptomic analysis using pan-allelic or allele-specific silencing vectors confirmed a role of HTT in many life-supporting cellular processes such as neural or retinal functions and cell adhesion. These results comfort the position of HTT as a multifunctional scaffold protein necessary to many life-supporting cellular events and highlight the relevance of an inducible silencing system to better understand the role of HTT and the impact of HD in cell differentiation and maturation.

Title: Mitochondrial Division Inhibitor 1 and mitochondria-targeted molecules Mitoq and ss31 protects against mutant htt-induced mitochondrial toxicities in Huntington's disease neurons

Authors: ***X. L. YIN**, M. MANCZAK, Y. SUNEETHA, R. KANDIMALLA, A. PANDEY, C. KURUVA, P. REDDY;

Abstract: BACKGROUND Huntington's disease (HD) is a fatal, progressive neurodegenerative disease with an autosomal dominant inheritance, characterized by chorea, involuntary movements of the limbs, and cognitive impairments. Recent studies have found that mutant Htt interacts with mitochondria fission protein Drp1, causing excessive fragmentation of mitochondria, leading to abnormal mitochondrial dynamics and neuronal damage in HD-affected neurons. Some progress has been made in developing molecules that can reduce excessive mitochondrial fragmentation while maintaining the mitochondrial dynamics and mitochondrial function and synaptic activity. The objective of this study was to determine the protective effects of mitochondrial division inhibitor 1 (Mdivi1) and mitochondria-targeted molecules - MitoQ and SS31 in striatal neurons that stably express mutant Htt STHHDhQ111/Q111. METHODS Using Seahorse XFe96 extracellular flux analyzer, we assessed real-time oxygen consumption ratio (OCR) in STHDhQ111/Q111 neurons that were treated and untreated with Mdivi 1, MitoQ and SS31. Further, using biochemical methods, cell viability, apoptosis, mitochondrial function and mitochondrial DNA (mtDNA) and nuclear DNA ratios were assessed in in STHDhQ111/Q111 neurons that were treated and untreated with Mdivi 1, MitoQ and SS31. RESULTS The XFe96 extracellular flux analyzer analysis of spare respiratory capacity, particularly oxygen consumption ratio was significantly increased in STHDhQ111/Q111 neurons treated with Mdivi 1, MitoQ and SS31 relative to untreated STHDhQ111/Q111 neurons. The Cell viability was significantly increased in STHDhQ111/Q111 neurons treated with Mdivi 1 (P=0.039), MitoQ (P=0.0367) and SS31 (P=0.0438) relative to untreated STHDhQ111/Q111 neurons. The cell apoptosis assays revealed that both apoptotic and necrotic cell deaths were reduced in

STHDhQ111/Q111 neurons treated with Mdivi 1, MitoQ and SS31 compared to untreated neurons. Mitochondrial ATP production was increased and hydrogen peroxide levels reduced in in STHDhQ111/Q111 neurons treated with Mdivi 1, MitoQ and SS31 relative to untreated STHDhQ111/Q111 neurons. mtDNA-nDNA ratios analysis revealed that mtDNA copy numbers were reduced in STHDhQ111/Q111 neurons treated with Mdivi 1, MitoQ and SS31 relative to untreated STHDhQ111/Q111 neurons. CONCLUSIONS These findings suggest that Mdivi1 and MitoQ and SS31 protective against mutant-Htt induced mitochondrial and synaptic damage in HD neurons and that Mdivi1 and MitoQ and SS31 are promising molecules to study *in vivo* using HD mouse models and also to study in clinical trials using HD patients.

Title: Role of TNFα in regulating corticostriatal synapses in the Huntington's disease

Authors: ***R. DUSEJA**[1,2], G. M. LEWITUS[2], H. F. ALTIMIMI[2], M. FRANQUIN[2], D. STELLWAGEN[2];

Abstract: Huntington's disease (HD) is caused by mutation of the huntingtin (HTT) gene leading to an expansion of glutamine in the protein. The disease is primarily characterized by the

degeneration of the medium spiny neurons (MSNs) in the striatum. MSNs are broadly classified as direct pathway neurons (primarily expressing dopamine D1 receptors) and indirect pathway neurons (preferentially expressing D2 receptors). Abnormal alterations in the corticostriatal glutamatergic inputs to the MSNs are thought to underlie many striatal dysfunctions, and contribute to the motor deficits that characterize HD. Mechanisms by which mutant HTT alters these synapses are largely unknown. One possibility is that synaptic strength may be regulated by the pro-inflammatory cytokine Tumor Necrosis Factor alpha (TNFα), a well-known component of HD. TNFα levels are elevated in the striatum, cerebrospinal fluid and plasma of the HD patients, but its contribution to the development of the HD is not well characterized. We recently identified TNFα as a novel factor regulating corticostriatal synapses. Here, we investigate the role of TNFα in regulating the corticostriatal synaptic strength in the YAC128 animal model of HD. At pre-symptomatic age (2 months), we observed a decrease level of TNFα protein in the striatum of YAC128 mice. This is accompanied by an increase in synaptic strength (as measured by an increase in AMPA/NMDA ratio) specifically on direct pathway D1-MSNs. No change was observed in the synaptic strength on D2-MSNs nor in release probability, suggesting the change in the synaptic strength is post-synaptically driven. To further investigate the role of TNFα, we generated the YAC mice on TNF null background. Interestingly, our preliminary data indicates that YAC128 mice on TNF null background do not demonstrate an increase in AMPA/NMDA ratio. We are also behaviorally characterizing these mice. So far, our behaviour data suggests that in comparison to WT mice, YAC128 mice have gait alteration. Conversely, YAC128 mice on TNF null background do not demonstrate any alteration in the gait. Overall, our data suggest that TNFα may be regulating synaptic strength and motor output of the striatum during HD.

Title: Reduced Foxp1 expression as a contributor to Huntington’s disease

Authors: *A. LOUIS SAM TITUS[1], S. D'MELLO[2];
[1]Dept. of Mol. and Cell Biol., UNIV OF TEXAS AT DALLAS, Dallas, TX; [2]Dept. of Biol. Sci., SOUTHERN METHODIST UNIVERSITY, Dallas, TX

Abstract: Huntington's disease (HD) is an inherited neurodegenerative disease caused by the abnormal expansion of a CAG repeat in the first exon of the huntingtin gene resulting in a mutant protein with a poly-glutamine expansion. Although mutant huntingtin (mut-Htt) is expressed ubiquitously in the brain, neurodegeneration in HD occurs selectively in the striatum and, to a lesser degree, the cortex. The reason for the selective vulnerability is not known. We propose that reduced expression of the Foxp1 gene is an important contributor to the selective vulnerability of the striatum and cortex in HD. We and others have found that Foxp1 is expressed highly and selectively in the striatum and, to a lesser degree, the cortex. Foxp1 expression is reduced in the striatum and cortex, but not in other brain regions of R6/2 mice. Other labs have reported reduced Foxp1 expression in the striatum of HD patients. Expression of Foxp1 is also reduced in cultured cortical neurons induced to die by oxidative stress, a feature implicated in HD-related neuronal loss, but not in dying cerebellar granule neurons which are not affected in HD. Knockdown of Foxp1 expression induces death in otherwise healthy cortical neurons suggesting that elevated expression of this gene is necessary for neuronal survival. Indeed, restoring elevated levels of Foxp1 protects cortical neurons against mut-Htt neurotoxicity. Foxp1 overexpression also prevents death of cortical neurons resulting from oxidative stress. Besides the commonly studied ~90 kDa isoform, there are two other isoforms that are ~50 and ~70 kDa in size. The ~70 kDa Foxp1 is also expressed highly and selectively in the striatum and cortex, is robustly and selectively downregulated in the striatum and cortex R6/2 mice, and is neuroprotective when overexpressed. Current studies in the lab are focused on investigating the mechanism underlying neuroprotection by Foxp1.

[2]Dept. of Psychiatry, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Huntington's disease (HD) is caused by a CAG repeat expansion in huntingtin (HTT). Recent evidence suggests that HD is a consequence of multimodal, non-mutually exclusive mechanisms of pathogenesis that involve both HTT protein- and HTT RNA-triggered mechanisms. Here we provide further evidence for the role of expHTT in HD by demonstrating that a fragment of expHTT is neurotoxic in the absence of any translation and that the extent of neurotoxicity is similar to the neurotoxicity of an expHTT protein fragment encoded by a transcript of similar length and with a similar repeat size. In addition, full-length (FL) expHTT is retained in the nucleus. Overexpression of the splicing factor muscleblind-like 1 (MBNL1) increases nuclear retention of expHTT and decreases the expression of expHTT protein in the cytosol. This suggests that MBNL1 plays a role in nuclear export of expHTT RNA. We propose that nuclear RNA export is an important component of the pathogenesis of HD and that preventing the retention of expHTT RNA may have therapeutic potential.

Title: Altered lysosomal positioning in a cellular model of Huntington's disease

Authors: M. L. LU[1], *J. WEI[2];
[1]Biomed. Sci., [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Huntington's disease (HD) is an inherited monogenic neurodegenerative disease caused by an abnormal polyglutamine (polyQ) expansion in the huntingtin protein (Htt). Full length Htt is a 350KDa cytosolic protein that has been demonstrated to regulate the dynamics and trafficking of various subcellular organelles, including mitochondria and lysosomes. In the current study, we investigated the subcellular distribution of lysosomes in two clonal striatal cell lines derived from wild-type (STHdhQ7/Q7, hereafter referred as STHdhQ7) and mHtt (STHdhQ111/Q111, hereafter referred as STHdhQ111) knock-in mice using both anti-lamp1 immunostaining and live-cell imaging with lysoTracker red DND-99. The degrees of lysosome segregation/positioning were quantified. We found that in STHdhQ7 cells lysosomes were distributed throughout the cytosol. In contrast, STHdhQ111 cells display a more segregated lysosome distribution mainly accumulated in the perinuclear regions. The same results were observed in primary fibroblasts derived from a healthy human individual and a HD patient. This perinuclear lysosomal accumulation can be reversed by ectopically expressing normal Htt in HD cells. Further characterizing the functional significance of the increased perinuclear lysosomal accumulation in HD cells, we demonstrate subsequently that basal mTORC1 activity is increased in HD cells. In addition, autophagic influx is also increased in HD cells in response to serum deprivation, which leads to a premature fusion of lysosomes with autophagosomes. Taken together, our data suggest that the increased perinuclear accumulation of lysosomes may play an important role in HD pathogenesis by altering lysosomal-dependent functions.

Title: Identification of Cellular Pathways that are Dysregulated in Huntington's disease

Authors: *A. BAHARANI[1], S. NAPPER[2];
[1]Dept. of Biochem., [2]VIDO, Dept of Biochem., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Huntington's disease (HD) occurs worldwide and the occurrence of the disease is 5 to 7 among 100,000 people. HD is an autosomal dominant, most commonly inherited neurological disorder that includes prominent motor, psychiatric and cognitive symptoms resulting from degeneration of neurons in the striatum and cerebral cortex. The genetic defect is the presence of expanded CAG repeats in the huntingtin gene resulting in long (>36) repeats of the amino acid glutamine in the huntingtin protein. The identification of signal transduction pathways that are dysregulated in HD will be completed through analysis, which will allow us to verify probable kinase targets.

Abstract: Huntington’s disease (HD) is the most common inherited neurodegenerative disease and is caused by CAG trinucleotide repeat expansions in the huntingtin gene. Although many neuronal cell types exhibit pathology in HD, medium spiny neurons (MSNs) of the striatum are among the most vulnerable cell populations. The reason for this enhanced vulnerability is unknown but could offer opportunities for therapeutic intervention and a better understanding of the molecular mechanisms underlying mutant Huntingtin action. In both human HD and mouse

models of the disease, MSNs lose expression of cell type-specific markers, including Ppp1r1b (DARPP-32), Drd1a, Drd2, and Penk, suggesting that loss of MSN molecular identity is a hallmark of HD pathogenesis. We have previously shown an increase of polycomb repressive complex 2 (PRC2) activity in mouse models of HD. Here we show preliminary data suggesting that the PRC2-dependent mark H3K27me3 is present at MSN marker genes along with the canonical H3K4me3 mark of transcriptional activation, indicating that these genes are "bivalently" marked. By experimentally increasing H3K27me3 in wild-type mouse striatum, we demonstrate decreased expression of MSN markers and motor phenotypes reminiscent of HD. Our data suggest a model in which the loss of MSN identity and motor phenotypes caused by mutant huntingtin are linked to PRC2 activity.

Abstract: Huntington's disease (HD) is a neurodegenerative disorder caused by an expansion of poly-glutamine (or polyQ) repeats in the *huntingtin* (*HTT*) gene. Interestingly, striatum and deep layer cortex undergo widespread degeneration while other brain regions are less affected. This differential vulnerability cannot be explained merely by expression of the mutated HTT, as the protein is found across all brain regions. In order to gain insight into the molecular basis of this selective neurodegeneration, we took advantage of the translating ribosome affinity purification (TRAP) methodology to uncover any differences that may underlie this phenomenon. Profiles of 25 different brain regions revealed elevated expression of non-HTT polyQ repeat proteins in

vulnerable HD cell types, namely striatal medium spiny neurons and deep layer cortical pyramidal cells, in contrast to less vulnerable regions. These proteins are mostly nuclear-localized transcription factors and RNA-interacting proteins. It is known that polyQ proteins can interact with expanded HTT, influencing its aggregation and toxicity. Moreover, certain polyQ proteins have been demonstrated to co-aggregate with mutant HTT, leading to a loss of their function which can be rescued by their overexpression. Based on our initial findings, we hypothesized that a cell's polyQ load might dictate its vulnerability to mutant HTT-induced degeneration. Analysis of HD mouse models reveals co-aggregation of mutant HTT with striatal- and cortical-enriched polyQ proteins identified by TRAP. These proteins lose their typical diffuse nuclear expression in HD, which may interfere with their ability to bind DNA and regulate transcription. Interestingly, this phenomenon of polyQ co-aggregation was specific to mutant HTT as opposed to other expanded CAG repeat proteins. The ataxin proteins contain expanded glutamine repeat stretches in the spinocerebellar ataxia diseases, yet striatal- and cortical-enriched polyQs do not co-aggregate with expanded ataxin proteins in the absence of striatal involvement. Taken together, our work suggests that elevated expression of polyQ proteins defines vulnerable cell populations in HD. The co-aggregation of these proteins with mutant HTT and their subsequent loss of function contributes to the striatal and cortical degeneration observed in HD.

Title: Frontal hypoconnectivity in the 16p11.2 microdeletion autism model

Authors: ***A. BERTERO**[1,2], G. DAVID[2], A. LISKA[2], A. GALBUSERA[2], M. PASQUALETTI[2,1], A. GOZZI[2];

Abstract: Autism spectrum disorder (ASD) has been often associated to the presence of reduced or aberrant functional brain connectivity as measured with resting state functional Magnetic Resonance Imaging (rsfMRI). However, great heterogeneity exists in the distribution and expression of these alterations, and little is known on the pathophysiological and genetic determinants underlying these deficits. Human chromosome 16p11.2 microdeletion, a trait associated to mild intellectual disability, is the most common gene copy number variation in autism, accounting for approximately 0.5-1% of all ASD cases. By using rsfMRI in a mouse model of human chromosome 16p11.2 microdeletion, we show that this genetic alteration results in circuit specific functional connectivity reductions. Specifically, we show that 16p11.2+/- mice exhibit reduced rsfMRI connectivity between retrosplenial and dorsal prefrontal areas of the mouse "default mode network". Similarly reduced connectivity was observed between insular and prefrontal portions of the mouse "salience network". Evidence of reduced thalamo-prelimbic connectivity was also observed. No genotype-dependent inter-hemispheric, fronto-hippocampal, and local connectivity differences were recorded. Collectively, our findings recapitulate hallmark neuroimaging findings in ASD and identify plausible macroscale circuital alterations underlying some of the cognitive deficits produced by 16p11.2 microdeletion.

Title: Motor and behavioral phenotypes in a novel transgenic rat model of Rett Syndrome

Authors: ***K. PATTERSON**, K. ARPS, M. OLSEN;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Rett Syndrome is an x-linked neurodevelopmental disorder caused by mutations in the transcriptional regulator MeCP2, affecting approximately 1 in 10,000 girls annually.

Historically, researchers have utilized transgenic mouse models in the study of this disease. Recently, Sage® Labs made available a transgenic rat model of Rett Syndrome (SD- Mecp2 ^{tm1sage}). This model, which contains a 74 base pair deletion in exon 4 of the MECP2 gene, displays a functional knockout of MeCP2 protein. Here, we track changes in growth as well as motor and behavioral deficits of male and female rats throughout development, and outline the utility of this specific model in the study of Rett Syndrome. Heterozygous females develop symptoms at varying developmental time points, with the majority displaying abnormalities such as increased body weight by 4 months of age. Mutant males are noticeably symptomatic as early as weaning, displaying lethargy and an unkempt appearance. Malocclusion develops in the majority of mutant males by the 4th-5th week of life. Body weights do not differ between mutant and wild type males when animals affected by malocclusion are excluded from analysis. Our data suggest that mutant males demonstrate decreased brain weight by postnatal day 14, and display motor deficits as early as the fourth postnatal week as assessed by Rotor-Rod™ and Catwalk™ analysis. Additional deficits are observed in open field during advanced disease. Batteries of identical tests are underway utilizing females from weaning age through late adulthood.

Title: Loss of MeCP2 in the rat uniquely models regression, impaired sociability, and transcriptional deficits of Rett syndrome

Abstract: Mouse models of the transcriptional modulator Methyl-CpG-Binding Protein 2 (MeCP2) have advanced our understanding of Rett syndrome (RTT). RTT is a 'prototypical' neurodevelopmental disorder with many clinical features overlapping with other IDD/ASD whose pathogenesis may be similar. Therapeutic interventions for RTT may therefore have broader applications. However, the reliance on the laboratory mouse may present challenges in translating findings from the bench to the clinic, and the need to identify outcome measures in well-chosen animal models is critical for preclinical trials. Therefore, we set out to identify disease-relevant neurobehavioral deficits that can be uniquely modeled in a rat model of Rett syndrome, and to compare transcriptional changes in MeCP2 rodent models and human Rett brain tissue. We found that female *Mecp2* rats display psychomotor regression of a learned skill and impairments in juvenile play, two behavioral deficits that are unique to the rat model and that are highly relevant to RTT. We also demonstrate that the strategy of analyzing the loss of *Mecp2* in both mouse and rat may result in higher predictive validity with respect to transcriptional changes in human RTT brain. These data underscore the similarities and differences caused by the loss of MeCP2 among divergent rodent species which may have important implications for the treatment of individuals with disease-causing *MECP2* mutations. Taken together, these findings demonstrate that the *Mecp2* rat model is a complementary tool with unique features for the study of RTT and highlight the potential benefit of cross-species analyses in identifying potential disease-relevant preclinical outcome measures.

Abstract: Mouse models of autism spectrum disorders (ASD) have been instrumental in our current understanding of the neurobehavioral consequences caused by disease-causing human mutations. Neurobehavioral deficits are prominent in ASD, and the use of genetic tools such as the laboratory mouse, is one approach to identify potential therapies that may improve these impairments. However, given the concerns that findings from mouse models may not necessarily reflect changes that are relevant to the human condition, and the possibility that such models may be sub-optimal for translational studies, we set out to test the neurobehavioral phenotypes in novel rat models of specific ASD genes to determine the extent to which genetic manipulation of these genes in a second mammalian rodent species results in similar and/or different neurobehavioral deficits. Focusing on *Fmr1* male rats, and *Pten, Cntnap2, Nrxn1* and *Met* male and female rats, we evaluated juvenile animals using both conventional neurobehavioral assays and assays that can be uniquely studied in the rat. We found that several of these rat lines displayed phenotypes that are not completely consistent with reported findings in the mouse, including abnormalities in social behavior and rodent communication (ultrasonic vocalizations), two core features of ASD. However, for other secondary features of ASD such as sensorimotor gating deficits and cognitive impairments, we found that some lines displayed alterations that were consistent between rat and mouse ASD models. These data suggest that the ASD rat models may prove to be complementary tools to the existing repertoire of ASD animal models, providing certain unique advantages for studying behavioral phenotypes including social and cognitive assessments. Moreover, given the conflicting data between mouse and rat ASD models, these findings underscore the importance of investigating the consequences of disease-causing human mutations in a variety of animal model systems.

Title: Assessing the mecp2 (bird) model of rett syndrome across species, sex, and age

Authors: D. BRUNNER[1], *P. A. KABITZKE[1], M. OSBORNE[2], A. BARBOZA[2], L. THIEDE[1], N. ROBERTS[1], T. HANANIA[1];
[1]Psychogenics, Tarrytown, NY; [2]Psychogenics, Montvale, NJ

Abstract: X-linked MECP2 gene mutations in humans have been shown to be associated with loss of voluntary movements, including speech and hand movements. Male MECP2 homozygous mice are commonly used in preclinical studies and show a distinct phenotype but typically do not survive past 3 months of age and cannot perform many behavioral tests due to their compromised state. The female MECP2 Bird mouse (Mecp2tm1.1Bird) lacks one copy of the Mecp2 excised with Cre-loxP technology, has normal survival and appears quite healthy. However, we found that this model shows increased hindlimb clasping, weaker grip strength, and impaired ability to remain on the rotarod. The female Mecp2 Bird mouse also exhibits decreased acoustic startle response and decreased optokinetic response as measured by turning of the head in the direction of stripe movement, a measure of reflexive behavior and smooth eye tracking. In addition, female Bird mice reproduce the apnea phenotype seen in Rett. Lastly, female Bird Rett mice from 6 weeks of age onward demonstrate a distinct gait phenotype as measured in PsychoGenics' proprietary NeuroCube® System. This high- throughput system can quantitatively asses a disease phenotype, can quantify drug recovery, and has been validated in many drug discovery and screening studies. A novel model, the Mecp2 heterozygous rat (SAGE) showed similar gait deficits starting at 8 weeks of age, extending the availability of robust models of Rett with face validity.

Title: Serotonin abnormalities in the mouse model of 16p11.2 deletion syndrome

Authors: C. M. PANZINI[1], A. M. ALCHAHIN[1], Y. GUO[1,2], *K. G. COMMONS[3]; [1]Anesthesia, Boston Children's Hosp., Boston, MA; [2]Second Affiliated Hospital, Harbin Med. Univ., Harbin, China; [3]Anesthesia, Children's Hosp, Harvard Med., Boston, MA

Abstract: In humans the 16p11.2 deletion syndrome is caused by a loss of a chromosomal segment that encodes about 25 genes. This microdeletion results in variable deficits and features of autism, developmental delay and intellectual disability are common. Mouse models of 16p11.2 deletion syndrome have been developed and these animals have several behavioral abnormalities and are typically hyperactive. In addition, there is evidence for altered basal ganglia organization in 16p11.2 deletion syndrome mice. Serotonin neurotransmission has long been associated with autism, yet it remains poorly understood if altered serotonin neurotransmission could represent a common deficit in autism generated by distinct genetic or environmental factors. In this study, we evaluated several measures of serotonin neurotransmission in 16p11.2 deletion mice (df/+) and their wild-type (WT) littermates (Jackson Labs B6129S-Del(7Slx1b-Sept1)4Aam/J; Horev et al., PNAS 2011). Bred with B6129F1/J for at least 8 generations, df/+ mice were present in a Mendelian ratio but weighed less then their WT siblings at postnatal day 28. Behavior in response to an acute stress (swim) was studied, as this stimulus is known to activate the serotonin system. While WT mice habituated during the swim test and showed increasing passive coping with time, df/+ mice perseverated with an active coping strategy. HPLC analysis of monoamine content of the dorsal striatum showed that swim

changed the levels of dopamine and its metabolites in both genotypes, but in addition df/+ mice had altered serotonin turnover after the swim. 5-HT2A receptors are involved in basal ganglia function and some drugs used for autism interact with 5-HT2A receptors. To evaluate the role of 5-HT2A receptors in altered behavior we tested the effects of the antagonist, M100907 (Volinanserin). Df/+ mice were more sensitive to M100907 then their WT siblings, and a dose of 0.01 mg/kg attenuated their behavioral abnormalities in the swim. Parallel results were found with locomotor behavior in the open field. Taken together, these findings suggest altered endogenous 5-HT2A receptor tone may exist in df/+ mice, and may contribute to their behavioral phenotype.

Title: Absence of parvalbumin results in an Autism Spectrum Disorder-like phenotype in mice

Authors: *F. FILICE, B. SCHWALLER;
Anat. Unit, Univ. of Fribourg, Fribourg, Switzerland

Abstract: Autism spectrum disorder (ASD) patients are characterized by impairments in social interaction, communication and stereotyped patterns of behavior, interests, and activities. ASD-associated genes often encode proteins that are implicated in synaptic transmission and/or structure. Functionally these changes result in an impairment of neurotransmission at individual synapses and at the network level, in modifications of e.g. the excitation/inhibition (E/I) balance that might be caused by mutations in ASD risk genes during earlier steps in neurodevelopment. Within the global neuronal network, interneurons play a key role in the maintenance of the overall balance of activity and interneuron dysfunctions are linked with cognitive impairment in neuropsychiatric disorders. In particular, the number of fast-spiking interneurons (FSI) expressing the calcium-binding protein parvalbumin (PV) has been reported to be decreased in different well-assessed mouse models of ASD. PV-deficient mice (PV-/- and PV+/-) show ASD-like symptoms similar to ones reported in other “canonical” ASD mouse models (Wöhr et al.,

2015). According to the current view, the decrease in PV-immunoreactive (PV-ir) neurons in mouse ASD models is the result of a “loss” of PV-expressing FSI, leading to a change in the E/I balance. Based on the ASD-like phenotype observed in mice with reduced (PV+/-) or absent PV (PV-/-) expression, we hypothesized that PV-downregulation, i.e. without a loss of the PV neurons, might be sufficient to elicit the ASD-like traits. Stereology-based analyses of a particular extracellular matrix component surrounding most PV-ir neurons, termed the perineuronal nets (PNNs), revealed the number of PNN-positive cells to be unchanged in WT, PV+/- and PV-/-. Thus, a mere down-regulation of PV affecting intracellular Ca2+ signaling appears to be sufficient to result in an ASD-like behavioral phenotype. Current experiments aim to testing whether PV-downregulation and/or PV-neuron loss is the cause for the previously reported decrease in the number of PV-ir neurons in other well-established mouse ASD models. An unchanged number of “PV-FSI” in those genetic models would indicate that PV-downregulation might represent a common/convergent pathway for some types of ASD with different genetic etiologies.

Title: Generation and analysis of autism model marmoset

Authors: ***N. KISHI**[1,2], K. SATO[3], M. OKUNO[1,2], H. J. OKANO[4], E. SASAKI[1,2,3], H. OKANO[1,2];
[1]RIKEN BSI, Saitama, Japan; [2]Dept. of Physiol., Keio Univ. Sch. of Med., Tokyo, Japan; [3]CIEA, Kawasaki, Japan; [4]Jikei Univ. Sch. of Med., Tokyo, Japan

Abstract: In the human brain, there are two major functional domains. One has been conserved in all mammals through evolution and governs fundamental functions such as reward, emotion and memory; the other is unique to primates, and is acquired through the enlargement of the cerebral cortex governing special functions such as tool use, language, and self-consciousness.

Thus, to properly understand these brain functions, we need appropriate animal models for studying each function. Animal models that are used to analyze brain functions are different in each case. In the former, a reductive approach is adopted based on gene manipulation using models such as genetically-modified fish and rodents, while in the latter, the main approach is psychological and involves complex behavior analysis using non-human primates such as macaque monkeys. Many researchers believed that the complementary nature of genetic engineering technologies in rodent and fish models and cognitive neuroscience techniques in primate research would lead to progress in this research field. However, due to lack of appropriate animal models that can be analyzed in both aspects of the brain's functions, contact points between these two approaches have been limited. The development of genetically engineered non-human primates has attracted attention for its potential to connect the two research fields. Recently, we succeeded in creating the world's first transgenic primate using marmosets. This technological breakthrough provides a potential paradigm shift by enabling researchers to analyze both the brain functional domains using various model marmosets. Currently, we are developing a technique for creating knockout marmosets using zinc finger nuclease (ZFN) technology. By combining this technique with the development of cognitive information for marmoset brain analysis, innovative MRI imaging technology and marmoset genetic analysis tools, we created and are analyzing MECP2 mutant marmosets suitable for research on Rett syndrome, to understand the pathogenesis, and to contribute to new therapeutic strategies to treat Rett syndrome.

Title: Early postnatal treatment with lipopolysaccharide (LPS) as a mouse model of immune-mediated ASD

Authors: A. J. ALEXANDER[1], S. M. LANDINO[1], C. J. MCDOUGLE[2], *B. C. FINGER[1], W. A. CARLEZON[1];
[1]Dept. of Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA; [2]Lurie Ctr. for Autism, Massachusetts Gen. Hosp., Lexington, MA

Abstract: The role of immune responses in the etiology of autism spectrum disorder (ASD) has long been hypothesized. Indeed, it is thought that a "multiple hit" model may apply to ASD whereby multiple immune insults early in life may increase the risk of developing an ASD. To further investigate this hypothesis, we developed a mouse model of immune-mediated ASD using a double-immune challenge approach. Pregnant mice were injected with the viral mimic poly(I:C) (20 mg/kg) on day 12.5 of pregnancy. The offspring were subsequently injected with lipopolysaccharide (LPS) (10 mg/kg) on postnatal day 9.5 to induce a bacterial infection. A battery of tests were performed in a 2x2 factorial design to characterize the behavioral phenotype in relation to the core symptoms of ASD: deficits in communication and social interaction, and increases in stereotyped behaviors. To assess deficits in communication, ultrasonic vocalizations were recorded from male pups during a maternal separation test on postnatal days 10-16 and from adult males at 9 weeks in a female encounter test. In pups, postnatal LPS treatment significantly increased the number of calls emitted, independent of prenatal treatment. However, this altered communication did not persist into adulthood, with no significant difference between groups in a test involving an encounter with a female conspecific. To assess deficits in social interaction, a one-chamber social interaction test was performed using males and females at 8 weeks. In males, postnatal LPS decreased social preference independent of prenatal treatment. There was no effect of prenatal or postnatal treatment on social preference in females. To assess anxiety, both males and females at 10 weeks of age were scored on an open field test. There was a mild anxiogenic phenotype in mice that received postnatal LPS, irrespective of sex or prenatal treatment. Additionally, to assess stereotypic behavior, mice were tested in a marble-burying task at 11 weeks. In males only, postnatal LPS caused an altered pattern of behavior that was independent of prenatal treatment. Our results indicate that postnatal immune challenge with LPS causes alterations in communication, social preference, anxiety and stereotypic behavior. However, prenatal poly(I:C) did not reliably produce any of these ASD-related phenotypes, and did not increase phenotype severity when administered in combination with postnatal LPS, going against the multiple-hit hypothesis. More experiments are necessary to further characterize this model, but these data suggest that immune insults early in postnatal development may produce behavioral changes that can be used to study immune-mediated ASD.

Title: Effects of cerium oxide nanoparticles on learning and motor behavior in the valproic acid rat model of autism spectrum disorder

Authors: W. E. DECOTEAU[1], A. E. FOX[1], J. LICATA[1], J. PARISE[1], *A. Y. ESTEVEZ[2]; [1]Psycholgy, [2]Biol., St. Lawrence Univ., Canton, NY

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by communication deficits, repetitive behaviors, and impairments in social interactions. Increased oxidative stress, possibly from the exposure to environmental toxins has been proposed as a cellular mechanism contributing to the development of ASD. Valproic Acid (VPA) is an environmental toxin that generates oxidative stress and has been linked to ASD. The VPA model is one of the most widely used rodent models of ASD; however, it is unclear whether this model exhibits learning and behavioral deficits similar to those observed in humans with ASD. It is also unknown whether those deficits could be ameliorated by treatment with cerium oxide nanoparticles (CeNPs), a powerful and novel anti-oxidant. In the present experiment, we examined whether *in utero* exposure to VPA (500mg/kg, ip) can generate specific learning and behavioral deficits and, if so, whether pre-treatment with CeNPs (20 mg/kg, iv) can serve as a therapeutic protection against those deficits. Pregnant rats were treated with either CeNPs or vehicle on gestation day 11.5 and then exposed to VPA on gestation day 12.5. A third group was given vehicle injections on both gestation days. Pups from each group were weaned and then tested on a battery of tasks that assessed their motor skill, temporal discrimination, and novelty detection. Abnormal motor behavior, usually in the form of hyperactivity, was observed in the VPA rats across all tasks. Compared to controls, VPA rats displayed poor habituation and re-exploration on the novelty recognition task. Interestingly, VPA rats learned the time discrimination task faster than controls and exhibited transient elevated response rates. Motor skill deficits were moderately ameliorated in animals treated with CeNPs *in utero*. This result is consistent with the therapeutic effect of CeNP that has recently been described in animal models of motor neurodegeneration.

Title: The genetic intersection of neurodevelopmental disorders and shared medical comorbidities-relationships that translate from bench to bedside

Authors: A. J. STEVENSON[1,2], *J. PLUMMER[1], P. LEVITT[1,2];
[1]The Saban Res. Institute, Children's Hosp. Los Angeles, Los Angeles, CA; [2]Keck Sch. of Medicine, Univ. of Southern California, Los Angeles, CA

Abstract: The search for the heritability of mental illness and neurodevelopmental disorders (NDDs) has led to the discovery of underlying genetic and cellular mechanisms. While there is brain enrichment in the expression of NDD risk genes, these typically exhibit expression in peripheral tissues as well. Thus, there is potential shared biological liability, which has led to the present hypothesis that there are specific patterns of convergent medical comorbidities related to NDD genes. To explore this possibility, we examined the phenotypes associated with approximately 200 NDD risk genes. We conducted a comprehensive search of Psychiatric Genomics Consortium, ADHDgene, Simons Foundation Autism Research Initiative, Online Mendelian Inheritance in Man, and NCBI Gene databases - PhenGen, ClinVar and the Genetic Testing Registry. The database search included >500 genes, of which 200 were prioritized based on 1) brain expression, 2) citation by multiple studies and/or 3) functional validation. These 200 genes were initially grouped by their primary NDD association, then further stratified by additional genetically-associated organ system disorders and comorbidities. NDD gene network analysis revealed underlying relationships among psychiatric disorders and peripheral comorbidities that include cancer, cardiovascular disease, renal disorders, respiratory disorders and metabolic disorders, demonstrating a broader impact of brain-associated genes in other developing organ systems. Patterns of genes with overlapping comorbidities emerged, highlighting that genetic mutations in patients with NDDs can specifically affect other organ systems. These relationships emphasize the clinical importance of recognizing NDDs as more than simply brain disorders. In an era when personalized medicine is becoming an expected part

of clinical practice, understanding the comorbidities associated with given genetic mutations will facilitate the identification of additional health challenges. Ultimately, data can be used to optimize holistic treatment and management of patients with NDDs.

Title: Dissecting autism heterogeneity in developing mice

Authors: ***M. KAS**;
Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: About 1 in 100 children suffers from an autism spectrum disorder (ASD). These neurodevelopmental disorders are clinically defined by impairments in social interaction and by restricted, repetitive and stereotyped behavior. Most of the autistic behaviors become manifest in the first years of life; a time when brain circuits are being shaped by sensory experiences. However, ASD is a highly heterogeneous disorder with respect to severity and variability of symptom expression; some patients show predominantly stereotyped behaviors whereas others may have mainly deficits in social behavior development. As human genetic studies have identified over 200 ASD risk genes, the challenge is to understand how these gene defects lead to individual variation in impaired social interaction and/or stereotyped behavior. By implementing a longitudinal behavioral test battery in mice, we have shown that genetic mouse models for ASD displayed different characteristics of impaired social interaction or stereotyped behavior at different stages in development. Understanding these neurodevelopmental trajectories may open up the possibility of reversing these core phenotypes by means of adequate therapeutic strategies.

Title: Animal model module of AutDB aligns its PhenoBase with ASD phenotypes

Authors: I. DAS, *M. A. ESTEVEZ, S. BANERJEE-BASU;
Mindspec, Inc., Mc Lean, VA

Abstract: The Autism Database (AutDB) is a publicly available, manually annotated, modular database that serves as an ongoing collection of genes linked to Autism Spectrum Disorders (ASD). Here, we describe the design, development and integration of the animal model module of AutDB which catalogues ASD-related rodent models. All data is extracted from published, peer-reviewed primary reports. In addition to ASD models, the animal model module also contains rescue models based on existing parent ASD models. The new release of the database also includes rat models in addition to mouse models, since both of these species are widely used in current research. We aim to include other species as the database grows. The metadata is standardized in a phenotypic database (PhenoBase), which is a routinely updated comprehensive list of phenotypic terms (pheno-terms) and experimental paradigms. These pheno-terms reflect the actual research and are divided into categories that align with human ASD phenotypic features. The recently updated PhenoBase has been standardized to about 380 pheno-terms divided into 16 categories. This standardization allows for data mining and bioinformatics analysis that coupled to our large curated dataset can be used to elucidate ASD research trends and etiology.

Title: Is the sympathetic hyperactivity involved in the cardioprotection against to myocardial lesions by ischemia and reperfusion in hypertensives animals?

Authors: *F. S. MENEZES RODRIGUES[1], J. G. P. TAVARES[2], P. R. ERRANTE[2], M. C. M. REIS[3], R. MIRANDA-FERREIRA[2], L. DE PAULA[2], B. LUNA FILHO[3], A. CARICATI-NETO[2];
[1]Pharmacol., Univ. Federal De São Paulo - EPM, Diadema, Brazil; [2]Pharmacol., [3]Cardiol., Univ. Federal de São Paulo - Escola Paulista de Medicina, São Paulo, Brazil

Abstract: INTRODUCTION: It is well known that cardiac lesions by ischemic (I) and reperfusion (R), typical of acute myocardial infarction, compromise cardiac structure and function, and yet that these lesions induce sympathetic hyperactivity (Lameris et al, Circulation, 2000). Although the sympathetic mechanisms could be involved in cardioprotective response (Tavernier et al, Cardiovasc. Res., 2003), the cardioprotector role of these mechanisms remain unclear. OBJECTIVE: Using a study model of arterial hypertension (Spontaneously Hypertensive Rats, SHR), which sympathetic activity is increased (Miranda-Ferreira et al, JPTE, 2009), we decided to investigate if the response to cardiac I/R is altered in situations related to sympathetic hyperactivity such as hypertension. METHODS: Male SHR and its normotensive controls (NWR) of 12 to 16 weeks were anesthetized (urethane 1.25 g/kg, i.p.), kept under mechanical ventilation and submitted to surgical procedures to induce cardiac I/R by means occlusion of left anterior descendent coronary artery (10 min) and reperfusion (120 min). Electrocardiogram (ECG) system was coupled to rats submitted to cardiac I/R to evaluate the incidence of ventricular arrhythmia (VA), atrioventricular blockade (AVB) and lethality (LET). The serum concentration of specific marker of myocardial lesions, creatine kinase-MB (CK-MB), was evaluated. The effects of ischemic preconditioning (preIC) in NWR submitted to cardiac I/R was studied. RESULTS: Compared to NWR, systolic blood pressure and cardiac mass are significantly increased in SHR (51% and 20%, respectively). Incidence of VA, AVB and LET resultant of cardiac I/R was significantly lower in SHR (40%, 20% and 21%, respectively) than in NWR (85%, 79% and 70%, respectively). The increase of serum concentration of CK-MB induced cardiac I/R lesions was lower in SHR (16%) than in NWR (129%). These results suggest that SHR could develop adaptive cardioprotective responses similar those produced by preIC. This hypothesis was confirmed by results obtained in the NWR pretreated with preIC and submitted to cardiac I/R, in which the values of VA (28%), AVB (0%) and LET (14%) were significantly lower compared to NWR submitted to cardiac I/R alone. CONCLUSIONS: The similar responses to cardiac I/R observed in SHR and NWR pretreated

with preIC suggest that sympathetic hyperactivity associated to arterial hypertension and cardiac I/R could stimulate a set of adaptive responses able to mitigate myocardial dysfunctions and lesions caused by I/R. Financial support - FAPESP, CAPES and CNPq

Title: Rare inherited genetic variation in a multiplex family with autism and language disorders

Authors: ***L. JONSSON**[1], C. MINISCALCO[2], M. JOHNSON[2], T. MARTINSSON[3], J. MELKE[1];
[2]Gillberg Neuropsychiatry Centre, Inst. of Neurosci. and Physiology, the Sahlgrenska Acad., [1]Univ. of Gothenburg, Goeteborg, Sweden; [3]Dept. of Clin. Genet., Inst. of Biomedicine, Sahlgrenska Univ. Hospital, Univ. of Gothenburg, Gothenburg, Sweden

Abstract: BACKGROUND: Genetic studies of autism spectrum disorders (ASDs) support an important role for multiple rare variants in the etiology of these conditions. Identified genetic variants include both copy number variations (CNVs) and single nucleotide mutations. Furthermore, inherited as well as de novo variants seem to contribute to the risk of developing an ASD. METHODS: In our study, we explore both rare single nucleotide mutations and CNVs in a multiplex family with two children with autism. Thirteen family members, of whom several have variable degrees of ASD related conditions and language problems, are included in the analyses. The index children both have an ASD diagnosis as well as language disorder. We used both CNV (Affymetrix 6.0) and whole exome sequencing (Illumina) to identify rare inherited variation. *In vitro* functional assays using COS-1 cells have been performed for one of the identified mutations in the CYP11A1 (p.T369M), coding for the cholesterol side-chain cleavage

Deleted: In vitro

enzyme (P450scc). RESULTS: Our main finding is a rare gain-of-function mutation in CYP11A1 (p.T369M) that codes for the first enzyme in steroidogenesis.The mutation was found in both index children and in five other family members. Three rare paternally inherited CNVs have been identified in regions with no or few previously reported CNVs; 6q15 (~40 kb deletion), 11q21 (~75 kb deletion) and 4q34.3 (~57 kb deletion). Only the deletion in the 6q15 region contains a gene; the RNA Guanylyltransferase And 5'-Phosphatase (RNGTT) gene that is involved in transcription regulation. DISCUSSION: Our exploratory investigation of a family searching for both CNVs and rare single nucleotide mutations using WES has identified both rare CNVs and mutations that may be of importance in this family. In our analyses we did not find any previously identified causal variants for autism, however the identified gain-of-function mutation in CYP11A1 is in line with previous findings suggesting increased steroidogenic activity in autism.

Title: Rescuing forebrain commissure defects in a mouse model of autism: Can we also alter relevant behaviors?

Authors: K. MANLEY[1], A. SNYDER-KELLER[1,2], G. W. BOTHE[1], K. KLUETZMAN[1], *V. J. BOLIVAR[1,2];

Abstract: Mouse models, such as the BTBR T+ Itpr3tf/J (BTBR) strain, play an important role in the elucidation of the biological mechanisms underlying autism spectrum disorder (ASD) and the development of new therapeutic interventions. BTBR mice display multiple ASD-relevant behavioral abnormalities (e.g., reduced social interactions, impaired communication, increased

repetitive movements). However, the genetic and neurological bases for these behavioral abnormalities remain unknown. As BTBR mice also exhibit corpus callosum (CC) and hippocampal commissure (HC) malformations, we hypothesized that these neuroanatomical phenotypes could be related to ASD-relevant behaviors. We recently developed two CC/HC rescue models on a BTBR genetic background. We developed a congenic mouse line by transferring a locus on the distal end of Chromosome 4 from FVB/NJ (FVB) to BTBR and a C57BL/6 (B6) derived BAC from the same Chromosome 4 locus was used to create a transgenic line. Mice from these two lines were evaluated in a behavioral test battery (open field, zero maze, social approach, self-grooming). We also determined structure size by staining sections using 0.2% gold chloride and measured midsagittal CC and HC area. BTBR mice carrying none, one, or two copies of the FVB locus were evaluated in littermates from the congenic line, and hemizygous B6 BAC transgenic mice were compared to non-transgenic littermates. The congenic mice revealed rescue of the CC and HC phenotypes in the presence of one or two copies of the FVB locus. The B6 BAC transgene was sufficient to rescue CC/HC phenotypes in hemizygous BTBR mice. We are also correlating structure size with performance on each of the behavioral assays. Our research should lead to a better understanding of the biology underlying forebrain commissure development and the subsequent effects on ASD and related behavioral phenotypes.

Abstract: Serotonin (5-HT) is known to play a role in the neural development, affecting cortical connectivity (Lauder, 1990, Bonnin et al., 2007, Bonnin et al., 2011). Due to the long history of 5-HT as a biomarker for autism spectrum disorder (ASD), alterations in 5-HT metabolism have become a focus of interest in attempting to determine the etiology of ASD (Persico et al., 2014). In addition to classical deficits in social communication repetitive behaviors, sensory symptoms are a core diagnostic feature of ASD (DSM-5). Given the importance of 5-HT in early cortical development, and the evidence for sensory disturbances that extend beyond a single sensory system, a plausible hypothesis is that changes in serotonin signaling may play an underappreciated role in the abnormal connectivity patterns in sensory cortices in ASD. To study this question, we used a mouse model with a known Gly56Ala mutation in the serotonin transporter SERT (or 5-HTT), encoded by the SLC6A4 gene. In humans this mutation causes increased serotonin reuptake and has been associated with autism and compulsive behavior. The knock-in (KI) mice were compared to the 129s4/s6 hybrid background mice. The goal was to examine the laminar organization and distribution of thalamocortical axons and serotonin axons in primary visual cortex (V1) and a known multisensory cortical area (V2L). Adult mice from each group were perfused and brains cut in either the coronal or parasagittal plane. Sections were immune-stained for vesicular glutamate transporter 2 (VgluT2) to identify thalamic axons and 5-HT to label serotoninergic axons. Adjacent sections were also stained for cytochrome oxidase (CO) to identify cortical layers. Cortical layers were equally distinct between the KI and WT animals in V1 and V2L in CO sections. In VgluT2 stained sections, however, distinct differences could be seen in V1, with significantly less label in layer 4 and in the superficial layers of the mutants compared to background mice. In V2L VgluT2 was very dense in layer 4 and layer 1 of both groups but did not appear to differ between the mutant and background groups in any cortical layer. In the 5-HT immunostained sections the most obvious difference was in the distribution of axons in V2L. Here, in KI animals the 5-HT labeled axons were much more diffusely distributed within the cortex and showed less clear laminar boundaries. These findings support the idea that alterations in cortical connectivity associated with changes in 5-HT signaling may play an important role in the known pattern of sensory and multisensory deficits in ASD.

Title: Detailed spectral analysis of Fragile X Syndrome mice vocalizations, a model to study speech deficits

Authors: *A. BELAGODU, A. JOHNSON, R. GALVEZ;
Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Fragile X (FX) Syndrome is the leading form of inherited mental retardation. It is caused by the transcriptional silencing of fmr1, the gene which codes for the fragile X mental retardation protein. Patients that have FX have been shown to exhibit numerous behavioral and cognitive impairments, such as ADHD, OCD, and autistic-like behavior (Miller et al., 1999; Cordeiro et al., 2011). In addition to these behavioral abnormalities, FX patients have also been shown to exhibit various deficits in speech and language. Studies in human FX patients have shown that they form abnormal sentence structures and have issues with utterances, increased repetition of sounds and words, and articulation (Largo and Schinzel, 1985; Hanson et al., 1986; Price et al., 2008). To study the biological underpinnings of these speech abnormalities, studies have used a mouse model of the fragile X syndrome. These studies have examined pup ultrasonic vocalizations (USV) due to either maternal or mating separation in FX mice and have shown various differences in the number and duration of vocalizations produced (Rotschafer et al., 2012; Roy et al., 2012; Lai et al., 2014). However, these findings were inconsistent between age groups, and did not provide a detailed investigation into spectral properties of the USVs. Deficits in USV spectral properties, such as mean frequency and frequency modulation rate, have been shown to be indicators of vocal deficits in other rodent disease models, such as aging and Parkinson Disease (Johnson et al., 2015). Therefore, detailed spectral analysis of FX mouse USVs could reveal vocal deficits and strengthen the neuroethological relevance of this model. To assess the spectral qualities of USVs in FX mice, a standard mating separation procedure was used (Johnson et al. 2011). Individual adult male mice were briefly exposed to an adult female mouse. Once the male expressed an interest in the female, the female was removed which elicited USVs from the male. The male USVs were recorded using an ultrasonic recording system (Avisoft, Germany) and analyzed using an existing custom MatLab program designed to detect, spectrally analyze, and classify mouse USVs (Holy and Guo, 2005). Our findings demonstrated that adult FX mice exhibited differences in various spectral properties and syllable formation compared to their wild-type counter parts. Furthermore, differences in USV production and quality in FX mice mirrored many vocal deficits seen in human FX vocalization patterns. This study provides a vital model for examining the biological factors mediating voice and speech abnormalities in Fragile X patients.

Title: Fragile x knockout mice show alterations in activity levels and ultrasonic vocalization behaviors

Authors: S. NOLAN, C. REYNOLDS, G. SMITH, A. HOLLEY, M. VOLQUARDSEN, T. JEFFERSON, A. PANDIAN, T. SMITH, J. HUEBSCHMAN, *J. N. LUGO, JR;
Psychology and Neurosci., Baylor Univ., Waco, TX

Abstract: Fragile X Syndrome (FXS) is a neurodevelopmental disorder caused by an overexpansion of a trinucleotide (CGG) repeat in the FMR1 gene coding for fragile x mental retardation protein. This disorder is characterized by intellectual disability as well as other behavioral abnormalities. In this study we examine ultrasonic vocalizations on postnatal days 10 and 12; locomotor activity, anxiety, and repetitive behavior in adult male and female FMR1 wild type and knockout (KO) mice using the FVB strain. We found that FMR1 knockout mice produce more ultrasonic vocalizations at the 60 kHz $t(1, 25) = 2.7$, $p < 0.05$; and at the 80 kHz level $t(1,25) = 2.3$, $p < 0.05$. They also produced a longer duration of 60 kHz calls at compared to the WT mice $t(1,25) = 2.4$, $p < 0.05$. When we examined the FMR1 knockout mice in adulthood we found several behavioral differences compared to wild type mice. We found a significant increase in total distance moved $t(1,31) = 3.7$, $p < 0.001$; increase in stereotypy time $t(1,31) = 2.32$, $p < 0.05$; and increase in rearing behavior $t(1,31) = 2.3$, $p < .05$ in the FXS knockout mice compared to wild type. We did not observe any significant alterations in anxiety through the elevated plus maze test or alterations in repetitive behavior through the marble burying test. Our results demonstrate that KO mice have altered communicative behavior during the early developmental periods, are hyperactive, and demonstrate some alterations in repetitive behavior. We are examining social behavior and learning and memory through other tests to examine the behavioral phenotype of the FMR1 knockout mice.

Title: Fmr1 knockout rats express hippocampus-dependent, spatial and episodic-like memory, impairments

Authors: ***A. ASIMINAS**[1,2], S. M. TILL[3,2], S. CHATTARJI[5,6], D. J. A. WYLLIE[3,2,6], P. C. KIND[3,2,6], E. R. WOOD[4,2];
[2]Patrick Wild Ctr., [3]Ctr. for Integrative Physiol., [4]Ctr. For Cognitive and Neural Systems, [1]The Univ. of Edinburgh, Edinburgh, United Kingdom; [5]Natl. Ctr. for Biol. Sci., Bangalore, India; [6]Ctr. For Brain Develop. And Repair, Bangalore, India

Abstract: Fragile X syndrome (FXS) is the most common monogenic cause of intellectual disability and Autism Spectrum Disorder. It is, in most cases, caused by epigenetic silencing of the fragile X mental retardation gene (Fmr1), causing a loss of Fragile-X mental Retardation Protein (FMRP). The mouse model of FXS (Bakker et al., 1994) has been proven invaluable in FXS research so far, however the subtle and strain-specific behavioural phenotype has raised question over the validity of the model. The recent generation of a rat model of FXS paves the way for determining whether certain phenotypes are species or strain-specific or persist across mammalian species. We have recently shown that Fmr1-/y Sprague-Dawley (SD) rats exhibit a

deficit in object-place-context task recognition (OPC) (Asiminas et al, SfN 2014. Poster 699.15). This hippocampus-dependent task requires the integration of object-location and contextual cues to form an episodic-like memory (Langston & Wood 2010). Here, we explore whether Fmr1-/y Long-Evans-Hooded (LEH) rats exhibit the same deficit, to determine whether this phenotype persists across strains. LEH rats (n=16 Fmr1-/y, n=16 Fmr1+/y) were tested in 4 spontaneous exploration tasks: novel object preference (NOP), object-context (OC), object-place (OP), and object-place-context (OPC). These tasks assessed the ability to discriminate novel from familiar objects, and novel from familiar object-context, object-place and object-place-context associations over a short (2 min) delay. Both groups showed significant memory in NOP, OC and OP tasks but only Fmr1+/y performed above chance in OPC task. Fmr1-/y rats showed a decreased preference for novelty in OC and OP, and their ability to discriminate novel from familiar object-place-context (episodic-like) associations was significantly impaired. Spatial and object recognition memory were further assessed using object-displacement (OD) and NOP tasks at both short (2min) and long (24h) delay. Fmr1-/y rats performed significantly worse than Fmr1+/y littermates in OD task at both delays and in NOR at the 24h delay. These data are consistent with your previous findings in SD rats and indicate that episodic-like (OPC) memory and spatial (OD) memory are impaired in Fmr1-/y rats - across strains (LEH and SD). Deficits in these hippocampus-dependent tasks strongly suggest impaired hippocampal function which agrees with well-reported plasticity deficits in the mouse model of FXS and our recent work with SD Fmr1-/y rats (Till et al, SfN 2013. Poster 810.10). This robust deficit in Object-place-context memory, across rat strains, provides an assay against which potential therapeutics could be tested.

Title: Study the fmr1 gene knock- out effects on the development of social- related behaviors by using zebrafish model

Authors: ***M. T. HSU**[1], Y. J. WU[1], Y. L. YANG[2], K. T. LU[1];
[1]Dept. of Life Sci., Natl. Taiwan Normal Univ., Taipei, Taiwan; [2]Biochem. Sci. and Technol., Natl. Chia-Yi Univ., Chia-Yi, Taiwan

Abstract: Fragile X syndrome (FXS) is most generally hereditary form of human mental retardation. Previous research indicated that the most frequently cause of FXS was induced the abnormally function of the fragile X mental retardation 1 (fmr1) gene by triplet repeat expansion (CGG) mutation. The common symptoms of fragile X patients included learning disabilities, inattention, hyperactivity, anxiety, autistic behaviors, social impairments et al. In the present study, the fmr1 KO zebrafish model was applied for studying the behavioral effect of fmr1 gene, in order to clarify the relationship between the gene and the animal behaviors. We studied variable behavioral phenotypes, including shoaling behavior, social preference behavior, locomotor activity, and anxiety-like behavior. In summary, comparing with wild-type control, we found that 14 dpf fmr1 KO fish showing lessen total moving distance on locomotor activity. Conversely, there was more moving distance in the 28 dpf KO fish. Previous results showed the shoaling behavior would form in 14 dpf either wild- type or the fmr1 KO fish. However, the duration of closing to cluster of fishes would increase in the 28 dpf fmr1 KO fish. Then, according to another research, it showed that precocious development of social preference behavior in the 14 dpf fmr1 KO zebrafish, and the effect would sustain into adulthood. In addition, we wanted to investigate the factors of inducing above phenotypes, and we specially focused on the anxious expression. Therefore, we used the novel tank, a popular model for studying anxiety- like behavior, to analyze anxiety of the fmr1 KO fish. Results indicated that the fmr1 KO fish spent less time in upper half in the third 5 minutes interval, which displayed higher anxiety in the late larval stage of the fmr1 loss- off function. In conclusion, our results indicated that having highly relationship between the functions of fmr1 and the development of social- relative behaviors. Furthermore, the elevated anxiety status may account for the abnormal social- relative behaviors in fmr1 KO fish. We suggested that fmr1 KO zebrafish is an idea model for pre-clinical drug screening of autism.

Title: Effects of reduced levels of BDNF expression on the differentiation of neural progenitors in Fragile X syndrome

Authors: *V. S. ACHUTA, G. TURCONI, M. CASTREN;
Physiol. Dept., Univ. of Helsinki, Helsinki, Finland

Abstract: Fragile X syndrome (FXS) is the most common cause of inherited intellectual disability and a well characterized form of autism spectrum disorder. A triplet repeat expansion in the *FMR1* gene leads to transcriptional silencing and the absence of FMR1 protein (FMRP) in FXS. FMRP is a RNA binding protein essential for maturation and function of synapses and neuronal networks. Neural progenitor differentiation is altered in the absence of FMRP. Studies of *Fmr1* knockout (KO) mice, a mouse model of FXS, have revealed alterations of glutamate and brain-derived neurotropic factor (BDNF)/TrkB signaling in FXS brain. BDNF signaling is also affected in FMRP-deficient progenitors. We compared the differentiation of FXS and wild-type neural progenitors and examined the role of BDNF in the alterations of the differentiation of neuronal cells in FXS neurospheres. Mouse cortical progenitors were generated from *Fmr1* KO mice and double transgenic mice deficient of both FMRP and BDNF. Human neural progenitors were differentiated from induced pluripotent stem (iPS) cell lines reprogrammed from somatic cells of individuals with a triplet repeat mutation in the *FMR1* gene and characterized by pluripotency markers, karyotyping, and genetic mutation analysis. Cell imaging and intracellular calcium recordings with Fura-2 were used to examine the cell kinetics and functional responses to glutamate receptors at different stages of neuronal differentiation. We found alterations in the responses to activation of metabotropic glutamate receptors by (S)-3,5 dihydroxyphenylglycine (DHPG) and ionotropic glutamate receptors by kainate and N-methyl-D-aspartate (NMDA) in human and mouse FXS neural progenitors. The reduced BDNF expression modified the maturation of glutamate responses and cell migration in mouse progenitors lacking FMRP. Altogether, our results show that BDNF contributes to the alterations of transmitter plasticity in FXS.

Title: Deficits in adult neurogenesis in Fragile X Syndrome

Authors: *C. DAVIS[1], M. DEMARS[2], J. LARSON[3], O. LAZAROV[2];
[2]Anat. and Cell Biol., [3]Psychiatry, [1]Univ. of Illinois At Chicago, Chicago, IL

Abstract: Fragile X Syndrome (FXS) is the most prevalent inheritable form of mental retardation in humans and is the most common known genetic cause of autism. FXS is an X-chromosome-linked disorder characterized by hypermethylation of a CGG repeat expansion in the promoter region of the Fmr1 gene causing gene silencing and subsequently a deficiency of the fragile X mental retardation protein (FMRP). Studies have demonstrated impaired synaptic function and plasticity in the brain in the absence of FMRP. However, the mechanism underlying mental retardation is not fully elucidated. Adult neurogenesis is implicated in learning and memory and in brain plasticity. Neurogenesis takes place in the subgranular layer (SGL) of the dentate gyrus (DG) of the hippocampus and the subventricular zone (SVZ). Here, we examined whether deletion of fmr-1 affects neurogenesis in adult Fmr1 knockout (Fmr1-KO) mice. We show that the number of fast-proliferating cells is dramatically reduced in the SVZ and the SGL in Fmr1-KO mice when compared to wild type littermates. Additionally, the rate of survival of neuroblasts in the SGL was dramatically compromised. Finally, we show that these impairments result in significantly fewer mature neurons in the DG of the Fmr1-KO mice. Taken together, these results suggest that compromised neurogenesis may cause reduced plasticity and may underlie learning deficits in FXS.

Title: Postnatal hippocampal neural precursor cells show an altered cell cycle profile in the Fragile X mouse

Authors: ***M. SOURIAL**, H. LIANG, L. C. DOERING;
McMaster Univ., Hamilton, ON, Canada

Abstract: Fragile X Syndrome (FXS) is the leading single gene cause of autism and inherited intellectual impairment. It results from the epigenetic transcriptional silencing of the Fragile X Mental Retardation 1 (*FMR1)* gene, and the consequent loss of expression of the Fragile X Mental Retardation Protein (FMRP). FMRP plays an important role in synaptic plasticity and has been implicated in neural precursor cell (NPC) proliferation and differentiation. We have shown that hippocampal NPCs isolated from *Fmr1* knockout (KO) mice have different expression profiles of SOX2, Nestin, and Ki67 *in vitro* compared to their wild type (WT) counterparts, which indicated an altered proliferative capacity of *Fmr1* KO NPCs. Thus, the current experiments assess the *in vivo* expression of NPC markers and the cell cycle profile in the hippocampus of postnatal *Fmr1* KO mice. Postnatal day 4 (P4) mouse hippocampi were dissociated and fixed with ethanol and the DNA was stained with propidium iodide to analyze cell cycle phases. Preliminary results indicate that hippocampi from *Fmr1* KO mice show an increased proportion of cells in the S and G2/M phases compared to WT mice. Based on the fact that cells with low to medium levels of CD133 and an absence of CD24 generate neurospheres (spherical clusters of NPCs *in vitro*), continuing experiments using flow cytometry comparing NPC expression of CD15, CD24, and CD133 will help to elucidate the effects of FMRP on the proliferative capacities of NPCs. In line with our previous findings, our current results demonstrate that the proliferation of NPCs in the hippocampus is significantly affected in FXS.

Title: Auditory stimulation differentially deactivates ERK in the amygdala of juvenile FMR1 KO mice susceptible to audiogenic seizure (AGS): effect of GABA(A) modulation

Authors: M. H. DAVENPORT[1,2], A. A. ASHWORTH[1], M. S. STEGMAN[1], C. A. ERICKSON[1], *T. L. SCHAEFER[1];
[1]Div. of Psychiatry, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Biomed. Engin., Univ. of Cincinnati, Cincinnati, OH

Abstract: Fragile X Syndrome (FXS) is the most common single gene cause of autism spectrum disorder and intellectual disability. FXS is caused by a CGG repeat expansion in the 5' UTR of the Fragile X Mental Retardation 1 (FMR1) gene that leads to loss of expression of the Fragile X Mental Retardation Protein (FMRP). Patients are characterized by a range of intellectual, behavioral, and physical impairments, including increased risk of seizure, hypersensitivity to auditory stimuli, and increased fear and anxiety. These phenotypes are recapitulated in the Fmr1 knock out (KO) mouse model of FXS. The immediate early gene, extracellular signal-regulated kinase (ERK1/2), has long been implicated in FXS pathophysiology and basal levels of ERK1/2 activation have been shown to be increased in brain regions important for fear processing and cognition. In the context of FXS, ERK signaling is thought to be a convergence point for a variety of cellular signaling cascades and is used as an indication of aberrant cellular signaling in both mouse and human studies. In normal behaving rodents, cell-type and regionally specific coordination of activation and deactivation of ERK is known to be required for appropriate behavior. Here, we show an increased number of immuno-positive cells expressing activated ERK in the central amygdala (CeA; output center of the amygdala) with no differences in sporadic expression in the lateral amygdala (LA; main input center of the amygdala) during basal conditions in juvenile Fmr1 KO mice. However, immediately following an audiogenic seizure (AGS) paradigm, ERK1/2 phosphorylation is dramatically reduced in the CeA and increased in the LA of Fmr1 KO mice that experience tonic/clonic seizure activity compared to both WT and Fmr1 KO mice that do not seize. To reduce hyper-excitability in the brain of FXS mice, we acutely treated juvenile Fmr1 KO mice with a GABA(A) alpha 2, 3 agonist (AZD7325). AZD7325 treatment reduced the seizure susceptibility of Fmr1 KO mice in a dose dependent manner. Even in this treatment experiment, mice who exhibited seizure activity regardless of dose still demonstrated ERK deactivation in the CeA and increased activation in the LA. This indicates that region specific alterations in ERK activity within the amygdala are concomitant with seizure activity and further demonstrates that ERK phosphorylation change upon sensory stimulation plays an important role in FXS associated signaling and behavioral deficits. We are currently working to determine the specific cell types that express activated ERK in the CeA and LA at both basal and following AGS to better understand the circuitry that is disrupted in the developing FXS brain.

Title: Nmdar nr2a and nr2b specific pkc-dependent regulation of mglur is defective in the fragile x syndrome mouse model

Authors: ***T. G. BANKE**, A. K. H. TOFT;
Aarhus Univ., Aarhus, Denmark

Abstract: The Fragile X Syndrome (FXS) animal model, the Fmr1 knock-out (KO) mouse, has demonstrated an increased mGluR5-mediated long-term depression (LTD). However, surprisingly little information exists about other ion channels/receptors and their effects on FXS, including NMDA receptors (NMDAR). Here we focus on the two main types of hippocampal LTD: (1) NMDA-dependent, and (2) mGluR-dependent but NMDA-independent, at different developmental stages. We applied the mGluR agonist DHPG in the presence or absence of the NMDAR competitive antagonist, APV, hereby unmasking the NMDAR component in this process. As reported by several labs, using the field potential recording technique in acute slices from young mice (P30-40), application of DHPG, in the presence of APV, induced more LTD in the KO mouse than in the control mouse (41+/-5%, n=7 vs. 21+/-4%, n=5, $P<0.05$). In the absence of APV, DHPG induced the same amount of LTD in KO vs WT (39+/-6%, n=11 vs. 33+/-5%, n=7, P=0.2), suggesting that NMDARs play an insignificant role in DHPG-induced LTD in both the KO and WT mouse at this young developmental stage. As with young mice, in slices from mature WT mice (P60-80), there was no significant difference in DHPG-induced LTD in the absence of APV (28+/-6%, n=12) or in the presence of APV (32+/-5%, n=8). Equivalent LTD was obtained in the KO mouse in the presence of APV (36+/-6%, n=9). This was in sharp contrast to recordings from KO mice where we found in the absence of APV, no or very little LTD (7+/-5%, n=15). Similar results were observed when mature KO slices were

preincubated with the protein kinase C activator (PMA), or inactivator (chelerythrine), suggesting that NMDAR activation leads to PKC regulation of mGluR-LTD. Surprisingly, preincubation WT with the NR2B specific NMDAR inhibitor CP-101.606 completely blocked DHPG-induced LTD. This blockage was reversed by either preincubation with PMA or by co-application of the NR2A antagonist TCN-201. In contrast, application of TCN-201 alone had no apparent effects. Our data suggest a model where NMDARs regulate mGluR-LTD through regulation of PKC. Furthermore, in this model it appears that NR2B activation stimulates PKC, while NR2A activation halts or reverses this effect. In addition, in the KO mice, the coupling between specific NMDAR subunits and mGluR-LTD activity through PKC seems defective in an age-dependent manner. These findings suggest strong developmental involvement of NMDARs in the pathophysiology of FXS and highlight a novel potential path for FXS treatment.

Title: Network-level plasticity of Up states and evoked activity in Fragile X Syndrome circuits

Authors: ***H. MOTANIS**, D. BUONOMANO;
Dept. of Neurobio. and Pshychology, and Integrative center for learning, UCLA, Los Angeles, CA

Abstract: Since the generation of the first mouse model of FXS a broad range of neurophysiological phenotypes have been reported. However, it remains unclear which phenotypes are casually related to the cognitive deficits associated with FXS. Indeed, because many of these phenotypes are known to be modulated by experience, a confounding factor in the interpretation of many studies is whether some phenotypes are an indirect consequence of abnormal development or experience. *In vitro* developmental studies provide one approach towards addressing these confounds since observed phenotypes are more likely to arise from the genotype and not from abnormal experience or development. We previously found a significant developmental delay in the emergence of spontaneous activity and Up states in FXS circuits, demonstrating that developmental delays characteristic of FXS are recapitulated during *in vitro*

Deleted: In vitro

Deleted: in vitro

development, and that Up state abnormalities are likely direct consequence of the disease. Here we explore activity-dependent modulation of evoked and spontaneous activity in Fmr1-/y circuits. We used chronic optogenetic stimulation of organotypic slices to emulate a developmental increase in externally driven activity, and induce homeostatic plasticity of spontaneous and evoked network activity. After transfection AAV5-CaMKIIa-ChR2(H134R)-EYFP, slices from WT and Fmr1-/y mice were optically stimulated for 2 days. Whole-cell recordings were made from layer II/III pyramidal neurons. Chronic optical stimulation of both WT and Fmr1-/y circuits resulted in a significant reduction of spontaneous Up states: Up state frequency were significantly reduced following stimulation ($F_{2,46}=25.42$, $p<10^{-7}$). And there was no genotype difference in the homeostatic decrease in Up states, indicating that Fmr1-/y circuits exhibit normal homeostatic plasticity. Chronic optical stimulation also induced a significant decrease of evoked EPSP strength ($F_{1,41}=9.28$, $p<0.005$), as measured by the asymptotic strength of the evoked EPSP, and two-way ANOVA revealed a significant genotype effect ($F_{1,41}=8.08$, $p<0.01$). Importantly, the EPSP strength in unstimulated Fmr1-/y circuits was smaller compared to unstimulated WT circuits ($p<0.05$) indicating abnormal baseline response in Fmr1-/y circuits. These results indicate that while activity induced plasticity of spontaneous Up states is normal in "mature" cortical Fmr1 circuits, the baseline EPSP strength and plasticity of EPSPs is not. These results provide the first steps towards using cortical organotypic cultures as a reduced system to unravel the circuit level mechanisms that underlie the learning deficits that characterize FXS.

Title: Altered number of neural population activity patterns in Fragile-X mice

Authors: ***C. O'DONNELL**[1], J. T. GONCALVES[1], C. PORTERA-CAILLIAU[2], T. J. SEJNOWSKI[1,3];
[1]Salk Inst. For Biol. Studies, La Jolla, CA; [2]Departments of Neurol. and Neurobio., UCLA, Los Angeles, CA; [3]Div. of Biol. Sci., UCSD, La Jolla, CA

Abstract: Brain disorders such as Fragile X syndrome (FXS), autism and schizophrenia have been associated with different changes in neural function, such as an imbalance in excitation and inhibition, hyperexcitability, and altered synaptic connectivity. Why or how these particular changes would be detrimental for neural coding remains unknown. Here we test the hypothesis that these cellular changes affect information processing by shifting the typical number of activity patterns used by the circuit. We analyzed spontaneous activity of neural populations in somatosensory cortex recorded *in vivo* using two-photon calcium imaging in both wild-type and Fmr1 knockout mice, a model for FXS. We developed a new statistical model for the probability distribution of all 2^N possible neural population activity patterns that required only N^2 parameters, where N is the number of neurons. Using this analysis method, we found that even subtle alterations in neural firing rates and correlations in Fmr1 knockout animals, relative to wild-type, across development lead to dramatic shifts in the typical number of circuit activity patterns. Adolescent Fmr1 knockout mice showed fewer neural activity patterns than wild-type, while the opposite was true in adult mice. Using a computational model of mouse layer 2/3 somatosensory cortex, we explored the contributions of the underlying circuit components, leading to two main conclusions: first, there are multiple non-exclusive neurobiological routes to altered circuit dimensionality. Second, the type of parameter changes needed to reverse the FXS deficits is qualitatively different in adolescent versus adult mice. If also true in humans, this result suggests that a pharmaceutical intervention that can successfully reverse symptoms in adults with FXS might prove ineffective or possibly even exacerbate symptoms in children with this disorder. Altogether, our findings show how relatively small changes in neural circuit parameters in brain disorders can have dramatic consequences for information processing.

Title: Regulation of protein synthesis by Bcl-xL and its potential application in the treatment of Fragile X

Authors: ***P. LICZNERSKI**[1], P. MIRANDA[1], H.-A. PARK[1], M. BROWN[2], L. K. KACZMAREK[2], R. J. LEVY[3], E. A. JONAS[1];

Abstract: We have found previously that Bcl-xL, a member of the Bcl-2 family of proteins, acutely and chronically enhances synaptic connectivity in multiple ways. Bcl-xL- is necessary for certain forms of synaptic plasticity, alters mitochondrial positioning and metabolism in the synapse and directly affects vesicle trafficking. Our studies suggest that Bcl-xL could play a role in aberrant development of synapses observed in Fragile X syndrome (FXS). Indeed, studies in two different Fmr1 mutant strains showed increased expression of BcL-xL. So far we have found that: 1) Inhibition of Bcl-xL by the small molecule inhibitor ABT-737 produces a marked enhancement of protein translation. 2) The increased rate of protein translation produced by ABT-737 is comparable to or greater than that produced by FMRP knock out. 3) The increase in protein translation produced by ABT-737 is occluded in the Fmr1-/- mouse neurons, suggesting that inhibition of Bcl-xL or genetic deletion of Fmr1 both produce an effect on protein translation perhaps through the same mechanism. The present study examines the gene pool translationally-regulated by Bcl-xL and addresses the possibility of Bcl-xL to regulate protein translation by modulating the cross-talk between mitochondria and endoplasmic reticulum (ER) via Mitochondria-Associated Membranes (MAMs).

Abstract: Fragile X Syndrome is caused by loss of FMR1 gene activity and is the most commonly inherited form of cognitive impairment and autism. Patients with this disorder also suffer from hyperactivity, attention deficit disorder, irritability, sleep problems and have noted neuro-anatomical defects. A *Drosophila* fragile X model, based on loss of dfmr1 function, displays several relevant phenotypes, including defects in circadian regulation, social interaction (with peers and in naïve courtship), memory and morphology of some neurons in the brain. Here we show that the memory deficits displayed by dfmr1 mutants can be rescued by reducing histone deacetylase activity. We demonstrate that pharmacologic treatments with trichostatin A or sodium butyrate given in development and in adulthood can rescue immediate recall memory, short term memory and long term memory in fragile X flies. Our results indicate that histone deacetylase inhibitors can rescue cognitive phenotypes displayed by the *Drosophila* fragile X model, and thereby revealing another pathway that can be targeted by new and current drugs to treat fragile X patients.

Title: Altered cellular physiology of astrocytes in a model of fragile x syndrome

Authors: *A. L. SCOTT[1], C. CHENG[2], L. C. DOERING[1];
[1]Dept. of Pathology an Mol. Med., [2]McMaster Univ., Hamilton, ON, Canada

Abstract: Neural communication and the intricate choreography of signals required for the formation and preservation of neural connections is heavily dependent on reciprocal neuronal and glial interactions. Astrocytes are key participants in neurodevelopmental processes and defects to astrocyte signaling are implicated in many disease states characterized by abnormal neural circuitry, such as Fragile X Syndrome (FXS). In FXS, the loss of the Fragile X mental retardation protein (FMRP) expression from astrocytes in particular is associated with delayed dendrite maturation and improper synapse formation. These findings emphasize the importance of astrocyte-derived signals to the establishment of neuronal connections and illustrate the negative consequences an imbalance to these signals can cause. During development astrocytes release a wide range of neurotransmitters; however, the use of ATP is one of the predominant means of communication between astrocytes and neurons within the CNS. ATP is a fast, excitatory neurotransmitter known to act on astrocytes, modulate glio-neuronal transmission, and in this way regulate synaptic function. Given the integral role of ATP, and its various metabolites (ADP, AMP, adenosine), to the regulation of synaptic development and function, we compared the physiological responses of astrocytes isolated from either post-natal wild-type (FMRP+/+) mice or from transgenic fmr1 knockout (FMRP-/-) mice to exogenous ATP application. The ratiometric analysis of intracellular calcium levels measured with the calcium indicator Fura2-AM, revealed a significantly greater flux of intracellular calcium in FMRP-/- astrocytes in response to ATP than observed in FMRP+/+ astrocytes. The differences in calcium responses suggest that the sensitivity of the FMRP-/- astrocytes to ATP is abnormally enhanced, and may underlie atypical neural communication present during development in FXS. Future analysis of the effects on astrocyte-neuron purinergic signaling in the FMRP-/- model will help elucidate the

potential role these signals play in FXS. This work is supported by Brain Canada and the Azrieli Neurodevelopmental Research Program. A.L. Scott is a FRAXA postdoctoral fellow.

Title: Reduced cortical expression of astrocyte-secreted glypicans 4 and 6 in the fragile X mouse model

Authors: ***J. WALLINGFORD**, L. C. DOERING;
Pathology and Mol. Med., McMaster Univ., Hamilton, ON, Canada

Abstract: Astrocytes play an important role in the development and maintenance of proper neural circuitry within the CNS. Many neurodevelopmental disorders have been associated with aberrant astrocyte signalling and function, including fragile X syndrome (FXS). FXS, the most common inherited single gene cause of autism, is characterized by a deficiency in fragile X mental retardation protein (FMRP) via the silencing of the *fragile X mental retardation 1* (*FMR1*) gene. FMRP, which is expressed by both astrocytes and neurons, acts as an important regulator of synaptic development through its ability to bind, transport, and regulate the local translation of particular synaptic mRNAs. Using a Fragile X knockout (KO) mouse model we examined whether there are altered expression levels of the astrocyte-secreted factors SPARC-like 1 (SC1; also known as Hevin) and glypicans 4 and 6 (GPC 4/6), corresponding to FMRP deficient astrocytes. These factors play important and complementary roles during excitatory synapse development. While the matricellular protein SC1, a known target of FMRP, promotes the structural development of synapses, they are postsynaptically silent due to their lack of postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs). GPC 4/6, members of the heparin sulphate proteoglycan family, are involved in recruiting AMPARs to the postsynaptic membrane surface, inciting postsynaptic function. Cortical tissue from KO and WT mice (n=4/group) was collected at postnatal day 19 and analyzed for SC1 and

GPC 4/6 expression via Western blotting. Although we found no difference in cortical levels of SC1 between the groups, GPC 4/6 was reduced in the cortex of KO mice compared to controls. Further experiments will examine SC1 and GPC 4/6 levels in the hippocampus and at additional developmental time-points. These preliminary results suggest that reduced levels of GPC 4/6 may contribute to improper synapse development in FXS. This work is supported by Brain Canada and the Azrieli Neurodevelopmental Research Program.

Title: Developmental reductions in thrombospondin-1 expressing astrocytes characterize the fragile x mouse model

Authors: *C. CHENG, S. K. M. LAU, J. WALLINGFORD, L. C. DOERING;
McMaster Univ., Hamilton, ON, Canada

Abstract: Astrocytes are key participants in many aspects of brain development and function. Defects in astrocyte signaling are implicated in neurodevelopmental disorders characterized by abnormal neural circuitry, such as Fragile X syndrome (FXS). FXS is the most common inherited form of intellectual disability and autism spectrum disorders. FXS is caused by silencing of the fragile X mental retardation 1 (FMR1) gene, which results in the loss of the fragile X mental retardation protein (FMRP). Thrombospondin-1 (TSP-1) is an astrocyte-secreted protein that plays a critical role in regulating synapse formation and integrity during development. TSP-1 is expressed in immature astrocytes and its expression peaks during the first postnatal week in mice, which coincides with the expression of FMRP. Our earlier findings revealed that FXS astrocytes express a deficiency in cellular and secreted TSP-1, and affect synapse and spine development *in vitro*. In this study, we examine the developmental trajectory of TSP-1 expression in cortical astrocytes of fmr1 wild-type (WT) and knockout (KO) mice at 7, 14 and 21 days *in vitro* (DIV). We assessed TSP-1 expression by semi-quantitative

Deleted: in vitro

Deleted: in vitro

immunocytochemistry in cells co-labeled with the astrocyte markers, glial fibrillary acidic protein (GFAP) and aldehyde dehydrogenase 1 family, member L1 (ALDH1L1). Our results showed the highest expression of TSP-1 positive astrocytes in both WT and fmr1-KO mice to be at 7 DIV. The expression of TSP-1 subsequently declined in both WT and fmr1-KO astrocytes at later time points. Significant differences between WT and fmr1-KO astrocytes in TSP-1 expression were observed at 14 and 21 DIV. These results indicate that defects in the secretion of astrocyte-specific molecules during a critical window of development contribute to FXS neurobiology. This work is supported by Brain Canada and the Azrieli Neurodevelopmental Research Program.

Title: Astroglial fragile X mental retardation protein contributes to pathogenesis of Fragile X Syndrome

Authors: *H. HIGASHIMORI[1], C. SCHIN[2], Y. YANG[2];
[1]Neurosci., Tufts Univ., Boston, MA; [2]Tufts Univ., BOSTON, MA

Abstract: Fragile mental retardation protein (FMRP) is enriched in neurons and has been characterized as an important translational repressor in neurons; however, a selective deletion of FMRP in a significant number of cortical and hippocampal neurons showed only limited FXS related phenotypes. Here we aim to investigate what role the astrocyte specific loss of FMRP plays in FXS pathophysiology. We generated the inducible astrocyte specific fmr1conditional knock out (astro-fmr1-cKO) mice to investigate the pathogenic role of the selective deletion of astroglial FMRP in FXS. We found that the selective loss of astroglial FMRP particularly contributed to the reduction of GLT1 expression and function to a level similar to that of fmr1-/- animals we had previously observed. Moreover, the loss of astroglial GLT1 function in the astro-

fmr1-cKO mice was sufficient to increase the firing rate of neocortical layer 5 somatosensory pyramidal neurons by exposure to low doses of dihydrokainic acid (DHK), a GLT1 specific inhibitor. DHK did not have this effect on cortical neurons from control animals. Our findings thereby demonstrate that GLT1 dysfunction can reduce glutamate uptake in the astro-fmr1-cKO mice, causing neuronal cells to become hyper-excitable. We also found that the enhanced cortical neuronal excitability is due to the persistent activation of NMDA receptors by glutamate. This provides an increased tonic excitatory drive to somatosensory pyramidal neurons. We also observed immature synaptic morphology and increased cortical protein synthesis in the astro-fmr1-cKO mice, which recapitulates the FXS related phenotype. To further investigate the role of astrocytic FMRP function, we generated the inducible astrocyte specific fmr1 conditional restoration mice (astro-fmr1-cON). Inducing expression of FMRP in Astro-fmr1-cON mice restored cortical GLT1 expression, tonic excitatory drive and enhanced NMDA activation in the somatosensory cortex. This study is the first to address whether the dysfunction of the astroglial FMRP and glutamate transporter GLT1 contributes to the development of FXS. In the future, we will perform various behavioral assays on astrocytic conditional knockout and restoration mice.

Title: Effect of 5-HT7 receptor activation on dendritic spines in wild-type and Fmr1 knockout mice

Authors: M. SPATUZZA[1], S. D'ANTONI[1], G. LA QUATRA[1,2], C. M. BONACCORSO[3], M. LEOPOLDO[4], *L. CIRANNA[2], M. V. CATANIA[1,3];

Abstract: Serotonin (5-HT) is an important neurotransmitter expressed in different brain areas. 5-HT is involved in remodeling brain structures and circuits during development, through the modulation of several processes including neural cell proliferation, migration and differentiation, neurite outgrowth, axon guidance and synaptogenesis, control of dendritic spine shape and density. Recently, we have shown that activation of 5-HT7 receptors reverses metabotropic glutamate receptor-mediated long-term depression (mGluR-LTD) in wild-type (WT) and Fmr1 knockout (KO) mice (Costa et al., Biol Psychiatry. 2012, 72(11):924-33), a mouse model of Fragile X syndrome (FXS), which is characterized by an abnormally enhanced mGluR-LTD. Here, we extended our study to the examination of dendritic spine morphology and density, which are abnomal in FXS. We studied the expression of 5-HT7 receptors in synaptic plasma membranes (SPMs) prepared from cortices and hippocampi of WT and Fmr1 KO mice, and found that in SPMs of both regions 5-HT7 receptors are present in the post-synaptic fraction in both genotypes. We tested the effects of an acute systemic administration of the compound LP-211 (3 mg/Kg), a potent, selective and brain-permeant 5-HT7 receptor agonist in WT and Fmr1 KO mice. We evaluated dendritic spine density and morphology in the cortex and the CA1-CA3 areas of hippocampus by analyzing confocal microscopy images from slices labeled with the lypophilic tracer DiI. Our results indicate an increased spine density in both cortex and hippocampus in Fmr1 KO mice, which was not detected after LP-211 administration in both brain regions. Interestingly, the reduction of spine density in LP-211-treated Fmr1 KO mice affected thin spines. Our data suggest that *in vivo* administration of a selective agonist of 5-HT7 receptors results in the correction of increased spine density, a hallmark feature of FXS, suggesting that targeting of 5-HT7 receptors might be considered as a new therapeutic strategy for FXS.

Title: NKCC1 inhibitor rectifies critical period synaptic development and plasticity in Fragile X mice

Authors: ***Q. HE**[1], C. PIOCHON[2], A. CONTRACTOR[3];
[1]physiology, Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL; [2]Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [3]Physiology, Neurobio., Northwestern Univ. Feinberg Sch. of Medicine,Northwestern Univ. Weinberg Col. of Arts and Sci., Chicago, IL

Abstract: Disruptions in GABA signaling are prevalent in Fragile X syndrome (FXS) and may contribute to the alterations in synaptic development and hyperexcitability in the cortex of the mouse model of FXS (Fmr1-/y). We have recently determined that there is a delay in the normal polarity switch in GABA responses in cortical neurons during the critical period in FXS mice. This delay is accompanied by elevated expression of the juvenile chloride cotransporter, NKCC1. Here we have tested whether postnatal administration of the NKCC1 inhibitor bumetanide can correct the dysregulated progression of GABA reversal potential (EGABA), and whether this rescues known synaptic alterations in the developing somatosensory cortex. Fmr1-/y and littermate control (Fmr1+/y) pups were injected daily with bumetanide (0.2mg/kg) or saline solution beginning at postnatal day P0. Perforated patch-clamp recordings were made to measure EGABA in layer 4 cortical neurons in acute slices at postnatal day P10. In saline injected Fmr1-/y mice, EGABA remained relatively depolarized at -54 ± 7 mV (n=14). In contrast, recordings from bumetanide injected Fmr1-/y mice EGABA was hyperpolarized -82 ± 9 mV ($n = 8$, $P < 0.05$) and similar to EGABA in vehicle treated littermate controls. We next determined whether chronic bumetanide injection could also rectify the delay in synaptic development and critical period plasticity. EPSCs were evoked with a bipolar electrode placed in the ventrobasal thalamus and the amplitudes of the NMDAR and AMPAR components measured to calculate the NMDAR/AMPAR (N/A) current ratio. In saline injected Fmr1-/y, N/A ratio was 1.05 ± 0.11 ($n = 12$) at postnatal day P7. In contrast, bumetanide treatment reduced the N/A ratio to 0.76 ± 0.06 ($n = 12$ $P < 0.05$) in Fmr1-/y, which is similar to that in vehicle treated controls. In a separate cohort of animals we determined whether bumetanide could also rescue critical period synaptic plasticity alterations. This NMDAR dependent long-term potentiation, that is present at early postnatal times and absent at the closure of the critical period (P7), persists to a later developmental age in Fmr1-/y mice. In saline treated Fmr1-/y at P7, 1 Hz presynaptic stimulation paired with postsynaptic depolarization lead to a 130 ± 8 % ($n = 12$) potentiation of EPSCs. In recordings from bumetanide treated Fmr1-/y animals no significant potentiation was observed at this developmental stage (94 ± 7 %, $n = 8$, $P < 0.05$) similar to vehicle treated Fmr1+/y controls. Taken together our results demonstrate that chronic treatment with an NKCC1 inhibitor during the postnatal critical period can rectify synaptic development and plasticity phenotypes in the cortex of the FXS mouse model.

Title: Gaba signaling in adult-born neurons in fragile x syndrome

Authors: *C. REMMERS[1], A. CONTRACTOR[1,2];
[1]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Dept. of Neurobio., Northwestern Univ. Weinberg Col. of Arts and Sci., Chicago, IL

Abstract: Fragile X syndrome (FXS) is the most common form of inherited human mental retardation and also the single most common known cause of autism. FXS most often results from the expansion of a CGG repeat sequence in the 5' untranslated region of the gene, which leads to loss of expression of the Fragile X mental retardation protein (FMRP). Loss of FMRP in mutant mice (Fmr1 KO) leads to multiple phenotypic alterations including impaired learning and memory and alterations in synaptic plasticity. One important regulator of neuronal development that is disrupted in FXS is the inhibitory neurotransmitter GABA. During early development GABA is excitatory, and depolarizing GABA has trophic effects on proliferation, differentiation, dendritic morphogenesis, and synaptogenesis. These effects may be mediated by synaptic responses or by tonic activation of extrasynaptic GABA receptors. Recent studies in our laboratory have demonstrated that the switch in GABA polarity from depolarizing to hyperpolarizing responses is delayed in the cortex of perinatal Fmr1 KO mice. This delay is accompanied by elevated expression of the chloride co-transporter that is primarily responsible for maintaining the depolarized reversal potential for chloride ions, NKCC1. In the adult brain, depolarizing GABA is critical for the survival and development of adult-born neurons in the hippocampus. Previous studies have clearly demonstrated a role for FMRP in adult neurogenesis in the dentate gyrus; however, the mechanisms of this impairment are not known and the progression of the developmental switch in depolarizing GABA in adult-born neurons has not been assessed in the mouse model of FXS. Therefore there is a strong possibility that the impaired neurogenesis and related learning deficits are a result of an alteration in maturation of the GABA polarity switch. In this study we have used a retroviral labeling technique to birth-date newborn dentate granule cells in Fmr1 KO mice. Using perforated patch recordings from retrovirus labeled neurons we are able to determine whether the time course of depolarizing GABA in adult-born neurons is disrupted in Fmr1 KO mice. In addition, recording of tonic currents will determine whether there are changes in the driving force through GABA channels,

which could influence excitability of adult born neurons. Taken together these studies will be the first to determine whether alterations in GABA polarity can influence the functional properties of newborn neurons in FXS mice.

Title: Quantification of FMRP in human and mouse tissues by capture immunoassays

Authors: *W. BROWN, T. ADAYEV, R. KASCSAK, R. KASCSAK, C. DOBKIN, S. NOLIN, G. LAFAUCI;
Dept Human Genet., Inst. Basic Res., Staten Island, NY

Abstract: The Fragile X syndrome is due to mutations of the FMR1 gene that result in the absence of fragile X mental retardation protein (FMRP). We have developed a rapid, highly sensitive method for quantifying FMRP from dried blood spots and lymphocytes. This assay uses two new antibodies mAb 6B8 (Biolegend) and R477, a bacterially expressed abbreviated FMRP standard, and a Luminex platform to quantify FMRP. The assay readily distinguishes between samples from males with fragile X full mutations and samples from normal males. It also differentiates mosaic from non-mosaic full-mutation male samples. We have employed the assay to screen 2000 newborn dried blood spots (DBS) and present their distribution. We also applied the assay in a retrospective study of 76 newborn DBS that had been stored for an extended period and included full mutation males as well as normal individuals. We were able to correctly identify all 5 known male fragile X positive cases among samples stored up to 47 months. Using mAb 5C2 (Biolegend) and R477, we have also developed a similar immunoassay for the quantification of Fmrp in mouse tissues. This assay was used to quantify Fmrp in brainstem, cerebellum, hippocampus, and cortex strains of mouse (C57 BL and FVB) in seven and ten week-old animals, showing developmental variation. The latter assay will allow studying the developmental variation of Fmrp expression in different organs.

Title: A new proteomic profiling approach reveals dysregulation in ASD proteomes

Authors: *S. ARYAL[1,2], A. BHATTACHARYA[2], H. BOWLING[2], G. ZHANG[1], P. SMITH[3], K. KIRSHENBAUM[3], M. CHAO[1], T. NEUBERT[1], C. VOGEL[4], E. KLANN[2];

Abstract: Autism spectrum disorder (ASD) affects 1 in 68 children in the U.S. One of the hypotheses for a common molecular mechanism underlying certain ASDs is dysregulated protein synthesis that most likely arises from altered translational control. Mouse models that exhibit dysregulated translation, such as eIF4E transgenic mice (eIF4E Tg) and fragile X syndrome (FXS) model mice, display characteristic deficits in synaptic physiology and behaviors reminiscent of ASD. Therefore, identification and quantitation of the proteins that are synthesized and expressed aberrantly in the intact circuits of these ASD model mice could yield important clues in the pathophysiology of ASD. To accomplish this, we utilized an in-house developed combinatorial method of proteomic profiling that we term BONLAC (BONCAT-SILAC), which combines two established protein detection and profiling techniques. Using the technique, we were able to assess *de novo* protein synthesis and altered protein expression in hippocampal slices of eIF4E Tg and FXS mice as compared to their wild-type littermates. Using rank-order statistics based analysis, we measured over 500 consistently dysregulated de novo synthesized proteins in FXS mice and over 300 such proteins in eIF4E Tg mice, respectively. We also performed Gene Ontology and functional clustering analyses, which revealed enrichment of synaptic, cytoskeletal, and metabolic proteins in our results across the two ASD models. We

validated several of the candidate proteins using Western blots. We also performed bioinformatics analysis of the mRNA sequences of the newly synthesized proteins to explore any commonalities in sequence features that could serve as potential sites of convergent cis-regulation. Our results suggest that mRNA sequences of the proteins that are upregulated and downregulated in the eIF4E Tg and FXS mice have different cis-regulatory signatures in their untranslated regions. Our findings reveal systems level insights on the altered translational landscape in intact circuits of two mouse models of ASD.

Title: Defects in tactile stimulus evoked responses of layer 2/3 pyramidal neurons in the Fmr1-/y mouse model of Fragile X Syndrome

Authors: ***A. A. FRICK**, A. BHASKARAN, K. LE CORF, M. GINGER, G. BONY; INSERM U862, Neurocentre Magendie, Bordeaux, France

Abstract: Fragile X Syndrome (FXS) is the most common form of inherited mental retardation syndrome and a frequent cause of autism spectrum disorders (ASD). Defects in sensory information processing are a common feature of both FXS and ASD, but their underlying mechanisms are poorly understood. To understand the cellular and network basis of this phenomenon, we measured the sensory stimulus evoked properties of pyramidal neurons of layer (L) 2/3 of the primary somatosensory (S1) cortex of Fmr1-/y mice and their wildtype WT) littermates. Whole cell patch-clamp recordings were performed in the hindlimb area of S1 in anesthetized animals (P24-31) and sensory responses evoked using stimulation of the contralateral hindpaw. A companion poster (Bony et al., SFN 2015) describes the intrinsic

properties of these neurons and their sensory receptive fields under normal physiological conditions. In the Fmr1-/y mouse, sensory stimulation evoked postsynaptic potentials of similar amplitude (c.f. WT mice; ~9 mV). However, we found an increased onset latency and half-amplitude duration ($P < 0.05$). Moreover, our preliminary also data suggest an increase in the hindpaw stimulus-evoked action potential activity in the Fmr1-/y mice. In addition, these neurons showed a greater propensity for responding to forepaw stimulation, suggesting an alteration of the receptive field properties. We also found a change in certain intrinsic properties of L2/3 pyramidal neurons. In contrast, we observed no effect of genotype on the spontaneous activity of these neurons. Lastly we present evidence suggesting that changes in their connectivity contribute, at least in part, to the exaggerated response to sensory stimuli observed in Fmr1-/y mouse.

Title: Dysregulated Dscam levels act through Abelson tyrosine kinase to enlarge presynaptic arbors

Authors: *G. R. STERNE, J. KIM, B. YE;
Life Sci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Increased expression of Down syndrome cell adhesion molecule (Dscam) is implicated in the pathogenesis of several brain disorders, including Down syndrome, intractable epilepsy, and possibly Fragile X syndrome (FXS). Though targeting the overabundance of Dscam or its downstream signaling might yield novel therapeutics for these disorders, little is known about Dscam's downstream signaling. Here, we show that the cellular defects caused by dysregulated Dscam levels can be ameliorated by genetic and pharmacological inhibition of

Abelson kinase (Abl) both in an experimental model and a *Drosophila* model of fragile X syndrome. This study establishes Abl as a downstream effector of Dscam function and offers Abl as a potential therapeutic target for treating brain disorders associated with dysregulated Dscam expression.

Title: The actin-depolymerizing factor, cofilin, plays a critical role in the dendritic spine abnormalities associated with fragile x syndrome

Authors: ***A. PYRONNEAU**[1], R. S. ZUKIN[2];
[2]Neurosci., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: Fragile X Syndrome (FXS) is the most common form of inherited intellectual disabilities and autism. The primary cause is an unstable CGG trinucleotide repeat expansion leading to hypermethylation and transcriptional silencing of the *FMR1* gene. The Fragile X Mental Retardation Protein (FMRP), the *FMR1* gene product, is an mRNA binding protein that represses >1000 mRNA targets. Loss of FMRP causes unchecked translation of neuronal proteins normally regulated by FMRP. The neuroanatomical hallmark of FXS is an overabundance of long, thin dendritic spines. However, the molecular mechanisms linking loss of FMRP to aberrant spine morphology remain unclear. Rac1 is a member of the Rho family of small GTPases, which regulates the actin cytoskeleton. Rac1 promotes phosphorylation/inactivation of the actin depolymerizing factor cofilin, enhanced actin polymerization, and spine remodeling. The underlying hypothesis of my research is that loss of

FMRP causes enhanced Rac1 activity, inactivation of cofilin and an overabundance of immature spines. Here we show that the actin depolymerizing factor cofilin, which is a major contributor of dendritic spine structure, is dysregulated in FXS and contributes to these spine abnormalities. We found that cofilin phosphorylation is elevated in *Fmr1* KO mouse somatosensory cortex at an age of substantial synaptogenesis (1 week) but not at later ages (4 weeks). In addition, consistent with aberrant cofilin signaling we show (1) the Rho GTPase, Rac1, exhibits elevated activity, (2) PAK1 (a Rac1 effector) exhibits elevated activity, (3) phosphorylation and inactivation of Slingshot and phosphorylation/activation of Lim kinase (two key downstream targets of PAK1 and upstream regulators of cofilin) are elevated, (4) abundance of profilin 2 (an actin polymerizing factor downstream of Rac1) is elevated and (5) F/G actin ratio, a functional readout of cofilin, is elevated in the somatosensory cortex of 1 week old Fragile X mice. Furthermore inhibition of PAK with a small molecule inhibitor completely restores cofilin signaling in Fragile X mice. Moreover viral delivery of a constitutively actin cofilin mutant (cofilin S3A) in the somatosensory cortex of young *Fmr1* KO mice rescued the immature dendritic spine phenotype indicating a causal relation between elevated cofilin phosphorylation and aberrant dendritic spine morphology in Fragile X. These findings are consistent with a model whereby elevated Rac1/cofilin signaling plays an important role in the dendritic spine defects in Fragile X.

Title: Thalamic hyperexcitability in the Scn8a model of absence epilepsy

Authors: ***C. D. MAKINSON**[1], J. SOROKIN[1], C. A. CHRISTIAN[2], J. R. HUGUENARD[2]; [1]Neurol., [2]Stanford Univ., Palo Alto, CA

Abstract: Absence epilepsy is a CNS disorder characterized by loss of consciousness and spontaneous generalized spike-and-wave discharges (SWDs). The underlying pathophysiology of SWDs is thought to involve dysfunction of the thalamo-cortical loop, which is comprised of reciprocal glutamatergic corticothalamic (CT) and thalamocortical (TC) connections and GABAergic inhibition from the thalamic reticular nucleus (nRT) onto TC neurons. In fact,

deficits in the synaptic and intrinsic excitability of these cell types have been observed in models of absence epilepsy. Recently, absence seizures have been observed in humans and in mice carrying mutations in the voltage-gated sodium channel (VGSC) gene Scn8a, encoding the protein Nav1.6. Nav1.6 strongly modulates neuronal excitability and is important for initiating and propagating action potentials. Given the established importance of thalamic networks to the expression of absence seizures, we sought to evaluate the possibility that loss of Scn8a leads to hyperexcitability of cortical or thalamic networks contributing to absence seizures in these mice. To this end, we performed extracellular multielectrode and whole-cell electrophysiological recordings of critical cell types and regions within the thalamo-cortical loop of Scn8a deficient animals. We found that isolated thalamic networks from Scn8a-deficient mice are in fact susceptible to the generation of spontaneous epileptiform oscillations. Additionally, electrically-evoked oscillations in Scn8a-deficient animals persisted longer (wild-type 1.8 ± 0.7 sec vs. Scn8a+/- 6.9 ± 1.5 sec) and involved a greater number of burst discharges (wild-type 12.1 ± 4.5 vs. Scn8a+/- 64.6 ± 17.7) than wild-type littermate controls. Furthermore, we observed reduced tonic and burst firing behavior in nRT neurons, which are the sole inhibitory GABAergic cell type within this thalamic network, but not in glutamatergic TC neurons, from Scn8a mutant animals compared to wild-type controls. These results document a specific dysfunction in thalamic inhibition, which may contribute to the observed hyper-oscillatory activity of the thalamocortical circuit. Additionally, these findings reveal the importance of Scn8a in shaping thalamic activity and point to a novel mechanism of SWD generation.

Title: Excitability of CA3 hippocampal neurons in a mouse model of Dravet syndrome

Authors: *H. B. FERNANDES[1], J. A. KEARNEY[2], A. L. GEORGE, Jr.[2], A. CONTRACTOR[1];
[1]Physiol., [2]Pharmacol., Northwestern Univ., Chicago, IL

Abstract: Dravet syndrome is an epileptic disorder that results from mutations that produce haploinsufficiency of the *Scn1a* gene that codes for the $Na_V1.1$ sodium channel subunit. Mutations in this gene produce a disorder characterized by generalized seizures with a febrile component starting in infancy, and with a parallel cognitive delay independent of seizure activity. While a reduction in sodium channel expression may be expected to produce an overall reduction in network excitability, a number of studies have demonstrated that $Na_V1.1$ is selectively expressed in GABAergic interneurons in the forebrain. Hence haploinsufficiency of *Scn1a* paradoxically results in enhanced network excitability, attributed to a reduction in inhibition. Recent evidence using isolated hippocampal pyramidal neurons from a knock-in mouse model of Dravet syndrome suggests that parallel changes in other sodium channel subtypes may occur concomitantly to changes in $Na_V1.1$ expression, however the precise changes in neuronal excitability in different hippocampal regions in this mouse model are still unknown. To determine how haploinsufficiency of *Scn1a* affects excitability of neurons during a critical period (P21-P25) in the hippocampus, we used single cell electrophysiological recording of hippocampal neurons in acute slices from Dravet mice and wild-type (WT) littermates. This approach has several advantages over studies in isolated cells. Inhibitory influences on cell excitability remain intact, and a more precise identification of neuronal subtype can be made based on neuroanatomical region and cellular morphology. Previous studies in Dravet mice have largely focused on the CA1 region of the hippocampus but nothing is known about possible alterations in intrinsic excitability of neurons within the CA3 region. This is a critical knowledge gap, as the CA3 auto-associational network is an ideal locus for seizure generation and propagation. We used whole-cell patch clamp in both voltage and current clamp modes to examine cellular excitability and ion channel current amplitudes in both pyramidal cells and interneurons within the CA3 region of hippocampal slices. Comparative measurements were made of intrinsic properties, neuronal excitability, and synaptic properties between Dravet mice and littermate controls. These data will provide insight into the cellular and synaptic changes that occur in the CA3 region of the Dravet syndrome mouse model.

Title: Altered connectivity of the hippocampal CA2 region in temporal lobe epilepsy

Authors: ***U. HAUSSLER**[1], J. SULGER[1], K. RINAS[1], A. KILIAS[2,3,4], C. A. HAAS[1,4];
[1]Exptl. Epilepsy Research, Dept. of Neurosurgery, Univ. of Freiburg, Freiburg, Germany; [2]Lab. for Biomicrotechnology, Dept. of Microsystems Engin. - IMTEK, Fac. of Engin., Freiburg, Germany; [3]Fac. of Biol., Univ. of Freiburg, Freiburg, Germany; [4]Bernstein Ctr. Freiburg, Freiburg, Germany

Abstract: In temporal lobe epilepsy (TLE) seizures are often accompanied by structural changes in the hippocampus such as cell loss in the CA3 and CA1 region and hilus, reactive gliosis and granule cell dispersion. In addition, sprouting of mossy fibers (MF) leads to aberrant recurrent connectivity in the dentate gyrus. In contrast, the CA2 region seems rather resistant to the pathological changes. Nonetheless, the structure and connectivity as well as the functional role of CA2 in TLE have not been thoroughly investigated yet. Only recently, MF input to CA2 has been shown in the healthy hippocampus (Kohara et al., 2013, Nature Neuroscience; Hitti and Siegelbaum, 2014, Nature), based on a molecular definition of CA2 which contrasts the traditional view which assigned CA2 as the region adjacent to CA3 but without MF input. We used a mouse model for TLE to investigate the integration of CA2 in the epileptic hippocampal network and asked (i) whether the MF input to CA2 is altered, (ii) where CA2 output projections target to, since CA1 suffers from cell loss and (iii) whether CA2 contributes to epileptic activity. To this end we injected kainate (KA) into the septal hippocampus of C57Bl/6 and transgenic Thy1-eGFP mice (M-line, Feng et al., 2008, Neuron), which express eGFP mainly in dentate granule cells and MF, and implanted intrahippocampal electrodes for *in vivo* recordings. Subsequently, we performed immunocytochemistry with CA2-specific antibodies (regulator of G-protein signaling 14 and Purkinje-cell protein 4) and synaptoporin to detect MF synapses. In addition, we injected a fluorescence-tagged adeno-associated virus into CA2 to trace its projections. We show that CA2 pyramidal cells survive after KA injection but are dispersed resulting in an elongated CA2 region. Concomitantly, MF undergo major reorganization processes and sprout into the pyramidal cell layer of CA2 where eGFP+synaptoporin double-positive MF boutons surround pyramidal cell somata, introducing somatic in addition to dendritic excitation. On the postsynaptic side, CA2 projects to CA1 in the temporal hippocampus and to the contralateral hippocampus indicating its network integration. Epileptic activity in CA2 occurs only with a delay relative to the dentate gyrus indicating that CA2 rather transfers than generates epileptic activity, yet, the development of fast ripples in CA2 during epileptogenesis points towards a functional impact of the altered synaptic integration of CA2. Title: Structural and functional plasticity of entorhinal input contributes to an epileptic hippocampal circuitry

Authors: ***P. JANZ**[1,2], S. SAVANTHRAPADIAN[3], U. HÄUSSLER[1,2], A. KILIAS[1,4], S. NESTEL[5], O. KRETZ[6], M. KIRSCH[5], M. BARTOS[3], U. EGERT[4], C. HAAS[2];

Abstract: Dentate granule cells (DGCs) receive their major excitatory input from the entorhinal cortex through the perforant path. Although several studies emphasized a role for the entorhinal cortex in epilepsy, it remains uncertain whether its synaptic connections with DGCs are altered. We therefore asked if synaptic inputs from the medial entorhinal cortex (MEC) via the medial perforant path (MPP) are morphologically and functionally changed in chronic epilepsy. To address this question, we first induced mesial temporal lobe epilepsy in adult C57Bl/6 or transgenic Thy1-EGFP mice by injecting kainate into one side of the hippocampus. Saline injections served as controls. Subsequently, we traced the MPP by stereotactic infusion of an anterograde neuronal tracer (biotinylated dextran amine) into the MEC 14 days later. After a survival period of 21 days, brain sections were immunohistochemically processed for identification of MPP fibers, localization of their presynaptic terminals and postsynaptic

partners, using antibodies against biotin, vGLUT-1 and PSD-95 respectively. Quantitative analysis was performed by applying Imaris-based 3D reconstruction. Furthermore, we investigated the ultrastructure of MPP synapses with electron microscopy. Functional properties were inferred in acute slice preparations, by combining whole-cell patch-clamp recordings of individual DGCs and simultaneous extracellular stimulation within the MPP termination zone. We show that under epileptic conditions the MPP is preserved on both the mesoscopic and the synaptic level, despite severe hippocampal sclerosis and granule cell dispersion. Remarkably, MPP synapses exhibited ultrastructural changes such as enlargement of presynaptic boutons and postsynaptic spines, increase in size and complexity of postsynaptic densities, and number of putative contacts. These structural changes are similar to the ones observed upon induction of long-term synaptic potentiation. Moreover, spine densities increased at dendritic segments within the MPP termination zone, and immunohistochemical staining for PSD-95 and vGLUT-1 suggested that newly generated spines are functionally mature and receive glutamatergic input. Finally, whole-cell recordings of DGCs indicated an increase in maximal amplitude of evoked excitatory postsynaptic potentials in the epileptic hippocampus. In conclusion, our findings suggest that structural and functional changes of MPP synapses contribute to an epileptic hippocampal circuitry. Title: Theta oscillation impaired along the septo-temporal axis of the epileptic hippocampal formation

Authors: *A. KILIAS[1,2,3], U. HÄUSSLER[4], K. HEINING[1,2,3], U. P. FRORIEP[5], A. KUMAR[6], C. A. HAAS[4,3], U. EGERT[1,2];

Biol., KTH Royal Inst. of Technol., Stockholm, Sweden

Abstract: Mesio-temporal lobe epilepsy (MTLE) manifests in the hippocampal formation as recurrent epileptic activity (EA) and histopathological changes. While the anatomical changes are persistent, EA is intersected by periods of putatively normal brain activity. These EA-free periods comprise network oscillations that are well studied in the healthy hippocampus. We investigate these rhythms in the epileptic brain and search for altered network properties that render the hippocampal formation susceptible to seizures. We investigate these network oscillations in the intrahippocampal kainate mouse model of MTLE, in which a unilateral injection of kainate into the septal dentate gyrus (DG) induces histopathological changes resembling human MTLE. The severity of these changes decreases towards the temporal pole of the hippocampus. Recently we showed that the power of EA in the DG is unequally distributed along the gradually changed septo-temporal axis (Häussler et al., 2012) but it remains an open question whether theta band power and frequency also show position-dependent changes. We further found that the coupling of theta rhythms between medial entorhinal cortex (MEC) and the sclerotic septal DG is phase-shifted in epileptic animals (Froriep et al., 2012), but it was unknown whether this shift persists along the septo-temporal axis and whether it is accompanied by corresponding changes in neuronal firing. To address these questions, we implanted wire electrodes and custom-made multi-site silicon probes at several positions of the hippocampal formation (HF) and simultaneously recorded local field potentials (LFPs) and multi-unit activity (MUA) in freely behaving mice. We observed theta oscillations at all tested septo-temporal locations in the DG and in the MEC of epileptic animals. Its mean frequency, however, was reduced throughout the extent of the DG and in the MEC of epileptic compared to healthy animals. In contrast, theta band power increased in the MEC but decreased in the septal sclerotic DG. In line with prominent theta oscillations throughout the HF, neurons in all substructures fired phase locked to the rhythm. Neurons of the weakly sclerotic temporal DG as well as of the MEC and Parasubiculum showed a preserved theta phase distribution of firing compared to those obtained from healthy mice. Even though theta oscillations in epileptic animals are slower and power is unequally distributed across the HF neurons still fire phase coupled to the rhythm.

Title: Two-photon imaging reveals the population dynamics of spatiotemporally compartmentalized ictal networks *in vivo*

Deleted: *in vivo*

Authors: ***M. WENZEL**, J. P. HAMM, D. S. PETERKA, R. YUSTE;
Columbia Univ. / Biol. Sci., New York, NY

Abstract: Recent advances in understanding epileptic population dynamics have challenged the classical view of epilepsy as a condition of stereotyped ictal events. Several studies have revealed far more heterogeneous epileptic network activity patterns at the microscale than previously appreciable at a macroscopic level. Yet, studies on ictal networks with fine spatiotemporal resolution have remained sparse, especially in the intact brain. It remains a question of great conceptual and therapeutic interest if reliable patterns of neural recruitment to ictal activity exist at the level of individual assemblies or cells. As for the neural network as a whole, progress towards greater complexity has also been seen regarding the role of neuronal subtypes in epilepsy. While numerous studies indicate that the failure of local inhibition is causally related to ictal expansion and that the activation of interneurons might help suspending seizures, others have observed interneuronal involvement in the induction of epileptic discharges. We combine LFP recordings with 30Hz resonant two-photon calcium imaging in a mouse model of acute pharmacological seizures (4-AP) allowing us to study neural population dynamics during ictogenesis and epileptic spread, with single cell precision *in vivo*. We observe strikingly differential intra-focal and penumbral network activity dynamics with saltatory ictal progression within the epileptic focus versus a smooth invasion of the ictal penumbra. We show that the epileptic network displays partially reliable spatio-temporo-progressive neural recruitment in both cortical compartments, even at the single cell level. This reliability is found despite great temporal network variability consistent with a stretchable neural mesh where ictal

Deleted: in vivo

progression may vary in time but cannot betray current neural connectivity. Finally, we perform population imaging of parvalbumin positive interneurons (PVs) and confirm that they form integral part of the inhibitory restraint, yet also observe unexpectedly non-participant PVs during maximal network excitation and provide insight into how this neural subtype could in fact also support the formation of a critical hyperexcitatory mass. Title: Understanding the role of interneurons in seizure initiation, propagation, and termination using an optogenetic mouse model of seizures

Authors: ***S. KHOSHKHOO**[1], V. SOHAL[2];
[2]Dept. of Psychiatry, [1]Univ. of California, San Francisco, San Francisco, CA

Abstract: Epilepsy is a disorder of brain microcircuits that arises from aberrant neuronal synchronization. Traditionally, this has been attributed to excessive levels of excitation that is able to overcome inhibitory regulation by GABAergic interneurons within abnormal neuronal circuits. However, recent studies have raised the possibility that selective optogenetic activation of interneurons, can not only terminate, but also, under the right conditions, initiate, seizures in the mouse hippocampus. Similarly, within *in vitro* models of seizures, optogenetic inhibition of PV interneurons can reduce the frequency of spontaneous epileptiform discharges. These findings inspired us to further investigate the role of parvalbumin (PV), somatostatin (SOM), and vasoactive intestinal peptide (VIP) interneurons during seizures. To facilitate temporally specific, on-demand seizure initiation, we developed an *in vivo* optogenetic kindling model of ictogenesis by focally expressing ChR2 within excitatory neurons in the mouse neocortex. We simultaneously carried out cell type-specific bulk calcium imaging in the contralateral cortex using Cre-dependent expression of the genetically encoded calcium indicator, GCaMP6f, within

Deleted: in vitro

Deleted: in vivo

PV, SOM, or VIP interneurons, or excitatory neurons. We find distinct, cell-type specific temporal patterns of activity relative to seizure onset or termination. In particular, our results suggest that specific classes of GABAergic neurons may play important roles in the initiation and spread of seizures, in addition to seizure termination. In the future, we hope to take advantage of our novel experimental setup to further elucidate the functional significance of different interneurons in seizures using optogenetic manipulation.

Title: Functional impact of minimal KCC2 in the reticular thalamus on regulation of thalamic oscillations

Authors: ***P. KLEIN**, M. E. HARPER, P. A. DAVOUDIAN, M. P. BEENHAKKER; Univ. of Virginia, Charlottesville, VA

Abstract: Absence seizures, which fall within the larger spectrum of epileptic disorders, are defined by recurrent 3 Hz spike-wave cortical discharges and accompanying loss of consciousness. These seizures are characterized by increased activity in the thalamus, which is produced by an oscillatory circuit between thalamocortical and reticular thalamic neurons. This typically produces bursts of activity during sleep, yet a prevalence of evidence indicates that absence seizures occur when the mechanisms which typically desynchronize activity within the thalamic circuit become disrupted, and activity becomes highly synchronized and generalizes to other regions of the brain. GABAergic signaling within the reticular thalamic nucleus is believed to prevent hypersynchronous firing, yet the exact mechanism by which this occurs is still an active subject of debate. Indeed, studies in the last few years have proposed an inhibitory, an undetectable or even an excitatory role for GABAergic signaling within the reticular thalamic nucleus. While the combined evidence is most supportive of an excitatory role, the mechanisms by which such signaling between reticular thalamic neurons constrains network excitability are unknown. The reversal potential for GABAergic currents is largely determined by intracellular chloride concentrations, which in turn are established by the ion transporters NKCC1 and KCC2. Developmental regulation of NKCC1 and KCC2 in the thalamus has not previously been examined. Using immunohistochemistry, we have found that throughout development, reticular

thalamic neurons in rats largely lack expression of KCC2, consistent with previous findings in adult mice (Sun et al., 2012). This reduced expression of KCC2 in reticular thalamic neurons indicates that intracellular chloride levels are elevated and suggests that seizure suppressing connectivity between reticular thalamic neurons is the result of excitatory GABAergic signaling. Indeed, through calcium imaging of population level activity within the thalamus, we have found that addition of the NKCC1 antagonist bumetanide is capable of increasing both amplitude and synchrony of activity between reticular thalamic neurons. A more complete and accurate understanding of the baseline and seizure-generating states of the thalamic oscillatory circuit will provide opportunities for both improved knowledge of the role the thalamus plays in epilepsy, as well as insights for improved targeting and development of therapies.

Title: Optogenetic dissection of ictal propagation of temporal lobe epilepsy in hippocampal-entorhinal cortex circuitry

Authors: ***Y. LU**, C. ZHONG, Y. ZOU, L. WANG;
Shenzhen Inst. of Advanced Technologies, Chinese Acad. of Sci., Guandong, China

Abstract: Temporal lobe epilepsy (TLE) is one of the most common drug-resistant forms of epilepsy in adults and usually originates in the hippocampal formations. However, network mechanisms that support seizure spreading and the exact directions of ictal propagation remain largely unknown. To address the circuit-level mechanisms controlling seizure activity, we developed novel neural probes for drug delivery, as well as multi-site optical stimulation and

electrophysiological recordings in the hippocampal-entorhinal cortex structures *in vivo*. We induced TLE seizures by direct micro-injection of Kainic Acid (KA) into the dorsal hippocampus of VGAT-ChR2 transgenic mice, and performed multi-channel recordings from multiple brain regions. Based on the multi-region electrical recordings, we found significantly increased synchronizations between the recorded regions during ictal seizures. We calculated the temporal relationship between neural activities recorded in these brain regions, and identified a dominate propagating direction of ictal discharges. We also demonstrate that activating GABAergic interneurons (INs) in the upper stream of the epileptic circuitry can significantly inhibit the spreading of ictal seizures and largely rescue the behavioral deficits in KA-treated animals. These findings may have implications for existing and future therapeutic treatments of TLE.

Title: Heterogeneous pyramidal cell dynamics of high-frequency oscillations in an experimental model of temporal lobe epilepsy

Authors: ***M. VALERO**[1], J. AGUILAR[2], E. CID[1], L. MENÉNDEZ DE LA PRIDA[1]; [1]Functional and Systems Neurobio., CSIC, Madrid, Spain; [2]Hosp. Nacional de Parapléjicos de Toledo, Toledo, Spain

Abstract: Transient high-frequency oscillations (HFOs; 100-600 Hz) have been implicated in both physiological and pathological processes in human temporal lobe epilepsy (TLE). Two major pathological forms of HFOs have been described in the epileptic hippocampus: those associated to interictal spikes (IID-HFOs), and ripple-like HFOs that invade the fast ripple band (FR-HFOs). In this study we investigate the cellular basis of these two forms of HFOs in TLE rats with a combination of multisite silicon probe and intracellular sharp recordings and anatomical labeling. Under urethane anaesthesia, we found IID-HFOs and FR-HFOs of similar

features than those recorded in freely moving TLE rats. FR-HFOs events were typically recorded at the CA1 cell layer in association with a sharp-wave (SPW) of several hundred microvolts at the stratum radiatum (10/14 rats), similar to physiological SPW-ripples. The remaining rats (4/14) showed SPWs at the radiatum with disorganized multi-unit firing at the cell layer. A half of the animals (7/14) displayed IID-HFOs at the CA1 cell layer with a large spike at the radiatum in the millivolt scale. IID-HFOs and FR-HFOs coexisted in 4/7 rats. Intracellularly, FR-HFOs were typically associated with the influence of predominant depolarizing potentials (14/20 cells from 10 rats), most of which exhibited an up-regulated bursting phenotype (13/20 cells). In contrast, IID-HFOs were typically associated with an initial typically supratheshold depolarization followed by a large hyperpolarizing potential that correlated with decreased multi-unit activity (n=11 cells from 7 rats). We propose that different cellular processes underlie pathological forms of HFOs in the TLE hippocampus.

Title: Some high frequency oscillations are more normal than others: pHFOs and ripples in chronic epilepsy

Authors: ***L. A. EWELL**[1], K. B. FISCHER[1], S. LEUTGEB[1,2], J. K. LEUTGEB[1];
[1]Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC-San Diego, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, San Diego, CA

Abstract: Virtually all depth-recording studies from humans are performed in epilepsy patients who are candidates for surgical intervention. Human recording studies have provided a

framework for understanding the network dynamics that underlie human cognition, however, there always remains one caveat: the neural networks being studied are pathological and it is unclear to what extent normal memory mechanisms persist. In healthy hippocampal networks transient 150 - 250 Hz oscillations called sharp wave ripples (SWRs) reflect reactivations of neural ensemble activity that represent a past experience, and are thought to be necessary for memory consolidation. In epilepsy networks, pathological high frequency oscillations (pHFOs) emerge, and are similar to SWR in duration and sometimes frequency. It is currently unknown whether epilepsy networks still participate in normal SWR. To study this question, rats with chronic epilepsy (n = 4) and control rats (n = 4) were implanted with an electrode assembly that targeted the hippocampus. Rats were trained to forage in an open field while hippocampal local field potentials and CA1 single units were recorded. Foraging sessions were flanked with resting sessions so that sleep-related activity could be recorded. SWRs in control animals (n = 691, recorded during sleep and exploration) had an average frequency of 189 ± 0.7 Hz and were associated with a sharp wave voltage deflection that had an average amplitude of 308 ± 6.8 uV. When the same parameters were measured and plotted for HFOs recorded in chronically epileptic rats during sleep and exploration, three clusters emerged. One cluster was distinguished by a very large voltage deflection (an inter-ictal spike). HFOs in this cluster (n = 131) had an average frequency of 253.6 ± 1.9 Hz and were associated with inter-ictal spikes with an average amplitude of 795.1 ± 24.6 uV. Both the frequency and voltage deflection amplitude were significantly different from control ($p < 0.001$). Similarly the HFOs in the second cluster (n = 377) were clearly outside of the normal physiological range with an average frequency of 258.7 ± 1.8 Hz and inter-ictal spike amplitude of 411.8 ± 6.5 uV ($p < 0.001$). Interestingly the third cluster (n =275) completely overlapped with the control distribution with an average frequency of 188.6 ± 1.1 Hz and a sharp wave voltage deflection of 296 ± 8.0 uV, suggesting that CA1 networks in epilepsy are capable of generating activity patterns that appear normal in terms of shape parameters. Future work will assess if these ‘normal’ ripples follow control properties in terms of brain-state dependence and single unit recruitment in sleep and behavior.

Title: Dentate cannabinoid-sensitive interneurons develop selective strengthening of mutual synaptic inhibition in experimental epilepsy

Authors: *V. SANTHAKUMAR, A. PRODDUTUR, B. SWIETEK, J. YU;
Pharmacology, Physiol. & Neurosci., New Jersey Med. School, Rutgers, Newark, NJ

Abstract: Altered inhibition is a salient feature of hippocampal network reorganization in epilepsy. In the dentate gyrus, accommodating interneurons (AC-INs) including hilar interneurons with inner-molecular layer or total molecular layer axonal projections exhibit adapting firing and mediate cannabinoid receptor type 1 (CB_1R)-sensitive GABA release. Experimental epilepsy leads to changes in interneuronal CB_1R expression and reduction in CB_1R-sensitive GABAergic inputs to hippocampal and dentate projections neurons. Here we examined whether intrinsic physiology and inhibitory regulation of AC-INs is modified following pilocarpine-induced status epilepticus (SE). Single cell and paired recordings were obtained from interneurons in the granule cell layer-hilar border in hippocampal slices from male rats 5-10 days (post-SE) and > 40 days (epileptic, with spontaneous seizures) after pilocarpine induced SE and from age-matched, saline-injected controls. AC-INs showed no change in intrinsic active and passive properties in post-SE and epileptic rats. Unlike granule cells and fast-spiking basket cells, AC-INs showed no reduction in the frequency of spontaneous or miniature inhibitory postsynaptic currents (IPSCs) in post-SE and epileptic rats. In paired interneuronal recordings, the amplitude of unitary synaptic GABA currents between AC-INs doubled after SE (in pA, con: 19.4±2.6; post-SE: 38.7±5.5, $p<0.05$). Non-stationary noise analysis identified an increase in GABA receptor number at synapses between AC-INs after SE. However, baseline synaptic release and CB_1R antagonist-enhancement of release at AC-IN synapses were not different between control and post-SE rats. CB_1R agonist reduced the amplitude and suppressed a greater proportion of spontaneous IPSCs in AC-INs from post-SE and epileptic rats than in controls. These data demonstrate that dentate CB_1R-sensitive interneurons develop an early and persistent strengthening of mutual inhibition in epilepsy. The increase in frequency of CB_1R-sensitive sIPSCs in AC-INs was not associated with enhanced AC-IN excitability or changes in baseline endocannabinoid modulation suggesting that synapses between AC-INs may be preserved or increased after SE. Post-SE enhancement of inhibition between dentate AC-INs, which show facilitating short-term dynamics, could impact granule cell dendritic integration during normal activity and following dynamic increases in network excitability during seizures.

Title: Epileptic synapses trigger aberrant intrinsic plasticity in the dentate gyrus

Authors: *V. CREPEL, A. PERET, Y. MIRCHEVA, G. MARTI, J. ARTINIAN;
INMED, INSERM & Aix-Marseille Univ. UMR901, Marseille Cedex09, France

Abstract: Patients with temporal lobe epilepsy (TLE) often display cognitive comorbidity in addition to recurrent seizures. However, the cellular mechanisms underlying the impairment of neuronal information processing remain poorly understood in TLE. Within the hippocampal formation, neuronal networks undergo a major reorganization, including the sprouting of mossy fibers in the dentate gyrus; they establish aberrant recurrent synapses between dentate granule cells and operate via postsynaptic kainate receptors. In this study, we tested the hypothesis that this aberrant local circuit is able to alter information processing of perforant path inputs which constitute the major excitatory afferent pathway from entorhinal cortex to dentate granule cells. Our present data, obtained in patch-clamp in hippocampal slices, revealed that stimulation of recurrent mossy fibers triggered a repetitive firing regime of dentate granule cells in TLE. When used as conditioning trains, it increased more than 3 fold their firing rate in response to perforant path inputs during at least 30 minutes, altering durably granule cells input-output operation without increasing the synaptic strength. The recurrent mossy fibers-evoked repetitive firing regime was due to an aberrant readout of synaptic inputs by kainate receptors and the augmentation of perforant path-evoked firing rate was dependent on Ca2+ influx but not on NMDA receptors. Furthermore, we demonstrated that this perforant path-evoked firing increase is due to the aberrant activity-dependent potentiation of the persistent sodium current altering intrinsic excitability of dentate granule cells. We propose that this aberrant activity-dependent intrinsic plasticity, which lastingly impairs the information processing of cortical inputs the in dentate gyrus, may participate in hippocampal-related cognitive deficits such as those reported in patients with TLE.

Title: Epilepsy-induced dentate granule cell hyperactivation: progression and mechanisms in a mouse model of temporal lobe epilepsy

Authors: ***C. G. DENGLER**[1], C. YUE[3], H. TAKANO[3,2], D. A. COULTER[2,3];
[1]Neurosci., [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: In addition to its cognitive functions, the dentate gyrus (DG) plays an important role in the regulation of pathological activation of the limbic system, functioning as a regulated gate, restricting relay of synchronous network activity associated with epilepsy. A critical component of this gating function is the reluctance of granule cells to activate and their concomitant sparse activation, both *in vivo* and *in vitro*. In both human and animal models of epilepsy, there are multiple epilepsy-associated disruptions occurring within dentate circuitry, including mossy fiber spouting, alterations in local inhibition, and aberrant neurogenesis. Given these circuit changes, we hypothesized that the network activation properties of dentate granule cells (DGCs) would be corrupted. We therefore conducted multicellular calcium imaging using fast sweptfield confocal microscopy to probe activation of DGCs in hippocampal slices prepared from mice in a pilocarpine status epilepticus (SE) model of epilepsy to understand how development of chronic epilepsy alters circuit function in the dentate gyrus during epileptogenesis. We assessed proportional activation of DGCs responding to perforant path stimulation and found that control slices showed relatively sparse activation with 20% DGCs responding. Slices prepared 1 week post-SE displayed a significant collapse in normal sparse firing and increased to 90%. At 2 weeks post-SE there transient, partial restoration to 40% activation, followed by a significant secondary increase in responses at 2-3 months (65%) and at >6 months post-SE (90%) as animals become chronically epileptic. We assessed both sIPSCs and mIPSCs during epileptogenesis and found reductions in normal inhibitory function correlating with timepoints during epileptogenesis when DGCs displayed hyperexcitability. We have also previously shown that chloride regulation is also disrupted during epileptogenesis. Using GABA-A receptor and

Deleted: in vivo

Deleted: in vitro

KCC2 antagonists, we found that pharmacologically mimicking changes in inhibitory receptor function and chloride reversal potential were each individually sufficient to significantly disrupt the normal, sparse activation in DGCs increasing activation by 2-fold, and that disrupting both simultaneously produced an additive effect in increasing granule cell activation 4-fold. Given that the ensemble activation properties of DGCs are critical determinants in both hippocampal dependent cognitive function and control of aberrant excitation in the limbic system, erosion in these properties may play a critical role both in cognitive comorbidities and seizure propensity in epilepsy.

Title: A comparison of sparse activation in the dorsal and ventral dentate gyrus granule cells

Authors: ***J. B. KAHN**[1], H. TAKANO[1], D. A. COULTER[1,2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: The hippocampus exhibits distinct anatomy and behavior along is septotemporal axis, including differing patterns of gene and receptor expression, behavioral impact, and anatomical projections. The hippocampus also expresses differences in disease: epilepsy induces greater circuitry changes in the ventral than the dorsal hippocampus. Pronounced differences in circuit activity between the dorsal and ventral hippocampal microcircuits CA1 and CA3 are well documented, but the dentate gyrus (DG) has yet to be investigated extensively in this context. We examined cellular activation of the DG's principal cells, dentate granule cells (DGCs), which in a healthy brain have been shown to have sparse, selective activation characteristics. Previous *in vivo* tetrode work has shown that most of the DGCs do not fire in any spatial environment and remain functionally silent, while the small remaining population of DGCs fire in all environments. Our laboratory has similarly demonstrated this sparse activation, reporting only 5% of the DGC population activating in ventral hippocampal-entorhinal cortical slices. In this

Deleted: in vivo

study, we used two-photon multicellular calcium imaging in horizontal ventral hippocampal-entorhinal cortical slices and in coronal dorsal hippocampal slices. Slices were bulk loaded with the calcium indicator dye Fura-2 AM, which labels virtually the entire DGC population, visualized as POMC-Cre x Rosa tdTomato labeled DGCs. Maximal DGC population activation was determined by applying picrotoxin (50 uM), a GABA(A) receptor antagonist, to the bath at the end of the imaging session; cells that activated in the presence of picrotoxin were the denominator for the "percent of the activating population" calculation. A significantly larger proportion of the DGCs in dorsal slices activated in response to stimulation than our previously reported 5%; however, this result is a function of the stimulating electrode's placement in the slice. Coronal hippocampal slices must be stimulated in the DG's molecular layer, confounding perforant path afferent input with direct DGC dendritic stimulation. Positioning the stimulating electrode in a similar location in the ventral DG's molecular layer, rather than the perforant path in the entorhinal cortex, removed any significant differences in proportional activation. Our findings support previous work suggesting that the DGCs act as a sparsely activating network and suggest that this sparsity is maintained along the septotemporal axis.

Title: T-type calcium channels facilitate neuronal hyper-excitability in epileptic subiculum neurons

Authors: M. K. PATEL, B. BARKER, *J. A. HOUNSHELL;
Anesthesiol., Univ. of Virginia, Charlottesville, VA

Abstract: Temporal lobe epilepsy (TLE) is a common form of adult epilepsy. Seizures in patients with TLE can be difficult to suppress, resulting in approximately 30% of patients being classed as therapy resistant. Subiculum neurons serve as the primary output center for the hippocampus, receiving information directly from the CA1 and projecting out to cortex and subcortical regions. Subiculum neurons are spared in TLE and become hyper-excitable. Recent studies have suggested a role for T-type Ca2+ channels in facilitating increases in neuronal activity associated with TLE. We sought to determine if T-type Ca2+ channels are involved in maintaining neuronal hyper-excitability in the subiculum of TLE rats. To establish a role for T-

type Ca2+ channels we used 1μM TTAP, a potent and selective blocker of T-type Ca2+channels. T TLE in rats was induced by electrical stimulation of the hippocampus for 90 minutes to induce status epilepticus (SE). Rats having two or more spontaneous seizures per day by EEG, 3 months after SE were used in the study. Brain slices were prepared and membrane properties were recorded from subiculum pyramidal cells. Action potentials (APs) were evoked by a series of depolarizing current injection steps under whole-cell current clamp conditions. Subiculum pyramidal neurons from TLE rat brain slices demonstrated a higher AP firing frequency than control. Bath application of 1μM TTAP significantly reduced firing frequencies in both control and TLE neurons. Stimulation of the pyramidal cell layer of the CA1 region evoked a burst of APs in control neurons. In TLE neurons, stimulation evoked a greater number of APs and longer durations of depolarizing events. Application of 1μM significantly reduced the number of APs evoked in both control and TLE neurons. Rebound firing, firing believed to be largely driven by T-type Ca2+channels, is significantly decreased in control and TLE subiculum neurons in response to 1μM bath application of TTAP. In TLE, subiculum pyramidal neurons have a more hyperpolarized threshold (-50.4±0.6 mV) compared to controls (-45.7±0.3 mV). Bath application of 1μM TTAP however restores threshold properties (-44.6±1.7) in TLE subiculum neurons. These data suggest that T-type Ca2+ channels play an important role in controlling neuronal membrane excitability in subiculum neurons. Alterations in the activity of T-type Ca2+ channels could be important in facilitating neuronal hyper excitability in TLE.

Title: Electrophysiological properties of age-defined dentate granule cells in a rodent model of temporal lobe epilepsy

Authors: ***A. L. ALTHAUS**[1], S. J. MOORE[2], H. ZHANG[3], G. G. MURPHY[2,4], J. M. PARENT[3];
[2]Mol. and Behavioral Neurosci. Inst., [3]Neurol., [4]Physiol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Dysregulated hippocampal neurogenesis is a prominent feature of temporal lobe epilepsy (TLE). Anatomical data indicate that most dentate granule cells (DGCs) generated in response to an epileptic insult develop features that promote increased excitability, including ectopic location, persistent hilar basal dendrites (HBDs) and mossy fiber sprouting. However, some DGCs appear to integrate normally, and may promote reduced excitability. Using a retroviral (RV) GFP reporter to birthdate DGCs, our laboratory found that DGCs that were mature at status epilepticus (SE) are resistant to morphological abnormalities, while the majority of those born after SE display TLE-related pathology. This may suggest that post-SE generated DGCs promote pathological function while established DGCs retain normal function. To examine the relationship between DGC age and activity within an epileptic network, we used acutely prepared hippocampal slices to make whole-cell voltage clamp recordings from RV birth-dated DGCs born either neonatally, or during adulthood in an epileptic or intact animal. We found that, in TLE tissues, both adult-born and neonatal-born populations of DGCs appear to receive increased excitatory input compared with age-matched controls in intact tissues. Furthermore, adult-born DGCs that display aberrant morphology in TLE tissues appear to receive more excitatory input than their normotopic counterparts. In particular, ectopic DGCs receive the greatest amount of excitatory input and least amount of inhibitory input when compared to other age and morphology defined groups of DGCs. Taken together, these data suggest that aberrant adult-born DGCs may underlie pathophysiological network mechanisms that promote epileptogensis.

Title: Altered GluA2 expression provides a mechanism for efficacy of AMPA receptor blockade in preventing acute post-seizure cellular changes in the developing hippocampus

Authors: ***J. J. LIPPMAN BELL**[1], H. SUN[1], C. ZHOU[2], F. E. JENSEN[1];
[1]Neurol., Univ. of Pennsylvania Perelman Sch. of Medi, Philadelphia, PA; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Early-life seizures are highly prevalent, and can be associated with autistic-like behavior and spontaneous recurrent seizures in humans and rats. We previously showed a rapid, persistent increase in AMPAR function in CA1 hippocampal neurons after hypoxic seizures (HS) at postnatal day (P)10 in rats, and that this, like long-term development of spontaneous recurrent seizures and autistic-like behavior, could be prevented by acute, brief treatment with the AMPAR antagonist NBQX. Recently, we demonstrated that expression of synaptic GluA2 in CA1 decreases in rats 48hr post-HS, concurrent with functional changes that include LTD attenuation and increased Ca2+ responses. NBQX treatment prevented these functional changes, though the mechanism underlying the efficacy of NBQX on the rescue of these changes remained unclear. Given the critical role of GluA2-lacking AMPARs in seizure-induced changes in the developing hippocampus, we examined whether NBQX altered synaptic GluA2 levels 48hrs post-HS. Confocal immunohistochemistry showed that GluA2/synapsin colocalization was significantly higher in rats treated with NBQX administered immediately, 12, 24, and 36hrs post-HS than in vehicle-treated post-HS littermates ($p=0.01$, n=14 fields from 6 rats/group) and not significantly different from littermate controls ($p=0.22$, n=11 fields from 5 rats). NBQX treatment did not affect GluA2 in controls ($p=0.719$, n=7 fields from 4 rats). Demonstrating that this GluA2 rescue had a functional consequence, fura-2 imaging showed that percent change in peak response to KA before and after GluA2-lacking AMPAR blocker NASP incubation was significantly decreased in vehicle-treated animals ($p<0.0001$; n=6 slices from 4 rats; 10-26 cells/slice). Conversely, following *in vivo* NBQX treatment, NASP does not significantly alter the Ca2+ response ($p=0.79$; n=6 slices from 4 rats; 10-26 cells/slice). To confirm that *in vivo* NBQX treatment post-HS are functionally dampening CP-AMPARs, we used whole cell patch clamp to measure rectification ratios in adjacent slices. We observed restoration of rectification levels following NBQX treatment in slices taken from the same animals as the Ca2+ imaging (n=8 HS+Veh; n=7 HS+NBQX). Taken together, these results suggest that GluA2 expression is a modifiable factor that is critical to the effects of seizures on developing networks, and may provide a mechanism of action whereby NBQX rescues previously described seizure induced later life behavior deficits and epileptogenesis. Further evaluation of the subcellular mechanisms regulating GluA2 trafficking will be required to fully understand these effects.

Title: The brainstem is an independent generator of febrile seizures

Authors: M. PUSKARJOV[1], A. POSPELOV[1], A. YUKIN[1], M. S. BLUMBERG[2], *S. BÄCK[1], K. KAILA[1];
[1]Univ. Helsinki, Helsinki, Finland; [2]Univ. of Iowa, Iowa City, IA

Abstract: Febrile seizures (FS) are the most common type of convulsive events in children. The mechanisms underlying FS have been extensively studied in animal models. A widely held assumption is that FS are limbic in origin, and that the generalization of seizures, which is typical of FS, is caused by invasion of the brainstem by the initial limbic seizure activity. Based on a rat model of FS where 13-day-old rats are exposed to hyperthermia (Schuchmann et al., 2006 NatMed 12:817), we examined whether the brainstem by itself is able to generate tonic-clonic seizures. Rats with their forebrain surgically isolated from the brainstem (precollicular transection; Todd et al., 2010 BehavNeurosci 124:69) were exposed to hyperthermia. Sham-operated littermates were used as controls. Hyperthermia caused a similar increase in breath rate and blood pH between the two groups, which is important as we have previously shown that respiratory alkalosis is a major trigger of experimental FS (Schuchmann et al., 2006). Strikingly, we found that in transected animals tonic-clonic seizures occurred at a shorter latency (~7 min vs ~10 min) and with a lower temperature threshold (41.2 ºC vs 43.4 ºC) than in the sham-operated controls. We have shown before that FS are enhanced by low doses (150 µg/kg, i.p) of diazepam (DZP), whereas high doses (2.5 mg/kg, i.p) have a seizure-suppressing effect (Ruusuvuori et al., 2013 EMBOJ 32:2275). The latter is most likely caused by suppression of breathing by DZP and the consequent prevention of the FS-triggering respiratory alkalosis (Ruusuvuori et al., 2013). In line with this, the tonic-clonic seizures in the transected animals were not affected by 150 µg/kg DZP, while 2.5 mg/kg had a marked anticonvulsant effect. Systemic administration of kainate is known to produce limbic seizures which are thought to generalize after recruitment of brain stem networks. Notably, following kainate injection (3 mg/kg) in the transected rats, violent tonic-clonic seizures readily took place and, as was the case with the experimental FS, they had a shorter latency to onset than in the sham-operated controls. Our work suggests that the role of endogenous brainstem activity in generalized seizures should be re-evaluated in standard experimental models of limbic seizures. Moreover, the immobility that is commonly seen in rodents during cortical electrographic seizures may reflect a suppression of brainstem activity by hippocampal/cortical seizures (Ruusuvuori et al., 2013). This suggestion gains support from the

heightened proneness to tonic-clonic convulsions in the precollicularly transected animals in the two seizure models studied presently.

Title: Cardiac arrhythmogenic leaky ryanodine receptor 2 mutation increases cortical excitability and lowers threshold for spreading depolarization in mouse brain

Authors: ***I. AIBA**, J. L. NOEBELS;
Dept. of Neurol., Baylor Col. of Med., Houston, TX

Abstract: The ryanodine receptor (RYR) is an endoplasmic intracellular Ca2+ channel that, upon activation, releases Ca2+ into the cytoplasm. Mutations in the RYR2 subtype are found in congenital heart disease patients at risk of sudden cardiac death and victims of sudden unexpected death in epilepsy (SUDEP). Most pathogenic RYR2 mutations are gain-of-function, forming “leaky” channels that result in abnormal intracellular Ca2+ handling in cardiomyocytes and cardiac arrhythmias. Since RYR2 is also expressed in neurons, sudden death could also reflect CNS dysfunction. We recently showed that spreading depolarization (SD) is implicated in silencing brainstem cardiorespiratory activity in mouse SUDEP models. Since ryanodine receptor modulation of neuronal excitability has not been well studied, we investigated whether leaky RYR2 mutations might affect network excitability and SD threshold. We studied transgenic mice (4-8 weeks old) carrying the Ryr2 R176Q mutation, a dominant mutation identified in arrythmogenic right atrial dysplasia patients. In chronic EEG/EKG recordings, heterozygous mice (R176Q/+) showed periodic cardiac arrhythmias and cortical spikes. Rare seizures were observed. The cortical SD threshold was evaluated *in vivo* under urethane anesthesia by topical application of 1M KCl in a cranial window and detected in DC recordings with surface silver electrodes. The number of SD’s triggered in R176Q/+ mice was significantly

Deleted: in vivo

increased compared to WT control mice, suggesting a lowered SD threshold in the R176Q/+ mice. The SD phenotype of R176Q/+ mice was also characterized in acute cortical slices. Microinjection of 1M KCl triggered SD in both WT and RQ/+ slices. The SD propagation rate was significantly faster in slices from the heterozygous RQ mice. In other experiments, SD was generated by continuous exposure to modified artificial cerebrospinal fluid (ACSF) lacking Mg2+. Exposure to Mg2+ free solution resulted in spontaneous SD's as well as seizure-like activity. The number of SDs was higher in slices prepared from mutant mice than WT. On the other hand, the incidence of seizures was similar. SD threshold was also tested in the oxygen glucose deprivation (OGD; 0% O2, 2 mM glucose) exposure model. Exposure to OGD solution reliably triggered SD, and the latency to SD onset was significantly faster in R176Q/+ slices. Together, these results consistently indicate that leaky RYR2 channels facilitate SD generation, and support the hypothesis that RYR2 mutations found in people at risk of sudden cardiac death may increase risk of neurogenic death by lowering the threshold for SD.

Title: Epileptic encephalopathy mutations in KCNQ2 disrupt expression and function of KCNQ channels and affects hippocampal excitability

Authors: J. P. CAVARETTA, K. LEE, D. JOSHI, M. HONG, W. PANG, S. WANG, N.-P. TSAI, *H. CHUNG;
Dept Mol. and Integrative Physiol., Univ. of Illinois At Urbana Champaign, Urbana, IL

Abstract: KCNQ channels are voltage-gated potassium channels composed of KCNQ2 and KCNQ3 subunits. Highly concentrated at the axonal surface where action potentials initiate and propagate, they potently inhibit repetitive and burst firing of action potentials, which is the hallmark for neuronal hyperexcitability leading to seizures. Indeed, KCNQ2 and KCNQ3 mutations cause benign familial neonatal convulsion and myokymia. We have shown that some

of these mutations impair axonal enrichment of KCNQ channels by disrupting KCNQ2 binding to calcium-binding protein calmodulin, and blocking their trafficking from the endoplasmic reticulum (ER) to the axonal surface (Chung et al, 2006; Cavaretta et al., 2014). Recently, de novo mutations in KCNQ2 were discovered in patients with epileptic encephalopathy, severe symptomatic drug-resistant epilepsy with severe psychomotor retardation. Half of these mutations were found in the KCNQ2 C-terminal tail that interacts with calmodullin. Here, we show that epileptic encephalopathy mutations in KCNQ2 disrupt the axonal enrichment of KCNQ channels by reducing KCNQ2 binding to calmodulin and KCNQ3, leading to their ER retention. Importantly, expression of wild-type KCNQ2 but not epilepsy mutant KCNQ2 in hippocampal neurons suppresses their intrinsic excitability, suggesting that epilepsy mutant KCNQ2 is functionally defective. The ER resident chaperones mediate the retention of misfolded proteins in the ER and this process requires calcium in the ER lumen. Interestingly, depletion of calcium from the ER lumen could promotes the trafficking of wild-type and some epilepsy mutant KCNQ channels from the ER back to the axonal surface. These results provide an insight into the etiology of KCNQ2-associated epileptic encephalopathy, and may lay a firm foundation for targeting the ER chaperones as a possible therapy for epilepsy.

Florence, Firenze, Italy; [6]UMR U1129, Inserm-University Paris Descartes-CEA, Paris, Paris, France

Abstract: Early infant onset epilepsies might be a consequence of abnormal reemergence of depolarizing GABAA current during postnatal maturation of the central nervous system. To study the impact of the contribution of depolarizing GABA in distinct pattern of EEG activity, we used a lumped-parameter approach lying at the level of cortical neuronal population used to represent the generation of spontaneous EEG activity. The model includes one sub-population of pyramidal cells and two sub-populations of interacting interneurons: perisomatic-projecting interneurons (basket-like) with fast synaptic kinetics GABAA (fast, I1) and dendritic-projecting interneurons with slow synaptic kinetics GABAA (slow). Basket-like cells were interconnected to produce mutual inhibition (I1->I1). This model (Molaee-Ardekani et al., 2010) was modified to account for a number of neurobiological hypotheses. The firing rate of interneurons was adapted to mimic the genetic alteration of voltage gated sodium channels often found in Dravet syndrome, SCN1A-/-. We implemented the mechanism referred to as “dynamic depolarizing GABAA” mediated post-synaptic potential in the model, as a number of studies reported that the chloride reversal potential can switch from negative value to more positive value depending on interneuronal activity. The “shunting inhibition” promoted by GABAA receptor activation was also implemented. Finally, the dose dependent effect of benzodiazepine and Stiripentol on the generated field potential was considered in the model. We found that for unchanged parameters configurations of the computational model, the simple increase of the proportion of depolarizing GABAA mediated IPSP (I1->I1 and I1->P) is sufficient to switch the EEG activity from background to (1) interictal isolated polymorphic epileptic spikes, (2) to fast onset activity (chirp-like activity),(3) to seizure like activity and (4) seizure termination. Different morphologies of interictal spikes and patterns of seizures that we observed in several DS patients were reproduced in the model by tuning the amount of depolarizing GABAA postsynaptic potential. Finally, we implement the effect of two pharmacological product, benzodiazepine and stiripentol that were able to block dose-dependently this seizure-like activity, and found a synergic effect when these two drugs were combined.

Abstract: High frequency oscillations (HFO) are considered biomarkers of the seizure onset zone and its determination is crucial for the treatment of drug resistant epilepsy (DRE). It has been found that the most frequent DRE is the mesial temporal lobe epilepsy (MTLE) and its resistance has been proposed to be due to hippocampal sclerosis. Also, it has been found that there exist an increased ratio of fast ripples / ripples in patients with drug resistant MTLE and hippocampal sclerosis compared with those without the last one. Then in order to address this, we analyzed interictal electroencephalograms recorded with deep brain electrodes from patients with DRMTLE included in a protocol for deep brain stimulation. Preliminary results confirm that the ratio of fast ripples / ripples is increased in patients with hippocampal sclerosis, and they correlate with the side of the hippocampal sclerosis as reported from magnetic resonance image and spectroscopy. One case of a patient with bilateral onset zone and unilateral sclerosis is also discussed.

Title: Single-unit activities and local field potentials during spontaneous seizures in the human hippocampus and insular cortex

Authors: *S. KOCHEN[1], B. GORI[2], M. GRANADO[3], A. BLENKMANN[2];
[2]Epilepsy Ctr., [1]Conicet, Capital Federal, Argentina; [3]Univ. of Buenos Aires, capital federal, Argentina

Abstract: We studied the spatiotemporal scale of focal epilepsy, the dynamics of its interaction, and the spread of epileptogenesis. We used wide-bandwidth electrophysiological intracranial recordings using clinical macro- and research microelectrodes in patients with epilepsy. All seizures were identified by an epileptologist from the macroelectrode recordings. We analyzed 23 spontaneous seizures of two patients with insular epilepsy (IE) and frontal epilepsy (FE). For further analysis, we only included seizures (n=11) that presented a local field potential (LFP) with single unit activity during ictal period and at least within 15 minutes before seizure onset. LFP and single units were recorded across multiple days using Ad Tech (40 um width) microwires. Single units were classified by an automated cluster identification program (wave_clus, MATLAB). When a given unit was identified as a single cell across multiple seizures and multiple days, results were manually grouped based on similarities in waveform, spike widths, spike density, and interspike interval histogram. The firing rate (FR) during basal, preictal, ictal, and postictal periods was calculated as the total number of action potentials per unit of time. In the IE case, microelectrodes were localized within the epileptogenic zone (EZ) in the posterior ínsula. However, seizures recorded with macroelectrodes were not simultaneously observed with adjacent microelectrodes in all cases. LFP with single unit recording during seizures showed unstructured activity different to basal period, but did not present epileptiform discharges. The FR either remained constant or decreased. In the FE case, microwires were localized in the hippocampus, outside the EZ. When seizures spread to the hippocampal area, the macroelectrode recorded epileptiform discharges that were simultaneously observed on LFP, showing sharp waves higher than 2 Hz. In this case, a marked increase in FR was observed in all seizures. The areas involves directly in the seizure or its propagation that showed hypersynchronous discharges on LFP, presented an increased in FR. While the LFP did not show epileptiform discharges in spite of being part of the EZ, the FR only show low-level, and unstructured activity. These findings could have important implications for how we localize seizure activity and how we map its propagation.

Title: Evidence for the implant effect in chronic ambulatory human ECoGs

Authors: *S. ARCOT DESAI, F. T. SUN, T. K. TCHENG, M. J. MORRELL;
NeuroPace, Mountain View, CA

Abstract: Electrocorticographic records (ECoGs) collected from chronically implanted NeuroPace depth and/or cortical strip leads in 126 subjects with epilepsy were analyzed. All subjects were participating in a double-blind, randomized, sham-stimulation controlled trial of a responsive neurostimulator (RNS® System, NeuroPace, Inc.) as an adjunctive treatment for medically intractable partial onset seizures. To be included in this analysis, subjects must have had at least 100 interictal ECoGs stored over at least one year since implantation of the RNS® Neurostimulator and NeuroPace leads. The analysis included an average of 763 scheduled ECoGs per subject, for a total of 96,162 ECoGs. Overall power and normalized power within delta, theta, alpha, beta, low gamma, and high gamma frequency bands, and spike rate were measured on each channel of the scheduled ECoGs. Month-to-month differences were assessed for each patient ECoG channel, and group statistics were calculated by averaging the within-channel results. There were significant month-to-month changes in overall power, normalized power within frequency bands, and spike rate that were most pronounced in the first 3 to 5 months after implant. There was a significant change in over half (55%) of all the ECoG channels from the first to the second month ($p < 0.05$, two-sample t-test), including 68% of the channels recorded from strip lead electrodes and 47% of the channels recorded from depth lead electrodes. After 5 months, the overall power became more stable, with significant month-to-month changes seen on average in less than 20% of the channels recorded from depth lead electrodes and less than 25% from strip lead electrodes. Similar patterns of changes were observed with normalized power within frequency bands as well as for spike rate. While power-related changes may be predominately related to changes at the electrode-tissue interface that impact impedance, spike rate changes suggest that there may be additional neurophysiological changes in the first few months following implantation - “the implant effect”. Hence the ECoG data collected in the 3 to 5 months after implantation of depth or subdural electrodes are not stable and may not be representative of the chronic state.

Title: Delay differential analysis: a framework for the analysis of large-scale epileptic electrocorticography recordings

Authors: ***J. WEYHENMEYER**[1,2], C. LAINSCSEK[2,3], S. S. CASH[4,5], T. J. SEJNOWSKI[2,3]; [1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Howard Hughes Med. Institute, Computat. Neurobio. Hosp., Boston, MA

Abstract: High density electrocorticogram (ECoG) electrodes are capable of recording neurophysiological data with high temporal and reasonable spatial resolution. Such recordings are a window to understanding how the human brain processes information and subsequently behaves in healthy and pathologic states. At present, many of the computational methods utilized in the analysis of ECoG recordings are strictly linear, require significant pre-processing, and fail to provide high-level information with respect to the state of the neurological system. In the following study, we describe and implement delay differential analysis (DDA) for the characterization of ECoG data obtained from human patients with intractable epilepsy. DDA is a time domain analysis framework based on embedding theory in nonlinear dynamics. An embedding reveals the nonlinear invariant properties of an unknown dynamical system (here the brain) from a single time series (ECoG signals). The DDA embedding serves as a low-dimensional nonlinear functional basis onto which the data are mapped. Since the basis is built on the dynamical structure of the data, preprocessing of the data, e.g. filtering, is not necessary. DDA yields a low number of features (four or less), far fewer than traditional spectral techniques. This greatly reduces the risk of overfitting and improves the method's ability to fit classes of data. One single three term DDA is shown to qualitatively discriminate between different neurologic states and epileptic events for a set of 13 patients from the raw ECoG data. Singular value computation across the feature space is shown to delineate global and local dynamics. The global and local dynamics differentiate electrographic and electroclinical seizures while also providing insight into a highly localized seizure onset and diffuse seizure termination. Thus, DDA is shown as a new form of computational analysis for ECoG data obtained from the epileptic patient.

Title: Robust long-range high-gamma phase synchronization in human cortex

Authors: ***G. ARNULFO**[1,2], A. ZHIGALOV[2], J. HIRVONEN[2], L. NOBILI[3], P. PROSERPIO[3], M. M. FATO[1], G. LO RUSSO[4], S. PALVA[2], J. M. PALVA[2];

Munari", Dept. of Neuroscience, Niguarda Hosp., Milano, Italy; [4]"C. Munari", Dept. of Neuroscience, Niguarda Hosp., Milano, Italy

Abstract: Mammalian cortical activity is thought to exhibit long-range synchronization only in frequency bands up to ~100 Hz. While high-gamma-frequency band (100-250 Hz) activities have been observed and found to be associated both with behaviourally relevant neuronal processing and epileptiform activity, they have been thought to be strictly local. We report here that long-range synchronization in the high-gamma band is, in fact, a robust and widespread physiological phenomenon in the human brain. Stereo-electroencephalography (SEEG) is a routine clinical method used in presurgical identification of epileptic foci by intra-cerebral recording of local field potentials in subjects suffering from refractory epilepsy. SEEG is emerging as an increasingly used tool in neuroscience research because it yields spatially and temporally accurate, gold-standard-quality like recordings of local field potentials (LFPs) in awake humans. We used a cohort of 22 subjects for which the SEEG electrode contacts were automatically

localized with sub-millimetre accuracy in the individual cerebral volume. We quantified phase and amplitude correlations between electrode contacts located in cortical or subcortical grey matter. These LFP recordings were locally re-referenced to closest contacts in the underlying white matter. We found that, as expected, the phase and amplitude correlations decayed as a function of frequency and distance up to approx. 100 Hz. This decay, however, was reversed after ~100 Hz and exhibited a peak in the high-gamma frequency range at around 200 Hz. To the best of our knowledge, this is the first observation of long-range (3-10 cm) phase synchrony in the high-gamma frequency band. We show that these interactions were not attributable to volume conduction, specific referencing schemes, technical or epileptic spike artefacts, harmonics of line noise, or volume-conducted muscular activity signals. We found also that the interactions between the deep and superficial cortical layers exhibited distinct spectral profiles and while this long-range synchronization was salient between subcortical and cortical structures, it was also significant among cortical regions Importantly, high-frequency gamma synchrony was observed not limited to cortical regions in or connected with the epileptic zone but rather was equally characteristic to putatively healthy parts of the neocortex. These data suggest that long-range phase correlations among high-gamma-band oscillations are a genuine physiological phenomenon and are not attributable to artefactual sources or limited to the network connected to the epileptic zone.

Title: Characteristics of seizure termination in primary and secondarily generalized seizures

Authors: *M. BORZELLO[1], A. MAHESHWARI[2], C. CHU[1], M. KRAMER[3], B. M. WESTOVER[1], S. S. CASH[1];
[1]Neurol., Massachusetts Gen. Hospital, Harvard Med. Sc, Boston, MA; [2]Baylor Col. of Med., Houston, TX; [3]Mathematics and Statistics, Boston Univ., Boston, MA

Abstract: The vast majority of seizures end spontaneously. Understanding the mechanisms underlying this phenomenon would be useful not only in understanding what happens when a seizure becomes prolonged, evolving into status epilepticus, but also in designing effective clinical interventions. The purpose of this study is to compare the termination patterns of two canonically distinct categories- seizures with electrographically focal onset that become secondarily generalized (sGTC) and seizures appearing to have electrographically generalized onset as seen in idiopathic generalized epilepsy (IGE) or childhood absence epilepsy (CAE). We examined the termination pattern of a total of 167 seizures in 57 patients- 71 with focal onset that secondarily generalized (scalp EEG: 45, intracranial EEG: 26) and 96 seizures with generalized onset (IGE:10, CAE: 86). Our results expose characteristics that occur at the end of each type of epileptic episode suggesting a common final mechanism. We found that while the two classes of seizure onset under investigation - focal and generalized - seem to terminate in their own unique way, there are common characteristics between the two types. Analyzing secondarily generalized seizures from scalp and intracranial recordings, we identified a conspicuous electrographic motif- a “burst suppression pattern” similar to those in anesthesia recordings. With scalp data, we observed robust synchrony amongst channels and a simultaneous end in which seizure activity terminated in all leads at the same time. Activity from scalp electrodes was generally more homogeneous than the intracranial electrodes. The length of suppressions significantly increased toward seizure end while the length of bursts showed no significant change. Furthermore, we analyzed generalized seizures from scalp data and found a similar burst suppression pattern, though not identical to that of the focal-onset seizures. In contrast to both IGE and sGTC, seizures from patients with CAE showed a general trend of slowing and decreased amplitude at seizure end but no clear burst-suppression pattern. These characteristic ending patterns can be used to constrain mechanistic models of spontaneous seizure cessation and inform ideas about new therapies designed to curtail seizure intensity or end them altogether.

Title: Reactivation of neuronal ensemble spiking patterns during human focal seizures

Authors: *F. GERHARD[1], S. S. CASH[3], W. TRUCCOLO[1,2,4];
[1]Dept. of Neurosci., [2]Inst. for Brain Sci., Brown Univ., Providence, RI; [3]Dept. of Neurol., Massachusetts Gen. Hosp. and Harvard Med. Sch., Boston, MA; [4]Ctr. for Neurorestoration and Neurotechnology, DVA, Providence, RI

Abstract: The collective dynamics of neuronal ensembles during focal seizures is a fundamental problem in neuroscience and in the development of new therapies for pharmacologically intractable epilepsy. It remains unknown whether neuronal subsets are randomly recruited to engage with different patterns of activity in every seizure, or whether reoccurrence of seizures leads to reactivations of similar patterns in the same neuronal ensemble. By contrast to a random recruitment hypothesis, here we characterize patterns of neuronal reactivations that are stereotypical and highly reproducible across propagated seizures within the same patient. Ensembles of single neurons were simultaneously recorded via 96-microelectroded arrays implanted in the neocortex of patients undergoing neuromonitoring prior to resective surgery. In a few patients, we were able to record the same neuronal ensemble across different seizures. Two complementary statistical modeling approaches were applied to characterize the collective dynamics in recorded multivariate neuronal point processes and capture the recurring network patterns. One approach is based on a low-dimensional hidden linear dynamical system that drives the firing rates of individual single-neurons in the ensemble. The other approach couples neurons' firing rates to the ensemble activity through a dense network of effective connections and a newly introduced mean-field coupling. We find that both models could predict single-neuron firing equally well: Cross-validated prediction scores based on the area under ROC curves ranged from 0.7 to 0.9 for two types of seizures with qualitatively different dynamics. Furthermore, predictions of both models were partially correlated, indicating that models captured similar dynamical features of the spiking patterns. We hypothesize that a combination of both models could further improve prediction. Both models provide a generative mechanism for the underlying seizure dynamics that could not otherwise be derived from simpler,

descriptive statistics. Overall our findings indicate that the reactivation of the stereotypical patterns of neuronal activity during seizures can be captured by the evolution of collective dynamics in the recorded ensemble. The reoccurrence of activity patterns in neuronal ensembles points to the existence of temporally stable, effective microcircuits that are reactivated during seizures. Furthermore, compact statistical descriptions of high-dimensional neural recordings such as those presented here are a major step towards better algorithms to detect and control seizures in people with pharmacologically resistant seizures.

Title: Identification of epileptogenic network using intrinsic evoked potentials

Authors: ***S. KARUNAKARAN**[1], C. M. KADIPASAOGLU[2], G. P. KALAMANGALAM[3], B. AAZHANG[4], N. TANDON[5];

Abstract: It is becoming increasingly accepted that seizures are a manifestation of aberrant network function involving disseminated cortical and subcortical brain regions rather than a single epileptogenic focus. Identification of patient-specific epileptogenic networks is a crucial first step in modulating these networks to decrease seizure probability. Characterizing the seizure network involves identifying anatomical regions (i.e. nodes) of increased excitability, and estimating the intensity and direction of information flow between these nodes. Intracranial recordings in patients undergoing pre-surgical evaluation for medically refractive epilepsy provide a unique opportunity to evaluate and isolate seizure networks. Traditionally, cerebral connectivity is estimated using cortico-cortical evoked potentials (CCEPs) in response to external electrical stimulation. CCEPs have also been used to delineate ictal-onset regions and regions of early and late seizure propagation. Similar to these CCEPs, responses to endogenous inter-ictal spikes provide an indirect measure of functional connectivity. We propose to use evoked potentials from endogenous inter-ictal signals, particularly inter-ictal spikes to identify

and visualize functional connectivity among brain regions. We hypothesize that inter-ictal spikes will evoke strong responses from sub-regions of the networks involved in seizure propagation.Three hundred spontaneously occurring epileptiform spike discharges were used to align recordings from other cortical regions in two patients. We found that the majority of electrodes having large average responses to inter-ictal spikes overlay regions exhibiting rhythmic discharges during seizures. In addition to nearby regions that are expected to have large responses, regions distant from the reference region also showed large responses suggestive of aberrant connectivity that likely represents the epileptic network.In comparison to the stimulation paradigm for obtaining CCEPs, which is time-consuming and determined by clinical needs, intrinsic evoked potentials (IEPs) from endogenous spikes utilize the routinely collected inter-ictal data. The precise patient-specific information obtained using these methods can then be used to target the most susceptible nodes by ablative or neuromodulation strategies.

Title: Evaluation of the components of the cortico-cortical evoked potentials with single and paired pulse subdural electrical stimulation in epilepsy patients

Authors: B. HAJNAL[1,2], *L. ENTZ[1,3], E. TOTH[3], I. ULBERT[4], D. FABO[1], L. EROSS[1]; [1]Natl. Inst. of Clin. Neurosciences, Budapest, Hungary; [2]Semmelweis University, Sch. of PhD studies, Budapest, Hungary; [3]Fac. of Information Technol. and Bionics,Pázmány Péter Catholic Univ., Budapest, Hungary; [4]Inst. for Psychology,Hungarian Acad. of Sci., Budapest, Hungary

Abstract: Cortical electrical, and transcranial magnetic stimulation (CES and TMS) can be reliably used in the investigation of cortical excitability, localization of the seizure focus and mapping of the cortico-cortical networks. Moreover these modalities can be effective in the therapy of drug-resistant epilepsy. Paired-pulse TMS study delivering preconditioning and test stimulus with various ISIs showed short interval inhibition (1-6ms), a short interval excitation (8-30ms) and a long interval inhibition (50-200 ms). Recently our group found that CES applied on

subdural electrodes resulted in a single wave of slow oscillation (SO) regardless of the vigilance state of the patient. Physiological mechanisms underlying electrophysiological changes observed during cortical electrical stimulation is barely known in humans, although there are presumptions regarding to the excitatory and inhibitory neuronal mechanisms during paroxysmal discharges.We studied single (n=10) and paired-pulse (n=4) electrical cortical stimulation on drug-resistant epilepsy patients implanted with subdural grid and strip electrodes, and laminar multielectrodes (24 contact, 200μm). We applied brief single (10mA, 0.2ms, 0.5Hz) and paired (ISI: 6.6, 10, 20, 30, 40, 50, 100, 200, 500, 1000ms, on the best single response electrode-pair) current pulses on adjacent contacts of the grid and strip electrodes. Various phases of cortico-cortical evoked potentials (CCEP) were analyzed using custom scripts in Matlab. We found P1, N1, P2, N2 components with average latencies of 12, 30, 60, 160 ms respectively. The larger was the distance between stimulating and recording electrodes on the same gyrus, the longer latency components were evoked only. The laminar profile showed surface current sink and layer IV source for N1, surface source and layer IV sink for P2, and a wide source for N2 in the middle layers. Amplitude difference of P1-N1, N1-P2, P2-N2 was correlated with ISI. Values measured at 2000ms ISI was used as baseline. We found similar N1-P2 curve characteristics in 3 out of the 4 patients evaluated with an excitation at ISI 7 and 10ms, inhibition at ISI 20-50ms and a long interval excitation at ISI 200 and 500ms.We were able to describe the laminar profile of different phases of the CCEPs, and succeeded to identify excitatory (P1, N1) and inhibitory (P2, N2) components. Previously reported evoked SO was identical to N2 in the present abstract. In our paired pulse stimulation setting we demonstrated these inhibitory and excitatory effects on the second CCEP response.

Title: Robust threshold estimation for detection of discrete neural events in long-term human recordings

Authors: ***M. AGHAGOLZADEH**[1], F. GERHARD[1], W. TRUCCOLO[1,2];
[1]Neurosci., Brown Univ., Providence, RI; [2]DVA, Ctr. for Neurorestoration and neurotechnology, Providence, RI

Abstract: The detection of neural events over long time periods introduces new challenges to an already complicated signal detection problem, e.g. detecting spike-wave discharges from local field potentials (LFPs) or action potentials from broadband recordings in human neocortex. In relatively artifact-free data, the background noise tends to be stable over hours/days due to the stability of resistance/capacitance features of electrodes in these time scales. However, current state-of-the-art methods for estimating detection thresholds (e.g., methods based on standard deviation (SD) of the noise) are not robust to fluctuations in ongoing neural activity and thus cannot reliably detect discrete neural events. Here, we examine an approach for estimating the detection threshold for individual electrodes based on maximizing the log-likelihood of a probabilistic mixture model, in which a separate model is assigned for the background noise and neural signal. In particular, we consider the case of a mixture of an Exponential-Gaussian density function to fit the highly skewed noise distribution, and a Gaussian density function to fit the target neural signal distribution. Under significant fluctuations in the level of neural activity in our datasets, the parameters of the Gaussian density function (mean and variance) and the mixture weight varied substantially over time, while the parameters of the Exponential-Gaussian density function, which identifies the distribution of the background noise, tended to remain almost constant. A simpler two-class Gaussian mixture model (GMM) failed to provide reasonable estimates of the detection threshold due to the skewness of the noise distribution. In comparison with the two-class GMM, the proposed mixture model significantly reduced the Kullback-Leibler divergence between the empirical and estimated signal distribution. Visual inspection of the data indicated that the new proposed approach led to more stable estimation of the detection threshold and fewer false positives in comparison to previous SD and two-class GMM methods.

Abstract: Seizures in patients with acute encephalopathy, biphasic seizures, and late reduced diffusion (AESD) are varied. The aim of the current study was to evaluate how the duration of initial and/or subsequent seizures interacts with the occurrence of AESD and prognosis of pediatric emergency patients with their first febrile seizures. Seventy-three patients (M:F [39:34]; age range, 0-14 years; mean years, 2.8 years), who were evaluated in our pediatric emergency department with their first febrile seizure, were retrospectively reviewed. Prolonged seizures > 30 min in length (status epilepticus), clusters of complex partial seizures < 30 min in length, and brief seizures occurred in 33, 5, and 35 patients, respectively. All 73 patients had brain MRI including diffusion weighted image (DWI) within 24 h of arrival at our hospital. Based on clinical and electroencephalogram (EEG) findings, 10 (M:F [5:5]; age range, 0-6 years; mean age, 2.5 years) of 33 patients (M:F[18:15]; age range, 0-10 years; mean age, 2.3 years) with prolonged seizures resulted in AESD; none of the remaining 40 patients with initial seizures < 30 min developed AESD. Six of 10 patients had a subsequent seizure of shorter duration than the initial seizure, 2 patients had clusters of complex partial seizures for several days, and 2 patients did not have a secondary seizure. One of the 2 patients without a secondary seizure had subcortical diffuse abnormalities in the initial MRI, a high fever lasting several days with delirium, and had the worst prognosis of the 10 patients. Nine of 10 patients had no abnormalities on the initial MRI, and all 9 patients had MRI abnormalities between 2 and 5 days after initial MRI. Subsequent seizures were not related to the prognosis in the 9 patients. Appropriate medical care for the first onset febrile seizure < 30 min could prevent subsequent seizures and the occurrence of AESD, although prolonged seizures could not be avoided.

Abstract: Impaired consciousness in epilepsy is highly detrimental to patients' quality of life, but is difficult to quantitatively characterize in a reliable manner. Information about impaired consciousness or responsiveness during seizures guides decisions about driving safety and helps determine the severity of seizures for surgical decision making. In previous studies, we developed and validated a prospective responsiveness in epilepsy scale (RES) which yielded standardized classifiers of patient cognition levels during seizures. Up to now, we relied on trained hospital personnel to sit at the bedside continuously in order to administer the RES to patients during seizures. Since this process was both error-prone and prone to missing seizures entirely, our aim was to fully automate the RES using a combination of seizure detection and structured playback of RES video clips. The computerized version of the RES ("Robo-RES") was created to eliminate errors made during testing, to capture more seizures, and to reduce the latency between seizure onset and onset of the RES questioning without sacrificing the comprehensive set of sensorimotor and cognitive functions of interest. To build the Robo-RES, we recorded videos of the RES questions and dynamically combined them in a PsychoPy experiment task to be viewed by patients immediately after seizure onset on an all-in-one PC mounted in the patient's room. The Robo-RES testing is triggered either by a patient pushbutton event or by Persyst 12 automatic seizure detection from the clinical video/EEG monitoring computer. To test functionality of the system we simulated seizure events using pre-recorded video/EEG data from 14 seizures in 4 patients. The Robo-RES was able to correctly initiate automatic behavioral testing for 100% (14/14) of seizures with a mean time lag of 2.1 s and no false-positive test initiations. The user interface was fully integrated with and did not impede the clinical recording system. Further testing in the Yale Comprehensive Epilepsy Center Video/EEG monitoring unit will enable full implementation of the Robo-RES for patients as part of their clinical care. Automatic ictal and postictal behavioral testing of epilepsy patients has the potential to greatly enhance information obtained during video/EEG monitoring that will help guide decisions about seizure severity and therapeutic interventions for people with epilepsy.

Title: Mechanisms of seizure identified from causal connectivity inferred using directed information

Authors: *R. MALLADI[1], G. KALAMANGALAM[2], N. TANDON[3], B. AAZHANG[1]; [1]Dept. of Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Dept. of Neurol., [3]Dept. of Neurosurg., Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: Epilepsy is a common neurological disorder affecting nearly 1% of the world's population. The current treatments for epilepsy based on medication and surgical resection are not effective. Learning how seizures originate is crucial to develop next generation treatments for epilepsy. We analyzed the changes in causal connectivity over time in five epileptic patients to improve our understanding of seizures. The causal connectivity between electrodes implanted in an epileptic patient is estimated from electrocorticographic (ECoG) recordings using directed information (DI) from multiple shifted time-windows. Figure 1 plots the results of our analysis from a seizure of patient P1. The solid vertical black lines in Figure 1 represent the seizure start and end times as determined by neurologist. In addition, there is no significant seizure activity between 250s and 350s in this seizure. The mean and standard deviation of the average strength of the outgoing connections from all channels outside seizure onset zone (SOZ) and all channels in SOZ to the channels outside SOZ is plotted in Figure 1. The red and blue curves correspond to the connections from electrodes outside SOZ and within SOZ, respectively. It is clear from this figure that the electrodes outside SOZ become more synchronous during seizures implying that seizures occur when the regions outside SOZ become sufficiently hyper synchronous. We also observed a `trigger' pulse (two small spikes in the blue curve) from the electrodes in SOZ to those outside at the beginning of the seizure activity. These trends are broadly observed in the remaining patients as well. In addition, we present the connections between the inferences made from our dynamic connectivity analysis in human patients and the seizure generation mechanisms observed in animal models of epilepsy. This could be the first step towards development of novel treatments for epilepsy. **Figure 1: Dynamic causal connectivity of patient 1 inferred using directed information**

Title: Hippocampal theta connectivity networks in normal and epileptic subjects demonstrated by magnetoencephalography

Authors: ***A. ALHOURANI**[1,1], M. J. RANDAZZO[1], T. A. WOZNY[1], E. D. KONDYLIS[1], M. J. WARD[1], A. NIRANJAN[1], A. BAGIC[2], A. S. GHUMAN[1], R. RICHARDSON[1];
[1]Neurolog. Surgery, [2]Neurol., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Understanding human memory relies, in part, on the study of the hippocampus. The subcortical location of the hippocampus, however, limits the neurophysiological sampling of hippocampal activity to electrophysiological recordings obtained from invasive depth electrodes or, indirectly, to metabolic changes observed using fMRI. Fortunately, recent developments in magnetoencephalography (MEG) analytic techniques are refining our ability to reliably record neural activity from subcortical structures. The objective of this study was to demonstrate the baseline hippocampal functional connectivity network using neural signals recorded with MEG. Eleven subjects (9 healthy controls and 2 subjects with unilateral mesial temporal lobe epilepsy (MTLE)) underwent 5 minutes of non-task-related MEG recordings with their eyes open. The signals were preprocessed and projected to source space onto a volumetric grid for the

hippocampal sources using Brainstorm MATLAB suite. Since multiple studies have linked the theta rhythm to hippocampal memory function and to information transfer to cortical areas, the weighted phase lag index (WPLI) for the theta frequency (4-8Hz) was averaged over 30 randomly selected, artifact-free 4 second epochs and averaged per subject. The same procedure was done on the empty room recording. Functionally connected regions were defined by selecting the regions showing WPLI values greater than 2.5 standard deviations from the mean (calculated using the Rayleigh statistic after subtracting the WPLI values for the empty room from the subject's WPLI values to account for the imperfect inverse solution). The non-task, hippocampal theta network comprised parts of the limbic system and both the dorsal and ventral attention networks. In normal subjects, significant WPLI values were found between the anterior hippocampus and the ipsilateral anterior cingulate, orbitofrontal, anterior prefrontal, frontal eye field, premotor, superior parietal, fusiform, entorhinal and parahippocampal cortical areas. WPLI values indicated bilateral connectivity to temporopolar, occipital and middle temporal cortical areas. Patients with MTLE showed a similar pattern, however the epileptic hippocampus showed significantly reduced connectivity ($p < 0.01$) compared to the non-involved side in both patients. Here we provide evidence that MEG can detect hippocampal-based networks using resting state data and that MTLE reduces hippocampal-cortical functional connectivity in the theta frequency band

Title: Differential activation of calpain-1 and calpain-2 following kainate-induced seizure activity in rats and mice

Authors: ***J. SEINFELD**[1], N. BAUDRY[1], X. XU[2], X. BI[1], M. BAUDRY[1];
[1]Western Univ. of Hlth. Sci., Pomona, CA; [2]USC, Los Angeles, CA

Abstract: Systemic injection of kainate produces repetitive seizure activity in both rats and mice. It also results in acute synaptic modifications as well as delayed neurodegeneration. The signaling cascades involved in both acute and delayed responses are not clearly defined. The calcium-dependent protease calpain is activated in various brain structures following kainate injection, although the precise involvement of the two major calpain isoforms, calpain-1 and calpain-2, remains to be defined. Calpain-2 selectively truncates the phosphatase PTEN, and calpain-1 and calpain-2 play opposite roles in NMDA receptor-mediated neuroprotection or neurodegeneration. In the present study, we determined KA-induced activation of calpain-1 and calpain-2 in hippocampus by analyzing changes in different calpain substrates, including spectrin, PTEN and drebrin in both rats and mice, both wild-type and calpain-1 knock-out (ko) mice. As PTEN is selectively cleaved by calpain-2 but not by calpain-1, decreases in PTEN levels detected by western blots or immunohistochemistry reflect selective calpain-2 activation. Similarly, changes in calpain substrates detected in calpain-1 ko mice are the results of calpain-2 activation. The results indicate that while calpain-2 is rapidly activated (less than 1 h) in pyramidal cells throughout CA1 and CA3, early calpain-1 activation (1-4 h) is restricted to selective population of parvalbumin-expressing interneurons in CA1 and CA3. As previously reported, neither calpain-1 or calpain-2 is activated in the dentate gyrus. In addition, calpain-1 knock-out mice exhibit increased long-term neurodegeneration in CA1 and CA3. These results suggest that calpain-1 and calpain-2 are differentially activated by seizure activity in different cellular populations in hippocampus. They strengthen the notion that calpain-1 activation is neuroprotective, while calpain-2 activation is neurodegenerative. Thus, a selective calpain-2 inhibitor could be beneficial for limiting the debilitative consequences of seizure activity.

Title: Signaling of β-catenin and neuronal death in cerebellum of kindling rats

Authors: *A. ROSILES[1], M. C. RUBIO-OSORNIO[1], C. TREJO-SOLÍS[2], J. J. GUTIÉRREZ[1], V. CUSTODIO[1], A. EGUILUZ-MELÉNDEZ[3], J. C. MARTÍNEZ[1], E. GONZÁLEZ[1], L.

HERNÁNDEZ-LÓPEZ[1], C. CASTILLO[1], C. PAZ[1];

Abstract: Epilepsy is one of the most common neurological disorders in humans, and the role of cerebellum in its physiopathology remains subject of study. Bergmann glia (BG) in the cerebellar cortex regulates the homeostasis of Purkinje cells (PC), whose axons targets the dentate and interpositus nuclei, which form the main cerebellar output to other structures in the central nervous system involved in Epilepsy. *Sox-1* is a transcription factor expressed in BG and its binding to β-Catenin (βC) further inhibits the canonical *Wnt* pathway. It has been reported βC signaling is increased as the hippocampus receives repeated electrical stimuli and this is related with apoptosis of neurons. In the cerebellum, the recurrence of seizures results in PC death, although the mechanisms remain unclear. Here we present the expression of βC and the type of PC death in cerebellum of rats with seizures induced by amygdala kindling. We used Wistar rats separated into groups that received 3, 15, 45 stimuli and our controls. Once animals sacrificed, the cerebellum was processed for immunohistochemistry assay for βC, TUNEL and caspase-3. We found increased immunopositivity for βC expression in the nucleus and citosol of neurons in the 45-stimuli group compared to the controls and the rest of groups. TUNEL assay in the PC showed apoptosis in the 15-stimuli group and necrosis in the 45-stimuli group. Caspase-3 assay shows statically significant increased immunopositivity ($p \leq 0.05$) in the 45-stimuli group compared to the others groups. We concluded that there are higher activity of βC associated with increased number of stimuli may be related with the presence of apoptosis and necrosis in the cerebellum treated with amygdala kindling. In this way we suggest this mechanism as a one possible explanation of PC death in epilepsy.

Abstract: Seizures generate an inflammatory response through the activation of microglia facilitating the epileptogenesis. The aim of this study was to test the Honokiol and Magnolol components of Magnolia officinalis (MG) on the inflammatory response in a epileptogenesis model induced by recurrent crises with AK. Method: Sham, kainic acid (AK), Celebrex (CLBx), Magnolia officinalis (MG): Male Sprague Dawley 10 PN, n = 48 rats were used and divided into four groups. The AK was administered at doses of 1.5 mg / kg ip from 10pn-14PN and treated with MG extract (300mg / kg) via esophageal from the 15th PN day and celecoxib (20mg / kg po) was tested as a control drug. Spontaneous seizure activity was evaluated at the 30th and 60th PN days through the evolution of motor behavior and the pro inflammatory COX2 proteins, IL1-β in temporal cortex, amygdala and hippocampus were quantified by Western Blot. In the Western Blot analysis, a significant reduction is observed $P < 0.05$ over the expression of COX2, IL1β in amygdala in comparison with the hippocampus and temporal cortex at the 30th and 60th PN. This indicates that the MG treatment had anti-inflammatory effects and reduced the spontaneous crises over the SNC, indicating the role that inflammation has on the development of epilepsy. Title: A novel therapeutic strategy to reduce brain inflammation and injury after status epilepticus

Authors: *J. JIANG[1], R. DINGLEDINE[2];
[1]James L. Winkle Col. of Pharm., Univ. of Cincinnati, Cincinnati, OH; [2]Pharmacol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Status epilepticus (SE) in humans causes high mortality and extensive morbidity in survivors. The only effective treatment currently is to stop the seizures quickly enough to prevent brain damage. However, reliance on acute therapies alone would be imprudent due to the required short response time, and more than one third of SE patients do not respond to current antiepileptic drugs. Thus, follow-on therapies that can be delivered well after seizure onset are needed. SE triggers a sequential of molecular, cellular and systemic alterations in the brain that often culminate in the appearance of spontaneous seizures, i.e., epilepsy. Although the mechanisms underlying these alterations in the brain are not fully understood, we and others have provided evidence for the involvement of cyclooxygenase-2 (COX-2) cascade in the seizure-triggered pathogenesis. COX-2 is rapidly induced by prolonged seizures and synthesizes prostanoids, which then activate specific G protein-coupled receptors and contribute to brain-blood barrier disruption, brain inflammation and injury, and functional loss. As a dominant product of COX-2 in the CNS, prostaglandin E2 (PGE2) promotes oxidative damage and neurotoxicity in models of chronic inflammation and neurodegeneration, where PGE2 receptor EP2 subtype has been proposed to exert a major role via activating microglia and promoting powerful cytokine storms. Our newly-discovered novel antagonists for EP2 receptor with sufficient pharmacokinetic profiles (Patent: US20140179750) enabled us to directly investigate the candidacy of the EP2 receptor as a therapeutic target to mitigate the pathology following SE. Treatment with these EP2 antagonists significantly reduced glutamate receptor-mediated neuronal excitotoxicity in hippocampal cultures comprising neurons, astrocytes and microglia.

Administration of a brain-permeant EP2 antagonist in mice commencing two hours after seizure onset for two days reduced delayed mortality and functional deficits after a one hour episode of SE induced by kainate or pilocarpine. In addition, EP2 antagonism via this compound also reduced the severity of cytokine storms and neuronal death in hippocampus after SE. In sum, these preclinical findings, together with follow-up studies in other seizure models and species, demonstrate the feasibility of blocking PGE2/EP2 signaling by small molecules to treat SE. The promising salutary actions from these novel EP2 selective antagonists should also be relevant to other neurological conditions including Alzheimer's disease, multiple sclerosis, strokes, glioblastoma, etc., in which COX-2/PGE2-driven neuroinflammation plays pivotal roles.

Title: Spatiotemporal profile of microglial changes in the hippocampus following prolonged continuous seizure activity in an experimental model of acquired epilepsy

Authors: *S. HERR, N. SCHARTZ, L. MADESN, S. WYATT, J. WOODLIFF, A. BREWSTER;
Purdue Univ., West Lafayette, IN

Abstract: Long-lasting continuous seizure activity (status epilepticus) (SE) is often associated with hippocampal neuronal and dendritic injury and the subsequent development of spontaneous recurrent seizures (epilepsy). One hallmark often associated with SE-induced hippocampal injury is activation and proliferation of microglial cells, the neuroimmune cells of the brain. Under pathological conditions, microglia infiltrate, accumulate, and develop an inflammatory phenotype that includes a change in morphology from highly ramified to hypertrophied, and the production and release of immunological messenger molecules such as pro-inflammatory cytokines. Also, microglia have been implicated in alterations in dendritic arborization and in synaptic pruning under both physiological and pathological conditions. Thus, we hypothesized that SE-induced activation and proliferation of microglial cells precede the associated hippocampal dendritic pathology. To investigate this possibility we used a combination of immunohistochemistry (IHC) and flow cytometry to map the spatiotemporal profile of SE-induced microglial changes in the hippocampus. SE was induced in rats with the

chemoconvulsant pilocarpine and stopped after one hour with the anticonvulsant diazepam. Controls were given saline. Tissue was fixed at 4 hours, 1-, 3-, 14-, and 35-days after SE for IHC and microglia were identified using antibodies against IBA1. Also, hippocampi were dissected at 14 days after SE for flow cytometry analysis using antibodies against CD45, CD11b, and MHC Class II. IHC showed a homogeneous distribution of IBA1 throughout the hippocampus of control rats. SE precipitated microglial morphological changes from ramified to hyperthorpied that were evident as early as 4 hrs after SE. Drastic accumulations hypertrophied microglia were evident at 3 days after SE in all hippocampal regions. The remarkable accumulation of microglia in the CA1 area that occurred at 14 days post-SE was resolved by 35 days after SE. Flow cytometric analysis showed an increased number of CD45+/CD11b+/MHCII+ cells 14 days post SE compared to controls. These data support that SE triggers acute changes in microglia activation and promotes a transient proliferation that is very specific to the CA1 area. Furthermore, these data suggest that microglia may contribute to the SE-induced neuronal and dendritic decline that often parallels the time course examined in this study.

Title: The neuroprotective effect of antioxidant compounds in an *in vitro* model of epilepsy

Deleted: *in vitro*

Authors: L. P. MONTES, *V. I. NAVARRO, K. FENELON;
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: Under physiological conditions, radical species such as nitric oxide (NO) are regulatory mediators in various biological processes. However, excess of radical species are also implicated in a wide variety of neurological insults such as stroke and epilepsy. In fact, free radical production is enhanced during epilepsy, leading to seizure-mediated neuronal injury. Experimental seizure-like events are characterized by abnormal synchronized electrical activity and elevated NO seen in various brain regions including the hippocampus. Despite scientific efforts, about 30-40% patients with temporal lobe epilepsy are drug resistant. This is partly

because the current and commonly used anti-epileptic drugs lack anti-oxidant properties to scavenge radical species. Therefore, the development of antioxidant drugs bearing neuroprotective properties should be promising as an additional treatment of epilepsy. Ferrostatin-1 (Fer-1) is a small molecule with antioxidant properties that can prevent cell death (Dixon et al., 2012). Thus here, the objective of the present study was to evaluate the neuroprotective effect of Fer-1 in a simple *in vitro* model of epilepsy. To do so, we used extracellular field electrophysiological recordings in rodent hippocampal slices. Epileptic form activity was induced in acute hippocampal slices treated with Gabazine (10 µM), a GABAA receptor antagonist, added to the perfusing solution. Gabazine synchronized the activity of excitatory neurons which was shown as repetitive activity in the electrophysiological recordings made in the CA3 region, typical of epileptic-like events. The epileptic activity was quantified by measuring the amplitude and the frequency of the epileptic-like events. Our results show that upon Fer-1 addition, the amplitude of the Gabazine-induced epileptic-like events decreased, where as their frequency was left unchanged (N = 11). We then decided to test two other Fer-1 analogs (N = 6) also shown to exhibit antioxidant properties assessed through the use of DPPH assay. In addition and as a control, we also compared the effects of Fer-1 to vitamin E, a known antioxidant (N = 2). Among these tested compounds, Fer-1 demonstrated the strongest efficiency by decreasing the amplitude of the epileptic-like events. Fer-1 possibly acted by scavenging the excess NO produced in the hippocampal slice during epileptic activity. We conclude that small antioxidant molecules such as Fer-1 could eventually be combined with currently used drugs as a novel therapeutic strategy for diseases with reactive species imbalances, such as epilepsy.

Title: Early life seizures diminish silent synapses in developing cortex

Authors: ***H. SUN**[1], J. J. LIPPMAN-BELL[1], M. HANDY[1], T. K. HENSCH[2], F. E. JENSEN[1]; [1]Dept. of Neurol., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Neurol., Boston Children's Hosp. and Harvard Med. school, Boston, MA

Abstract: Early life seizures are often refractory to conventional antiepileptic drugs and can result in chronic later-life epilepsy and long-term cognitive deficits including autism. Our previous studies have shown that early life seizures increase AMPAR function at least in part due to reduction of NMDAR-only silent synapses in hippocampal pyramidal neurons (Rakhade et al., 2008; Zhou et al., 2011). To determine whether this occurs in other developing synaptic networks, we examined the effects of early life seizures on AMPAR function and silent synapses in developing primary auditory cortex. Early life seizures were induced by daily pentylenetetrazol (PTZ) injections (60mg/kg, i.p.) from P9-11. Whole-cell patch-clamp recordings were performed from Layer IV (L4) A1 pyramidal neurons in auditory thalamocortical slices from P12-13 post-seizure mice and littermate controls. We found that L4 neurons in slices from post-seizure pups showed a significant increase in the amplitude of AMPAR sEPSCs (−13.29 ± 0.64 pA; n = 8; p0.05) comparable to controls (0.31 ± 0.06 Hz; n = 8). In addition, minimally evoked AMPAR-mediated EPSCs through stimulating single fibers of thalamocortical circuits showed significantly higher amplitudes in neurons from post-seizure mice (18.09 ± 2.21 pA; n = 8, $p<0.05$) compared to neurons from controls (12.63 ± 1.11 pA; n = 7). We next measured the changes in the ratio of NMDAR-only silent synapses in L4 A1 pyramidal neurons following early life seizures. Silent synapses are determined by the difference of failure rates of evoked eEPSCs at negative membrane potentials (-60 mV) and positive potentials (+40mV). Auditory thalamocortical slices from P12-13 controls exhibited a failure rate of 51.21 ± 4.35% at -60mV and a failure rate of 17.94 ± 2.05% at +40mV (n=8, p0.05), yielding a significant decrease in the NMDAR-only silent synapses (21.77 ± 6.61%, n=8, $p<0.05$) compared to controls. Taken together, these data demonstrated the presence of NMDAR-only silent synapses in the developing primary auditory cortex. Importantly, these silent synapses are modifiable and converted to functional synapses by early life seizures, suggesting the potential effects of early life seizures on function and synaptic plasticity of auditory cortex.

Title: The effect of limbic and nonlimbic kindling on hippocampal interneuron populations

Authors: *J. J. BOTTERILL[1], H. J. CARUNCHO[2], L. E. KALYNCHUK[3];
[1]Psychology, [2]Col. of Pharm. and Nutr., [3]Col. of Med. (Neurology), Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: GABAergic inhibitory interneurons are critical in regulating neuronal excitability and cognition. Many factors can alter GABAergic neurotransmission and function within the brain, but one noteworthy factor is epileptic seizures. In the present study we utilized the kindling model of epilepsy in rats to determine whether specific hippocampal GABAergic interneuron populations are affected by seizures. Kindling refers to the gradual development and intensification of elicited motor seizures resulting from electrical stimulation of a discrete brain site. We conducted 99 kindling stimulations of limbic (basolateral amygdala, dorsal hippocampus) and non-limbic (caudate nucleus) brain sites in rats. Within 24 hours of the final kindling stimulation, rats were sacrificed and their brains were prepared for immunohistochemistry. We then conducted profile counts of several GABAergic interneuron markers in the hippocampus, including somatostatin, parvalbumin, calretinin, and GAD67. The results of our study revealed that the number of somatostatin immunoreactive (ir) interneurons were relatively unaffected by kindling. In particular, we found a small increase of somatostatin-ir cells in the CA1 pyramidal cell layer following limbic kindling. However, we also noticed that the hippocampal somatostatin-ir cells of limbic-kindled rats displayed significant hypertrophy (e.g., sprouting), which was confirmed by conducting surface area measurements of somatostatin-ir cells. In contrast, parvalbumin-ir cells was resilient to the effects of kindling and the surface area remained of these cells was also unchanged. We also found that limbic kindling resulted in a very mild reduction of calretinin-ir cells in the dentate gyrus, but no other hippocampal subfields. Lastly, our preliminary results indicate that GAD67 cells are also resilient to the effects of kindling. Taken together, our results suggest that kindling does not cause a gross loss of interneuron populations. Rather, we see small alterations in the absolute number of immunolabeled interneurons, but significant plasticity of specific interneuron populations (e.g., sprouting/hypertrophy of somatostatin-ir cells). Collectively, these results suggest that some interneuron populations undergo greater plasticity than others in response to epileptic insults.

Title: Enhancing GABA signaling exacerbates febrile seizures and elicits axonal sprouting in the hippocampus

Authors: *X. SUN, R. KOYAMA, Y. IKEGAYA, H. UEDA;
Lab. of Chem. Pharmacol., Tokyo, Japan

Abstract: Enhancing GABA signaling exacerbates febrile seizures and elicits axonal sprouting in the hippocampus Xuezhu Sun, Ryuta Koyama, Hideaki Ueda, Yuji Ikegaya Laboratory of Chemical Pharmacology, Graduate School of Pharmaceutical Sciences, The University of Tokyo Febrile seizure (FS) is the most common convulsive event that appears in early childhood. Especially, prolonged complex FSs could be a risk factor for the future development of temporal lobe epilepsy (TLE). To relieve complex FSs, GABA enhancers such as diazepam are widely used for reinforcing the inhibitory action of GABA in neural circuits. However, accumulating evidence suggests that GABAergic signaling depolarizes immature neurons, which has presented questions about the efficacy of GABA agonist for the therapy of neonatal seizures. To evaluate the effects of GABAergic activation during neonatal seizures, we induced complex FSs in mice at postnatal 11 days (P11). Specifically, we investigated the effects of several GABA enhancers including diazepam on the latency to seizure induction, the duration of seizures, and the hippocampal sclerosis, an epileptogenic hallmark suggested as a cause for the future development of epilepsy. We found that mice pre-treated with GABA enhancers demonstrated severer FS phenotypes, such as earlier onset and longer duration of seizures compared to control FS mice without the treatment of GABA enhancers. Among several GABA enhancers, the effect of pentobarbital on the seizure phenotype was the most prominent. Then we further determined the long-term effects of pentobarbital on FSs by analyzing anatomical changes in the hippocampus at P60 such as the dispersion of dentate granule cells, the hippocampal mossy fiber sprouting, and the degeneration of CA3 pyramidal cells, all indicative of the hippocampal sclerosis. The dispersion of dentate granule cells was comparable between control, FS, and FS + pentobarbital mice. In contrast, the mossy fiber sprouting was observed only in FS + pentobarbital mice. In addition, the number of unhealthy cells with aggregating DAPI staining in CA3 was increased in FS mice compared to control, which was prevented in FS + pentobarbital mice. In conclusion, our findings suggest that GABA enhancers could exaggerate early-life FSs

febrile seizure in immature brain and cause the mossy fiber sprouting, while they may prevent FS-induced cell loss in CA3.

Title: Comparing microarray profiles of hippocampal subregions with amygdala cortical complex reveals distinct gene expression following multiple early life seizures

Authors: ***L. K. FRIEDMAN**[1,2], S. HU[1], A. M. SLOMKO[1], K. C. YEE[1], J. M. MANCUSO[2]; [1]New York Med. Col., Valhalla, NY; [2]Neurosci., NYIT, Old Westbury, NY

Abstract: Previously we showed that postnatal (P) P20 rats are relatively resistant to hippocampal CA1 injury when they have a history of two earlier neonatal seizures, whereas other limbic areas are less spared. Transcriptome profiling of the CA1 subregion following single (1×KA) and multiple early life seizures (3×KA) showed many common and uncommon genes were up and downregulated. To gain further understanding of which genes are actually involved in spatially protective vs. neurotoxoic effects, we profiled genes of the CA3, dentate gyrus (DG), and amygdala entorhinal complex (Amg/Ercx) under similar conditions. Within the CA1 and CA3, autophagy and pro-inflammatory genes were triggered; however, many protective genes were also differentially upregulated, particularly after 3×KA. These included but were not limited to Ca++ modulated proteins, apoptosis inhibitors, adaptor-related protein complexes, ADAM metalloproteinases, adaptor ATG autophagy genes, caspase cascade activators, ATP-mediated gliotransmitters, GTP binding proteins, cyclins, F-box proteins, growth factors, interleukins, heat shock proteins, certain GABAergic, ionotropic and metabotropic glutamate neurotransmitter receptors and synthesizing enzymes. Differential downregulation included genes encoding ankyrin-repeat proteins, adenosine receptors, ATP synthases, caspases, Ca++ channels, certain heat shock proteins, NFKB activating proteins, synaptosomal associated proteins, K+ voltage gated channels, and zinc finger domains. In contrast, within the DG, autophagy, pro-inflammatory, pro-apoptotic, and anti-apoptotic transcripts were absent. Instead, dual specificity phosphatases that negatively regulate members of the mitogen-activated protein (MAP) kinase superfamily, axonal and vesicular motility (e.g. dynein) and ATP/ITP metabolism gene regulators predominated which likely contribute to increased Ca++ transport.

Downregulated genes of the DG included ankyrins, reelin, vimentin and other adhesive and guiding transcripts, ionotropic GluR1 subunit, and several G-protein-coupled receptors. In contrast, the Amg/Ercx showed unique upregulation of cholinergic nicotinic and adrenergic receptors, and distinguished downregulation of dopamine, cholinergic muscarinic, histamine, and serotonergic receptors. Results indicate that sustained seizures during early life induce marked region specific brain differences in a large number of critical neurotransmitter genes that encode glutamatergic, adrenergic, chloninergic, and monomonergic receptors to influence the seizure threshold, neuronal vulnerability, proliferation and migratory domains.

Title: Alterations in long-term potentiation (LTP) and gene expression of ionotropic glutamate receptors and neurotrophic factor caused by undernourishment, recurrent neonatal seizures and environmental enrichment

Authors: *A. D. SEBBEN, D. R. MARINOWIC, Z. S. M. COSTA-FERRO, S. D. SALAMONI, J. T. OLIVEIRA, V. H. OLIVEIRA, R. BREDA, M. L. NUNES;

Abstract: Undernourishment associated with recurrent neonatal seizures induces the reduction in brain cell number and suppression of glutamatergic synapses, causing deficits in spatial learning and memory. It has been shown that environmental enrichment improves learning and retention of memory and enhances long-term potentiation in the hippocampus, being able to reverse the cognitive impairment generated by undernourishment and recurrent seizures. The purpose of the present study was to evaluate the alterations of undernourishment, recurrent neonatal seizures and environmental enrichment in LTP and the expression of genes related to neuroreceptors and neurotrophins. Male Wistar rats were divided in two groups: undernourished + seizures (US) and nourished (N). Undernourishment model consisted in maternal and nutritional deprivation from post -natal day 2 (P2) to P15. From P7 to P10, recurrent seizures were induced in the rats by fluorothyl exposition five times per day. Both groups were exposed to the enriched environment between P30 and P60. At P61, the animals were euthanized and one hippocampus was separated

for *in vitro* electrophysiological study (LTP) and the other one for evaluation of expression of NMDA receptor subunits (NR1A, NR2A, NR2B, NR2C and NR2D), AMPA receptor subunits (GluR1, GluR2 and GluR3) and BDNF by qRT-PCR. Preliminary data demonstrated a hippocampal LTP induction in nourished group after environmental enrichment, unlike the undernourished + seizures group in which no induction of LTP was obtained, despite being exposed to the environment enriched. There were an increase in the NR1A, NR2D, GluR2 and BDNF expression genes and a decrease in the NR2A, NR2B, NR2C, GluR1 and GluR3 expression genes in the hippocampus in all groups.

Title: Effects of the intrahippocampal injection of dantrolene in the expression of synaptic plasticity-related proteins during epileptogenesis

Authors: ***P. X. ROYERO**[1], G. S. V. HIGA[2], B. A. SANTOS[1], E. R. KINJO[1], A. H. KIHARA[1];
[1]Núcleo de Cognição e Sistemas Complexos, Univ. Federal Do ABC, Sao Bernardo Do Campo, Brazil; [2]Univ. de São Paulo, São Paulo, Brazil

Abstract: Status epilepticus (SE) is a clinical emergency that can lead to the development of temporal lobe epilepsy (TLE) after neuronal injury. The term epileptogenesis refers to the transformation of the normal neuronal network into a long lasting chronically hyperexcitable state. In most patients presenting TLE, the development and maintenance of spontaneous seizures are linked with hippocampus scleroses-induction, which comprise neuronal loss, reactive gliosis and synaptic modifications following the first injury. It has been shown that SE

produces increase in ryanodine-dependent intracellular calcium levels in hippocampal neurons that remain elevated in animals that develop epilepsy. The aim of this work was to investigate the participation of intracellular calcium released from ryanodine receptors during epileptogenesis, by analyzing the pattern of distribution of some synaptic plasticity-related proteins such as PSD-95, synapsin I and the activity-regulated cytoskeleton-associated protein (arc). Male wistar rats weighting 290-320 g were submitted to stereotaxic surgery for cannula implantation in CA1 region of the hippocampus. After a recovery period of ten days, animals were treated with methyl-scopolamine (1 mg/kg, subcutaneous) followed by pilocarpine injection (360 mg/kg, intraperitoneal). Thirty minutes after the establishment of SE, the ryanodine receptor blocker dantrolene (1 mM) was administered through intrahippocampal injection. Control animals received saline diluted in vehicle instead of dantrolene. A third group consisted of animals that were not submitted to pilocarpine injection, named sham group. One hour after dantrolene or saline treatment, animals received diazepam (10 mg/kg, subcutaneous) in order to interrupt the SE. Animals were sacrificed 48 hours after SE induction and the brains were collected for immunofluorescence analysis. Our results showed that pilocarpine-induced SE caused increased immunolabeling of synapsin I and PSD-95 principally in CA1 region, while arc immunoreactivity was more intense in all regions of the hippocampus. Dantrolene treatment did not affect the expression of the synaptic proteins synapsin I and PSD-95. However, dantrolene decreased the number of cells highly immunoreactive for arc, especially in the CA3a subregion, producing a pattern of staining similar to the sham group in this region. Our results suggest that the dynamic changes in intracellular Ca2+ concentration produced by ryanodine receptors may play a role in the structural changes produced after SE that could lead to the development of epilepsy.

Title: Analysis of connexin expression during seizures induced by 4-aminopyridine in the rat hippocampus

Authors: ***L. G. MEDINA-CEJA**, C. R. SÁNCHEZ-CASTAÑEDA, X. N. FLORES-PONCE, A. MORALES-VILLAGRÁN;
Univ. de Guadalajara, Zapopan, Mexico

Abstract: *In vitro* studies in the rat hippocampus (HIP) have found epileptiform activity in the absence of chemical synapses. This fact suggests that other mechanisms may be involved in epilepsy, such as electrotonic coupling between cells. This electrotonic coupling is produced by gap junctions (GJs). GJs are formed by the combination of two hemichannels, each composed of six connexins. The convulsive drug 4-aminopyridine (4-AP) produces epileptiform activity even at low doses, without affecting glutamate levels; therefore, GJs could participate in its effect. Accordingly, in this study, the expression of Cx 32, Cx 36 and Cx 43 protein and mRNA in the HIP of rats treated with 4-AP was evaluated. The evaluation of connexins was carried out by chemifluorescent immunoassay, semiquantitative RT-PCR and immunofluorescence to detect the amount and distribution of connexins and their cellular markers in the HIP and dentate gyrus (DG) of animals treated with NaCl and 4-AP in the right entorhinal cortex. Also, in these animals, convulsive behavior and EEG signals were analyzed. The 4-AP treated animals showed convulsive behavior and epileptiform activity 60 min after the administration. A significant increase in the protein expression of Cx 32, Cx 36 and Cx 43 was found in the HIP contralateral and ipsilateral to the site of 4-AP administration. A trend toward an increase in the mRNA of Cx 32 and Cx 43 was also found. An increase in the cellular density of Cx 32 and Cx 43 was found in the right HIP and DG, and an increase in the cellular density of oligodendrocytes in the DG and a decrease in the number of cells marked with NeuN were observed in the left HIP. In conclusion the Cx 32 and Cx 43 associated with oligodendrocytes and astrocytes, respectively have an important role in the first stages of seizures induced by 4-AP, whereas Cx36 localized in neurons could be associated with later stages. In addition, these results contribute to our understanding of the role of connexins in acute seizures and the possibility about other new anticonvulsant strategies for seizure treatment. Support contributed by the grant from LMC, CONACYT-SEP-CB 106179.

Title: Prolonged seizures trigger transient alterations in NeuN and Map2 expression in hippocampal CA1 cells

Authors: N. D. SCHARTZ, L. MADSEN, R. MURILLO, *A. L. BREWSTER; Psychological Sci., Purdue Univ., West Lafayette, IN

Abstract: Epilepsy is characterized by spontaneous recurrent seizures (SRS) that are often drug resistant. The complexity of epilepsy is broadened by brain injury associated with episodes of prolonged continuous seizures (status epilepticus) (SE). SE can severely disrupt vulnerable neuronal networks such as those in the hippocampus thereby increasing the predisposition for SRS, the development of temporal lobe epilepsy (TLE), and cognitive comorbidities. Several studies in well-established models of SE and acquired TLE support that single episodes of SE promote long-lasting homeostatic instability of hippocampal neurons and dendrites that may contribute to neuronal hyperexcitability and aberrant synaptic plasticity. Some of the associated events include reduction or loss of the dendritic protein Microtubule associated protein 2 (Map2) and the neuronal marker NeuN. However, the time course of SE-induced changes in these proteins has yet to be described. Therefore, in this study we determined the temporal pattern of SE-induced changes in Map2 and NeuN in the hippocampal formation. We used immunohistochemistry (IHC) with antibodies against NeuN and Map2 to stain neurons and dendrites, respectively. Pilocarpine was used to induce 1hr of SE which was stopped with diazepam. Rats were then perfused at various time points after SE (4hr, 1-, 3-, 7-, 14-, and 35-days). IHC showed strong NeuN staining within the hippocampal CA1-3 pyramidal and granule cell layers and dense Map2 signal throughout all the dendritic regions in control hippocampi. After a single episode of SE a transient decline in NeuN and Map2 immunostaining was evident mainly within the CA1 region between 3-14 days after SE. Interestingly, at 3 days post SE the Map2 signal was reduced from the CA1 stratum radiatum and was more intense within the CA1 pyramidal cell body layer compared to controls. At 2 weeks, Map2 staining was drastically reduced from both cell bodies and dendritic fields of CA1 cells relative to control hippocampi. Despite the drastic loss of Map2 at 2 weeks post-SE, golgi staining at this time point showed vast dendritic arborizations in CA1 in morphologically viable cells. These SE-induced changes in NeuN and Map2 were not evident 5 weeks post-SE. Instead, at 5 weeks NeuN and Map2 signal were more robust that at 2 weeks post SE and just slightly weaker than controls suggesting a transient decline in the expression of these markers. Taken together these data suggest that SE promotes a transient decline NeuN and Map2 proteins that may be associated with a homeostatic instability of viable hippocampal cells.

Title: The complex role of microRNA-124 in epileptogenesis

Authors: *G. P. BRENNAN[1], D. DEY[1], K. P. PATTERSON[2], E. J. MAGNETTA[1], A. HALL[1], Y. MEI[1], T. Z. BARAM[1];
[1]Pediatrics, [2]Anat. & Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Introduction: Epileptogenic insults such as status epilepticus (SE) induce rapid changes in cellular properties caused by large scale changes in gene expression and regulation. Among the regulatory pathways triggered by epilepsy-inducing insults and might contribute to epileptogenesis, are the transcriptional repressor NRSF and the inflammatory cascade. Inhibiting NRSF activity following SE significantly ameliorated, but did not eliminate, the subsequent epilepsy (1). Efforts to block inflammation have also failed to prevent epilepsy (2) suggesting that targeting of single pathways may be insufficient to alter disease course. Therefore, identification of key molecules which regulate multiple epileptogenic pathways could lead to the development of effective anti-epileptogenic therapies. MicroRNAs are small non coding RNAs which post-transcriptionally regulate gene expression by targeting mRNA. Recent work suggested that mir-124 acts as a repressor of inflammation, and has been reported to regulate NRSF during neuronal maturation. Here we tested if mir-124 might play a dual role in epileptogenesis by regulating both NRSF and inflammation and investigated its therapeutic potential. Methods: SE was induced in adult rats by systemic KA. mRNA levels were quantified by qPCR. Protein levels were measured by w.blot. To test the effect of miR-124 treatment on epileptogenesis rats received miR-124 mimic infusion via ICV after SE and were monitored using 24h video-EEG for 60 days. To determine miR-124 mediated regulation of NRSF expression and inflammatory pathways, miR-124 mimics were infused via ICV, immediately after SE cessation. Results: SE robustly reduced hippocampal mir-124, and increased NRSF mRNA and protein levels as well as many pro-inflammatory cytokines. MiR-124 restitution failed to prevent epilepsy development. We explored why miR-124 had no effect on seizure development. MiR-124 restitution prevented seizure-induced NRSF expression and activity however, unexpectedly, miR-124 mimics exacerbated inflammation, indicating a dual counter-balancing role of miR-124 in epileptogenesis. Conclusion: MiR-124 plays a complex role in epileptogenesis. Reduced miR-124 is pro-epileptogenic leading to increased NRSF expression

and activity. While reduced miR-124 is anti-epileptogenic because reduced miR-124 dampens the inflammatory response induced by epileptogenic insults. Although miR-124 restitution was unable to prevent epileptogenesis we have identified the regulatory mechanisms underlying aberrant NRSF activity during epileptogenesis and also revealed a more complex role for miR-124 in regulating inflammation.

Title: Visualization of post-seizure vessel constriction in acute hippocampal slices

Authors: ***L. S. DAVID**[1], J. S. FARRELL[2], G. C. TESKEY[3];
[1]Hotchkiss Brain Institute, Cumming Sch. of Med., [2]Hotchkiss Brain Institute, Cumming Sch. of Med., [3]Hotchkiss Brain Institute, Cummiung Sch. of Med., Univ. of Calgary, Calgary, AB, Canada

Abstract: Our laboratory has demonstrated in adult rats that following seizure termination, the areas of the brain involved in the seizure are subjected to a prolonged period of severe hypoxia (pO2 < 10 mm Hg) that often lasts over an hour. We also showed that this hypoxia was in part mediated by a reduction in blood flow as we observed a ~30% decrease in perfusion using an indirect measure; laser Doppler flowmetry. This was supportive evidence of a long-lasting vasoconstriction, but we wanted to directly measure a change in vessel diameter in relation to post-seizure hypoxia. The first goal of this study was to examine the characteristics of post-seizure hypoxia *in vivo* using young rats, since young rats are better suited for work in acute hippocampal slices. Using both standard electrical kindling and 3 Hz stimulation on P25 to P40 rats *in vivo*, we observed hippocampal pO2 levels fall below 10 mmHg and lasting approximately an hour, much like adults rats. In order to determine if the seizure-induced severe hypoxic episode could result in vasoconstriction, we investigated blood vessel diameter using transverse hippocampal slices following 2 minutes of 3 Hz stimulation applied to Schaffer collaterals in rat hippocampus. We measured lumen diameter before and after stimulation to

Deleted: in vivo

Deleted: in vivo

determine the amount of vasoconstriction. We also determined if we could prevent vasoconstriction both *in vivo* and *in vitro* using the nonspecific COX-2 antagonist acetaminophen. The results from this study potentially provide insights into the development of preventative therapeutic approaches to prevent ischemia/hypoxia induced by seizures.

Title: Does the ischemia/hypoxia that follows seizures contribute to brain damage?

Authors: ***J. S. FARRELL**[1,3], G. C. TESKEY[2,3];
[1]Neurosci., [2]Cell Biol. and Anat., Univ. of Calgary, Calgary, AB, Canada; [3]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Seizures can result in a pathology that is remarkably similar to that seen following stroke. Neuronal death, glial activation, blood-brain barrier permeability are common features of both insults suggesting a common link. Using implantable oxygen sensors, laser Doppler flowmetry, and immunohistochemistry, we previously demonstrated that following seizure termination, local tissue oxygenation drops to severely hypoxic levels (<10mmHg) which co-occurs with a ~30% drop in blood flow. This ischemic/hypoxic period lasts for over an hour and is specific to brain regions involved in the seizure. Furthermore, this phenomenon is prevented by pre-administration of COX-2 antagonists. Using COX-2 antagonists as a tool to dissociate the seizure from the ischemic/hypoxic event, we hypothesized that it is the ischemic/hypoxic event following seizures (and not the seizure itself) that causes pathological changes to the brain. We approached this hypothesis by examining anatomical changes following 5 seizures elicited over 3 days. We expect that the acute effects from the most recent seizure (on day 3) and enduring changes from previous seizures (days 1 and 2) should capture a complex range of damage. We examined microglia and astrocyte activation, markers of neuronal death, and release of HMGB1 in rats that experienced seizures with hypoxia (vehicle) or without hypoxia (acetaminophen). In a

separate experiment, to assess blood-brain barrier permeability, we examined the leakage of circulating Evan's Blue dye into the brain parenchyma 45-minutes following seizures with or without hypoxia. Given the potent effects of ischemia/hypoxia on the indices of damage under examination, we expect that the hypoxia observed after seizures plays a major role in the detrimental effects of seizures. These experiments are important because if therapies (COX inhibitors) are highly effective in preventing damage induced by this phenomenon, they could serve as candidates for translation to the clinic.

Title: Long-term amelioration of seizure-induced hypoxia: Effect on epileptogenesis and behavioural disturbances

Authors: *M. D. WOLFF, S. C. SPANSWICK, J. S. FARRELL, G. C. TESKEY;
Univ. of Calgary, Calgary, AB, Canada

Abstract: We recently determined that following cessation of brief seizures, a long-lasting, severe hypoxic event occurs in the brain regions involved in the seizure. Following a hippocampal seizure, for example, local tissue oxygenation drops below 10 mmHg and remains below this severe hypoxic level for over an hour. Previous research has demonstrated that repeated hippocampal seizures in rats results in behavioural deficits in hippocampal-dependent memory tasks. However, the contribution of the hypoxic period that follows a seizure on these tasks has not been determined. We hypothesized that rats which received 20 electrically kindled seizures but without severe hypoxia (via pre-administration of acetaminophen) will not have deficits in hippocampal-dependent memory tasks relative to rats that have seizures and post-seizure hypoxia. We also hypothesized that prevention of seizure-induced hypoxia will modulate the epileptogenic process (epileptogenesis). We used the electrical kindling model to induce brief seizures. Adult male Long-Evans rats were implanted with a chronic bipolar electrode in the ventral hippocampus and a pO2 detecting optrode into the dorsal hippocampus. Oxygen levels in the hippocampus were measured with a platinum-based fiber-optic probe, which provided a

recording of local pO2 levels in an awake, freely moving rat. We separated rats into five groups: (1) no seizure; (2) no seizure + vehicle; (3) no seizure + acetaminophen; (4) seizure + vehicle; (5) seizure + acetaminophen. Thirty minutes prior to each kindling or sham kindling session, rats were injected (i.p.) with either vehicle or acetaminophen. Seizures were elicited once per day until 20 seizure-induced severe hypoxic events occurred in the seizure + vehicle group. Twenty-four hours following the final kindling session, behavioural testing was initiated. Behavioural testing consisted of novel object/context mismatch and a moving platform version of the Morris water task. To analyze the contribution of seizure-induced hypoxia on epileptogenesis, we measured the afterdischarge duration and behavioural stage of each seizure.

Title: Glucose metabolism is unchanged despite impairments in TCA cycling in the chronic epileptic stage of the pilocarpine model

Authors: *T. MCDONALD[1,2], M. HODSON[3], C. CARRASCO-POZO[2,4], K. BORGES[2]; [2]Sch. of Biomed. Sci., [3]Australian Inst. of Bioengineering and Nanotechnology, [1]Univ. of Queensland, St Lucia, Australia; [4]Dept. of Nutr., The Univ. of Chile, Santiago, Chile

Abstract: There is growing evidence that dysfunctions in energy metabolism play a role in the pathophysiology of epilepsy with reports that amino acids produced from glucose metabolism such as glutamate and glutamine are reduced. However little is known about where the pertubations in the metabolic pathways of glucose occur. Here we used assessment of the percent enrichment of carbon-13 in various metabolites extracted from hippocampi following the injection of U-13C glucose (i.p.) during the chronic phase of the pilocarpine status epilepticus (SE) model of epilepsy to identify the problem in metabolism. The carbon-13 enrichment in hippocampal intermediates of the glycolytic, pentose phosphate and TCA cycle intermediates

were measured via liquid chromatography tandem mass spectroscopy. No changes in the enrichment of carbon-13 was found in either glycolytic or pentose phosphate pathway intermediates. These data correlate with the lack of significant changes in the maximal activity of enzymes involved in these pathways, thus indicating that hippocampal glucose utilisation is not altered in the chronic epileptic stage. The percent enrichment of carbon-13 resulting from the first turn of the TCA cycle was reduced in citrate (17%**), aconitate (17%*), succinate (35%**), fumarate (20%**) and malate (20%*). Tthis reduction was even more pronounced in the percent enrichment in citrate (34%), a-ketoglutarate (47%*) and succinate (54% **, all n=10-11), produced in the second turn of the carbon-13 label in the TCA cycle,indicating a reduction in TCA cycling, which is further corroberated with a 55%* (n=7-8) loss in the maximal activity of α-ketoglutarate dehydrogenase. We are currently assessing if pyruvate dehydrogenase activity and/or oxidative phosphorylation are impaired .. Together our results indicates that the impairments in the TCA cycle are not due to changes in glycolysis. The lack of enrichment in the TCA cycle intermediates may be due to reduced pyruvate entry, however the further reduction in enrichment during the second cycle indicates there is reduced TCA cycling during the chronic phase and thus impaired NADH production. Taken together, we show dysfunctions in energy metabolism in the epileptic brain, which support the use of alternative fuels that feed into the TCA cycle to improve cycling and thus energy production.

Title: Neuropathology and morphological changes in dendritic spines caused by sarin-induced seizures in juvenile female rats

Authors: *F. ROSSETTI[1], L. K. WRIGHT[2], L. A. LANGE[2];
[1]Blast Induced Neurotrauma Br., Walter Reed Army Inst. of Res., Silver Spring, MD;
[2]Analytical Toxicology, US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Chemical warfare nerve agents (CWNA), such as sarin (isopropyl methyl phosphonofluoridate, GB), produce status epilepticus, extensive neuropathology and long-term performance deficits if seizures are not controlled. Seizures, as caused by CWNA, may directly aff ect the morphological and functional properties of dendritic spines, and these changes may lead to the cognitive deficits associated with epilepsy. We investigated the effects of GB-induced seizures on dendritic spines of the CA1 region of the hippocampus and the basolateral amygdala (BLA) of juvenile female rats. Female Sprague-Dawley rats were exposed subcutaneously to GB (0.6 or 1.0 LD50) or saline on postnatal day (PND) 42. The rats were deeply anesthetized at 1, 6, 24, or 72 h post-exposure, and brains were removed and fixed in Golgi-staining solution from FD Neurotechnologies, Inc. Dendritic spines were quantified by Sinq Systems, Inc., to include spine density, lengths of dendrites and branches in hippocampal CA1 and BLA. Spectral analysis of EEG was analyzed to calculate the time spent in seizures (TSS). The EEG TSS analyses showed that only 1.0 LD50 GB caused seizures as seen at the 1 h (966 ± 391 s), 6 h (7617 ± 1861 s), 12 h (12395 ± 5503 s), and 72 h (18780 ± 8227 s) time points. These rats showed reduction of dendritic spine density in BLA (0.896 ± 0.026 spines/µm2) in relation to the saline group (1.101 ± 0.022 spines/µm2) 6 h after exposure. Analysis of the number of branches per Golgi+ neurons and length of the dendrites showed that, 24 h after 1.0 LD50 GB, the CA1 had shorter dendrites per neuron (1.29 ± 0.09 mm) in relation to the saline group (1.66 ± 0.15 mm). The BLA showed a decreased number of branches per neuron (13.01 ± 1.13 and 12.57 ± 1.79, 1 h, and 72 h respectively), and shorter dendrites per neuron (0.45± 0.04 mm and 0.45 ± 0.06 mm, 1 h and 72 h respectively) after 1.0 LD50 GB exposure, in relation to saline group: branches per neuron (19.17 ± 1.19 and 19.07 ± 1.33, 1 h and 72 h respectively); length per neuron (0.64 ± 0.03 mm and 0.65 ± 0.04 mm, 1 h and 72 h respectively); $p<0.05$, ANOVA test. The seizures induced by exposure to 1.0 LD50 GB led to a reduction in the length of dendritic spines in CA1 and BLA neurons, as well as a reduction in the number of branches and spine density in BLA neurons of PND 42 female rats. These results show a strong deficit in dendritic growth in the CA1 and BLA and the sensitivity of BLA dendritic spines when these females were exposed to a seizure-inducing dose of GB (1.0 LD50). In conclusion, seizures induced by exposure to 1.0 LD50 GB cause severe formation changes in the dendritic spines in juvenile female rats, mainly in the amygdala formation, which may lead to significant cognitive deficits in adulthood.

Abstract: Introduction: The dentate gyrus of the hippocampus is among the few regions of the brain where neurogenesis continues throughout life. Epilepsy inducing insults such as status epilepticus alter both the rate of neurogenesis and the developmental outcome of newly generated or immature dentate gyrus granule cells (DGCs). Normally, immature DGCs have a basilar dendrite that is then lost, so that mature DGCs have only apical dendrites that fan into the DG molecular layer. Weeks after epilepsy inducing insults, dysmature DGCs with basilar dendrites are found, presumably representing aberrant stabilization of the basilar dendrites by network hyperactivity. Basilar dendrites may be important for epilepsy because they can create hyper- excitable loops within the dentate gyrus making for a seizure-prone hippocampal circuit. Understanding the mechanisms by which basilar dendrites are retained, leading to aberrant connectivity, may lead to interventions that abort epileptogenesis. Methods: Hippocampal organotypic slice cultures were obtained from P7 Thy1- YFP mice. Seizure- like events were induced at DIV 7 by incubating the cultures for 24 hours in a medium containing kainic acid (6 µM; KA). Controls were exposed to normal medium. BrdU was applied to the cultures at various timepoints before or after the KA. At DIV 21 and 28, cultures were fixed with fresh, ice cold 4% PFA. Cultures were washed with 0.01M PBS, mounted on glass slides and coverslipped. Endogenous YFP in DGCs were visualized using fluorescent microscopy. All assessments were conducted blinded. Measured parameters include: the numbers of YFP positive DGC per culture and the proportion of these cells that maintain basal dendrites. Results: Somata and dendrites of DGCs were clearly filled with YFP. The introduction of KA to culture medium had a significant effect on the number of DGC: There were more YFP + DGCs in cultures with KA than in controls (T= 225.0, p= 0.0027; Mann-Whitney's U test). Furthermore, there was a significant increase in both the number of DGCs with basilar dendrites in the epileptiform group at both time points (e.g., DIV 21: p= 0.0149) and the ratio of total YFP positive cells over DGCs with basilar dendrites e.g., (DIV 21: p=0.0356). The birth-dates of the dysmature cells are under evaluation. Discussion: 1. KA *in vitro* causes increased DGC birth, providing a useful system to study changes in DGCs following epilepsy provoking insults.2) Using this system, an increase in basilar dendrites on DGCs is found mimicking *in vivo* models. 3) Mechanisms of DGC dysmaturation may now be studied using this system, focusing specifically on the potential role of augmented NRSF after epilepsy provoking insults.

Title: Visual processing in a mouse model of focal neocortical epilepsy

Authors: A. PANARESE[1,2], A. MAZZONI[2], E. VANNINI[1], M. PIETRASANTA[1], S. LAI[2], S. MICERA[2,3], M. CALEO[1], *L. RESTANI[1];

Abstract: Epilepsy is the second most common neurological disorder after stroke, affecting over 0.5% of the world population. A percentage of patients (30%) remain resistant to drug treatments. This pharmacoresistance predominantly affects patients with focal epilepsy, which are 40-50% of total incidence cases. Electrophysiological studies of refractory epilepsy are currently in progress to get insights into the mechanisms of circuit remodeling, thus paving the way for alternative therapeutic options. However, how plastic rearrangements within the epileptic focus trigger cortical dysfunction and hyperexcitability is still incompletely understood. We employ a model of neocortical, non-lesional epilepsy based on local delivery of the clostridial enzyme tetanus neurotoxin (TeNT) in mouse visual cortex. TeNT is a metalloprotease that enters synaptic terminals and cleaves the synaptic vesicle protein VAMP/synaptobrevin, resulting in preferential blockade of inhibitory neurotransmission. Delivery of TeNT to the adult cortex results in refractory epilepsy with electrographic seizures persisting for several months, even after the toxin has been cleared from the system (Mainardi, Pietrasanta et al. 2012). Here we use anesthetized TeNT mice to investigate how epileptic rearrangements impact on sensory processing. We recorded local field potentials and spiking activity both during baseline conditions and after presentation of visual stimuli, in control and TeNT-injected mice, at the completion of TeNT effects (i.e 45 days following injection). In TeNT-treated cortices we found that spontaneous neuronal discharge was increased and visual responses were less reliable, with a higher proportion of failure trials, associated to higher spiking activity before stimulus presentation. Electrophysiological and behavioral visual acuity (spatial resolution) was also

consistently impaired in TeNT-injected mice. We also investigated how contrast-driven modulations in spiking activity and local field potential spectra were affected by TeNT injection. These analyses will shed light on circuit modifications associated to epileptic activity. To further understand layer-specific rearrangements within the epileptic focus, we recorded control and TeNT mice using multichannel linear probes (16 channels), spanning the whole cortical thickness, allowing a layer-specific analysis. Our data contribute to elucidate neuronal mechanisms underlying the network hyperexcitability observed in neocortical focal epilepsy.

Title: Neuronal nitric oxide synthase contributes to pentylenetetrazole-kindling-induced hippocampal neurogenesis

Authors: ***X. ZHU**;
Med. Sch. of Southeast Univ., Jiangsu, China

Abstract: Neuronal nitric oxide synthase (nNOS), the major nitric oxide synthase isoform in the mammalian brain, is implicated in the pathophysiology of several neurological conditions, including epilepsy. Seizure induced neurogenesis in hippocampal dentate gyrus (DG) have been widely accepted to be associated with epileptogenesis. Few studies, however, have addressed the role of nNOS in seizure associated neurogenesis. The present study, therefore, investigated the role of nNOS in pentylenetetrazole (PTZ)-induced kindling as well as PTZ-kindling-induced neurogenesis in hippocampal DG. Our results showed that nNOS expression and enzymatic activity were significantly increased in the hippocampus of PTZ-kindled mice. Meanwhile, these PTZ-kindled mice were characterized by significant enhancement of new born cells proliferation and survival in hippocampal DG, and these survived cells are mostly co-labeled with NeuN and

only a small portion were co-labeled with GFAP, indicating a vast majority of kindling-induced new born cells differentiated into neurons in hippocampal DG. Selective inhibition of nNOS by 7-NI, however, suppressed PTZ-induced kindling as well as PTZ-kindling-induced hippocampal DG new born cells proliferation and survival, suggesting that nNOS contributes to PTZ-kindling-induced hippocampal neurogenesis and this PTZ-kindling-induced neurogenesis might be associated with kindling development.

Title: Serotonin receptor antagonists increase fast ripple activity in rats treated with kainic acid

Authors: *C. G. GARCÍA-BARBA, L. MEDINA-CEJA;
Ctr. Universitario De Ciencias Biológicas Y Agro, Zapopan, Mexico

Abstract: Fast ripples (FR) are pathological high frequency oscillations (250-600Hz) associated with epileptic activity in the hippocampus and are an important biomarker in temporal lobe epilepsy as well as in extratemporal epilepsies. Successful modulation of FR by serotonin was observed in a previous study of this laboratory, in which the elevation of serotonin levels induced by citalopram (4.14 ± 0.30 nM) reduced the occurrence of spontaneous FR (57%), the mean number of oscillation cycles per FR event (34%) and the average frequency of FR (33%). According, we assumed that inhibition of serotonin by the receptor antagonists increase FR in rats treated with kainic acid (KA). For this propose, intrahippocampal KA treated animals (dose 0.8 µg/0.5 µl) of fifteen days post administration, were implanted with a mobile device with eight microelectrodes into the right region of the hippocampus in order to easily detect FR. Control implanted rats were injected with WAY 100135 (dose 0.2 mg/kg, i.p.; n=3), Ritanserin (dose 0.2 mg/kg, i.p.; n=3) and only KA (0.8 µg/0.5µl). For the experimental group (n=6) the first antagonist (WAY 100135) was injected 24 hours after the surgery and the second antagonist (Ritanserin), 72 hours after the first injection. The evaluation of the frequency of appearance of spontaneous FR, number of oscillations per event of FR, frequency and duration of each event of FR were analyzed. Results showed that animals from control and experimental

groups had normal behavior and none of the experimental animals presented seizures during the EEG recordings. The intracranial EEG analysis showed slow activity in control groups and fast activity within the range of ripples was observed particularly during sleep. WAY 100135 increased the number of events of FR significantly during the first 60 minutes after the administration of the antagonist ($p<0.0001$), and there was an increment in the duration of each FR event during 120 minutes after the administration of the drug ($p<0.030$), while Ritanserin increased the number of events of FR within the first 60 minutes after its administration ($p<0.0001$), and there was a significant increment in the amplitude of FR during 60 minutes after drug administration ($p<0.014$). In conclusion, the serotonin receptor antagonists WAY100135 and Ritanserin increase the occurrence of FR activity as well as their duration and amplitude; in addition these results support the modulation of FR by serotonin and participation of the 5HT1a and 5HT2 receptors as possible mediators of its effect.

Title: mTOR inhibition after controlled cortical impact alters hilar interneuron excitability

Authors: ***C. R. BUTLER**[1], J. A. BOYCHUK[1,2], B. N. SMITH[1,2,3];
[1]Physiol., Univ. of Kentucky, Lexington, KY; [2]Univ. of Kentucky, Epilepsy Ctr., Lexington, KY; [3]Univ. of Kentucky, Spinal Cord and Brain Injury Res. Ctr. (SCoBIRC), Lexington, KY

Abstract: Traumatic brain injury (TBI) is among the most common causes of acquired temporal lobe epilepsy (TLE). The latent period after injury and prior to expression of seizures includes plasticity events that support epileptogenesis, including cell loss and synaptic reorganization in the dentate gyrus. A murine model of TBI using controlled cortical impact (CCI) injury was used to examine the effect of daily rapamycin treatment (3 mg/kg) on excitability of surviving GABAergic hilar interneurons in mice that express GFP in a subset of inhibitory neurons (FVB-Tg(GadGFP)4570Swn/J; i.e., GIN mice). GFP-labeled hilar interneurons ipsilateral to CCI injury were reduced in number relative to controls, and rapamycin treatment did not inhibit this cell loss. Whole-cell patch-clamp and on-cell recordings *in vitro* were used to examine spontaneous

Deleted: in vitro

EPSC frequency and action potential firing rates of surviving GFP-labeled hilar interneurons in GIN mice that were treated with rapamycin for 8-12 weeks after CCI injury. An increase in spontaneous EPSC frequency and action potential firing rate of GFP-labeled hilar interneurons ipsilateral to CCI injury was detected, relative to cells contralateral to the injury. Relative to CCI injury alone, daily rapamycin treatment resulted in a reduction in the increase in sEPSC frequency and spontaneous firing rate of GFP-labeled hilar interneurons and reduced mossy fiber sprouting ipsilateral to the injury. Although reduced relative to CCI injury, these measures were not normalized to control levels; analysis of the effects of high-dose rapamycin treatment (10 mg/kg) is underway. Rapamycin treatment therefore reduces the enhanced synaptic excitation of hilar interneurons after CCI injury in a manner consistent with suppression of reactive plasticity in granule cells. Ongoing experiments utilizing glutamate photolysis to activate granule cells and CA3 pyramids will test the hypothesis that effects of rapamycin treatment are mainly due to selective effects on mossy fiber sprouting.

Title: Exploring the role of p75NTR signaling pathway on GABAergic circuit maturation following neonatal hypoxia induced seizure

Authors: B. CHATTOPADHYAYA, M. BERRYER, D. DUFOUR-BERGERON, N. SANON, S. DESGENT, C. BOSOI, L. CARMANT, *G. DI CRISTO;
Res. Ctr., CHU Ste.justine-University of Montreal, Montreal, QC, Canada

Abstract: Perinatal hypoxic-ischemic encephalopathy is the most important cause of acute mortality and morbidity in newborns. The most common acute effect of hypoxic-ischemic encephalopathy is neonatal seizures, which are very often refractory to conventional seizure medications. Hypoxia-induced seizures (HIS) are associated with a high incidence of epilepsy as well as cognitive disabilities later in life. Despite the significant long-term morbidity of HIS in

the neonates, there is currently no specific treatment. Further, our understanding of how HIS changes the developmental trajectory of neuronal circuit development, and ultimately results in epileptogenesis and cognitive dysfunction, is still mostly unknown. Understanding the precise mechanisms by which HIS affects brain development, and how its effects can be ameliorated, can help us in designing the appropriate therapeutic approaches towards preventing the consequences of neonatal hypoxia. Using a combination of molecular tools, electrophysiological recordings and imaging techniques, we studied the affects of HIS particularly on inhibitory GABAergic synapse development in rodent neocortex. In particular we determined that HIS affects the maturation and function of distinct GABAergic interneuron populations, parvalbumin (PV)-positive and somatostatin (SOM)-positive interneurons differentially in the neocortex and in the hippocampus. In particular, we show that PV expressing interneurons in the neocortex remain morphologically and functionally immature. This correlates with a reduction in gamma oscillation power during exploration, and with impaired working memory and social novelty recognition. We are currently investigating the molecular mechanisms involved, specifically looking at the role of neurotrophin receptor (p75NTR) mediated signaling pathways in ameliorating the deficits induced by HIS on GABAergic circuit development.

Title: The over-expression of BDNF on adult neurogenesis and seizure vulnerability using a transgenic mouse model

Authors: *C. ISGOR, P. COOMBS, D. JOSEPH, K. GUTHRIE;
Charles E. Schmidt Biomed Ctrr, Florida Atlantic Univ., Boca Raton, FL

Abstract: Mice that overexpress brain-derived neurotrophic factor (BDNF) under the alpha-calcium/calmodulin-dependent protein kinase IIa promoter (termed TgBDNF mice) develop a mild cognitive deficit that is evident by 2-3 months of age that progresses to emergence of spontaneous seizures at ~6 months of age. Slow developing nature of behavioral disruptions observed in TgBDNF mice led to the hypothesis that chronic and sustained elevations in local BDNF are critical for progressive remodeling of hippocampal circuits implicated in

epileptogenesis. We have previously shown that the mossy fibres, axonal projections from the dentate gyrus granule neurons that innervate the CA3 field, are expanded in volume in TgBDNF mice compared to wildtype (WT) controls at 2-3 months of age prior to seizure development. The aim of this project is to determine whether alterations in normal adult neurogenesis in TgBDNF mice are antecedents to the onset of spontaneous seizures, and possibly contributing to the hyperexcitability of the circuitry. We compared the rate of adult neurogenesis in the TgBDNF mice to that observed in WT controls by use of bromodeoxyuridine labeling coupled with immunohistochemical staining for age-specific cell markers to identify proliferative pool size, neuronal differentiation and survival of new-born cells. Our preliminary analyses showed ~30% increase in the number of immature granule neurons in the TgBDNF compared to WT controls without a change in the number of proliferating cells, suggesting for increased number of adult-born granule neurons in BDNF enriched hippocampus. Furthermore we crossbred the TgBDNF mice with a strain that expresses the green fluorescent protein (GFP) under the GAD67 promoter transiently for the first 4 weeks after cell division. We will be assessing axonal and dendritic maturation rates of adult-born granule neurons in the TgBDNF mice using 3-D reconstruction of entire granule neurons. Understanding the mechanisms that contribute to the progression of seizures in this animal model will facilitate our ability to intervene and prevent adult-onset epilepsy of unknown causes. This work is supported by a collaborative FAU Seed Grant awarded to Drs. Isgor & Guthrie.

Title: Optically tracked interneuron dynamics during seizure initiation

Authors: M. L. MIRI[1], M. A. VINCK[1], *J. A. CARDIN[2];
[1]Neurobio., [2]Dept. of Neurobio., Yale Univ., New Haven, CT

Abstract: GABAergic inhibition is critical for regulation of excitation and maintains neural network stability through a precise balancing process. Loss or dysfunction of inhibitory interneurons is thought to lead to abnormal activity patterns and ultimately to seizure initiation. Two major GABAergic interneuron classes that may contribute to this process are the Parvalbumin-expressing (PV), fast-spiking cells and Somatostatin-expressing (SOM) cells. Using combined optical and electrophysiological tools, we investigate network dynamics during the development of seizures by monitoring the activity of individual interneurons and synchronization between multiple hippocampal cell types. Using AAV-DIO-ChR2-mCherry, we selectively targeted Channelrhodopsin-2 expression to PV or SOM interneurons in CA1. We used tetrode arrays to record the activity of many simultaneous cells in hippocampal CA1 in animals lightly anesthetized with ketamine/xylazine. We identified targeted ChR2-expressing PV and SOM interneurons in the recorded population by stimulating with brief pulses of blue light. Light pulses were continued intermittently throughout the experiment to track identified neurons without significantly altering the pattern of spontaneous activity. Using a pharmacological model of seizure induction (PTZ), we performed measurements of neural activity during baseline and multiple preictal periods. We assessed the pattern of spontaneous PV and SOM interneuron and excitatory neuron activity, changes in interneuron spike probability, and the temporal relationship between inhibitory and excitatory neuron activity during each period. We find that both PV and SOM cells exhibit a decrease in evoked spike probability during the transition from baseline to late preictal stages. To further characterize these progressive changes in spike probability, we measured the input-output function of ChR2-identified interneurons in response to a calibrated range of light intensities. We find a decrease in the slope of the input-output function as well as decrease in dynamic range for evoked spike probability for both PV and SOM IN populations leading up to seizure. Additionally, we find significant changes in the spike-triggered LFP average with respect to excitatory neuron firing during both early and late preictal periods. These results demonstrate the power of these combined approaches for dissecting network activity *in vivo* during seizure initiation and identify a complex pattern of alterations in interneuron activity that may contribute to the loss of E-I balance in the hippocampal network.

Title: An optogenetic kindling model of neocortical epilepsy

Authors: *E. CELA[1,2], A. J. CHUNG[1], T. WANG[1], P. J. SJÖSTRÖM[1];
[1]Neurol. and Neurosurg., Montreal Gen. Hosp., Montreal, QC, Canada; [2]Integrated Program in Neuroscience, McGill Univ., Montreal, QC, Canada

Abstract: It is not well understood how otherwise healthy neuronal circuits become susceptible to seizures during epilepsy. To investigate local circuit restructuring associated with seizures, we developed a novel optogenetic animal model of epilepsy that is inspired by the classical kindling paradigm. We hypothesized that repeated and persistent simultaneous activation of a group of excitatory neurons should eventually elicit seizures in otherwise healthy mice. We expressed Channelrhodopsin-2 (ChR2) in primary motor cortex (M1) of male C57BL/6J mice by stereotactically injecting AAV-CaMKIIa-hChR2-E123T/T159C-p2A-EYFP bihemispherically. We allowed 21 days for recovery and ChR2 expression, after which animals were kindled by repeatedly illuminating M1 in 3-second-long 50-Hz burst every 48 hours using a 445-nm laser. Animals were monitored by EEG and video during each session. In 6 out of 6 animals, seizures progressively developed after 15.3±2.1 sessions. We defined seizures as EEG power exceeding background levels by two standard deviations for longer than 3 seconds. Seizure duration was quantified by EEG, and severity by a revised Racine scale. We found that seizure duration ($r=0.52$, $p<0.001$, $n=4$) and severity ($r=0.59$, $p<0.001$, $n=4$) increased with session, while seizure threshold was decreased ($r=-0.59$, $p<0.001$, $n=4$). Additionally, the number of seizures also increased with session ($r=0.48$, $p<0.001$, $n=6$). We next examined if animals rekindled after a 36-day-long pause retained their high seizure susceptibility. Indeed, seizures had higher Racine score ($p<0.05$, $n=5$) and lasted longer ($p<0.01$, $n=4$). The seizure threshold was also lowered ($p<0.01$, $n=4$), and the number of sessions until first seizure was reduced ($p<0.05$, $n=4$). Finally, preliminary immunohistology for NeuN and GFAP indicated that there was no major neuronal loss or appreciable glial activation. In summary, we found that repeated optogenetic stimulation of awake behaving animals eventually elicited seizures in the absence of gross brain damage, and that animals retained an elevated seizure susceptibility for weeks. As our model allows for the

identification of directly activated cells, it enables the investigation of the role of specific cell populations in epileptogenesis.

Title: Direct imaging of calcium pathology preceding kainic acid induced seizure activity in freely behaving mice

Authors: T. K. BERDYYEVA[1], L. ALUISIO[1], S. OTTE[2], *R. M. WYATT[1], C. DUGOVIC[1], J. SHELTON[1], K. GHOSH[2], M. J. SCHNITZER[2,3], T. LOVENBERG[1], P. BONAVENTURE[1]; [1]Janssen Res. and Develop., San Diego, CA; [2]Inscopix, Palo Alto, CA; [3]Stanford Univ., Palo Alto, CA

Abstract: The changes in calcium dynamics that precede convulsive states are unknown. Here we used calcium imaging combined with electroencephalographic measures (EEG) to study changes in calcium levels in the CA1 region of hippocampus following kainic acid administration (15 mg/kg) in freely behaving mice. Fluorescence changes in the GCaMP6f calcium sensor expressed under the CaMKII promoter were measured using a miniature fluorescence microscope directly attached to the head of the animal. We first demonstrated that the imaging procedure did not impact the seizure threshold. Calcium dynamics were studied specifically during non-convulsive states, where we observed that kainic acid treatment led to massive prolonged increases in calcium sensor florescence that were >10 fold greater in amplitude and >100 fold greater in duration than changes observed after vehicle administration. Such spreading (~1 mm/min) increases in fluorescence ("calcium waves") were visible in the entire field of view (~1mm2) and were preceded by a series of brief full field spikes in calcium fluorescence that escalated both in frequency (2-10 Hz) and intensity (1.5-10 fold brighter relative to baseline) and were geometrically and temporally distinct from the calcium waves. The first onset of pathological calcium events temporally coincided with the first, and usually brief, (<3 min) onset of a bout of epileptiform spikes (Stage 2, or spike-wave complexes, SWC), as assessed via simultaneous EEG recordings. Subsequent pathological calcium events re-occurred in >60% of the animals and were usually concordant with epileptiform EEG spikes. Similar calcium pathologies were observed in animals treated with different pro-convulsant agents

(NMDA or PTZ), suggesting that the described calcium abnormalities were signatures of seizure activity rather than other potential pathological actions specific to kainic acid. Comparable calcium abnormalities were also observed in animals pre-treated with the anticonvulsant drug valproate (300 mg/kg), despite a reduction in the behavioral severity of the seizures. Prolonged exposure to abnormally high calcium concentrations that anticipate seizure activity in the absence of convulsive manifestations could be the basic mechanism underlying detrimental brain reorganizations and cognitive decline not only in epileptic patients, but also in other patients with similar metabolic insults. Therefore, direct visualization of calcium dynamics provides valuable insights into mechanisms of brain pathologies inaccessible by commonly used traditional methods.

Title: An integrated platform for behavioral and electrophysiological phenotyping: Application to an epilepsy mouse model

Authors: J. PANG[1], *D. VOLFSON[2,1], Y. PI[1], J. DUERR[1], S. M. O'NEILL[1], T. SAMAD[1], L. SCOTT[1], D. L. BUHL[1];

Abstract: Understanding of electrophysiological correlates to behavior is important for the development of biomarker strategies and high-throughput assays for drug development. We report on the development of an integrated platform, which couples intelligent video monitoring

with electrophysiological measurements. We have applied a supervised machine learning approach to establish an automated video analysis system. To accomplish this, we employed a combination of static and dynamic features extracted from the video streams to segment episodes of distinct behavior such as walking and grooming, as well as disease-specific manifestations such as epileptic seizures. We then used synchronized electroencephalography (EEG) to derive event-locked signatures and establish context-dependent associations between behavior and electrophysiological endpoints. Here, we demonstrate the utility of the platform using the KA-induced epilepsy model in WT and GFAP-IL6 transgenic mice. To build an accurate behavioral assessment combined with EEG, multi-angle video streams coupled with EEG recordings from the cortex and CA1/CA3 regions of the hippocampus were synchronized with sub-second accuracy. We then developed a supervised learning approach that enabled robust identification of seizure subtypes defined according to Racine scale, along with the identification of EEG signatures for both convulsive and sub-convulsive seizures. In addition, we assessed morphology and statistical properties of ictal, preictal, and interictal spike events modulated by KA dosage and genotype. Our work demonstrates how a platform for automated behavioral and electrophysiological phenotyping could be used to study clinically translatable endpoints for models of chronic epilepsy, in which both sub-convulsive and convulsive activity must be continuously measured for extended periods of time.

Abstract: It is well established – though relatively unknown – that cerebral malaria (CM) leads to epilepsy. For the nearly 500,000 children who survive CM per year in sub-Saharan Africa, the estimated epilepsy rate after two-years is approximately 16%. Worldwide, this corresponds to the initiation of approximately 300,000 new cases of potentially preventable epilepsy per year. We investigated murine models of CM for evidence of post-malarial epilepsy and similarities to human CM. A post-malarial epilepsy model would serve both to identify critical mechanisms of damage, and provide a platform for investigation of adjunctive therapy. We investigated four combinations of different mixtures of mouse strain (C57BL/6, CBA, and Swiss-Webster SW) and Plasmodium-berghei (Pb) parasites (NK65 and ANKA). Eight cohorts of three-week old littermates were inoculated with parasitized erythrocytes. We rescued animals with Artesunate when they demonstrated signs of advanced CM. Age matched controls were inoculated with non-parasitized erythrocytes, and received identical drug treatment time matched to the infected animals. We developed a chronic recording system for long-term monitoring of brain and heart dynamics with DC sensitivity. Animals were implanted with EEG, EMG and ECG electrodes 14 days post treatment, and video-EEG continuously monitored for up to 8 months per animal. EEG data was analyzed for focal and generalized seizures. Of the mice surviving to recording: 88% (15/17) SW-PbNK65 had a uniform mixture of cortical, hippocampal, and primary generalized seizures, with median latency of 95 days to first convulsive seizure; 83% (10/12) SW-PbANKA had seizures with a predilection for focal hippocampal origin, with median latency of 36 days; 53% (8/15) C57BL/6-PbANKA developed epilepsy, with a high frequency of interictal generalized epileptic spikes, cortical secondarily generalizing seizures, and some hippocampal focal seizures, with a median latency of 40 days; 75% (3/4) CBA-PbANKA developed epilepsy with a predominance of primary generalizing seizures with median latency of 36 days. No seizures were observed from the control animals. We have developed multiple models of post-CM epilepsy that display various characteristics seen in human epilepsy. These models have high potential to enable us to, for the first time, explore physiological mechanisms that underlie epilpetogenesis in humans that survive CM, and to develop rational adjunctive therapies based on these mechanisms to reduce this incidence.

Abstract: It is well established - though relatively unknown - that cerebral malaria (CM) leads to epilepsy. For the nearly 500,000 children who survive CM per year in sub-Saharan Africa, the estimated epilepsy rate after two-years is approximately 16%. Worldwide, this corresponds to initiation of approximately 300,000 new cases of potentially preventable epilepsy per year. A post-malarial epilepsy model would serve both to identify critical mechanisms of damage, and provide a platform for investigation of adjunctive therapy. We investigated all combinations of three mouse strains (C57BL/6, CBA, and Swiss-Webster SW) and two Plasmodium berghei (Pb) parasites (NK65 and ANKA) during the infection for their similarities to human CM. Cohorts of three-week old littermates were inoculated with parasitized erythrocytes from homologous donors. Age and sex-matched controls from each litter were inoculated with non-parasitized erythrocytes. Peripheral blood parasitemia was tracked daily. Animals were sacrificed on day 6 or 7 for histology when the animals displayed signs of severe CM. Human CM neuropathology hallmarks include adhesion and sequestration of infected red blood cells (iRBC) in brain microvessels, ring hemorrhages, microvascular thrombosis, and brain edema. Brains from all infected animals showed signs of severe edema, including tissue separation around blood vessels not seen in controls. Stereological methods were used to quantify densities of red blood cells (RBC), white blood cells (WBC), iRBC, and hemorrhages in subdivisions of the hippocampus and entorhinal cortex, especially to quantify different patterns of sequestration and focal ischemia in comparison with human CM. Our primary findings included that total blood cell densities were as much as 4 times higher in infected SW models compared to SW controls. Although hemorrhages were observed, they did not account for more than a few percent of this increase. The commonly used sequestration index (ratio of brain to peripheral parasitemia) did not accurately reflect the observed degree of sequestration. White blood cell densities were elevated 5-10 times over the controls throughout the brain for all models, reflective of a severe inflammatory response. We used these histological findings to guide our choice of models to investigate with chronic recordings for post-malarial epilepsy.

Abstract: It is well established - though relatively unknown - that cerebral malaria (CM) leads to epilepsy. For the nearly 500,000 children who survive CM per year in sub-Saharan Africa, the estimated epilepsy rate after two years is approximately 16%. Worldwide, this corresponds to initiation of approximately 300,000 new cases of potentially preventable epilepsy per year. We investigated murine models of CM for evidence of post-malarial epilepsy by combining four mouse strains and two Plasmodium berghei (Pb) parasites (NK65 and ANKA): Swiss-Webster SW-PbNK65, SW-PbANKA, C57BL/6-PbANKA, and CBA-PbANKA. Cohorts of three-week old littermates were inoculated with infected erythrocytes. We rescued animals with Artesunate when they demonstrated signs of advanced CM. Controls were inoculated with uninfected erythrocytes. We developed a chronic recording system for long-term monitoring of brain and heart dynamics with DC sensitivity. Animals were implanted with EEG, EMG, and ECG electrodes 14 or more days post treatment, and video-EEG monitored continuously for 1-8 months per animal. In all model combinations studied, recurrent spontaneous seizures were observed in a large fraction (50-90%) of the animals that survived to recording. Post treatment death rates prior to implant were observed in some mixtures, with the largest rate in SW-PbANKA. In these cases, death was accompanied by typically a single seizure-like event followed either by immediate death or a severe decrement in health. We recorded many seizure-

related deaths including 5/13 SW-PbANKA and 8/20 SW-PbNK65. All epileptic mice showed significant changes in cardiac activity associated with seizures. In 80% of the seizures, a transient preictal episode of bradycardia occurred, followed by ictal and late-ictal tachycardia. This was accompanied by a prevalence of missed beats (66%) before ictal activity. In contrast, no spontaneous seizures were observed in recordings of control animals, all of which demonstrated normal heart activity. Our findings suggest that repeated seizures cause or exacerbate serious cardiac pathologies and point to an autonomic nervous system disorder that later reinforces the epileptic state. These observations are consistent with what is currently known about the human condition of sudden unexplained death in epilepsy (SUDEP). These post-CM murine combinations therefore provide a platform for the study of the mechanisms of SUDEP and models to investigate interventions. Such interventions are critical to reduce the SUDEP risk in the estimated 1.8-2.4 million children that survive CM per year.

Title: Activation of mTOR signaling pathway is secondary to neuronal excitability in a mouse model of mesio-temporal lobe epilepsy

Authors: ***N. NITTA**[1,2], F. SUZUKI[3], A. SHIMA[3], K. NOZAKI[2], A. DEPAULIS[4]; [1]Neurosurg., Otsu/Shiga, Japan; [2]Neurosurg., Shiga Univ. of Med. Sci., Otsu/Shiga, Japan; [3]Neurosurg., Koto Mem. Hosp., Higashiomi, Japan; [4]Grenoble-Institut des Neurosciences, Grenoble, France

Abstract: Objective Recent studies in animal models have suggested that the mammalian target of rapamycin (mTOR) signaling pathway is involved in several features of mesio-temporal lobe

epilepsy (MTLE). Here, we addressed whether mTOR activation promotes MTLE epileptogenesis or rather mediates neuroplasticity associated with hippocampal sclerosis. Method Male C57/bl6 mice were injected with KA (1 nmol) in the dorsal hippocampus and were treated with vehicle or rapamamycin (80mg/kg i.p. 5h after KA injection then 40 mg/kg/day i.p. from 1 to 20 days after KA). Immunohistolabelling of p-S6, ZnT3 and NeuN was performed at 21 days post KA and electroencephalography was recorded in animals implanted with hippocampal electrodes for 3 h at 25 days post KA. Resuts In mice injected intrahippocampally with kainate (1 nmol) we showed a biphasic increase of phospho-S6 ribosomal protein expression, the downstream product of mTOR signaling pathway, in dispersed granule cell layer of dentate gyrus (GCL) with a second phase lasting up to 6 months. Chronic treatment with rapamycin suppressed p-S6 expression, granule cell dispersion and mossy fiber sprouting but did not reduce hilar cell loss nor the development of hippocampal paroxysmal discharges. Neuronal inhibition by midazolam (2x10mg /Kg, i.p. at 21 days post KA) abolished the increased expression of p-S6 in dispersed GCL. Conclusion Our data suggest that activation of mTOR signaling pathway results from the increased neuronal excitation that develops in hippocampus and contribute to MTLE morphological changes in this structure. However, they do not support the role of this pathway in the development of MTLE nor its use as a therapy for this form of epilepsy.

Abstract: The expression of astroglial glutamine synthetase (GS), a key enzyme in the glutamate/GABA-glutamine cycle, is perturbed in brain disorders such as Alzheimer's disease, schizophrenia, depression, and mesial temporal lobe epilepsy (MTLE). In human MTLE, GS is lost from astrocytes in specific subfields of the hippocampal formation; however, the consequences of such a loss are not fully understood. Here, we used either hippocampal infusion of the GS inhibitor methionine sulfoximine (MSO) or adeno-associated virus (AAV) to assess the consequences of GS suppression in C57Bl/6J mice. Conditional knockouts for GS were generated in C57Bl/6J mice by insertion of loxP sites at the front of the 2nd and 7th exon in the GS gene. Delivery of Cre recombinase to floxed-GS mice (10-12 weeks) was mediated by AAV5-Cre-GFP delivered unilaterally into the hippocampus. In the contralateral hippocampus, control AAV5-GFP virus was delivered. On both sides, a total of 0.5 µL of virus with a titer of ~$1x10^{12}$ was delivered. As controls, wild-type mice (10-12 weeks) were injected following the same protocol. Separate groups of wild type mice (10-12 weeks) were implanted with an osmotic pump that infused either MSO or phosphate buffered saline (PBS) unilaterally into the hippocampus. Video-intracranial electroencephalogram (EEG) recording was performed immediately following placement of the pump, and 4 weeks after injection of virus, to monitor for seizures. Severity of seizures was characterized using a modified Racine Scale. Mice were perfusion fixed with 4% paraformaldehyde after 2-3 weeks of EEG monitoring. Brains were horizontally sectioned at 40 µm with a Vibratome. Virus injected sections were co-labeled for GS and GFP to assess GS levels. All of the MSO-infused mice and none of the PBS-infused mice developed spontaneous recurrent seizures including convulsive, behavioral seizures. In the ipsilateral hippocampus, mice exhibited glial proliferation and patterned loss of neurons, whereas minimal brain injury was present elsewhere. In the floxed-GS mice, GS levels were decreased in the Cre-injected side at 4-5 weeks after viral delivery whereas minimal reduction in GS was noted in the control injected side. These findings suggest a key role of GS suppression in the causation of MTLE and provide useful laboratory tools for further investigation on the role of GS in health and disease.

Title: Seizure progression in a PTEN KO model

Authors: *S. KHADEMI;
Cincinnati Children's Hosp., Cincinnati, OH

Abstract: Temporal lobe epilepsy is one of the more common and difficult to treat of adult epilepsies. Patients with temporal lobe epilepsy can have simple partial seizures, in which consciousness is preserved, or complex partial seizures in which consciousness is lost during the event. Patients can exhibit one or both types of seizures, but importantly, some patients will transition from simple to complex seizures, indicative of increasing disease severity. The mechanisms regulating disease progression are unknown. To explore potential mechanisms of epilepsy progression, we have developed a novel genetic mouse model of epilepsy in which deletion of phosphatase and tensin homologue (PTEN) from a subset of late-generated hippocampal dentate granule cells produces an epilepsy syndrome. The percentage of granule cells in which PTEN is deleted from can be experimentally controlled in this model. We have now demonstrated that PTEN deletion from >20% of granule cells in three-week-old mice leads to the development of spontaneous complex seizures about nine weeks later; evident as seizure spread to motor cortex. For the present study, we will test the hypothesis that the seizure phenotype in these animals is regulated by the percentage of PTEN KO cells. We predict that PTEN deletion from fewer cells will produce simple partial, rather than complex partial seizures - the latter evident as focal hippocampal seizures. Accumulation of abnormal granule cells occurs in a number of epilepsy models, and if seizure phenotype is dependent on abnormal granule cell number, this accumulation could account for disease progression in some epilepsy patients. If correct, preventing this accumulation might prevent disease worsening.

Neurosciences, Alberta Children Hosp. Res. Institute, Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: Surgically-resected tissues from patients with epilepsy at times exhibit disruption of the neuronal cytoskeleton, and mutations in genes encoding components of the cytoskeleton - critically involved in neuronal network development - can lead to malformations of cortical development and medically intractable epilepsy. However, it is unknown whether postnatal modification of cytoskeletal structure and/or function can lead to epilepsy. Here, we generated a conditional knockout mouse of the microtubule-associated/signaling protein Ndel1 (Ndel1 CKO, by breeding CaMKIIα-Cre transgenic mice with Ndel1-LoxP mice) in forebrain excitatory neurons, and tested the hypothesis that postnatal dysregulation of the cytoskeleton results in aberrant hippocampal structure and neuronal excitability. Confocal/electron microscopy, video-EEG, molecular, cellular and behavioral techniques were used to study CA1 hippocampus in Ndel1 CKO and WT mice. Genome-wide transcriptome profiling of hippocampi derived from both CKO and control mice was performed using RNA sequencing. Ndel1 CKO mice exhibit spontaneous recurrent seizures (SRS), frequent interictal spikes and die prematurely (~10.5 weeks). Further, CKO mice display hippocampal lamination defects (i.e., misalignment of CA1 pyramidal [pyr] cells). This CA1 dysplasia also involves primitive pyr cell dendritic arbors, atrophied spines, ~48% reduction in the number of asymmetric synapses and ~55% reduction in the number of pyr cell dendritic microtubules ($P<0.01$). These structural abnormalities are paralleled by increased excitability of CA1 pyr cells: ~26% increase in input resistance, ~35% decrease in threshold current and ~51% enhanced firing ($P<0.05$). Further, CKO have interneuron defects, including: ~54% reduction in the number of CA1 symmetric synapses and ~40% decrease in the frequency of mIPSCs recorded in pyr cells ($P<0.01$). Finally, genome-wide transcriptome analysis of CKO hippocampi revealed deregulation of genes associated with human epilepsy that can be normalized (rescued) with Reelin treatment. In summary, we have identified several postnatal changes in hippocampi of Ndel1 CKO mice that likely contribute to

SRS, specifically CA1 dendritic/synaptic pathologies, postnatal CA1 pyr cell dispersion and hyperexcitability, and an interneuronopathy. The identification of genes linked to epilepsy combined with morpho-functional abnormalities in Ndel1 CKO mice suggest that Ndel1 may represent an important target for the study of epilepsy and advances the notion that that the postnatal disruption of the cytoskeleton may be an important determinant of the epileptic state.

Title: Modification of the focal kainate model in rats for the use in pharmacological studies on antiepileptogenesis

Authors: R. KLEE[1,2], C. BRANDT[1,2], K. TÖLLNER[1,2], *W. LOSCHER[1,2];
[1]Univ. of Vet. Med. Hannover, Hannover, Germany; [2]Ctr. for Systems Neurosci., Hannover, Germany

Abstract: A large variety of brain insults, including a status epilepticus (SE), can induce the development of symptomatic epilepsies, particularly temporal lobe epilepsy (TLE). In the latent period after the initial insult multiple molecular, structural, and functional changes, called epileptogenesis, proceed in the brain. All these mechanisms can lead to spontaneous recurrent seizures (SRS). An urgent medical need is to develop antiepileptogenic strategies that modify or even prevent the development of SRS. In rodent post-SE models, kainate, a neurotoxic glutamate analogue, is widely used to induce SE for the investigation of epileptogenesis and TLE. Focal injection of kainate in the hippocampus induces an epileptic focus and alterations in the brain that are similar to human TLE. In mice, the chronic epileptic state in the focal kainate model is characterized by a high frequency of seizure-like events (SLEs) in EEG of the ipsilateral hippocampus and infrequent generalized convulsive seizures. In rats, only the infrequent generalized convulsive seizures are observed. The rat model is therefore much more time-

consuming and less suitable for investigating the antiepileptogenic potential of different drugs and their combinations. An advantage of the focal kainate model in rats is a high face validity with respect to human TLE.The reason for this species difference is not known, but the dose of kainate and the localization of kainate injection in the hippocampus may be involved. For this reason we modified the focal kainate model in rats and adapted it accordingly to the focal kainate model in mice. We injected kainate under anaesthesia, implanted an electrode in the hippocampal focus and changed step by step the injection site, the dose, and the volume of the kainate injection. Preliminary results indicate that neither the change of injection site in the hippocampus nor the increase of the kainate dose or volume lead to similar SLE frequencies as seen in mice. These findings support the conclusion, that it is not possible to mimic the advantages of the mouse model in rats, and therefore it remains more time-consuming to study antiepileptogenic effects in the rat model.

Title: mir-124 as a potential biomarker of traumatic brain injury

Authors: ***N. VUOKILA**[1], N. PUHAKKA[1], K. LUKASIUK[2], A. PITKANEN[1];
[1]A. I. Virtanen Inst. for Mol. Sci., Univ. of Eastern Finland, Kuopio, Finland; [2]Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: Traumatic brain injury (TBI) is one of the most common reasons for acquired epilepsy. Not all TBI patients develop seizures. We hypothesize that certain miRNAs are involved in post-traumatic epileptogenesis and investigation of changes in the expression level of miRNAs would provide both biomarkers and possible drug targets. TBI was induced to adult male Sprague-Dawley rats using lateral fluid-percussion. The miRNA of interest was determined with Ingenuity Pathway Analysis (IPA) using Affymetrics array data ($p<0.05$) derived from dentate gyrus 3 months post-TBI. To investigate networks related to the chosen miRNA we performed STRING analysis. Other targets of miR-124 were determined with database search using miRWalk, miRanda, miRDB, RNA22, TargetScan, DIANmT, PICTAR4, PICTAR5 and

PITA. Results from STRING and miRWalk were compared to transcriptome profiling with Gene Enrichment Analysis (GSEA). Circulating miR-124 was detected from whole blood samples at 2 days and 2 months post-TBI using RT-qPCR to investigate it as a possible biomarker. The results from blood RT-qPCR were analysed with receiver operating characteristic (ROC) test. IPA predicted miR-124 to be down-regulated as 18 of its targets were upregulated (z-score=-4.176, $p<0.01$). STRING analysis connected these targets to Jak/STAT pathway, APP processing and ubiquitination. In GSEA 31% (32/104, FDR<0.01) of the additional molecules suggested by STRING and 18% (57/321, FDR<0.05) of targets predicted by database search were enriched in transcriptome data. According to RT-qPCR the amount of circulating miR-124 at 2 day post-TBI seems to be elevated (189% compared to control, $p=0.0500$). ROC analysis indicates that at that timepoint miR-124 is a potential biomarker (area=0.803, $p<0.05$). At 2 months post-TBI no change was found when compared to control. Gene expression data suggests that miR-124 regulates pathways previously related to epilepsy. ROC analysis indicated that the elevated blood miR-124 content at 2 days post-TBI could be used as molecular biomarker for TBI.

Title: The impact of sex differences on the development of new antiepileptogenic treatments

Authors: ***K. TÖLLNER**[1,2], F. TWELE[1,2], C. BRANDT[1,2], W. LÖSCHER[1,2];
[1]Pharmacol., Univ. of Vet. Med., Hannover, Germany; [2]Ctr. for Systems Neurosci., Hannover, Germany

Abstract: Epilepsy is characterized by the occurrence of spontaneous recurrent seizures. In about 30% of patients epilepsy has a symptomatic cause, i.e. the disease develops after an initiating insult such as stroke, head trauma, or status epilepticus (SE). The period in between this insult and first chronic seizures is called latent period or 'epileptogenesis'. The term 'epileptogenesis' summarizes various processes, e.g., inflammation, neurodegeneration, and neuromodulation, which transform the normal brain into a seizure-generating one. Despite intensive research on these processes and possible targets to interfere, there are currently no

clinically available 'antiepileptogenic' drugs to prevent the development of epilepsy after an epileptogenic brain injury. Thus, the development of novel drugs to prevent or modify epilepsy in patients at risk is an urgent medical need. The intrahippocampal kainate model in mice, a post-SE model of mesial temporal lobe epilepsy, seems to be an ideal screening model in the search for antiepileptogenic drugs. Several groups reported that in male mice (Swiss or C57BL/6) a kainate induced SE is followed by a short latent period (days to weeks) after which focal seizures occur at a very high frequency, so that an antiepileptogenic drug effect can easily be detected without the need of long continuous video/EEG recording. In our hands - using female NMRI mice - no latent period could be observed. Therefore, we tried to modify the model in female mice by decreasing the kainate dose (from 1.0 nM stepwise down to 0.25), changing the location of the EEG electrode (hippocampus vs. cortex), changing the anesthetic used during kainate injection (chloral hydrate vs. isoflurane), or increasing the age at time of kainate injection (mid-adolescent to post-adolescent), but none of these modifications yielded a latent period - until we switched to male mice. A clear latent period could only be seen in male NMRI mice but not in female mice of three different mouse strains (NMRI, C57BL/6, FVB/N). Moreover, focal hippocampal paroxysmal discharges (HPDs), which are considered the typical focal seizure in this model, only occurred frequently in male mice but almost never in females of the examined mouse strains. The present data demonstrate for the first time marked sex-related differences in the latent period, which most certainly will affect the preclinical antiepileptogenesis study design and analyses of outcome measures.

Title: Hippocampal volume and T2 signal changes in the pilocarpine model of temporal lobe epilepsy

Authors: ***R. BARBOSA**[1], A. S. VIEIRA[2], A. H. B. DE MATOS[2], B. M. DE CAMPOS[1], R. F. CASSEB[1], R. GILIOLI[3], I. LOPES-CENDES[2], F. CENDES[1];

Abstract: Background: The limbic structures of the temporal lobe are more susceptible to brain injuries related to epileptogenesis, such as the ones observed in patients with temporal lobe epilepsy and animal models. However, some of these structural brain changes during the development of epilepsy are still unknown.Objectives: To analyze neuroimaging changes (volumetry and T2 signal) in the hippocampus within the first 30 days after pilocarpine induced status epilepticus (SE). Methods: A total of 10 adults male Wistar rats were submitted to magnetic resonance imaging (MRI) with acquisition of T2-weighted images using a volumetric coil with 8 integrated channels and resources for positioning and anesthesia (Rapid Biomedical GmbH, Wurzburg, Germany) in a 3 Tesla Philips scanner . Images were acquired prior to any intervention and then 48 hours, 15 days and 30 days after pilocarpine SE induction. These rats were pre-treated with methyl scopolamine (1mg/kg) to reduce systemic cholinergic side effects. Thirty minutes after, rats received a systemic injection of pilocarpine hydrochloride (380mg /kg) and after 4 hours of the onset of SE, (4 mg/kg) diazepam to interrupt crises. The analysis of behavioral seizures followed the classical parameters by direct visual inspection, according to the Racine scale. The anatomical boundaries of the hippocampus were defined by the brain atlas rats (Paxinos & Watson, 1986) and volumetric analysis was performed using the Display program. SE was observed between 1-2 hours after each injection. The SE-related mortality was 50% in this study. Results: Four out of 5 rats developed SE. Overall, the mean hippocampal volumes increased progressively after SE induction; however, there was a great individual variation. Considering rats which developed SE, one showed a small reduction of hippocampal volumes after 48 hours and all four rats had an increase of hippocampal volumes 15 days after inducing SE. Only 2 animals showed a further increase of hippocampal volumes in the MRI 30 days after SE. The animal that did not develop SE had a small reduction of hippocampal volumes 48 hours and 15 days after SE, and an increase of hippocampal volumes 30 days after SE. The visual assessment of T2-weighted images showed a progressive increase of signal intensity in hippocampus after inducing SE in all four rats with SE. The rat without SE after pilocarpine did not have T2 signal changes in the scans. Conclusion: The main finding of this preliminary longitudinal study confirms changes in hippocampus volumetry and T2 signal after SE induction by pilocarpine. Early changes in T2 hippocampal signal precedes volume changes and is related to the occurrence of SE.

Title: Respiration-induced seizures in the adult naked mole-rat

Authors: ***M. ZIONS**, T. DZEDZITS, D. MCCLOSKEY;
CUNY CSI, Staten Island, NY

Abstract: The African naked mole-rat (H. glaber) presents a unique opportunity to study the contributions of physiology and environment on neuronal synchrony and seizures. Besides their extreme longevity (> 30 years), and inducible reproductive and stress hormones (as cooperative breeders), naked mole-rats have a wide tolerance for ambient oxygen and carbon dioxide (as fossorial rodents), and a brain temperature that is tightly coupled to the environment (as poikilotherms). In addition, naked mole-rats appear to be prone to seizure, displaying sporadic spontaneous seizure behaviors *in vivo* and spontaneous hippocampal epileptiform burst discharges *in vitro*. However, the mechanisms underlying this lowered seizure threshold are not well understood. Here, we measured behavioral responses in response to hyperthermia (~41 C, ambient and rectal) and observed robust seizures into adulthood (>1 year). To determine whether these seizures were in response to brain temperature or alkalosis due to increased respiration (as reported by Kaila and colleagues in juvenile rat and mouse models of febrile seizures) we injected adult naked mole-rats with sodium bicarbonate (5 mM/kg i.p.) and seizures were confirmed on EEG and video. Administration of 5% CO2 in room air suppressed behavioral seizure and ictal spiking whereas restoration of normal CO2 was accompanied by renewed seizing. Nikethamide, a respiratory stimulant, was injected (100 mg/kg i.p.) and produced rapid, robust seizure activity in room air and temperature. Together, these results suggest that an enhanced sensitivity to brain alkalosis mediates the seizure susceptibility of this species, and posits the naked mole-rat as a new animal model in the study of febrile seizures.

Title: Ictal patterns in limbic and cortical circuitry in an epilepsy model induced by perforant pathway long-term stimulation

Authors: ***A. S. BROGGINI**[1], I. M. ESTEVES[2], R. N. LEÃO[3], R. N. ROMCY-PEREIRA[3], J. P. LEITE[2];
[1]Neurosci. and Behavior Sci., [2]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [3]Brain Inst., Natal, Brazil

Abstract: Abnormalities in encephalography (EEG) (e.g. increase in focal slow activity and interictal spikes) are often found in focal epilepsy. Hence, EEG can be potentially useful for seizure prediction. Recently, studies have focused on measures of brain activity, such as the total spectral power and the synchronization between regions. At the molecular level, it is known that immediate expression genes (Zif268) are neurobiological tools widely used for functional activity mapping. Here, we characterize the spontaneous recurrent seizures (SRS) and perform spectral analysis of local field potentials (LFP) before and after seizures detected in a temporal lobe epilepsy (TLE) model with ictal activity restricted to the hippocampus (hippo). The TLE model is generated by long-term intermittent electrical stimulation of the perforant pathway (PP). LFPs were recorded in dentate gyrus (DG) of hippo and medial prefrontal cortex (mPFC) and SRS were monitored by video-EEG. The power spectrum and coherence in oscillations between hippo and mPFc were measured in 2 minutes segments before and after seizures for the following frequency bands: delta, theta, beta, low gamma and high gamma oscillations. Behavioral patterns in these segments were categorized in awake, sleeping or exploration states. Besides, we assessed Zif268 and parvalbumin expression 2 hours after SRS to map the activation/synaptic plasticity and death of inhibitory interneurons. Eight out of 16 stimulated animals displayed at least one electrographic seizure, predominantly in the afternoon. The mean latency of the first SRS was 37 days. In 33 electrographic SRS observed in a total of 14 animals, we found a significant decrease in theta power after SRS in comparison to segments before seizures. Mean coherence in theta (hippo-PFC) increased in the last 30 seconds preceding seizures. The largest increase in hipo-pfc coherence was observed in animals that were sleeping before SRS. Rats in exploration state did not show significant difference in coherence preceding seizures. Stimulated animals showed clear expression of Zif268 in mPFC, entorhinal cortex and DG regions, 2 hours after SRS. In CA1, CA3 and hilus, where the neuronal loss was intense, Zif268 staining was absent. In CA2, where neuronal loss was mild, weak Zif268 expression was observed. Parvalbumin expression also decreased in mPFC (pre-limbic area) and DG regions 2 hours following seizures, compared with control animals. Taken together, these results show that an increase in hippo/mPFC coherence may serve as a predictor of SRS. Further analysis will reveal whether these EEG predictors are also correlated to the extent of network wiring or cell damage.

Title: Electrographic pattern of the kainic acid induced status epilepticus *in vivo*

Deleted: *in vivo*

Authors: **F. M. NOÈ**, C. ALESSI, A. CATTALINI, M. DE CURTIS, *V. GNATKOVSKY; IRCCS Inst. Neurologico C. Besta, Milan, Italy

Abstract: Status epilepticus (SE) is a neurological emergency associated with significant morbidity and mortality, characterized either by prolonged seizures or by a serie of seizures, lasting over 30 min. In many epilepsy animal models, SE is assumed to trigger the epileptogenic process. While chronic seizure events in animal models had been well described, very few studies are available about electroencephalographic SE development and on the resulting epileptogenic process. In our study we focused on the acute phase (first 3 days) following Kainic Acid (KA)-induced SE in guinea pig model *in vivo* (Carriero et al., Epilepsia 2012; Arcieri et al., Epilepsia 2014). Seven days after electrode implantation bilateral in hippocampi, and frontal and parietal cortices, KA (5mM, 1 µl) was injected unilaterally in the dorsal CA1 area. Continuous video-EEG recording was performed starting 24 h before till 3 days after SE induction. A preliminary group of 11 animals was analyzed and two principal EEG patterns were observed. In 5 animals, acute seizures were recorded, followed by a continuous, high-amplitude rhythmic spike activity at 15-25 Hz lasting 8-20 h. In 4 animals, high amplitude and frequency discharges (HAFDs, up to 5 h) followed by a low-amplitude spike activity with lower frequency rate, lasting about 8-10 h, were recorded. Finally, in 2 animals atypical patterns were observed. A variable number of HAFDs (5-90) was observed exclusively during the first 6 h of SE. HAFDs were always characterized by post-ictal depression and by spiking activity recovering between consecutive episodes. Long-term EEG frequency analysis showed increased 11-30 Hz activity during SE. This activity slowly increased during the transition from the KA-induced acute ictal phase to the spike activity phase. Behavioral observation revealed that the seizures correlated

Deleted: in vivo

with immobility, stereotyped movements and tonic-clonic pattern, whereas the spike activity was characterized by a slow return to normal behavior. When diazepam (DZP; 12.5 mg/kg, i.p. for 90 min; n=4), was administered in order to prevent SE induction, acute seizures were blocked and a continuous spike activity at 15-25 Hz was observed. After DZP withdrawal, EEG SE was resumed in all animals, despite the obvious lack of motor clinical manifestations. Preliminary histological evidence suggests that also DZP-treated animals showed KA-induced damage associated to spiking activity. Conclusions: Different EEG patterns can be generated during KA-induced SE. KA injection mainly correlates with fast spiking activity at 15-25 Hz at the injection site. Seizures, but not fast activity can be blocked by DZP.

Title: Histology of Epileptogenesis in Zebrafish

Authors: ***D. Q. PHAN**[1], M. BERBEROGLU[2], C. BEATTIE[2], C. W. HALL[2];
[1]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [2]Ohio State Univ., Columbus, OH

Abstract: Characterized by recurrent unprovoked seizures, epilepsy is a chronic lifelong disorder affecting 1% of the general population associated with higher rates of mortality, cognitive impairment, and psychosocial dysfunction at an annual economic cost of $12 billion USD. Although epilepsy is mostly treated with medications, medical therapy is ineffective for 25% of patients and produces severe side effects, emphasizing the need to explore alternative therapeutic approaches. To that end, a better understanding of epileptogenesis is needed. Epileptogenesis is a complex and dynamic process by which brain tisues become prone to spontaneously initiating and sustaining electrical seizure activity. Epileptogenesis results from changes in the brain's biochemical and micro-anatomic structures, including local inflammation, neurogenesis, and reactive gliosis. Each of these alterations is a potential therapeutic target for halting epileptogenesis, but little is known about which process or combination of processes would be optimum. Work in this area is slowed by the myriad of complicated and overlapping biological pathways involved, compounded by the relatively low throughput capacity of mammalian epilepsy models. The overarching goal of this study is to determine whether the

zebrafish epilepsy model can be used to study epileptogenesis. Like rodents, zebrafish have a completely tractable genome, vertebrate neural architecture, and are used to study many human diseases including epilepsy. The advantages of the zebrafish model over rodent models, especially as it pertains to epilepsy, include more cost effective generation and maintenance of transgenic lines and greater amenability to high throughput, stringently controlled experimentation. In our study, we found that drug-induced seizures caused epileptogenic histological transformations in the zebrafish brain, including inflammatory changes, increased neural proliferation and neurogenesis, and reactive gliosis. These findings lend support that the high throughput, cost-effective zebrafish epilepsy model may have utility in studying epileptogenesis.

Behavioral Neurol., Leibniz Inst. for Neurobio., Magdeburg, Germany; [3]Dept. of Neurol., [4]Dept. of Stereotactic Neurosurg., Otto-von-Guericke Univ., Magdeburg, Germany; [5]Ctr. for Behavioral Brain Sci., Otto-von-Guericke-University, Magdeburg, Germany

Abstract: For a better understanding of the pathophysiology of epilepsy in humans and the development of novel therapies, especially for patients with treatment resistant epilepsy, appropriate animal models are indispensable. Several animal models of epilepsy or seizure induction exist, e.g., chemically induced rodent models. However, they exhibit not negligible differences from the conditio humana, which hampers the transferability of results to humans. Therefore, we used long-tailed macaques as an animal model for experimental seizures, in which seizures are induced acutely by electrical stimulation of the motor cortex. Both stimulation and recording microelectrodes were placed intracortically into the ventral primary motor cortex. In addition to the intracortically recorded local field potentials, we obtained electrocorticograms from a surface electrode array above ventral primary motor cortex. To assess the influence of

stimulus parameters on the characteristics of the electrically induced epileptic activity, we varied the duration of the pulse trains from 1 to 4 seconds and the intensity from 10 to 500 µA. Pulse trains were applied with a constant frequency of 60 Hz. The epileptic activity was determined by the total number of epileptic spikes, their amplitude, and their frequency composition. Additionally, the animals were video monitored for clinically driven classification. This categorial seizure classification comprises 6 groups with increasing severity (from A: tonic and/or clonic convulsions of one muscle group to F: generalized tonic-clonic seizures). Three hundred forty stimulations were performed within 7 experimental sessions on different days in two monkeys. In about one fourth of these stimulations we were able to electrically induce epileptic activity, which was accompanied by clinical seizure manifestation in more than half of the cases. The number of epileptic spikes induced by one stimulus train and the duration of epileptic activity correlated with the intensity and the duration of stimulation. However, most strongly it depended on the applied charge, i.e., the product of current intensity and duration. With higher charge, longer epileptic seizures with higher clinical severity were induced. Here, we present a stable non-human primate model that allows repetitive and reversible induction of focal motor seizures. This model represents an excellent tool for preclinical testing of anti-ictal therapy modalities, such as deep brain stimulation, whose anti-ictal efficacy is based on the alteration of seizure propagation.

Title: Evaluation of acetylcholine and neuropathology following the administration of nerve agent and potential neuroprotective drugs in freely moving rats

Authors: **C. ACON-CHEN**, J. KOENIG, G. SMITH, A. TRUITT, T. THOMAS, *T.-M. SHIH; US Army Med. Res. Inst. Chem Defn, Aber Prov Grd, MD

Abstract: Organophosphorus nerve agents such as soman (GD) inhibit acetylcholinesterase, producing an excess of acetylcholine (ACh) that results in hypersecretions and respiratory distress in the periphery. These nerve agents also produce *status epilepticus* that contributes to

neuropathology. Several drugs (topiramate, clobazam, pregnanolone, allopregnanolone, UBP 302, cyclopentyladenosine [CPA], ketamine, midazolam, and scopolamine) have been identified as potential neuroprotectants that may terminate seizures and reduce brain damage. To begin to understand if these drugs mitigate neuropathology following nerve agent exposure, this study employed striatal *in vivo* brain microdialysis and high performance liquid chromatography to respectively collect and analyze extracellular ACh in freely moving rats following GD exposure and drug treatment at 20 minutes after seizure onset. Along with the evaluation of ACh levels, EEG seizure activity was recorded and neuropathology assessed 24 hrs later. The average time for seizure onset was 5.15 minutes after GD administration. The average basal ACh level was 0.97 pmol/10µL. GD-exposed groups showed a marked increase of ACh, peaking at 30 minutes post-exposure to approximately 800% of control levels. ACh concentration then steadily decreased toward baseline levels. Approximately 30 min after treatment, only midazolam (10 mg/kg) and CPA (60 mg/kg) caused a significant reduction of ACh levels. This reduction persisted for 1 hour for midazolam-treated groups and until the end of the collection period for CPA. While CPA reduced ACh levels more rapidly than midazolam, both drugs facilitated a return to baseline levels at least 2.5 hrs after treatment. At 24 hrs, only animals treated with CPA (64%), midazolam (18%), and scopolamine (27%) exhibited seizure termination. All treatments with the exception of topiramate demonstrated a decrease in total neuropathology 24 hours after exposure. While clobazam, pregnanolone, allopregnanolone, UBP 302, and ketamine only increased neuroprotection by at most 20%, CPA, midazolam, and scopolamine increased neuroprotection by at least 59%. Our results suggest that delayed treatment with CPA, midazolam, or scopolamine is effective at reducing GD-induced seizure activity and neuropathology, with CPA and midazolam able to facilitate a reduction in GD-induced ACh elevation as well. Title: Somatostatin reverses kindling-induced increases in type-1 progenitor cells in the dentate gyrus of adult rats

Authors: ***J. A. LEIBOWITZ**[1,2], G. NATARAJAN[1,3,4,5], M. A. KING[1,6,7], P. R. CARNEY[1,3,4,5,2], B. K. ORMEROD[1,2,5,4];
[2]Pruitt Family Dept. of Biomed. Engin., [3]Depts. of Pediatrics and Neurol., [4]Dept. of Neurosci., [5]McKnight Brain Inst., [6]Depts. of Pharmacol. and Therapeut., [7]NF/SG VHS Med. Ctr., [1]Univ. of Florida, Gainesville, FL

Abstract: There are approximately 2.2 million persons with epilepsy in the US. Temporal lobe epilepsy (TLE) is the most common epilepsy with over 25% of individuals resistant to antiepileptic drug treatment. Amygdala electrical kindling is a model of TLE that is used to identify the mechanisms of seizure evolution and maintenance and to test treatments. Kindling can increase the production of new cells that differentiate into granule neurons up to 8-fold in the hippocampus of adult rats. We have previously shown that somatostatin (SST) overexpression in the hippocampus prevents the development of severe seizure behavior in 70% of kindled rats and may even reverse kindling-induced seizure behavior along with the associated cognitive deficits. Male Sprague Dawley rats (225-250g) were implanted bilaterally into the amygdala with stimulating and recording electrodes and either sham kindled (n=5) or kindled (n=20) 2x per day (6h apart) until 3 consecutive grade 5 seizures were exhibited in the kindled rats. Some kindled rats received bilateral hippocampal injections (4µl each) of recombinant pAAV-CBa-GFP (n=4) or pAAV-CBa-SST-GFP (n=10) 48h after the last seizure. Three weeks later, rats were kindled every 48h for 3 weeks and seizure behavior was recorded. Rats were injected i.p. with the cell synthesis marker bromodeoxyuridine (BrdU; 100mg/kg) 48h after the final kindling session and perfused 4h later. Hippocampal sections were stained immunohistochemically to estimate total IBA+ microglia and dividing BrdU+ progenitor cell numbers stereologically and confirm resting, CD11B+ activated or CD68+ phagocytic IBA+ microglial and GFAP+/Sox2+ Type 1 or GFAP-/Sox2+ Type 2 BrdU+ progenitor cell phenotypes under confocal microscopy. Relative to sham-kindled rats, significantly more dividing BrdU+ progenitor cells were found in the hippocampi of kindled rats ($p < 0.001$) and kindled rats injected with a control GFP vector ($p < 0.01$) but not in kindled rats injected with a SST gene vector. Kindling upregulated proliferating Type 1 ($p < 0.05$) but not neuronally-committed Type 2a progenitor cells. Kindling did not alter the total number of microglia in the granule layer of the dentate gyrus but preliminary data suggest that a greater proportion of microglia were activated in the hippocampi of kindled rats. Data collected thus far support the hypothesis that kindling upregulates the division of naïve Type 1 neural progenitor cells and the number of activated microglia in the adult hippocampus and that SST gene therapy may protect neurogenesis and microglia from the effects of kindling and thereby reduce seizure severity.

Title: *In vivo* evidence of GABA-A receptor-mediated inhibition restraint in acute seizure model

Authors: ***J.-Y. LIOU**[1], M. ZHAO[2], E. SMITH[3], A. DANIEL[2], H. MA[2], C. SCHEVON[4], T. H. SCHWARTZ[2];
[1]Columbia Univ., New York, NY; [2]Dept. of Neurolog. Surgery, Brain and Mind Ctr., New York Presbyterian Hospital, Weill Med. Col. of Cornell Univ., New York, NY; [3]Dept. of Neurolog. Surgery, [4]Dept. of Neurol., Columbia Univ. Med. Ctr. and New York-Presbyterian Hosp., New York, NY

Abstract: Surround inhibition as a physiological defense mechanism against epileptiform activity remains poorly understood. We report an investigation of dual pharmacologically evoked seizure foci in an acute *in vivo* rat seizure model. One seizure focus was created by locally injecting 4-aminopyrine into somatosensory cortex. The focality and lack of propagation of this focus was verified using both a 96 channel microelectrode array arranged in a 10 x 10 grid with 400 um inter-electrode spacing implanted over the injection site, and *in vivo* calcium imaging. In order to focally disrupt the inhibitory restraint in a separate region, we injected bicuculline methiodide (a GABA-A receptor blocker) into another site 3-6 mm away to the 4-aminopyrine site. We found that this injection initiated seizure propagation and, in cases where bicuculine was injected distally from 4-aminopyrine focus, resulted in a new seizure focus that was non-contiguous to the 4-aminopyrine focus. Our analysis of temporal dynamics and spike timing demonstrated unit activity at the new noncontiguous focus exhibited opposed spike phase-locking and independent temporal dynamics. These experiments provide evidence that feedforward GABA-A synaptic conductance mediates an inhibitory restraint. Moreover, the effects of GABA-A synaptic conductance can occlude the presence of independent seizures arising from multiple noncontiguous sites in the low frequency local field potential. Furthermore, we found that ictal activity developed by interaction between the two sites can occur in the absence of pre-existing aberrant connectivity. Thus, this experiment counters the widely held hypothesis that a pre-existing, structurally abnormal “epileptogenic network” is necessary to

incite multiple cross-site interactions in focal epilepsy. Dissecting these network factors may lead to more accurate seizure localization methods in the surgical treatment of epilepsy.

Abstract: Tetramethylenedisulfotetramine (TMDT) is a hydrophilic neurotoxic compound mainly known for its use as a rodenticide. TMDT is highly potent, proconvulsant, odorless, colorless, and implicated in a significant number of accidental and intentional human poisonings, mostly in China. Despite bans worldwide, this compound is still illegally available in Chinese markets, making it a potential terrorism concern. Although TMDT is thought to act mainly as a GABAA receptor antagonist, exposure remains lethal to mice despite diazepam-induced anticonvulsant effects. Our recent studies report reduced lethality in TMDT-exposed mice treated with N-methyl-D-aspartate (NMDA) receptor antagonists, alone or in combination with benzodiazepines that enhance GABAA receptor activation. Brain inflammatory markers are elevated in rats exposed to TMDT and calcium influx is increased in cultured hippocampal neurons. Together, these data suggest that delayed neuronal death may be an ultimate outcome of TMDT exposure. Our objective was to establish organotypic hippocampal slice cultures as an *in vitro* model of TMDT toxicity for moderate-throughput screening of compounds that would minimize delayed neuronal death. In this model, organotypic slices were prepared from P8-P12 rats and, after a 1 week recovery period, incubated with varying concentrations of TMDT with or without drug treatment. After TMDT exposure, neuronal death was quantified by measuring

Deleted: in vitro

propidium iodide and activated caspase fluorescence in the CA1, CA3, and DG pyramidal cell layers of the hippocampal slices. We found that TMDT had minimal effect on cell viability after 2 hours, but produced significant neuronal death after a 24 hour exposure. Additionally, low concentrations of TMDT markedly enhanced delayed neuronal death elicited by the glutamatergic agonist NMDA, even after 2h exposure. Neuronal death was reduced by treating cultures with MK-801, an NMDA receptor open channel blocker, or diazepam, an allosteric enhancer of GABAA receptors. Taken together, our data suggest that the organotypic slice culture model recapitulates features of TMDT poisoning *in vivo*, making it a useful model for elucidating molecular mechanisms underlying TMDT-induced neuronal death, and screening potential neuroprotective compounds. Understanding the pathways involved in TMDT-induced neurotoxicity and identifying compounds to minimize cell death will be critical to improving long-term neurological outcomes for individuals exposed to TMDT, goals of potential importance to national security. Title: Development and validation of a rat model of delayed treatment for nerve agent intoxication

Authors: H. S. MCCARREN[1], S. COSTINAS[1], E. DUNN[1], W. DRIWECH[1], A. HUBBARD[1], C. JACKSON[1], R. KREMPEL[1], E. MCFARLAND[1], C. OPPEL[1], *J. H. MCDONOUGH, Jr.[2]; [1]Res. Div., US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD; [2]Pharmacol Br, US Army Med. Res. Inst. Chem Def, Gunpowder, MD

Abstract: Organophosphate nerve agents act by covalently binding to, and inhibiting the activity of, acetylcholinesterase. The resultant increase in acetylcholine at neuromuscular junctions and within the central nervous system causes dramatic systemic and neurological

effects in exposed individuals, including loss of muscle control, respiratory distress, status epilepticus, and often death. When administered within minutes of exposure, current therapies targeting the cholinergic and GABAergic systems can be extremely effective; however, awareness of a chemical threat and access to medical treatment is rarely so immediate. This is especially true in cases of widespread civilian exposure such as the attacks in Syria in 2013. Moreover, standard medical countermeasures lose efficacy against nerve agent-induced seizures because of recruitment of a variety of neurotransmitter systems and brain regions to the seizure generation and propagation process. An animal model of delayed treatment of central nervous system symptoms is critical for the development of more effective therapies. Here we describe a model in which adult male rats were exposed to a seizure-inducing dose of the nerve agent soman, began to show electroencephalographic evidence of seizures, and were then administered standard medical countermeasures (atropine sulfate, pralidoxime [2-PAM], and midazolam) at delayed time points after seizure onset. We then confirmed that this model is appropriate for identifying additive anticonvulsant and/or neuroprotective effects of potential test treatments by accompanying standard medical countermeasures with scopolamine, which has previously been shown to reduce seizure duration and associated neuropathology. We observed a dose-dependent increase in the termination of seizures as evidenced by a reduction in overall electroencephalographic power and specifically power in the gamma (20-70 Hz) range within one hour of scopolamine treatment. Similarly, the number of dying neurons quantified by FluoroJade B staining in the piriform cortex, the hippocampus, the amygdala, the thalamus, and the parietal cortex 24 hours after scopolamine treatment was reduced compared to controls. Current efforts using this model are focused on evaluating novel compounds solicited by the National Institute of Neurological Disorders and Stroke's CounterACT Neurotherapeutics Screening Program.

Title: Transcriptome and proteome profile of dorsal and ventral dentate gyrus of a rat epilepsy model induced by electrical stimulation that presents classical hippocampal sclerosis

Authors: *A. S. VIEIRA[1], A. M. CANTO[2], A. H. B. MATOS[2], C. S. ROCHA[2], B. CARVALHO[2], V. PASCOAL[3], R. GLIOLI[4], I. LOPES-CENDES[2];

Federal Fluminense, Nova Friburgo, Brazil; [4]Laboratory Of Animal Quality Control (Cemib), Univ. Estadual De Campinas, Campinas, Brazil

Abstract: An animal model based on eight hours of electrical stimulation of the perforant pathway (pp) in wake rats is capable of inducing hippocampal damage that more closely resemble that found in patients with mesial temporal lobe epilepsy. Furthermore, these animals develop spontaneous seizures after a latent period, however the molecular mechanisms involved in the induction of epileptogenesis remain unknown. RNAseq-based transcriptome analyzes and shotgun mass-spectrometry based proteomics offers the possibility of accurate profiling of global gene and protein expression. Therefore, the present study explores the molecular mechanisms responsible for epileptogenesis in this animal model using transcriptomics and proteomics tools. Electrodes were implanted bilaterally in the dentate girus (DG) and in PP of control (n=4) and experimental rats (n=4). After one week the PP of experimental rats were electrically stimulated for 8 hours after a protocol of two days pre-conditioning by PP electrical stimulation. Fifteen days following stimulation rats were euthanized and the brains processed for laser microdissected using Zeiss PALM LCM. Dorsal (dDG) and Ventral DG (vDG) were collected from each rat, total RNA and proteins were extracted, and libraries for RNAseq in Illumina Hiseq platform were prepared. Proteins were digested with trypsin and peptide fragments were analyzed in an HPLC coupled LTQ-Orbitrap Velos mass spectrometer. A total of 2,367 and 1,889 genes were found to be differentially expressed ($p<0,05$) when comparing the control and stimulated dDG and vDG respectively. Furthermore, a total of 42 and 50 proteins were found differentially expressed when comparing the control and stimulated dDG and vDG respectively. Gene onthology analysis indicated a predominance of inflammation related genes up-regulated in both dDG and vDG. Exclusively in the vDG there was a significant enrichment of axonal guidence and calcium signaling gene onthologies. It is noteworthy the presence of various differentially regulated genes involved in axonal guidance, synaptic function, neural electrical activity and neuropeptides. Moreover, different members of these families of molecules are exclusively differentially regulated in the dDG and vDG. The transcriptome and proteomics data explored in this study indicate many possible components of the molecular mechanisms responsible for epileptogenesis in an animal model that displays hippocampus sclerosis. Furthermore, even though similar mechanisms may be found in different DG sub-regions, the components involved in such processes seem to be region specific.

Abstract: Pyridox(am)ine 5'-phosphate oxidase (PNPO) is a rate-limiting enzyme in converting inactive vitamin B6 (VB6) from the diet to pyridoxal 5'-phosphate (PLP), the only active form of VB6. PLP is a co-factor for more than 140 enzymes required for amino acid metabolism, gluconeogenesis and neurotransmitter (e.g. serotonin and GABA) synthesis. In humans, autosomal recessive PNPO deficiency leads to neonatal epileptic encephalopathy (NEE). NEE is characterized by severe seizures in newborns. They usually appear within hours of birth and are unresponsive to commonly used anticonvulsant drugs. Untreated, most patients die within weeks. New mutations in human PNPO (hPNPO) have been increasingly identified in NEE patients, yet the underlying causes of seizures and lethality are not understood. We have previously identified a c.95C > A missense mutation in SGLL – a homolog of hPNPO in *Drosophila melanogaster* and have shown that flies that carry the c.95C>A mutation ($sgll^{95}$ flies) exhibited a lethal phenotype when fed on sugar-only diet. Here we report that the lethal phenotype of $sgll^{95}$ flies is associated with very low PLP levels, and that lethality can be rescued by either wild-type (wt) SGLL (*drosophila* PNPO (dPNPO)) or wt hPNPO, but not $hPNPO^{R95H}$, a mutant PNPO identified in NEE patients. In addition, $sgll^{95}$ flies exhibit a seizure-like phenotype, which can also be rescued by wt dPNPO or wt hPNPO, suggesting the functional conservation of PNPO between humans and flies. Furthermore, both lethality and seizures are observed in global *sgll* knockdown flies, but the phenotypes are more pronounced than that in $sgll^{95}$ flies. We are using tissue specific- and cell type specific- Gal4 drivers to determine the cell groups and neurotransmitter systems responsible for NEE-like phenotype. These *Drosophila* models

Title: Dose-response curve for pentylentetrazol-induced convulsions in developing rats

Authors: ***E. VELAZCO**[1], I. ZAMORA[1], A. A. PUIG[1], R. A. MEDEL[2], M. L. LOPEZ-MERAZ[1];

Abstract: Pentylentetrazol (PTZ) is a GABAA receptor antagonist and is widely used as a seizure model. Effects of PTZ in adult rats are well known; however, seizures induced by PTZ in developing rats have not been fully described. The goal of this study was to characterize seizures induced by different doses of PTZ in fourteen days-old (P14) rat pups. Wistar rats (both genders) were injected intraperitoneally with PTZ (Sigma) at doses of 45 (n = 4), 50 (n = 4), 55 (n = 10), 60 (n = 8), 65 (n = 8), 70 (n = 4) or 75 mg/kg (n = 4). The occurrence and latency to behavioral convulsions, as well as mortality rate was recorded for each experimental group. Data were analyzed using a proportion test or a Kruskall Wallis ANOVA. Results showed that 45 mg/kg PTZ caused myoclonic jerks but not generalized clonic-tonic seizures (GCTS). Twenty five percent of rats receiving 50 mg/kg PTZ had GCTS that eventually progressed to status epilepticus (SE). Rats injected with 55-75 mg/kg PTZ had GCTS (88-100%) and some of them developed SE (25-60%); however no differences in the proportion of rats displaying seizures were detected between the doses of PTZ tested ($p>0.5$). During SE, seizures were characterized by loss of righting reflex, swimming-like movements of forelimbs and hindlimbs and tremors. Mortality due to the GCTS was smaller in rats injected with 55 mg/kg PTZ when compared with 75 mg/kg PTZ ($p=0.03$). No difference in the latency to the CTGS was observed between the experimental groups ($p>0.5$). Our findings suggest that PTZ produces GCTS that evolve to SE at

doses from 55 mg/kg in P14 rat pups. An acute administration of PTZ could be a useful model to study SE in developing rats.

Title: The absence seizures in the myelin mutant taiep rat are sexually- and circadian- dependent

Authors: ***M. CORTES**[1], Y. SILVA[2], J. R. EGUIBAR[2];
[1]B. Univ. Autonoma de Puebla, Puebla, Mexico; [2]Intitute of Physiol., Benemerita Univ. Autonoma de Puebla, Puebla, Pue, Mexico

Abstract: The myelin mutant taiep rats have a progressive motor syndrome characterized by tremor, ataxia, immobility episodes (IEs), epilepsy and paralysis. It showed an initial hypomyelination followed by a progressive demyelination in the central nervous system. Continuous electroencephalographic (EEG) recordings in taiep rats showed a spike-wave discharge (SWD) in cerebral cortices and hippocampus similar to that reported in WAG/Rij and GAERS two well know absence epilepsy models. The aim of this study was to analyze the SWD in adult male and female taiep rats at 3 months of age. The rats were maintained under standard conditions with free access to rodent pellets and water. Using stereotaxic surgery three electrodes were implanted in the frontal, parietal and occipital cortices to record the electrocorticogram, two electrodes on the neck muscles for the electromyogram and one on the left extraocular muscles for electrooculogram, and bipolar electrode in the hippocampus to register the theta rhythm Our results showed higher incidence of SWD in the dark respect to light phase in female but not in male rats, (P<0-05). Mean duration of SWD in male taiep rats did not differ between light and

dark phase on the other hand female taiep rats mean duration is longer in the dark respect light phase (P<0.05). In conclusion, absence seizures is a sexual dimorphic behavior and also dependent of the light/dark phase suggesting that thalamo-cortical circuit that is modulated by steroid milieu as well as circadian cycle.

Title: Abnormal steady-state visual responses in a *Drosophila* model of epilepsy

Deleted: *Drosophila*

Authors: ***S. A. ALAMRI**[1,2], A. WADE[1,2], C. ELLIOTT[2,3];
[1]Psychology Dept., [3]Biol. Dept., [2]Univ. of York, York, United Kingdom

Abstract: Recent work using steady-state visually-evoked potentials (SSVEPs) has demonstrated abnormal visual gain control in human epilepsy patients (Porciatti et al 2000; Tsai et al 2011). In *Drosophila*, a mutation in the kcc gene (kccDHS1) renders young flies susceptible to light and shock-induced seizures (Hekmat-Scafe et al 2006) and has been used as a model of human juvenile epilepsy. Here, we used SSVEPs to study the age profile of contrast-driven photoreceptor and neuronal responses in both kccDHS1 and wild type (wt) *Drosophila*. To characterize gain control in these animals further, we also made measurements of contrast adaptation and spatial summation and suppression in the wild type and kccDHS1 visual system. Methods: Full field luminance flicker sequences generated by a high intensity LED were modulated at linear combinations of 12Hz and 15Hz about a mean level. Stimulus-locked responses were measured using the electroretinogram (ERG) (Afsari et al 2014). We verified that the 1st and 2nd harmonics of the input frequencies originated in the photoreceptors and neural synapses respectively using histamine gated chloride channel mutants (ort) that eliminate neuronal signaling from the photoreceptors (Pantazis et al 2008). We measured contrast vs response functions from groups of at least 10 kccDHS1 and wt flies aged 1, 2, 3, 7, 10, 20 and 30 days as well as measures of contrast adaptation and spatial summation in 1 day old animals.

Deleted: Drosophila

Deleted: Drosophila

Results: The wild type photoreceptor responses were relatively constant across age groups while response from kccDHS1 flies increased with age and peaked around d30. Young kccDHS1 flies exhibited large, noisy neural responses compared to wt animals and a relative absence of gain control. kccDHS1 flies also exhibited strong but transient oscillations after stimulus onset (at around 80Hz) and offset (around 20Hz). Responses from kccDHS1 animals became more similar to wt flies by d20 - corresponding to a decrease in susceptibility to seizure. Finally, young kccDHS1 flies showed extremely high levels of contrast adaptation and reduced spatial tuning which normalized in older animals. Conclusion: SSVEPs can be used to measure both photoreceptor and neuronal responses in *Drosophila*. SSVEP responses from flies exhibit similar characteristics to those from other animals and can be used to measure neuronal gain control in wt flies as well as genetic models of neurological disease. In kccDHS1 flies, increases in response amplitude and variability, adaptation and susceptibility to seizures are correlated. This technique has the potential to identify reliable, *in vivo* biomarkers of epilepsy in invertebrate models of neurological disease.

Title: The role of regulatory T cells in the modulation of heightened neuronal excitability in epilepsy

Authors: D. XU[1], S. D. MILLER[1], *S. KOH[2];
[1]Dept. of Microbiology-Immunology and Interdepartmental Immunobiology, Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL; [2]Pediatrics, Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Rationale: Recurrent seizures activate immune responses can create a deleterious positive feedback loop. We have detected brain-infiltrating innate and adaptive immune cells in the resected brain of patients with intractable epilepsy and mice with recurrent status epilepticus (SE). In experimental autoimmune encephalomyelitis (EAE), we have demonstrated supplementation of regulatory T cells (Tregs) could reduce the severity of both active and

adoptive transfer EAE. We aim to identify the role of Tregs in the modulation of neuronal excitability and epileptogenesis. Methods: C57Bl/6-FoxP3-eGFP transgenic or wt C57Bl/6 mice were injected with kainic acid (KA) or PBS (control) at post-natal day (P)14 to induce SE (1st hit). Mice received a 2nd KA at P28 and were perfused 7 days later. Cerebral cortex was harvested, processed to generate single cell suspension and stained with fluorescently labeled cell markers for immune cells for flow cytometry. Intracellular cytokine staining (ICS) was performed on the brain-infiltrating leukocytes *in vitro*. Results: We used FoxP3-eGFP transgenic mice to study the role of Tregs in the two-hit model of epilepsy. Brain-infiltrating Tregs were significantly increased in mice after two-hit of KA-SE compared to single-hit control. A boost in the Treg frequency suggested a compensatory role of these immune-suppressive T cells in mice that experienced early-life seizures. We then examined Tregs in the spleen, as well as the cytokine secretion profiles of the antigen presenting cells and CD3+ T lymphocytes in mice treated with immune-modulating nanoparticles. There were more Tregs that secreted anti-inflammatory IL-10 cytokine and upregulated programmed death-1 (PD-1) in mice that had received nanoparticles. A corresponding decrease in the ability to secret pro-inflammatory cytokines was observed in the CD4+ and CD8+ T cell compartment. The proliferative capacity of the total CD3+ T cells was also affected in the nanoparticle-treated mice. Conclusions: Our preliminary data demonstrated that the control of peripheral leukocytes infiltration into the brain of mice with SE can be achieved by upregulating Treg frequency. Manipulation of the regulatory T cell compartment in conjunction with augmenting anti-inflammatory cytokine in the brain can potentially be used therapeutically to reduce immune-mediated neuronal excitability and epileptogenesis. It may further promote repair cascade. Whether early intervention in brain-specific inflammation can reduce detrimental consequence of SE remains to be determined.

Title: Neuromodulation induced by low-intensity direct current stimulation: impact on interictal epileptic discharges

Authors: ***F. WENDLING**, F. MINA, G. DIEUSET, P. BENQUET;
Inserm U1099, Rennes, France

Abstract: Most patients suffering from mesial temporal lobe epilepsy (mTLE) are drug-resistant. In the seizure onset zone, abnormal hyperexcitability of epileptic tissue, due to long lasting unbalanced ratio between potentiated glutamatergic excitation vs decreased GABAergic inhibition, triggers spontaneous recurrent seizures. In the case where surgery is not indicated, alternative therapeutic approaches are required. *In vitro* animal studies have established that stimulation-induced uniform weak electric fields modulate neuronal activity in brain slices (Bikson et al., 2004). Overall, direct current stimulation (DCS) induces short-lasting effects (through immediate effects on neuron membrane potential) followed by longer-lasting aftereffects (through modulation of long term plasticity of glutamatergic synapses) (Ranieri et al., 2012). Therefore DCS might be used to reduce epileptic activity. To date, only few experiments were performed *in vivo* and still, evidence must be brought that *in vitro* results can be translated *in vivo*, in particular in freely moving epileptic animals with chronically implanted electrodes. One study reported a significant increase in the afterdischarge threshold in amygdala-kindled rats, based on the daily application of direct currents, at 5-15 µA intensity during 15 min (Weiss et al., 1998). This consideration led us to investigate the effects of invasive very low intensity Local Direct Current Stimulation (LDCS) applied for short periods in kainate-treated mice experiencing frequent hippocampal paroxysmal discharges (HPDs). Using a combined computational/experimental approach (Wendling et al., 2012), we first investigated the effects of low intensity LDCS on HPDs in a computational model accounting for stimulation-induced neuron membrane polarization. We then tested the model predictions *in vivo* and analyzed some safety issues like stimulation-induced heating and metal deposition (redox reactions) in the brain tissue. Our computational study shows that HPDs can be significantly reduced by cathodal DC stimulation. This prediction was confirmed in freely moving epileptic mice with no major thermal or histological damage. We observed beneficial effects on the occurrence of epileptic activity for very low stimulation intensities (1µA) and for short duration current applications (30s). In these conditions, stimulation effects were reversible and histological damage was not obvious. Nevertheless, iron deposit was detected in the stimulated hippocampus indicating the occurrence of redox reactions due to stimulation. Novel stimulation protocols are currently being investigated to overcome this limitation.

Title: Application of closed-loop optogenetics to uncover the role of hippocampal dentate gyrus microcircuits in temporal lobe epilepsy

Authors: ***A. BUI**[1], E. KROOK-MAGNUSON[2], C. ARMSTRONG[1], S. LEW[1], M. OIJALA[1], I. SOLTESZ[1];
[1]Anat. and Neurobio., Univ. of California, Irvine, Irvine, CA; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Temporal lobe epilepsy is the most common type of epilepsy in adults, but unfortunately, in over one-third of patients, seizures are not controlled with currently available treatment options. Understanding of the microcircuits alterations underlying seizure activity is a key step in the development of improved therapeutical approaches. One brain region that has been of intense interest is the hippocampal dentate gyrus, partly due to the fact that the dentate gyrus undergoes hallmark alterations in association with temporal lobe epilepsy, including hilar cell loss and mossy fiber sprouting. In chronically epileptic mice, using *in vivo* electrophysiological and closed-loop optogenetic methods, we are able to modulate specific populations of cells in the dentate gyrus immediately upon detection of spontaneous behavioral and electrographic seizures. With this approach, we have found that through optogenetic manipulation of excitatory populations of cells in the dentate gyrus, we are able to inhibit or amplify seizure activity through recruitment of different microcircuits. We showed that targeting either the granule cell circuitry or the sparse population of mossy cells can alter seizure dynamics. This study demonstrates the importance of the dentate gyrus circuit in the propagation of seizures, and as a promising target in the control of temporal lobe seizures.

Abstract: Temporal lobe epilepsy (TLE), the most common and intractable type of adult focal epilepsy, is typically associated with pathological alterations in the hippocampus and parahippocampal regions. TLE is an attractive target for cell therapy due to its focal nature and associated cellular defects. Neural stem/progenitor cells (NSPCs) can continuously self-renew and give rise to intermediate and mature cells of both neuronal and glial lineages. Following transplantation in the diseased brain, NSPCs exhibit the potential to migrate toward the lesion and replace degenerated or ablated cells, as well as deliver therapeutic substances. In this study, we transplanted human NSPCs (hNSPCs), derived from an aborted fetal telencephalon at 13 weeks of gestation and expanded in culture as neurospheres over a long time period, into the lateral ventricles of lithium-pilocarpine induced epileptic rats. Implanted hNSPCs migrated and integrated into the recipient brain. The majority of hNSPCs remained undifferentiated, although subsets of donor-derived cells differentiated into all three neural cell types of the central nervous system and expressed inhibitory neurotransmitter gamma-aminobutyric acid (GABA). We found that hNSPC transplantation significantly reduced the frequency and duration of spontaneous recurrent motor seizures (SRMS) at 2 and 3 months post-transplants. In addition, hNSPC-transplanted epileptic rats showed neuroprotection, restoration of astrocytic glial cell-derived neurotrophic factor (GDNF) expression, and up-regulation of anti-inflammatory cytokines in the hippocampus. Finally, we demonstrated that conditioned medium from hNSPCs has neuroprotective action in an *in vitro* model of glutamate excitotoxicity. These results suggest that hNSPC transplantation possesses a therapeutic potential for treating TLE.

Title: Neuronal mechanisms of the antiepileptic effects of human pluripotent stem cell-derived maturing GABAergic interneurons

Authors: ***J.-H. CHO**[1], M. CUNNINGHAM[2], S. CHUNG[2];
[1]Univ. of California, Riverside, Riverside, CA; [2]Psychiatry, McLean Hosp, Harvard Med. Sch., BELMONT, MA

Abstract: Seizure disorders debilitate more than 65,000,000 people worldwide, with temporal lobe epilepsy (TLE) being the most common form. Previous studies have shown that transplantation of GABA-releasing cells results in suppression of seizures in epileptic mice. Derivation of interneurons from human pluripotent stem cells (hPSCs) has been reported, pointing to clinical translation of quality-controlled human cell sources that can enhance inhibitory drive and restore host circuitry. We have previously demonstrated that hPSC-derived maturing GABAergic interneurons (mGINs) migrate extensively within the epileptic hippocampus and reduce seizure activity and other behavioral abnormalities in a mouse model of TLE. In this study, we used electrophysiological approaches to investigate the neuronal mechanisms of the antiepileptic effects of transplanted human mGIN. Although they showed immature passive membrane properties, approximately half of transplanted human mGINs fired spontaneous action potentials, indicating that they are tonically active even without extrinsic synaptic inputs. Moreover, transplanted human mGINs fully integrated into the hippocampal circuitry, receiving excitatory synaptic inputs from host glutamatergic neurons, and were therefore activated by host glutamatergic neuron. In turn, our optogenetic studies revealed that grafted human mGINs release inhibitory neurotransmitter GABA in an activity-dependent manner. Therefore, the activation of transplanted mGINs, either by spontaneous activity or by excitatory synaptic drive, can cause an increase of inhibitory synaptic responses in host hippocampal neurons, shifting excitation/inhibition balance toward inhibition and suppressing exaggerated neural activity in the epileptic brain. Our studies suggest that grafted human mGIN could reduce seizure activity by regulating inhibitory balance in the epileptic hippocampus.

Title: Neurogenic stem cell behavior in models of epilepsy with and without brain damage

Authors: T. WILSON, G. KIM, *K. W. THOMPSON;
Biol., Occidental Col., Los Angeles, CA

Abstract: Cell-based therapy has been proposed for intractable temporal lobe epilepsy. Targeting potentially therapeutic cells to the seizure-prone hippocampus has shown promise in both seizure reduction and neural repair/replacement. Several studies have suggested that embryonic stem cell-derived neural cells (ESC-NS) will have clinical utility because they can differentiate and integrate into the host brain. Objective: Here we investigated transplantation strategies with an ESC-NS line, which has been engineered to become neurogenic, in models of temporal lobe epilepsy. Methods: Neurogenic ESC-NS were transplanted into the hippocampi of rats that had either established seizures with brain damage (pilocarpine-treated (N=8)), or without brain damage (fully kindled (N=4)), or in animals prior to kindling-induced seizures (N=5), or in controls without damage (naïve N=3)) or controls with damage (6-OHDA-treated N=2)). To track the cell survival and distribution, weeks after transplantation, we used nissl stains, X-gal histochemistry, and immunohistochemistry for β-galactosidase. Results: We found that the pattern of stem cell dispersion, and the interaction of stem cells with resident hippocampal cells, is dependent on the model used. In a model that has both hippocampal damage and established seizures, stem cell markers were found distal to the transplantation site and in cells with morphologies consistent with mature hippocampal neurons. This pattern of staining was not seen in animals with established seizures but no damage, nor in animals transplanted prior to hippocampal seizure induction, nor in controls. Conclusions: We have shown here that the microenvironment produced by seizure-induced cell degeneration, but not seizures alone, participates in stem cell behavior after transplantation. These data are consistent with earlier studies that have shown that transplanted cells distribute uniquely in different models of disease. However, recent reports showing that ESC-NS have the capacity to fuse with host neurons raise caution around interpreting these data as purely cell replacement.

Title: GABAA receptor activation in newborn female rats increases the expression level of several GABAergic markers in the hippocampus and entorhinal cortex, and diminishes seizure susceptibility

Authors: ***M. E. URENA-GUERRERO**, K. FLORES-HUITRADO, J. MURGUÍA-CASTILLO, C. BEAS-ZÁRATE, A. FERIA-VELASCO;
Univ. De Guadalajara (CUCBA), Zapopan, Jalisco, Mexico

Abstract: High seizure susceptibility observed in neonates has been related to the immaturity of nervous system, which is characterized by a predominant excitatory activity linked to neuronal differentiation processes. Therefore, in early developmental stages GABA through GABAA receptor (GABAA-R), produces neuronal depolarization contributing to excitation, with the development the GABA effect changes to neuronal hyperpolarization and contributes to inhibition. The functional GABA change is related to a developmental regulated shift on chloride (Cl-) gradient. At neuronal level, NKCC1 acting as Cl- importer is highly expressed when the GABA induces neuronal depolarization, whereas KCC2 acting as Cl- exporter increases its expression in neurons to reach the establishment of GABA-mediated inhibition. *In vitro* studies have suggested that in early developmental stages, GABA-mediated neuronal excitation increases the KCC2 expression improving the neuronal inhibitory response to the GABA application. In this work, *in vivo* GABAA-R activation was induced in newborn female Wistar rats through the subcutaneous (s.c.) administration of muscimol (1 mg/kg of body weight) at postnatal day (PD) 0. After the treatment, at PD 15, the expression levels of KCC2, and alpha1 and gamma2 GABAA-R subunits were estimated in the hippocampus and entorhinal cortex using western-blotting assays. Furthermore, susceptibility to convulsive activity induced by 4-aminopyridine (4-AP; 2 mg/kg of body weight by s.c. administration) was behaviorally evaluated. Results indicate that muscimol treatment induced a significant increment in the expression level of all proteins in both cerebral studied regions, in at least two fold higher respects to control group. The treatment also reduced the susceptibility to 4-AP, increasing the

Deleted: In vitro

Deleted: in vivo

latency for the appearance of generalized tonic-clonic convulsions (GTCC), reducing the maximum number of GTCC episodes and the duration of convulsive activity. In previous work carried out in males, muscimol treatment had similar effects to those reported here. This suggests that an activation of GABAA-R in early developmental stages, when the excitatory activity of GABA is predominant, may improve the GABAergic inhibitory signaling and reduce the seizure susceptibility in both genders.

Title: Time-restricted feeding inhibits seizure susceptibility in a pharmacological seizure model by means of metabolic and epigenetic changes

Authors: ***J. LANDGRAVE-GÒMEZ**[1,2], O. MERCADO-GOMEZ[2], M. VAZQUEZ-GARCIA[2], V. RODRIGUEZ-MOLINA[2], R. GUEVARA-GUZMAN[2];
[1]Facultad de Ciencias, U.N.A.M., Distrito Federal, Mexico; [2]Physiol., Univ. Nacional Autonoma de Mexico, Mexico City, Mexico

Abstract: Introduction: Although new generation of antiepileptic drugs have emerged lately, approximately one-third of epilepsy patients do not respond to classical pharmacological treatments. Objectives: We investigated whether time restricted feeding (TRF) is able to ameliorate seizure susceptibility and if it involves associated-metabolism and epigenetic modifications. Methodology: The acute seizure model in rats consisted in a pre-treatment of lithium chloride (3 mEq/kg) followed by pilocarpine administration (60 mg/kg) with a previous injection of scopolamine nitrate (1 mg/Kg) 30 min before. Briefly TRF was to allow rats to feed for two hours daily during their light phase for 21 days; control and pilocarpine animals consisted feeding ad libitum. Biochemical changes were measured in each group along the 21 days and 24 h after drugs administration. Results: We found that TRF inhibits seizure

susceptibility including a prolonged latency to the first seizure; a decrease in seizure severity and fewer animals with status epilepticus. In addition, TRF showed a significant reduction of power of seizures compared with animals fed ad libitum (AL) as shown in electrophysiology measures. In order to understand which mechanisms may be involved on TRF beneficial effects we measured several physiological and metabolic parameters such as phosphorylation of kinases involved in regulation of metabolic pathways (AMPK and Akt); body weight, food intake, blood glucose and β-hydroxybutyrate (β-HB) concentration in blood. We found that TRF induces a general metabolic shift towards catabolic pathways; inducing an increase of phosphorylation on AMPK and decreasing the phosphorylation on Akt kinase in hippocampus and liver and therefore increasing the concentration of β-HB in blood. In addition, we also found a significant increase in acetylation of H3K9 and H3K14 in the hippocampus of this group compared with AL. Conclusion: Our data demonstrate that TRF is capable to diminish seizure susceptibility. This phenomenon may be mediated by chromatin remodeling of genes by means of inhibition of HDACs by β-HB of associated genes involved in generation of epileptic seizures. The first author received a fellowship from Conacyt. This project was supported by PAPIIT IN211913 and Conacyt 239594 grants.

Title: Lysophosphatidylinositol (LPI), an agonist of the noncanonical cannabinoid receptor GPR55, increases excitatory neurotransmitter release and reduces inhibitory synaptic strength

Authors: *E. C. ROSENBERG[1,2], O. DEVINSKY[3,1], R. W. TSIEN[1,2];

Abstract: Cannabis has been used as a treatment for seizures since ancient times. Two of the major phytocannabinoids in the cannabis plant are the psychoactive compound **Δ**9-tetrahydrocannabinol (THC) and its non-psychoactive counterpart cannabidiol (CBD). Recent studies indicate that CBD may prevent seizures and reduce mortality in epileptic animal models with low toxicity and high tolerability. While the exact mechanism of CBD is not well understood, new research indicates that CBD acts as an antagonist at the orphan G-protein coupled receptor, GPR55. When activated by the endogenous ligand L-**α**-lysophosphatidylinositol (LPI), GPR55 causes a transient increase in intracellular Ca^{2+} and vesicular release probability at excitatory hippocampal synapses (Sylantyev et al. 2013). CBD opposes this effect, suggesting a potential antiseizure action. In contrast to these clear findings at glutamatergic synapses, the role of GPR55 at inhibitory synapses remains unknown. In this study, we characterized the distribution and function of GPR55 at inhibitory hippocampal synapses *in vitro*. Results from immunocytochemistry suggest that GPR55 was localized in presynaptic excitatory terminals labeled with VGLUT to a greater degree than inhibitory terminals labeled with GAD65. Postsynaptically, GPR55 localized to somas and dendrites of CaMKII (+) pyramidal neurons, parvalbumin (PV+) interneurons, and somatostatin (SST+) interneurons. Furthermore, using whole cell patch clamp electrophysiology of hippocampal pyramidal neurons, we found that application of LPI increased the frequency of mEPSCs with no change in amplitude. Conversely, LPI application reduced the amplitude of mIPSCs with minimal change in frequency. Preliminary results suggest that LPI acts through GPR55 to reduce $GABA_AR$ expression, possibly mediated by a decrease in $GABA_AR$ 3 Ser 408/409 phosphorylation. Taken together, these results suggest that LPI increases the excitatory / inhibitory ratio in hippocampal neuronal networks by a dual mechanism: enhancing excitatory transmission and attenuating inhibition. This predicts that CBD, by opposing LPI action, may exert its beneficial anti-seizure effects on both excitatory and inhibitory synapses.

Title: Responsive transcranial focal electrical stimulation via tripolar concentric ring electrodes delayed the development of electrical amygdaliod kindling in the cat

Authors: *A. VALDÉS-CRUZ[1], W. G. BESIO[2], B. VILLASANA-SALAZAR[1], V. M. MAGDALENO-MADRIGAL[1], D. MARTÍNEZ-VARGAS[1], S. ALMAZÁN-ALVARADO[1], R. FERNÁNDEZ-MAS[1];

Abstract: Noninvasive transcranial focal electrical stimulation (TFS) is an experimental proposal to treat pharmacoresistant epilepsy. Our group investigated the effects of TFS on amygdaloid kindling (AK) epileptogenesis in cats. In initial experiments, 40 minutes application of subthreshold TFS through a tripolar concentric ring electrode (TCRE) (10 mm of diameter) placed on vertex, prior to kindling was not effective. Nevertheless, we found a reduction in spectral power after secondarily generalized seizures. These results suggest that TFS is not innocuous. Hence, the present study aimed to analyze the effect of TFS via CRE applied responsively on seizure activity induced by AK in freely moving cats. Nine adult cats were tested. Stainless steel bipolar electrodes were stereotaxically implanted into both temporal lobe amygdalae (AP: 11.5, L: 9.5, H: 5.0) and prefrontal cortices. In addition, a TCRE was fixed on the skull at the temporal bone bilaterally (P: 11.5, L: 15.0). Cats were assigned to two experimental groups: control AK group and AK-TFS group. In the first group, daily AK (1 second train, 1 ms pulses, 60 Hz, 300-600 μA) was performed until all animals reached kindling stage VI (tonic-clonic generalized seizures). In the AK-TFS group, AK was applied every 24 h, TFS through a TCRE placed in the temporal bone was delivered for 2 minutes (biphasic square pulses, 300 Hz, 200 μs, 2.5 mA) ipsilaterally and AK at the same time for 40 days. After, only AK was applied until animals reached kindling stage VI. The experimental variables quantified were the amygdaloid afterdischarge duration and frequency, the number of AK trials to reach kindling stage VI and the maintenance in kindling stages. We found a delay in the progression within behavioral stages of kindling and that animals remained in stage II (partial seizures) during the days of TFS. The number of stimulations to reach stage VI in control AK animals was 29.0 ± 4.0, and animals of AK-TFS stimulation showed a significant increase (84.33 ± 7.33, $p< 0.001$). In addition, behavioral development was retarded, with an increased number of stimulations required to reach stage III (control AK 9.66 ±7.33 vs AK-TFS 51.33 ±10.33, $p< 0.001$). In AK-TFS group, overall kindling development was delayed and amygdaloid afterdischarge duration and frequency of spikes did not showed a progressive increase as was observed in the control AK group. Our results suggest that TFS applied responsively interferes with the development of convulsive evolution and secondary generalization. This delay effect may be due to the interruption of abnormal EEG activity and the interference of the propagation pathways.

Title: Dual-site pontine and thalamic neurostimulation to restore consciousness during and after seizure

Authors: ***A. J. KUNDISHORA**[1], A. GUMMADAVELLI[2], C. MA[1], M. LIU[1], C. MCCAFFERTY[1], J. GERRARD[2], H. BLUMENFELD[1,2,3];
[1]Neurol., [2]Neurosurg., [3]Neurobio., Yale Sch. of Med., New Haven, CT

Abstract: In cases of medically or surgically refractory epilepsy, impaired consciousness during and following seizures has a dramatic impact on quality of life, morbidity and mortality. Improving consciousness in the ictal and postictal periods would be highly beneficial to patients. Our lab developed a rodent model of partial limbic seizures which mimics the human cortical electroencephalographic signature of neocortical slow waves and behavioral arrest associated with loss of consciousness in temporal lobe epilepsy. We additionally demonstrated EEG suppression of the arousal system, including the brainstem cholinergic, and intralaminar thalamic nuclei. Here we investigated the effects of combined intralaminar thalamic and pontine stimulation on cortical arousal in the rodent limbic seizure model. We targeted electrodes to the intralaminar central lateral thalamus (CL) and pontine nucleus oralis (PnO), and confirmed localization with histology. Seizures were induced by brief 2 second hippocampal stimulation at 60 Hz. We then stimulated bilateral intralaminar thalamic CL at 100 Hz and PnO at 50 Hz at varying current intensities during seizures for 120 seconds while synchronously recording electrophysiology and behavior. Single site stimulation of CL alone or PnO alone was insufficient to produce reliable cortical desynchronization and behavioral improvement during

seizures (n=12). In contrast, combined CL and PnO stimulation during seizures reduced cortical slow waves by more than 85% while simultaneously eliciting robust behavioral arousal as measured by spontaneous exploratory behavior (n=6). Effects of PnO and CL stimulation to reduce cortical slow waves and increase behavioral arousal resembled those seen with stimulation during physiological sleep (n=6) and under anesthesia (n=6). These data suggest a novel potential therapeutic approach for improving consciousness during the ictal and postictal states. If paired with responsive neurostimulation algorithms, it may lead to rapid implementation of a therapy for preventing impaired consciousness during and after seizures in epilepsy patients. Further work is needed to determine the degree of recovery in the ictal and postictal periods based on explicit behavioral tasks. Multi-site stimulation within the arousal networks appears to be a potent therapeutic approach which may also benefit other states of decreased consciousness such as vegetative and minimally conscious states.

Title: Effect of vagus nerve stimulation on PTZ-induced seizures in rats with thalamic reticular nucleus lesion

Authors: *E. VELÁZQUEZ-MIRANDA[1], R. D. CONTRERAS-LÓPEZ[2], S. ALMAZÁN-ALVARADO[2], R. FERNÁNDEZ-MAS[2], V. M. MAGDALENO-MADRIGAL[2];

Abstract: Vagus nerve stimulation (VNS) in experimental models of epilepsy has demonstrated to have anticonvulsive effects. However, the mechanisms through which it exerts these effects are still unknown. It has been suggested that the thalamic reticular nucleus (TRN), through the cortico-thalamic circuit could be participating in the anticonvulsive effect. The aim of this study was to analyze the effect of VNS on convulsive and non-convulsive seizures induced by pentilenetetrazole (PTZ). Wistar rats (300g) were used and divided into five groups: 1) TRN

lesion VNS group, which underwent lesion with radiofrequency in the TRN (AP -1.44, L 2.0, DV 6.2) and received VNS through a bipolar electrode designed in our laboratory that was implanted into the left vagus nerve, caudal to the larynx; 2) TRN sham VNS group, in which electrodes were introduced into the TRN, but no lesion was performed, and received VNS; 3) TRN lesion group, which received TRN lesion with radiofrequency but no VNS; 4) VNS group, which in contrast, received VNS but no TRN lesion; and 5) Control group, which received no manipulation other than the implantation of epidural stainless screws in the frontal, parietal and occipital cortices. All animals, with the exception of the Control group, were implanted with stainless steel bipolar electrodes into the hippocampus (AP -3.6, L 2.0, DV 3.5) and the posterior nucleus of the thalamus (AP -3.6, L 2.0, DV 5.4) and with epidural stainless screws in the frontal and parietal bones. VNS was administered continuously for 60 minutes or duty cycle (1min on/ 5 min off). To observe effects on both convulsive and non-convulsive seizures, PTZ was administered at low doses (10 mg/kg) every 15 minutes until the first generalized tonic clonic seizure (GTCS) was reached. Variables quantified were latency to reach GTCS, GTCS duration and number of PTZ doses needed to reach GTCS. We observed that both the lesion and the sham-lesion in the TRN reduced latency and number of PTZ doses necessary to reach a GTCS. Also, the TRN lesion group had longer GTCS in duration than the Control group. Our results suggest that TRN integrity is not necessary for the anticonvulsive effect of VNS. On the other hand, manipulating the TRN, in some cases with or without lesion, could be disrupting an important inhibitory thalamo-cortical pathway and this disruption facilitates seizure generalization.

Abstract: Significant limitations are associated with studying seizures induced by acute exposure to convulsants in otherwise normal *in vitro* and *in vivo* preparations. Traumatic brain injury is a major cause of medically intractable acquired epilepsy. The slicing preparation of organotypic hippocampal slice cultures parallels traumatic axonal shear injury and subsequently slices develop a dense recurrent connectivity that results in the development of spontaneous seizures after 1 week *in vitro*. We utilized this *in vitro* model of severe post-traumatic epilepsy with a reproducible, accessible and accelerated course of epileptogenesis to conduct a blind screen of over 500 drug-concentration combinations for anticonvulsant, antiepileptic and neuroprotective effects in chronic epilepsy. Lactate and LDH levels were assayed in spent culture media as biomarkers of seizure activity and ictal neuronal death, respectively, with the latter being correlated with seizure burden. Compounds exhibiting significant anticonvulsant activity in chronic-application screens advanced to a second stage consisting of wash-out screens to differentiate anticonvulsant from antiepileptogenic effects as well as *in vitro* electrophysiological confirmation. Anticonvulsant/proconvulsant and neuroprotective/neurotoxic effects were expressed as ratios of lactate production and LDH release in the presence of drug vs. control conditions. These effects were normally distributed about a zero mean effect. Both distributions exhibited a small skew toward therapeutic efficacy, with approximately 5% of all tested drug-concentration combinations demonstrating therapeutic effects on seizure activity and/or cell death rates that were > 3 standard deviations from the mean. These *in vitro* assays for anticonvulsant and neuroprotective effects in a model of severe pediatric post-traumatic epilepsy demonstrated that, just as in human trials, clinically-available anticonvulsants had modest antiepileptic effects. Several compounds demonstrated both anticonvulsant and neuroprotective effects that we interpret to represent reductions in seizure activity and consequent ictal cell death. The third stage was comprised of double-blind, crossover-controlled, *in vivo* EEG testing in the kainate model of chronic epilepsy to confirm the anticonvulsant effect of a lead compound, celecoxib, a cyclooxygenease-2 inhibitor. This technology comprises a promising strategy for the rapid, staged investigation of drug efficacy in pediatric post-traumatic epileptogenesis, and could be further scaled with available robotic technologies.

Title: Neuronal sodium elevation and COX-2 activation in post-traumatic epileptogenesis *in vitro*

Deleted: *in vitro*

Authors: ***T. BALENA**, Y. SAPONJIAN, K.-I. PARK, K. J. STALEY;
Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Post-traumatic increases in intracellular Cl^- can result in GABA becoming depolarizing, which could lead to disinhibition and early post-traumatic epileptic seizures. Increases in intracellular anions are likely to be balanced by an increase in intracellular cations, and the consequent salt accumulation could underlie cytotoxic edema. We investigated post-traumatic changes in intracellular Na^+ concentration ($[Na^+]_i$) using organotypic hippocampal slice cultures from wild-type C57BL/6J mice, imaged with the Na^+ dye SBFI. Two-photon imaging was used to excite SBFI at both Na^+-sensitive and -insensitive wavelengths, allowing for the ratiometric determination of the $[Na^+]_i$. Hippocampal neurons exhibited a broad distribution of $[Na^+]_i$ values, and in many cases $[Na^+]_i$ was significantly higher than has been reported in undamaged neurons. All values of $[Na^+]_i$ were stable for hours. Neurons with highest values of $[Na^+]_i$ were more likely to stain for propidium iodide, suggesting that $[Na^+]_i$ elevation is an early and possibly progressive biomarker of eventual neuronal death. Population studies indicated that high $[Na^+]_i$ values were more common immediately after slicing trauma, and returned to low levels within ~2 days. At longer incubation times, during which slices become epileptic, $[Na^+]_i$ again became elevated, returning to physiological levels at 20 DIV, at which age seizure intensity diminished. Acute perfusion of 10 μM of the Na^+/K^+ ATPase inhibitor ouabain or 100 μM of the KCC2/NKCC1 antagonist furosemide increased $[Na^+]_i$. 10 μM of the NKCC1 antagonist bumetanide or 100 μM of the Na^+/Ca^{2+} exchange antagonist benzamil also increased $[Na^+]_i$, indicating that in the days after trauma NKCC1 and the Na^+/Ca^{2+} exchanger operate in the reverse of their canonical directions by exporting Na^+ and, presumably, the cotransported ions. Application of 8 μM fluorescein conjugated to large dextran molecules indicated severe membrane disruption in only a small number of neurons, but a moderate amount of damage in a larger number of neurons, particularly as epileptogenesis progresses. Perfusion of 10 μM of the selective non-steroidal anti-inflammatory drug celecoxib significantly reduced $[Na^+]_i$ in nearly all neurons, and also caused significant reductions in the power, frequency, and duration of

seizures. Overall, elevated $[Na^+]_i$ is a promising new biomarker for compromise of neuronal membrane permeability, which precedes many traditional indicators of epileptic activity and ictal cell death, and the ability of celecoxib to mitigate elevated $[Na^+]_i$ thus represents a prime therapeutic target for the early treatment of epilepsy.

Title: Pharmacological targeting of the WNK-SPAK kinase complex to modulate neuronal Cl- homeostasis and cell volume in recurrent seizures

Authors: ***V. I. DZHALA**[1], Y. SAPONJIAN[1], K. KAHLE[2], K. STALEY[1];
[1]Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [2]Neurosurg., Boston Children's Hosp. and Harvard Med. Sch., Boston, MA

Abstract: Neuronal chloride concentration ($[Cl^-]_i$) is an important determinant of both post-synaptic $GABA_A$-receptor mediated signaling and cell volume regulation. Restoration of $[Cl^-]_i$ equilibrium after synaptic activity is achieved by the net regulated activities of the cation- Cl^- co-transporters (CCC) NKCC1 (mediating Cl^- influx) and KCC2 (mediating Cl^- efflux). Hypoxia-ischemia, acute brain trauma, and recurrent seizures not only alter the equilibrium value of Cl^- but also impair the functional regulation of the CCCs. The end result is cell swelling, acute and chronic accumulation of $[Cl^-]_i$, and GABA depolarizing responses, which foster seizures, epileptogenesis and anticonvulsant resistance via failure of inhibition. Antagonizing NKCC1 activity and/or stimulating KCC2 activity might reduce swelling and $[Cl^-]_i$ in injured neurons, restore GABAergic inhibition and suppress seizures. NKCC1 and KCC2 are stimulated and inhibited, respectively, by direct phosphorylation mediated by the Cl^--sensitive WNK (lysine-deficient protein kinase)-activated SPAK (proline/alanine-rich kinase) kinase. We therefore speculated that WNK-SPAK inhibition might be an especially potent strategy to promote neuronal Cl^- extrusion by coincident NKCC1 inhibition and KCC2 activation. We determined

the acute and chronic anticonvulsive and neuro-protective efficacy of STOCK1S-50699, a recently-identified compound that disrupts the WNK-SPAK interaction, antagonizes WNK signaling, and thereby inhibits NKCC1 and KCC2 phosphorylation. Organotypic hippocampal slice cultures from mice expressing the Cl^- sensitive fluorescent protein Clomeleon or Super Clomeleon were studied as a model of acute and chronic traumatic brain injury. After a 1-week latent period, slice cultures developed spontaneous seizure activity. We found that: STOCK1S (i) reduced the frequency and power of early recurrent seizures by 65% and 68% respectively; (ii) the anti-convulsive effect was irreversible and coincident with cytopathological deterioration suggestive of neurotoxicity; (iii) induced bi-directional effects on neuronal chloride transients and cell volume in different sub-populations of neurons; (iv) strongly reduced the amount of early and late seizure activity as assayed by lactate production; (v) strongly increased the amount of early LDH production indicating a severe neurotoxic effect. Our results demonstrate that STOCK1S, the only available inhibitor of WNK-SPAK signaling, significantly reduces seizure frequency and power but exhibits neurotoxicity, highlighting the need for novel non-toxic strategies of targeting the WNK-SPAK pathway for therapeutic benefit.

Title: An *in vitro* epileptogenesis mouse model for anticonvulsant drug screening

Deleted: *in vitro*

Authors: ***C. EHNERT**, A. GRAMOWKI-VOSS, B. M. BADER, O. H.-U. SCHROEDER; Neuroproof Gmbh, Rostock, Germany

Abstract: Epilepsy is characterized by spontaneous, recurrent seizures. A seizure is seen in an EEG by high excessive and synchronous activity and can be correlated with synchronized and high frequency firing of neuronal populations in the CNS. Here, we present a novel potential cell culture assay with the spontaneous occurrence of ictal activity episodes. We developed a culture protocol using primary hippocampal neurons from early embryonic mice, grown on microelectrode arrays (MEAs) and maintained for several weeks. The ictal activity is characterized by the appearance of sudden spontaneous synchronized bursts of action potentials with duration of at least 5 seconds. The activity patterns of the hippocampal network activity are recorded and analyzed by multivariate data analysis of 204 activity describing parameters using

our in-house software NPwaveX. These parameters quantify the network activity changes regarding general activity, synchronicity, connectivity, oscillation, and burst structure. The assay presented here enables the study of neuronal networks and their respective activity that resemble epileptogenic brain cells *in vivo*. Acute treatment with antiseizure drugs affects the burst structure parameters such as burst duration. Interestingly only long bursts are affected. A major advantage over hippocampal slice preparations, these cultures allow chronic treatment with novel compounds over several weeks thereby allowing studying epileptogenesis. Thus, further developing and validation of this assay could enable the discovery innovative drugs with new mode of actions. Applying this assay to a 48-well or 96-well MEA platform the throughput for compound screening will increase, hence enhancing the drug development for anticonvulsant and anti-epileptogenic compounds.

Deleted: in situ

seizurogenic effects stem cell-derived neuronal platforms will be physiologically relevant by incorporating the features of current neurotoxicity testing in animals and will further improve current state-of-art by offering higher throughput and higher content. Our aim was to increase biological complexity for an adequate phenotypic and functional read-out of human neuronal systems. Therefore we co-cultured commercially available hiPSC-derived neurons with glia cells or different neuronal populations in order to evaluate the functional effects induced by known seizurogenic compounds. We used multiwell microelectrode arrays (mwMEAs, Axion Biosystems, Inc.) for medium-throughput screening of electrophysiological maturation for several weeks *in vitro*. We tested known seizure-inducing compounds and excitatory/non-seizure-inducing compounds in concentration-response experiments which were analyzed by our in-house software NPwaveX computing 204 activity describing parameters from the spike train. With these compound specific activity profiles we developed a so called "seizure score" to evaluate drugs potential to induce seizurogenic activity. We compare the results from concentration-response experiments between human iPSC-derived neuronal networks and those of functionally mature primary mouse cortical networks. In summary, for the hiPSC-based model we increased biological and functional complexity by mixing glia and neurons and optimizing culture conditions to obtain relatively mature neuronal networks which are reactive to neurotoxic compounds. Based on the multi-parametric data, we computed a novel classifier "seizure score" which was calibrated by reference compounds. Thus, it is equivalent to our previously presented classifier based on primary mouse neuronal networks. In conclusion, our classification technology allows investigating and comparing the safety margin of novel drug candidates between rodent and human cell background and thereby dramatically increases the prediction of seizurogenic risks.

Title: Interaction between cannabinoid type 1 and serotonin 2C receptors in the pilocarpine model of status epilepticus in rat

Authors: *R. COLANGELI[1], M. PIERUCCI[1], R. DI MAIO[2], G. DI GIOVANNI[1];
[1]Physiol. and Biochem., Univ. of Malta, Msida, Malta; [2]Pittsburgh Inst. for Neurodegenerative Dis. and Dept. of Neurology, Univ. of Pittsburgh, USA., Pittsburgh, PA

Abstract: Status epilepticus (SE) is a neurological disorder characterized by continuous or rapidly repeating seizures. Cannabinoid type 1 receptor (CB1R) regulates neuronal excitability and has been shown to mediate the anticonvulsant effects of cannabinoids in several animal models of epilepsy. Several studies support the existence of crosstalk mechanisms between endocannabinoid (EC) and serotonin (5-HT) systems. The 5-HT2C receptor (5-HT2CR) subtype has received attention in epilepsy as KO mice for this receptor displayed increased seizure susceptibility, whilst its activation showed anticonvulsant effects in different models of epilepsy. Interaction between 5-HT2CR and CB1R has been shown; for instance CB1R KO mice exhibit altered expression and impaired functionality of the 5-HT2CR in several brain areas. Here we tested the interaction between 5-HT2CR and CB1R in the prevention of SE using the rat pilocarpine (PILO) model. Adult male Sprague Dawley rats were injected with PILO (360 mg/kg) and monitored for 3 hours by cortical electroencephalographic (EEG) and hippocampal local field potential recording. Seizure behaviour was also observed and severity was measured by Racine scale. Pre-treatment with the cannabinoid agonist WIN 55,212-2 (WIN), the 5-HT2CR agonist RO 60-0175 (RO) or their combination (RO+WIN) was performed 45 min before PILO administration. PILO induced SE in 12/14 rats (Racine scale 4-5). Both WIN and RO, administered alone, had no effect in preventing EEG seizures. However, WIN administered alone reduced the severity of behavioural SE (Racine scale 2-3). RO+WIN administered in combination significantly reduced the occurrence of SE. Power spectrum analysis revealed that RO+WIN significantly reduced the total power during SE, in respect to the vehicle group. The effect of RO+WIN was completely blocked by the administration of CB1R antagonist AM 251. Intriguingly, administration of 5-HT2CR antagonist SB 242084 prior to RO+WIN treatment strongly potentiated the antiepileptic effect of RO+WIN since no animal displayed SE. This suggests that different 5-HT receptor subtypes or other unknown receptors might be involved in SE RO-induced effects. Data so far obtained indicate a synergistic interaction between the 5-HT system and CB1R in SE, although the exact role of the 5-HT2CR remains to be clarified. Our findings suggest that the cross-talk mechanisms between EC and 5-HT systems might represent a suitable target for the identification of new antiepileptic treatment of SE.

Abstract: Possible aggravation of epilepsy by antiepileptic drugs is an already known phenomenon. Overdoses and drug interactions are the two main reasons. However, seizures can also be worsened because of an inadequate treatment. This is often the case for children epilepsies such as childhood absence epilepsy. We addressed the problem of whether an inadequate first-line treatment could abolish the efficacy of a second-line treatment that would have been successful if applied as a first-line treatment. We used an inbred mouse model for absence epilepsy, BS/Orl, manifesting spontaneous and recurrent spike-wave discharges. Mice were submitted to an experimental protocol where they received two consecutive treatments. From the age of five weeks, mice were given valproate (VPA - reference), vigabatrin (VGB - known to aggravate the absence epilepsies) or ethosuximide (ESM - a specific for absence epilepsies) during 14 days. And then, they all received VPA during 42 days. A fourth group has received a saline solution (PHY) during the whole experiment. The 4 groups were assessed at 5 different times: before any treatment, after the first-line treatment and 3 times during the second-line treatment. After the first-line treatment, the 3 groups VPA, VGB and ESM were differing significantly as expected: compared to PHY, VGB was found to worse seizures whereas VPA and ESM were found to reduce seizures with a much greater effect for ESM. Interestingly, the application of the second treatment showed various effects. While the seizure level in the ESM group was much lower than in the VPA group after the fist-line treatment, this benefit has progressively disappeared with the introduction of the VPA. Finally, after 6 weeks of VPA treatments, both ESM-VPA and VPA-VPA were presenting the same seizure occurence rate. Conversely, while the VGB has aggravated the seizure level compared to the PHY group during the first-line treatment, the introduction of the VPA as the second treatment, has failed to reverse the tendency of an aggravation of the seizure level due to the initial application of the VGB. This study illustrates that an inadequate first-line treatment, more than worsening seizures, can have long-term adverse effects by reducing the efficacy of a posterior treatment.

Title: BUM13, a novel bumetanide derivative with reduced diuretic but enhanced anticonvulsant activity

Authors: ***C. BRANDT**[1], K. TÖLLNER[1], P. W. FEIT[1], M. GABRIEL[2], W. LÖSCHER[1], T. ERKER[2];
[1]Univ. of Vet. Medicine/Dept. of Pharmacol., Hannover, Germany; [2]Dept. of Medicinal Chemistry,, Univ. of Vienna, Vienna, Austria

Abstract: The cation-chloride cotransporters NKCC1 and KCC2 seem to be crucial in the pathogenesis of epilepsy. In this respect, the diuretic drug bumetanide, an inhibitor of NKCC1, has attracted interest because it represents a valuable tool for studying the role of intraneuronal chloride concentrations in epilepsy. Further, it represents a potential therapeutic strategy to prevent or treat epilepsy. However, two major drawbacks of bumetanide, its diuretic potential and low brain penetration, restrict the utility of bumetanide in experimental and clinical settings. The aim of this study was to characterize the pharmacokinetic and functional characteristics of the bumetanide derivative BUM13 [5-(anilinomethyl)-3-(butylamino)-2-phenoxy-benzenesulfonamide], which was selected from a large series of bumetanide analogues designed to be more lipophilic for improving brain penetration. Furthermore, BUM13 exhibited decreased affinity to NKCC2, which is mainly expressed in the kidney and is responsible for bumetanide´s diuretic potency. All investigations were performed in female NMRI mice. Bumetanide and BUM13 were injected intravenously at equimolar doses. For determining the diuretic effect, urine production was measured 15, 30, 60, 90, and 120 min after injection. Plasma and brain concentrations of bumetanide and BUM13 were analysed 30 and 60 min after injection using HPLC. The anticonvulsant effect of bumetanide and BUM13 were evaluated in the maximal electroshock threshold test (MEST) in naive vs. epileptic mice, because NKCC1 is higher expressed in the epileptic vs. the nonepileptic adult brain. Beginning six weeks after a pilocarpine induced status epilepticus (SE), bumetanide and BUM13 were tested alone or in

combination with phenobarbital (PB). Age-matched sham-treated non-epileptic mice served as control group. BUM13 was hardly metabolized to bumetanide. Brain penetration and brain/plasma ratio of BUM13 were much higher but the diuretic effect was significantly decreased compared to bumetanide. BUM13 itself did not have an anticonvulsant effect in the MEST, but in combination with PB, BUM13 increased the seizure threshold by 240% in epileptic mice, while PB was ineffective when injected alone. In nonepileptic control mice this effect of BUM13 was much less pronounced. Bumetanide alone did not exert an anticonvulsant effect nor did it enhance the effect of PB in the MEST. The results of this study indicate that BUM13 is an interesting alternative to bumetanide for the treatment of epilepsy. The mechanism of the marked potentiation of PB's anticonvulsant activity needs to be further characterized, but inhibition of NKCC1 is a likely explanation.

Title: Effects of Calpain Inhibition on Epileptogenesis

Authors: *M. I. GONZALEZ, J. CARLSEN, P. LAM;
Dept. of Pediatrics Sch. of Med., Univ. of Colorado, Denver, Aurora, CO

Abstract: A characteristic of epilepsy is the appearance of unpredictable seizures arising from disordered and synchronous firing of neurons. In particular, temporal lobe epilepsy is a subtype of acquired epilepsy that often develops after stroke, traumatic brain injury or status epilepticus. Pathologic activation of calpain, a calcium dependent protease ubiquitously expressed in neurons, has been observed following experimental status epilepticus. Calpain activation after a brain injury triggers a series of neurotoxic signaling cascades that results on the cleavage of membrane receptors, cytoskeletal and structural proteins that negatively affect neuronal function and promote neuronal death. Unfortunately, the particular role of calpain overactivation on the

epileptogenic process is mostly unknown. This study is an initial evaluation of the possible role of calpain overactivation on epileptogenesis. Using the pilocarpine model of experimental epilepsy, we found that the time-course for the down-regulation of GABAergic proteins is similar to time-course of calpain overactivation. This suggested the possible role of calpain on the loss of inhibitory neurotransmission previously detected. In follow-up experiments, we found that pharmacological inhibition of calpain immediately after pilocarpine-induced status epilepticus delays epilepsy onset and reduces seizure burden. Ongoing studies in or laboratory are aimed to analyze the effects of calpain inhibition on additional hallmarks associated with epilepsy progression. A long-term goal of our studies is to generate a better understanding of the molecular events triggering epilepsy after a brain injury.

Title: Glycine transporter 1 is a target for the treatment of epilepsy

Authors: ***H. SHEN**[1], E. V. VLIET[2], K.-A. BRIGHT[1], M. HANTHORN[1], N. LYTLE[1], J. GORTER[3], E. ARONICA[4,2,3], D. BOISON[1];

Center, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Swammerdam Inst. for Life Sci., Ctr. for Neuroscience, Univ. of Amsterdam, Amsterdam, Netherlands; [4]SEIN- Stichting Epilepsie Instellingen Nederland, Heemstede, Netherlands

Abstract: Glycine is the major inhibitory neurotransmitter in brainstem and spinal cord, whereas in hippocampus glycine exerts dual modulatory roles on strychnine-sensitive glycine receptors and on the strychnine-insensitive glycineB site of the N-methyl-D-aspartate receptor (NMDAR). In hippocampus, the synaptic availability of glycine is largely under control of glycine transporter 1 (GlyT1). Since epilepsy is a disorder of disrupted network homeostasis affecting

the equilibrium of various neurotransmitters and neuromodulators, we hypothesized that changes in hippocampal GlyT1 expression and resulting disruption of glycine homeostasis might be implicated in the pathophysiology of epilepsy. Using two different rodent models of temporal lobe epilepsy (TLE) - the intrahippocampal kainic acid model of TLE in mice, and the rat model of tetanic stimulation-induced TLE - we first demonstrated robust overexpression of GlyT1 in the hippocampal formation, suggesting dysfunctional glycine signaling in epilepsy. Overexpression of GlyT1 in the hippocampal formation was corroborated in human TLE samples by quantitative real time PCR. In support of a role of dysfunctional glycine signaling in the pathophysiology of epilepsy, both the genetic deletion of GlyT1 in hippocampus and the GlyT1 inhibitor LY2365109 increased seizure thresholds in mice. Importantly, chronic seizures in the mouse model of TLE were robustly suppressed by systemic administration of the GlyT1 inhibitor LY2365109. We conclude that GlyT1 overexpression in the epileptic brain constitutes a new target for therapeutic intervention, and that GlyT1 inhibitors constitute a new class of antiepileptic drugs. These findings are of translational value since GlyT1 inhibitors are already in clinical development to treat cognitive symptoms in schizophrenia.

Natl. Univ. of La Plata, La Plata, Argentina; [4]Dept. of Neurosci. Research, Natl. Inst. of Psychiatry Ramon de la Fuente Muñiz, Mexico City, Mexico

Abstract: Previous studies indicate that the administration of propylparaben (PPB; an antimicrobial agent with low toxicity and widely used) reduces the seizure activity induced by pentylenetetrazole and inhibits voltage-dependent sodium channels in cardiomyocytes of the rat. The aim of the present study was to determine if PPB modifies the electrographic activity and the subsequent neuronal damage in hippocampus when applied after 2 h of Status Epilepticus (SE) induced by pilocarpine. Male Wistar rats previously implanted with a bipolar electrode into the right ventral hippocampus received an administration of pilocarpine (300 mg/kg, i.p.,) to induce SE. SE+DZP group (n=6) received an injection of diazepam (DZP 2.5 mg/kg, i.m.) 2 h after the SE establishment. The electrographic activity of hippocampus was analyzed using fast fourier transform method throughout all the experiment (up to 2 h after DZP). The SE+DZP+PPB group (n=6) was manipulated as described above, except that animals received PPB (178 mg/kg, i.p.) 1 h after DZP. One day after the SE, the animals were sacrificed and the brain used to evaluate the site of electrode implantation (Nissl staining), neuronal damage (FLUORO-JADE B) and neuronal preservation (NeuN inmunofluorescence) in ventral hippocampus. In both experimental groups, the SE was established at 43.2±2.5 min after pilocarpine injection. The electrographic activity revealed faster, high-voltage rhythmic spikes and increase in spectral potency in beta, gamma and ripples bands during the SE. After DZP injection, the SE+DZP group showed a decrease in the seizure activity, an effect associated with decline in the potency of ripples oscillations ($p<0.001$). In contrast, after of PPB administration the SE+DZP+PPB group demonstrated lower electrographic activity that correlated with reduced potency in gamma and ripples bands ($p<0.001$). When compared with SE+DZP group, SE+DZP+PPB group demonstrated decreased neuronal damage in ventral hippocampus (dentate gyrus 468%, $p<0.05$, CA3 453%, $p<0.001$ and CA1 609%, $p<0.001$)) as well as an increase in NeuN inmunopositive cells (CA3 377%, $p<0.05$ and CA1 353%, $p<0.01$). We conclude that the administration of PPB at the end of the SE reduces the epileptiform activity, an effect associated with a decrease in neuronal damage.

Title: Lactate dehydrogenase is a molecular target to regulate seizures

Authors: ***N. SADA**, T. INOUE;
Okayama Univ., Okayama, Japan

Abstract: Currently-available antiepileptic drugs are not effective for one third of patients with epilepsy. It is known that ketogenic diets are effective treatment for a part of the drug-resistant epileptic patients. Although ketogenic diets act on metabolic pathways, there are no antiepileptic drugs acting on metabolic pathways. In this study, we examined which metabolic molecules regulate membrane potentials in neurons and seizures in mice. Using slice patch-clamp techniques, we found that neurons were hyperpolarized by a switch from glucose to ketone bodies in ACSF. The hyperpolarization was recovered by an addition of lactate. Neurons were also hyperpolarized by inhibition of lactate dehydrogenase (LDH). We then examined effects of LDH inhibition on a chronic seizure model in mice, induced by intrahippocampal injection of kainate. *In vivo* recording revealed that LDH inhibition suppressed paroxysmal discharges in the seizure model. So far, there are no reports that LDH enzymes are inhibited by clinically-used antiepileptic drugs. We therefore explored LDH inhibitors from twenty clinically-used antiepileptic drugs, using an enzymatic assay. The enzymatic assay revealed that stiripentol, an antiepileptic drug for treatment of Dravet syndrome, was an LDH inhibitor. Furthermore, we found a stiripentol analog that inhibits LDH and strongly suppresses seizures in the mouse model *in vivo*. These results show that LDH enzyme could be a promising molecular target for antiepileptic drugs based on ketogenic diets.

Title: Antiepileptic effects of rutin on picrotoxin-induced seizures in female rats

Authors: ***H. GERGERLIOGLU**[1], A. OZTURK[2], F. SEFIL[2], C. TUMER[2], R. DOKUYUCU[2], I. KAHRAMAN[3], O. TUTUK[2], H. DOGAN[2];

[1]Selcuk Univ., Selcuklu - Konya, Turkey; [2]Dept. of Physiol., [3]Dept. of Biophysics, Mustafa Kemal Univ., Hatay, Turkey

Abstract: Introduction: Epilepsy is a common neurological disorder. Generalized epilepsies, which are characterized with fast neural discharges, lead to the myoclonic contractions and loss of consciousness. Antiepileptic drugs are ineffective in controlling seizures in about one-third of the patients. Therefore, drug resistant sufferers are in need for alternative treatment regimens. Flavonoids are suggested to possess potential benefits against epilepsy. In the present study, we investigated antiepileptic properties of rutin, a member of the flavonol subfamily. Methods: A total of 40 female Wistar were assigned to five groups as Con. (received vehicle (DMSO); n= 10), R10 (received 10 mg/kg rutin; n= 10), R50 (received 50 mg/kg; n= 10), and R100 (received 100 mg/kg; n= 10). Picrotoxin was administered intraperitoneally to all animals in a dose of 2,5 mg/kg to startle seizures. A single dose of rutin, according to the belonging group, was injected intraperitoneally 30 mins before the picrotoxin administration. The epileptic activity was scored by an experienced observer. Results: The administration of 10 and 50 mg/kg rutin prolongs the latency of the onset of seizure and decreases the total seizure count. The highest dose of rutin (100 mg/kg) shortens the total duration of seizure. Discussion: According to our results, different doses of rutin exert diverse effects on the pathophysiological processes in the model of picrotoxin-induced epilepsy. Picrotoxin is an antagonist of GABAA receptors and so, blocks Cl- channels. Decreased GABAergic and increased glutamatergic transmission are accused in epilepsy. Rutin seems to interact with these events to show an antiepileptic-like activity to some extent. Therefore, rutin may be considered as an adjuvant in drug resistant epilepsy.

Title: Diphenhydramine and latrepirdone effects on seizures and brain injury in rats rollowing exposure to the chemical warfare nerve agent soman

Authors: *J. W. SKOVIRA, T. L. DAO, J. A. LEUSCHNER, R. K. KAN;
United States Army Med. Res. Inst. of Chem. Def., Aber Prov Grd, MD

Abstract: Seizures complicate the treatment of casualties following nerve agent exposure and can lead to extensive brain damage and increased mortality if not controlled. Excessive cholinergic neurotransmission, predominately involving muscarinic receptors, is believed to initiate seizures following nerve agent exposure. Diphenhydramine is an antihistamine with potent antimuscarinic properties and has been shown to be a neuroprotectant. The present study was designed to evaluate two antihistamines, one with potent antimuscarinic effects (diphenhydramine) and a second with no antimuscarinic properties (latrepirdone) for their ability to prevent/terminate nerve agent-induced seizures and reduce neuropathology. Male Sprague-Dawley rats, weighing 250-300 g, were pretreated with HI-6 (125 mg/kg, ip) 30 min prior to GD administration (180 µg/kg, sc). One minute after GD challenge, animals were given atropine methyl nitrate (AMN; 2.0 mg/kg, im). Antihistamine treatments were given along with AMN or at the onset of seizures. The incidence of convulsions, percentage of mortality and extent of neuropathology were assessed. Diphenhydramine (40mg/kg) given as a treatment in combination with AMN one minute after GD challenge was effective in reducing the occurrence of convulsions, the incidence of mortality and the development of brain pathology in brain regions known to be vulnerable to GD-induced damage. When given after seizure onset diphenhydramine also significantly reduced the incidence of convulsions, improved mortality rate and prevented brain pathology. Latrepirdone (25mg/kg) failed to reduce the incidence of convulsions, mortality, and brain pathology following GD exposure. These observations suggest that diphenhydramine is effective in preventing GD-induced seizures, death and brain pathology. Further investigation of antihistamine drugs with anticholinergic properties for use as medical countermeasures to nerve agent poisoning is warranted.

Title: Efficacy of a second generation neuroactive steroid, SAGE-217, in a mouse model of chronic medial temporal lobe epilepsy

Authors: R. S. HAMMOND, *G. M. BELFORT, A. J. ROBICHAUD, J. J. DOHERTY; Sage Therapeut., Cambridge, MA

Abstract: Neuroactive steroids are a class of endogenous and synthetic compounds that potentiate both synaptic and extra-synaptic $GABA_A$ receptors. SAGE-217 is a potent and efficacious Second Generation neuroactive steroid $GABA_A$ receptor positive allosteric modulator with anti-convulsant activity in rodent pentylenetetrazole, 6 Hz and lithium-pilocarpine seizure models (Robichaud et al, 2015). Here we further characterized the anticonvulsant activity of SAGE-217 in the mouse kainate model of chronic mesial temporal lobe epilepsy (MTLE), a condition which affects an estimated 10% of the total epileptic population. Intraperitoneal injection of SAGE-217 at 1, 3 and 5mg/kg significantly suppressed the number and cumulated duration of hippocampal paroxysmal discharges (HPDs) in a dose dependent manner. A greater than 90% reduction in HPDs was obtained with 3 and 5mg/kg of SAGE-217 between 10 and 70 minutes post-injection and with the 5 mg/kg dose over the entire two hour recording period. *In vitro* activity at the $GABA_A$ receptor at concentrations determined in brain samples from satellite animals correlated with efficacy against HPDs. The capacity to reduce HPDs was benchmarked against other antiepileptic drugs. The activity of SAGE-217 at 3 and 5 mg/kg was superior to the effect of diazepam (2mg/kg). This study provides the first evidence of neurosteroid efficacy in the chronic kainate MTLE model and supports developing compounds of this class as novel antiepileptic drugs.

Title: Revealing strategies to combat pharmacoresistance epilepsy by understanding neurochemistry for resistance to PTZ kindling: A complimentary study

Authors: *R. K. GOEL[1], N. K. BHANGU[2];
[1]Professor,, Patiala, India; [2]Dept. of Pharmaceut. Sci. and Drug Res., Punjabi Univ., Patiala, India

Abstract: Purpose: Resistance to epileptogenesis is common in different animal models of epilepsy. It was hypothesized that comparative analysis of neurochemical status of brains of resistant and sensitive animals may be useful find treatment approaches for pharmacoresistant epilepsy Method: Chemical kindling in male swiss albino mice was induced by giving a subconvulsant dose of 35 mg/kg PTZ intraperitoneally (i.p.), every alternate day for 68 days. Animals were observed for 30 min, and seizure activity scored according to a slightly modified Racine scale. Sucessufully kindled and resistant animals were divided into groups (n=10) respectively, while another group of naïve animals served as control group. After 2 hours of last pentylenetetrazole administration, all animals were sacrified to remove their brains. Neurochemical [monoamines (norepinephrine, dopamine and serotonin), amino acids (glutamate, serine, arginine, glycine, taurine, alanine, GABA) and their metabolites (5-HIAA, DOPAC, Kynurenine)] changes were estimated using HPLC-ECD method, in discrete brain parts. Additionally, acetylcholinesterase activity and total nitrite levels were also estimated using microtitre reader method. PTZ brain and serum levels were also estimated. All experiments were approved by the IAEC of Punjabi University Patiala, India.(Approval No. 107/99/CPCSEA-2013-27) Results: The results of the neurochemical estimation demonstrated the remarkable changes in monoamines, amino acids and their metabolites, also elevated nitrosative and acetylcholinesterase activity in the kindled animals in comparison to resistant or naïve animals. Interpretation of these results suggested significant shift of 5HTP metabolic pathway to kynurine and subsequently to quinolinic acid responsible for induction of kindling in sensitive animals, whereas, its shift was observed towards serotonin in resistant animals. Conclusion: The present findings suggest that modulation of central 5HTP pathway may be one of the strategies for treatment of pharmacoresistant epilepsy. Ongoing studies are evaluating this approach in Lamotrigine kindling model of pharmacoresistance.

Title: Effect of spartein on the Status Epilepticus induced in rats by Pentylenetetrazole, Kainic Acid and Pilocarpine

Authors: *F. V. VILLALPANDO VARGAS, L. MEDINA-CEJA;
Biologia Celular y Mol., Univ. De Guadalajara, Guadalajara, Mexico

Abstract: The status epilepticus (SE) is defined as the prolonged seizure or recurrent seizures without full recovery between them, lasting longer than 30 min. Globally, the SE occurs one million per year, with a mortality rate of at least 30% in developing countries. The sparteine (Sp) is a quinolizidine alkaloid (QA) synthesized from most of Lupine species; the anticonvulsive effect of Sp was evaluated in the PTZ model of SE in which the Sp delayed the onset of convulsive behavior and increased the survival period. But there are not posterior efforts to determine clearly the anticonvulsive effect of Sp. For this reason we consider important to study the anticonvulsant effects of Sp at behavioral level and EEG activity in three different SE models. The convulsive behavior and survival period were analyzed 30 min after Sp administration (13mg/kg, i.p.) as well as the amplitude, frequency, duration and latency of epileptiform activity. The results showed normal behavior in control animals (saline solution, SS 0.9% and Sp administration) but in animals treated with only pentylentetrazole (PTZ, 90 mg/kg, i.p.; n=8), the convulsive behavior was progressive according Velisek scale (phase I-V), when the animals were pretreated with Sp a delayed in loss of animal posture was observed as well as an increase in latency to reach the scales III to V. While, animals with kainic acid (KA, 9mg/kg, i.p.; n=6) or pilocarpine (370 mg/kg, n=6) had a progressive convulsive behavior reaching the highest level in Racine scale (5); the animals treated with Sp before KA had a significant decrease in duration of seizures and an increase in latency to reach the scale 1 to 3. Animals treated with Sp before pilocarpine had an increase in survival. The EEG analysis showed slow activity in control animals (SS or Sp) as well as in the basal recordings of all the animals (before drug administration). The PTZ group presented rhythmic spike-waves and discharge trains of high amplitude and frequency. Animals with Sp before PTZ showed rhythmic spike-waves and discharge trains of low amplitude and frequency. While animals with KA showed an epileptiform pattern characterized by polyspikes and spike-wave, the pretreatment with Sp decreases the amplitude and frequency of epileptiform activity. The group with pilocarpina showed rhythmic spike-waves and discharge trains of high amplitude and frequency; the pretreatment with Sp decreases the amplitude and frequency of epileptiform activity. In conclusion, the anticonvulsant effect of the pretreatment of Sp 30 min before PTZ, AK and pilocarpine was observed in convulsive behavior (decrease of severity) and epileptiform activity (decrease in amplitude and frequency).

Title: Antioxidant effects of tridecanoin, the triglyceride of decanoate, appear to contribute to its anticonvulsant effects

Authors: *K. TAN[1], C. CARRASCO-POZO[1,2], K. BORGES[1];
[1]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia; [2]Dept. of Nutr., The Univ. of Chile, Santiago, Chile

Abstract: The medium-chain triglyceride (MCT) ketogenic diet has been proven effective in the treatment of pediatric epilepsy. Although ketone bodies, which increase significantly in the plasma of patients following the treatment, are thought to be the main contributors of the anticonvulsant effects, the correlations between ketone body levels and seizure control are yet to be established. Therefore, we investigated the anticonvulsant effects of two main components of the MCT ketogenic diet, triglycerides of eight-carbon octanoic acid and ten-carbon decanoic acid in acute mouse seizure models. We found that when given as 35% of total calories to male CD1 mice for ten days, tridecanoin but not trioctanoin was anticonvulsant in 6 Hz seizure model, increased latency to reach the first generalised seizures in fluorothyl model and improved the survival of mice in the pilocarpine model. The anticonvulsant effects appeared to be independent of the levels of ketone body β-hydroxybutyrate in the brain and plasma. We observed an increase in antioxidant power in the plasma and mRNA levels of heme oxygenase 1 and forkhead box O1 in the hippocampal formations of mice fed tridecanoin diet, suggestive of antioxidant effects of tridecanoin. Mitochondrial functions in cultured astrocytes were also assessed following a two-hour incubation with 200 μM of octanoic or decanoic acid in the form of oxygen consumption rate. Both octanoic and decanoic acids increased the basal respiration and ATP turnover but only decanoic acid resulted in an increase in proton leak of the mitochondria in comparison to 1 mM of sodium pyruvate. Taken together, the antioxidant effects and improvement of mitochondrial functions by decanoic acid may contribute to its anticonvulsant effects.

Title: Mechanistic approach to neuroprotective potential of Lacosamide in seizures

Authors: *B. KUMAR[1], B. MEDHI[2];
[1]Postgraduate Inst. of Med. Educ. and Re, Chandigarh, India; [2]Postgraduate Inst. of Med. Educ. and Res., Chandigarh, India

Abstract: Epilepsy is a chronic neurological condition characterized by recurrent seizures, almost affects people in every country throughout the World. Recently, the neuroscientists and neurologists have investigated the use of antiepileptic drugs to prevent neuronal loss and alter the cognitive impairment commonly seen with the progression of epilepsy. In this study, we evaluated the neuroprotective mechanism of lacosamide in MES induced seizures in rats. MES induced seizures lead to increased oxidative stress and activation of neuroinflammatory pathway. Treatment with lacosamide showed a significant reduction in seizure activity, decreased the lipid peroxidation and ameliorated the oxidative stress. The inflammatory processes in the brain contribute to the etiopathogenesis of seizures and epilepsy and this is increasingly recognized as a result of supportive evidence in experimental models and in the clinical setting. In this study, we found a significant increase in inflammatory mediators after MES seizures. However, the administration of lacosamide abolished the activation of neuroinflammatory cytokines. These results indicated the neuroprotective potential of lacosamide by preventing oxidative neuronal damage and activation of brain inflammatory mediators in seizures.

Title: Diazepam and midazolam effectively terminate tetramethylenedisulfotetramine-induced status epilepticus and enhance survival in mice

Authors: *D. ZOLKOWSKA[1], D. A. BRUUN[2], C. A. BOOSALIS[2], B. HAMMOCK[3], P. J. LEIN[2], M. A. ROGAWSKI[1];
[1]Dept. of Neurol., Sch. of Med., Univ. of California, Davis, Sacramento, CA; [2]Dept. of Mol. Biosciences, Sch. of Vet. Med., [3]Dept. of Entomology, Col. of Agr. and Envrn. Sci. and Cancer Ctr., Univ. of California, Davis, CA

Abstract: Tetramethylenedisulfotetramine (TETS) is a highly lethal neurotoxic rodenticide that is believed to act as a noncompetitive antagonist of GABA-A receptors. Severe TETS intoxication has been reported to produce refractory convulsive status epilepticus (SE). Here we characterized the therapeutic efficacy of the benzodiazepines diazepam and midazolam in a mouse model of TETS-induced SE. Mice were implanted with right frontal and parietal cortical screw EEG electrodes. An EMG electrode was implanted in the neck. Recordings were conducted with respect to a screw reference electrode situated in the left parietal cortex. After a recovery period, SE was induced with pretreatment of mice with a single dose of riluzole (10 mg/kg, IP) 10 min prior to administration of a lethal dose of TETS (0.2 mg/kg, IP). Riluzole does not inhibit GABA-A receptor antagonist seizures but does protect against the rapidly lethal effects of TETS in mice, allowing persistent SE. Animals were monitored with a video-EEG system. Seizure activity was scored by visual analysis of the behavioral seizure activity supplemented by EMG and by EEG. Diazepam or midazolam were administered at the human-equivalent does of 1.8 mg/kg at either 10 or 40 min after the first myoclonic twitch. Diazepam was administered intraperitoneally (IP) whereas midazolam was administered intramuscularly (IM). Latency to cessation of SE is defined as the interval between the first behavioral myoclonic twitch and termination of seizure activity. Vehicle treatment failed to terminate TETS-induced SE, resulting in mortality in more than 80% of the animals within 24 h. Diazepam and midazolam both effectively terminated SE. The latency to cessation of seizure activity was distinctly shorter when the treatment was administered early (10 min) than late (40 min). Either early or late diazepam prevented mortality in 100% of animals. Midazolam prevented mortality in 70% and 80% of animals when administered early and late, respectively. Animals rescued from TETS-induced SE by diazepam or midazolam exhibited reactive astrogliosis and microglial activation in some brain areas as determined by GFAP and Iba-1 immunoreactivity for at least 72 hours. In summary, both midazolam (IM) and diazepam (IP) terminated TETS SE and markedly increased survival. Midazolam has excellent bioavailability when administered IM whereas diazepam is poorly absorbed IM necessitating administration by a different route, in this case IP. Both treatments may be effective in the treatment of TETS-induced SE. Midazolam despite being slightly less effective in promoting survival may be of particular utility because it can easily be administered in the field.

Title: Ketogenic diet reduces the magnitude, but not maintenance, of hippocampal long-term potentiation in freely behaving juvenile rats

Authors: J. L. KORANDA, *D. N. RUSKIN, J. BLAISE, S. A. MASINO;
Trinity Col., Hartford, CT

Abstract: Ketogenic diets are low- carbohydrate, sufficient protein, high- fat diets with anticonvulsant activity and used primarily as a treatment for pediatric epilepsy. The anticonvulsant mechanism is thought to involve elevating inhibition and or otherwise limiting excitability in the brain. Such a mechanism, however, might also significantly affect normal brain activity and limit synaptic plasticity, effects which would be important to consider in the developing brain. To assess ketogenic diet effects on synaptic transmission and plasticity, electrophysiological recordings were performed at the perforant path/dentate gyrus in awake, freely- behaving juvenile male rats. Electrodes were implanted one week prior to recording. Animals were fed regular chow or a ketogenic diet ad libitum for three weeks before recording. Although the ketogenic diet did not significantly alter baseline excitability (assessed by input-output curves) or short- term plasticity (using the paired- pulse ratio), it did reduce the magnitude (roughly by half) of long- term potentiation at all poststimulation time points out to the last time measured (48 h). The results suggest an effect of ketogenic diet- feeding on the induction magnitude but not the maintenance of long- term potentiation. The lack of effect of the diet on baseline transmission and the paired- pulse ratio suggests a mechanism that limits excitation preferentially in conditions of strong stimulation, consonant with clinical reports in which the ketogenic diet alleviates seizures without a major impact on normal brain activity.

Limiting plasticity in a seizure- susceptible network may limit seizure- induced epileptogenesis which may subserve the ongoing benefit of the ketogenic diet in epilepsy.

Title: Is targeting P2X7 receptor an effective strategy to control seizure induction and recurrence?

Authors: *L. LIBRIZZI, F. M. NOÈ, M. DE CURTIS;
Fondazione Inst. Neurologico C. Besta, Milan, Italy

Abstract: Clinical and experimental evidence support the hypothesis that inflammatory mediators contribute to aberrant neuronal excitability in epilepsy. IL-1b synthesis and release are controlled by the complex NLRP3 inflammasome, activated by the P2X7/pannexin-1 pathway during epileptic seizure-induced massive ATP release. Therefore, a pivotal role of P2X7R has been hypothesized in the aetiology of epilepsy (Dona et al., 2009). We tested if blockade of P2X7R could interfere with seizure-induced brain born inflammation by counteracting ictal events generation itself. Brief application of bicuculline (50μM, 3min) consistently induced focal ictal discharge in the limbic region, as verified by simultaneous electrophysiological recordings of extracellular activity in medial entorhinal cortex (mERC) and CA1, and promoted the release of IL-1b from brain resident cells (Librizzi et al., 2012). Surprisingly, application of the P2X7R antagonists A-438079 (100μM) or BBG (50μM) 10 min before bicuculline application was notable to counteract bicuculline-induced ictal discharge. On the contrary, an increase of the time spent in seizure was often observed. P2X7Rs activation requires high concentration of ATP. We speculated that bicuculline-induced seizure was ineffective in releasing large amount of ATP. We concluded that P2X7 receptors are not strongly involved in GABA-A receptor mediated seizure events generation. We shifted to the KA acute model of seizure in order to facilitate a wider glutamate-mediated release of ATP by both neurons and astrocytes. Application of KA (6 μM, 50ml) induced synchronous oscillation in beta-frequency range, leading to a single ictal episode involving mainly hippocampal formation.

Also in this model, seizure events were associated with IL-1b release exclusively in areas involved in seizure generation (Noè et al, submitted). The 30-min infusion via the resident arterial system of the P2X7 receptor antagonist A438079 (100μM) initiated from 10 min before KA application, resulted into an altered synchronous recruitment of frequencies towards beta-activity and into a prevention of the ictal-activity in the 58% of the experiments. In the remaining 42%, synchronized activity at 15-30 Hz in limbic areas evolving to an ictal event occurred. In conclusion, even though NLRP3 inflammasome system has been demonstrated to be critically involved in aberrant neuronal excitability and seizures, its antagonism, through the upstream inhibition of the P2X7receptors, could not be a promising strategy to control seizures in focal epilepsies. Further research on P2X7R could provide novel targets to control ictogenesis.

Title: Sleep alterations in the gamma2R43Q mouse model of absence epilepsy, and treatment with ganaxolone

Authors: E. WALLACE[1], K. MANGAN[5], A. NELSON[6], J. PFAMMATTER[2], R. MAGANTI[3], C. CIRELLI[4], *M. V. JONES[2];
[1]Cell. & Molec. Pathology, [2]Dept Neurosci., [3]Neurol., [4]Psychiatry, Univ. Wisconsin-Madison, Madison, WI; [5]Cell. Dynamics Intl., Madison, WI; [6]Phys. Pharmacol. & Neurosci., CUNY Med. Sch., New York, NY

Abstract: Sleep disruption is a trigger for seizures, and epileptic patients often have sleep disorders (Semin Neurol. 29:419), suggesting a "vicious cycle" of interactions between sleep and epilepsy. Absence epilepsy is especially interesting because, like sleep, it involves a) loss of consciousness without convulsions, and b) reverberations between the thalamus and cortex. The gamma2R43Q knock-in mouse model (RQ) of absence epilepsy expresses a point mutation in the GABA-A receptor that causes absence epilepsy in patients. Like the human patients, RQ mice display behavioral arrests concurrent with generalized spike-wave discharges. We previously showed (SfN Abstr. 2013, 627.01) that a) tonic GABAergic inhibition is abolished in

RQ mice in thalamic and cortical neurons, b) pharmacological block of tonic inhibition in wild-type (RR) animals is sufficient to provoke absence seizures, and c) injection of ganaxolone (GANX, a synthetic analog of allopregnanolone that can rescue the loss of tonic inhibition) in RQ mice is sufficient to reduce their seizure frequency by ~60%. Here we asked whether RQ mice might also have sleep disruptions, and whether GANX might be effective at alleviating such disruptions. RR and RQ mice (n=3 each) were monitored with video and EEG recordings. After a baseline period, the RQ mice were injected with GANX (2 mg/kg i.p.). Sleep stages (Wake, NREM and REM) were scored visually from the EEG by an experienced scorer. EEG delta power (0.5-4 Hz) in NREM sleep was normalized by dividing by the non-delta power (6-100 Hz). RQ mice had ($p<0.05$, Kruskal-Wallis test) briefer Wake durations than RR, which was not reversed by GANX. RQ mice also had shorter durations of single NREM episodes than RR, but this was reversed by GANX. No groups differed in durations of REM. RQ mice experienced shorter "brief awakenings" (<= 16 seconds) than RR, and this was not altered by GANX, whereas the number of brief awakenings did not differ between any groups. During normal sleep time (daylight), RQ had higher normalized delta power than RR, and this was partially reversed by GANX. Higher normalized delta power in RQ was unexpected given the differences in NREM above, and may reflect changes in other bands that influenced the normalization. Future work will need to examine differences in the full EEG spectra between RR and RQ, in both sleep and epilepsy. Our preliminary results suggest that sleep alterations accompany absence epilepsy in RQ mice, particularly affecting NREM sleep. Some of these alterations can be reversed by GANX. Selective pharmacological manipulation of tonic inhibition may be a useful avenue for treating both seizures and related sleep disorders in the future.

Title: Evaluation of synthetic derivatives of medium chain triglyceride (MCT) fatty acids in mice

Authors: ***J. A. ARAUJO**[1], J. CASKENETTE[2], A. PATRICK[2], W. LAU[1], L. BALENCI[3], J. S. ANDREWS[3], S. ANNEDI[4], G. A. HIGGINS[1];

[1]InterVivo Solutions, Toronto, ON, Canada; [2]Vivocore, Inc, Toronto, ON, Canada; [3]Ketogen Pharma, Inc., Toronto, ON, Canada; [4]Vibrant Pharma, Brantforrd, ON, Canada

Abstract: The medium chain triglyceride (MCT) ketogenic (KG) diet is considered among the most effective therapies for certain refractory epilepsies and has also been proposed to be of value for the treatment of pain and inflammation conditions. The MCT KG diet contains medium chain fatty acids (MCFA) with caprylic acid (CA8) and capric acid (CA10) being primary constituents. Acute treatment with CA8 or CA10 increases blood levels of ß-hydroxybutyrate (ßHB) - a biomarker of ketosis, but both compounds show very modest effects in mouse seizure models compared with synthetic anti-epileptic drugs such as valproate. Recently Chang et al (JPET [2015] 352:43-52.) described a novel series of synthetic derivatives of MCFA with evidence for improved tolerability and efficacy compared to CA8 and CA10, and possible improvement over the MCT KG diet. The present studies benchmarked a selection of these synthetic derivatives to CA8, CA10 and acetone. All compounds were evaluated across; a standardized series of seizure tests (MES, scPTZ, 6Hz, corneal kindling (CK)), a pain model (spared nerve injury), tests of side-effect (body temperature, rotorod, motor activity) and blood ßHB level. All studies were conducted in male CD-1 mice. Acetone, CA8 and CA10 showed a varying degree of efficacy in the MES, 6Hz and scPTZ tests and increased blood ßHB level, but at doses that affected motor function. For example, acetone had a broad spectrum of anti-seizure activity (ED50: MES, 6Hz, CK = 12-20mmol/kg), yet side effects such as reduced rearing was evident at equivalent doses, i.e 20mmol/kg). Anti-seizure effects of CA8 and CA10 were considered marginal, even at doses that were poorly tolerated. In contrast two synthetic derivatives of CA8, 4-EOA and 4-BCCA, showed robust efficacy in the 6Hz, MES, scPTZ models and reduced side effect liability. For example, 4-EOA was active in each of the seizure tests with efficacy and potency significantly superior to both CA8 and CA10 (ED50 = 1-1.5mmol/kg), and a margin of separation improved from acetone. Consequently, these studies support the use of certain synthetic MCFA derivatives as an advance on the MCT KG diet for the treatment of refractory epilepsy and possibly pain and inflammation disorders.

Title: The tolerability and efficacy of an mTOR inhibitor Torin1 on spasms in the multiple-hit rat model of infantile spasms

Authors: T. BRIMA[1], W. MOWREY[2], *S. L. MOSHE[5,3], A. S. GALANOPOULOU[4]; [1]Saul R. Korey Dept. of Neurol., [2]Biostatistics, Epidemiology and Population Health, and Saul R. Korey Dept. of Neurol., [3]Saul R. Korey Dept of Neurology, Dominick P. Purpura Dept of Neuroscience, Dept of Pediatrics, [4]Saul R. Korey Dept. of Neurology, Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [5]Albert Einstein Col. Med., Bronx, NY

Abstract: RATIONALE: Infantile spasms (IS) are age-specific epileptic seizures typically seen in West syndrome, an infantile epileptic encephalopathy with poor outcomes. Better therapies for IS are needed. Early spasm cessation may offer some disease modification in IS patients of unknown etiology whereas structural etiologies render IS more refractory to current treatments: adrenocorticotropic hormone (ACTH) or vigabatrin. The multiple-hit rat model of IS is a chronic model of refractory IS due to structural lesions. In the multiple-hit model, there is overactivation of mTOR pathway. Pulse mTOR inhibition with rapamycin stops spasms and improved learning. To identify mTOR inhibitors with better therapeutic potential for IS, we tested the acute effects

of Torin1, a dual TORC1/TORC2 inhibitor, in the multiple-hit rat model. METHODS: On postnatal day 3 (PN3) Sprague-Dawley male rats received doxorubicin (DOX) (right intracerebroventricular) and lipopolysaccharide (LPS) (right intraparietal) infusions under isoflurane anesthesia, followed by intraperitoneal (i.p.) p-chlorophenylalanine on PN5. Daily monitoring of weights, surface righting time, open field activity, and negative geotaxis were recorded from PN3-PN5. We followed a randomized, blinded, dose and time response study design, administering a single injection of Torin1 (1, 5, or 10 mg/kg i.p.) or its vehicle on PN4, after spasms onset. Intermittent video-monitoring was done on PN4 and PN5 for pre- and post-injection scoring of spasms. Statistics included linear mixed model analysis of raw and normalized log-transformed spasm rates accounting for repeated observations. 11-4 rats were included in each group. RESULTS: All doses of Torin1, given after spasms' onset, acutely reduced both the raw and normalized frequencies of spasms in the multiple-hit model, for up to 5 hours after administration, dose-dependently and was well tolerated. DISCUSSION: Our results further support the role of mTOR signaling in the pathogenesis and treatment of IS in the multiple-hit model. All doses of Torin1 successfully reduced spasms in the multiple-hit model of refractory IS within the first 5 hours post injection, dose-dependently. Torin1 is a promising candidate drug for further evaluation for the treatment of refractory IS.

Title: Paradoxical effects of subchronically and acutely administered cyclooxygenase-2 inhibitors on pentylenetetrazol (PTZ)-induced seizures

Authors: *C. F. MELLO[1], F. R. TEMP[2], J. R. MARAFIGA[2], A. C. JESSE[2], L. H. MILANESI[2], A. T. HESSEL[2], L. M. RAMBO[2];
[2]Physiol. and Pharmacol., [1]Fed Univ. S. Maria (UFSM), Santa Maria, Brazil

Abstract: Cyclooxygenase-2 (COX-2) has been recognized a critical step in prostaglandin synthesis and inflammation. Accordingly, COX-2 inhibitors have been proposed to reduce neuroinflammation and its physiopathologic consequences. However, there is a dispute regarding the role of COX-2 in seizures, because there are reports that COX-2 inhibitors may either decrease or facilitate convulsive episodes. Thus, considering the current discrepancy regarding the pro- and anticonvulsant effect of COX-2 inhibitors, and the use of different drugs and administration regimens, the aim of the current study was to investigate whether acute and subchronic administration of celecoxib, etoricoxib and nimesulide alter PTZ-induced seizures in mice. Adult male Swiss mice were used. In acute experiments, vehicle (0.1% carboxymethylcellulose plus 5% Tween 80, 10 ml/kg, p.o.), celecoxib, etoricoxib or nimesulide (0.2, 2 or 20 mg/kg, p.o.) were administered 60 minutes before PTZ (50 mg/kg, i.p.). In subchronic experiments, mice received vehicle, celecoxib, etoricoxib or nimesulide (0.2, 2 or 20 mg/kg, p.o., daily) for 14 days. On the 15th day the animals were challenged with PTZ (50 mg/kg, i.p.) and monitored for 20 minutes for the appearance of seizures. The latency to myoclonic and generalized tonic-clonic seizures, number of seizure episodes, total time spent seizing and Racine score were recorded. The acute administration of nimesulide dose-dependently decreased PTZ-induced myoclonic jerks [$H(3)=11.63$; $p<0.05$], generalized tonic-clonic seizures [$H(3)=9.44$; $p<0.05$] and number of seizure episodes [$F(3,28)=4.2$; $p<0.05$]. Acute celecoxib and etoricoxib did not alter the parameters analyzed. The subchronic administration of nimesulide and etoricoxib significantly decreased the incidence of PTZ-induced tonic-clonic seizures [$H(3)=8.3$; $p<0.05$], [$H(3)=10.28$; $p<0.05$]. However, subchronic celecoxib significantly decreased the latency to PTZ-induced tonic-clonic seizures [$H(3)=8.73$; $p<0.05$]. Our results suggest that the effect of COX-2 inhibitors on seizures may vary depending on the drug, dose and regimen of drug administration. Such a discrepancy between the effects of COX-2 inhibitors may be due to differential COX-2 selectivity, putative interaction with other targets or pharmacokinetic issues.

Title: Attenuation of corneal kindling progression by 2-deoxy-D-glucose treatment is reflected in 18-F-fluoro-deoxy-D-glucose brain kinetics

Authors: *I. LEITER[1,2], P. BASCUÑANA ALMARCHA[2], A. THOMER[1], F. BENGEL[2], J. BANKSTAHL[2], M. BANKSTAHL[1];
[1]Univ. of Vet. Med. Hannover, Hannover, Germany; [2]Hannover Med. Sch., Hannover, Germany

Abstract: Rationale: Hitherto, processes leading to acquired epilepsy cannot be prevented. Recent studies suggest that modulation of cerebral glucose metabolism by 2-deoxy-D-glucose (2-DG, an inhibitor of glycolysis) treatment might exert antiepileptogenic effects. In this study, we used 18-F-FDG PET to investigate effects of 2-DG treatment during epileptogenesis. Methods: 6Hz-corneal kindling as epileptogenesis model was performed in male NMRI mice by twice daily electrical corneal stimulation for 21 days. Saline (n = 12) or 250 mg/kg 2-DG (n = 18) were injected i.p. 18 h before baseline scans and subsequently 1 min after each stimulation. Seizure response was scored using a modified Racine scale. Twelve additional mice received 2-DG without kindling. Dynamic 60-min 18-F-FDG PET/CT scans were acquired at baseline and inter-ictally on days 10 and 17. A standard MRI-based brain atlas was used to quantify 18-F-FDG uptake (%ID/cc). Kinetic modelling (FDG-2-compartment model) using an image-derived input function (vena cava caudalis) was performed to evaluate glucose metabolic rate MRGlu and uptake rate constant Ki. Results: Kindling progression was attenuated in the 2-DG-treated group, mainly in the early phase (up to 29.3 ± 11.8%, p=0.0009). Corneal kindling in combination with 2-DG treatment increased 18-F-FDG uptake by up to 36.0 ± 10.3% (p=0.0016) at day 10 in hippocampus and at day 10 and 17 in amygdala, striatum, cortex and cerebellum, compared to the unkindled 2-DG treated group. At day 10, the 2-DG treated kindling group showed an up to 1.56 fold increase in influx constant Ki compared to the unkindled group as well as a higher MRGlu at day 17 than the saline-treated kindling group. Kindling progression without treatment altered neither 18-F-FDG uptake nor kinetic parameters. Conclusions: Increases in F-18-FDG brain uptake are present only in mice undergoing both, 2-DG-treatment and corneal kindling. Increased F-18-FDG influx is associated with ameliorated kindling progression. As 2-DG treatment might reflect the crucial mechanism of ketogenic diet, an effective treatment scheme for pharmacoresistant epilepsy, ongoing investigations in the intrahippocampal kainate model of epileptogenesis will include a respective treatment.

Title: Dexamethasone and losartan fail to protect blood-brain barrier integrity during early epileptogenesis

Authors: *H. BREUER[1,2], M. MEIER[3], W. HÄRTIG[4], M. BANKSTAHL[2], J. P. BANKSTAHL[1];
[1]Preclinical Mol. Imaging, Dept of Nuclear Medicine, Hannover Med. Sch., Hannover, Germany; [2]Pharmacol., Univ. of Vet. Med., Hannover, Germany; [3]Central Lab. Animal Facility and Inst. for Lab. Animal Sci., Hannover Med. Sch., Hannover, Germany; [4]Paul Flechsig Inst. for Brain Res., Univ. of Leipzig, Leipzig, Germany

Abstract: Objective: Epileptogenesis can be initiated by primary brain insults and results in the occurrence of spontaneous recurrent seizures. Accumulating evidence suggests that insult-associated blood-brain barrier (BBB) leakage is a key step in the initiation of epileptogenesis and may contribute to disease progression. Therefore, BBB-protective treatment might prevent or attenuate epileptogenesis. In this study, a non-invasive theranostic imaging marker for BBB leakage was used to evaluate two potentially BBB-protective treatments, losartan and dexamethasone, during early epileptogenesis. Materials and methods: As primary brain insult, a 90 min status epilepticus (SE) was induced by fractionated pilocarpine injection (i.p.) in 24 adult female Sprague-Dawley rats. Ten rats were treated with dexamethasone (3 and 24 h post SE, 8 mg/kg i.p.; 48 h post SE, 4 mg/kg i.p.) or losartan (30 min post SE, 50 mg/kg i.p.; 24 h till 5 d post SE, 5 mg/kg i.p. b.i.d.; days 6 till 14, 100-150 mg/d via drinking water). Animals were scanned baseline and 48 h after SE, and the losartan-treated group additionally 5 h and 10 d after SE. 7T small animal MRI setup included a T2 sequence, followed by i.v. infusion of gadolinium (Gd)-DTPA and post-contrast T1-MDEFT. For data evaluation, MRI images were analyzed by co-registration with a rat brain atlas and T1- and T2-signal increase (normalized to pons) was calculated. Next, animals received green fluorescent FITC-albumin (i.v.) for subsequently intended histological evaluation of BBB-integrity, followed 2 h later by perfusion with

paraformaldehyde. Results: In controls, T1-signal after contrast agent and T2-signal increased up to 281% ($p < 0.0001$) and up to 42% ($p < 0.0001$), respectively, in typically SE-affected brain regions like hippocampus, thalamus and entorhinal cortex 48 h after SE. Neither dexamethasone nor losartan treatment influenced brain uptake of Gd-DTPA at 48 h after SE compared to controls. At 5 h and 10 d after SE, no MRI signal increase was present in controls, while T1-signal was increased in various brain regions of losartan-treated rats. Furthermore, in both dexamethasone- and losartan-treated animals, higher T2-signals were present in distinct brain regions at all investigated time points whereas controls did not show significant increases. Histological analysis of serial brain sections is currently performed. Conclusions: Contrast-enhanced MRI reveals BBB leakage 48 h after SE, which could not be counteracted by two potentially BBB-protective treatments. Furthermore, our data suggest that both treatments can exacerbate SE-associated cerebral edema in the pilocarpine post SE rat model.

Title: Seven year retrospective analysis of acute seizure management in children with intravenous levetiracetam

Authors: *B. F. KIRMANI, ESQ[1,2], P. LAKIREDDY[3], A. SARODE[4], O. KHAN[5]; [1]neurology, T, Georgetown, TX; [2]Scott and White Neurocience Institutexas A & M Hlth. Sci. Ctr. Col. of Med., Temple, TX; [3]Pediatrics, McLane Children's Hosp. and Texas A & M Col. of Med., Temple, TX; [4]Baylor Univ., Temple, TX; [5]Univ. of Chicago, Chicago, IL

Abstract: Intravenous Levetiracetam was approved in United States in August 2006 for patients aged 16 years and above. We retrospectively analyzed data at our institution of children who received intravenous levetiracetam for acute seizure management since not much information is available. Methods: A retrospective chart review was conducted on all children less than 18 years who received intravenous levetiracetam at Scott and White Hospital/ Texas A & M HSC College of Medicine, Temple, TX. Subject data were acquired from electronic medical records. Approval of this retrospective analysis was given by our hospital's institutional review board. Results: We retrospectively analyzed 80 patients who met our inclusion criteria for neonatal

seizures, status epilepticus and acute repetitive seizures and received intravenous levetiracetam from January 2008 to August 2014. The loading dose of intravenous levetiracetam was 50mg/kg in most patients followed by a maintenance dose of 25 mg/kg every 12 hours. The variables analyzed included clinical data, electrographic documentation, indication of initiation of this medicine, adverse events and seizure control at 6 month well child visits. Response to levetiracetam was favorable. 63 out of 80 patients reached seizure freedom within 24 hours and 14 within 48 to 72 hours. Seizures continued in one patient and two patients died because of seizure activity on three anticonvulsants. No serious side-effects were apparent. Patients were discharged on oral levetiracetam and did well at 6 month clinic visit. Conclusions: Intravenous Levetiracetam seems to be efficacious in acute seizure management in children.

Title: Evaluating the seizure suppression effect induced by electrical stimulation: an *in vitro* study using human hippocampal tissue

Deleted: *in vitro*

Authors: ***M.-C. HSIAO**[1], P.-N. YU[2], D. SONG[2], C. LIU[2], C. HECK[2], T. W. BERGER[2]; [1]Biomed Engin, [2]USC, Los Angeles, CA

Abstract: In our previous study, an *in vitro* seizure model from human hippocampal slices has been established. Using a multi-electrode array system, spatio-temporal inter-ictal activity can be consistently recorded in high-potassium (8 mM), low-magnesium (0.25 mM) artificial cerebrospinal fluid with additional 100 µM 4-aminopyridine (4AP). The inter-ictal spikes can be recorded in different subregions including dentate, CA1 and subiculum. Using this preparation, we found that electrical stimulation at the seizure focus can suppress 4AP induced inter-ictal spikes. In order to evaluate the suppression effect more quantitatively and efficiently, we analyzed and compared different features of the pre- and post-stimulation data including mean

Deleted: in vitro

spike rate, amplitude, interval and power. Detailed methods of slice preparation, seizure induction, signal processing, and preliminary results will be presented. This lays a foundation for future studies on finding the optimal electrical stimulation parameter for seizure suppression.

Title: Clinic0-radiological profile of neurocysticercosis patients & outcomes at bpkm cancer hospital

Authors: *Q. H. ANSARI;
BPKM Cancer Hosp., Bharatpur, Nepal

Abstract: Clinic0-radiological Profile of Neurocysticercosis patients & Outcomes at BPKM Cancer Hospital QH Ansari[1,3], LN Sing[1], A Pandit[1,3], BK Thapa[2]. 1- Department of Radiodiagnosis & Imaging,BPKM Cancer Hospital, Bharatpur, Chitwan, Nepal 2- Department of Neurology,BPKM Cancer Hospital, Bharatpur, Chitwan, Nepal 3- Surya Ganga Institute of Medical Science and Technology, Patna, Bihar, India Abstract Neurocysticercosis (NCC) is a major cause of neurological illness worldwide. It is the most common identifiable cause of partial seizure especially in the children of developing world. There is insufficient information about NCC in Nepal. This study was, therefore, conducted to evaluate the clinical, neuro-radiographic and therapeutic aspects of NCC at BPKM Cancer Hospital. **Material and Methods:** 100 patients with this Neurocysticercosis were studied prospectively in 12 months in the BPKM Cancer Hospital (BPKMCH), a secondary-level-referral hospital in the central Nepal. The diagnosis of NCC was based primarily on the neuro-imaging (CT scan) findings. **Results:** The patients were predominantly females (nearly 60%) with age ranging from 5 to 70 years. school-age children constituted 35% of the patients. The three common manifestations were seizures (95%), headache and or vomiting (40%). CT scan demonstrated a single parenchymal ring or nodular enhancing lesion (REL) in 84% of cases with perilesional edema in nearly 85% of cases. A large majority of patients were treated only with the anticonvulsant drugs (ACDs) for 9 months. Follow-up with repeat CT after 9 months showed a complete resolution of NCC in most of the cases without the need for cysticidal treatment. **Conclusion:** NCC should be

considered first in the differential diagnosis of new-onset seizure among the patients of developing countries, where taeniasis is endemic. Most of the patients with Neurocysticercosis do not need anticysticercal therapy.

Title: Therapeutic drug monitoring of oxcarbamazepine in mexican epileptic patients

Authors: *N. CASTRO, D. GONZÁLEZ-ESQUIVEL, H. JUNG;
Inst. Nacional De Neurología, Mexico, Mexico

Abstract: PURPOSE: Epilepsy is one of the most common dysfunctions of the nervous system. A Some antiepileptic drugs show a relationship between blood concentration and therapeutic effect then can be evaluated through use of therapeutic drug monitoring (TDM). Oxcarbazepine (OXC) is an analogue of carbamazepine, used for the treatment of partial seizure with or without secondary generalization, The mono-hydroxylated derivative (MHD) is the responsible for the anticonvulsant activity and its concentration is relevant in TDM. The purpose of this study was to investigate the pharmacokinetic variability of oxcarbazepine through clinical therapeutic drug monitoring (TDM) in mexican epileptic patients. METHODS: Data from serum concentration measurements of MHD were utilized. All included samples were drug-fasting in the morning at steady-state (Cmin). RESULTS: In total, 217 patient samples were included, men 51.2% and 48.8% women, average age 24.4 years (range 1.7 to 76.6 years). The mean serum concentration/daily dose(Cmin/D)-ratio was similar across genders; 68 % of the patients showed concentrations in the range of 10-25 mg/L. It was found a significative correlation between daily dose and plasma concentration ($r= 0.436$ $p< 0.001$) although significant differences were found in daily doses of OXC between adult and young patients ($p< 0.05$. U de Mann- Whitney). It was observed a wide pharmacokinetic variability in C/D-ratio). A significative difference was found in the C/D ratio between patients under monotherapy and those under co-administration with enzyme-inducing antiepileptic drugs (0.85 vs 0.62, $p< 0.05$). A significative correlation between CL/F (L/h) and OXC doses was found $r=0.472$,($p<0.001$) CONCLUSION: Oxcarbazepine is not routinely monitored in patients with epilepsy. The pharmacokinetic variability is extensive and it

would be desirable and relevant to monitor plasma MHD levels in order to individualize therapy, considering the influence of age and enzyme-inducing drugs, for estimation of OXC dose.

Abstract: It has been documented that the atrophy of the hippocampus in patients with temporal lobe epilepsy is due to oxidative stress-induced seizure activity, as well as neuronal remodeling by cell loss and target cells. The aim of this study was to identify peripheral biomarkers indicating damage and neuronal remodeling in blood of patients with temporal and extratemporal lobe epilepsy refractory to treatment who were candidates for surgery. Peripheral blood samples were taken before surgery from epilepsy clinic, a protein extraction were subsequently transferred to a nitrocellulose membrane were incubated with several antibodies of oxidative stress was used; Nitrotyrosine (NT), 4-hidroxinonenal (4HNE) malonaldehyde, to damage, S100β and inflammation pathway of prostaglandins (COX-2) and neuronal remodeling (neurotrophin-3), densitometry analysis of the bands was doing with a Analysis software, using the transferrin how control protein. The results showed an increased expression of proteins of

oxidative stress NT, 4HNE and malonaldehyde in sera of patients with ELT as compared with sera of healthy controls and extratemporal epilepsy patients, as well as presence of neurotrophin-3 in sera of patients with epilepsy but not in healthy controls. Expression in serum markers of stress and neuronal remodeling that are not found in the serum of healthy individuals indicates that these proteins can be used as biomarkers of damage and remodeling in the nervous system, as a noninvasive test. This project was funded by International Cooperation program PCI-2014-IMSS

Title: Parvalbumin expression in the hippocampus of patients with mesial temporal lobe epilepsy and psychiatric comorbidities

Authors: ***J. B. DE ROSS**, L. KANDRATAVICIUS, M. R. MONTEIRO, R. C. SCANDIUZZI, C. G. CARLOTTI, Jr, J. A. ASSIRATI, Jr, J. E. C. HALLAK, J. P. LEITE, J. A. S. CRIPPA; Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Objective: Recent studies have demonstrated distinct neuropathological features in patients with mesial temporal lobe epilepsy (MTLE) and psychiatric comorbidities. However, data demonstrating neurotransmitter dysfunctions are scant. Impairment of GABA-mediated inhibition is one of the main hypothesis to explain generation of seizure activity. Interneurons expressing parvalbumin are directly involved in the inhibitory control of pyramidal neurons, and are also involved in the pathophysiology of schizophrenia. The aim of this study was to quantify parvalbumin expression in the hippocampal formation of patients with temporal lobe epilepsy and psychiatric comorbidities. Methods: Retrospectively, 43 cases were selected from patients with pharmacoresistant MTLE who underwent surgery to epilepsy control. Specimens were divided into three groups according to psychiatric diagnosis: interictal psychosis (MTLE + P),

major depression (MTLE + D) and without psychiatric symptoms (MTLE). Tissue from autopsies without epilepsy were used as controls (CTRL). Sections were immunostained with an anti-parvalbumin antibody. Parvalbumin expression was estimated by quantification of positive immunoreactive area, with ImageJ software. Results: Compared to CTRL, MTLE patients showed significant lower parvalbumin expression in CA4, CA3, CA2, CA1 and entorhinal cortex. MTLE + P patients showed reduced parvalbumin expression in hilus, CA4, CA3 CA2, CA1, prosubiculum and entorhinal cortex, compared to CTRL, and in granular layer and hilus, compared to MTLE + D patients, the latter indicating a differential parvalbumin expression between psychiatric comorbidities groups. More specifically, comparing MTLE and MTLE + P groups, a lower parvalbumin expression could be demonstrated in CA1 and subiculum of MTLE + P patients. Interestingly, the subiculum of MTLE groups, unlike the other subfields, presented with the higher parvalbumin expression, even when compared to CTRL group. Conclusions: Our results indicate that patients with MTLE and interictal psychosis have decreased parvalbumin expression in several subfields of the hippocampal formation. This reduction may underlie the association of psychotic symptoms with MTLE, since postmortem studies have demonstrated a reduction in parvalbumin expression in patients with schizophrenia. Finally, the higher expression of parvalbumin in the subiculum of MTLE patients could act as a compensatory mechanism to control hyperexcitability, as the subiculum directly receives inputs from CA1 pyramidal neurons.

Title: Stereological estimates of expression of KCC2 inmunoreactive cells in tissue of patients with chronic medically intractable epilepsy

Authors: *L. GRANADOS[1], T. E. JUÁREZ-ZEPEDA[1], M. RUÍZ-GARCÍA[1], A. MARHX-BRACHO[1], R. R. RODRÍGUEZ-JURADO[1], M. ROJAS-MARURI[1], K. JERONIMO-CRUZ[1], L. CARMONA-APARICIO[1], E. COBALLASE-URRUTIA[1], P. DURÁN-HERNÁNDEZ[2]; [1]Inst. Naciona de Pediatría, Ciudad de México, Mexico; [2]Facultad de Ciencias, UNAM, Ciudad de México, Mexico

Abstract: As it is established, NKCC1 and KCC2 cation chloride transporters are membrane proteins which transport chloride within and outside the neurons respectivelly, regulating thus the intracellular concentration of this ion, which determines the strength and polarity of the of gamma-aminobutyric acid (GABA)-mediated neurotransmission. Alterations in homeostasis of these molecules could explain the hyperexcitability observed in epileptic tissue resected in epilepsy surgery. The objective of the present study was to quantify by stereological methods the expression of chloride transportador KCC2 in tissue of epileptogenic zone resected in surgery of pediatric patients with chronic medically intractable epilepsy (n = 6) and tissue obtained from autopsies of infants whose death were not related to a neurological disease (n = 7) (National Institute of Pediatrics and Institute of Forensic Science, México). Tissues were frozen and serial coronal sections (50 μm) were cut and collected. The sections were processed in parallel and incubated with KCC2 antibody, anti-rabbit biotinylated IgG, peroxidase complex and reveal with DAB. A systematic random procedure using optical fractionator (MBF Bioscience) was employed in counting the number of KCC2-inmunoreactive (IR) cells in the white matter. Results showed a reduction in the number of KCC2-IR cells present in the white matter of epileptogenic zone of pediatric patients with chronic medically intractable epilepsy. This work was supported by a grant from Consejo Nacional de Ciencia y Tecnología (86784), México and Fondos Federales-INP to L. Granados-Rojas.

Title: High expression levels of inflammatory-related molecules and nitric oxide synthase 2 and 3 in surgical resection tissue from frontal lobe epilepsy of patients

Authors: ***O. F. MERCADO-GOMEZ**[1], L. CÓRDOVA-DÁVALOS[1], D. GARCÍA-BETANZO[1], L. ROCHA[2], M. ALONSO-VANEGAS[3], R. GUEVARA-GUZMÁN[1]; [1]Natl. Autonomous Univ. of Mexico, Mexico City, Mexico; [2]Pharmacobiology, Ctr. of Res. and Advanced Studies, Mexico City, Mexico; [3]Neurosurg., Natl. Inst. of Neurol. and Neurosurg. "Manuel Velasco Suárez",, Mexico City, Mexico

Abstract: Introduction: Epilepsy is a neurological disorder characterized by recurrent and spontaneous seizures. Several reports have shown that neuroinflammatory process has a crucial role in epilepsy because of contributes to the etiophatogenesis of seizures. On the other hand, it has recently described that nitrosative stress mediated by overproduction of nitrogen reactive species (NRS) could have an important role in epileptogenesis. Although inflammation and NRS are well described in experimental rat models and brain tissue samples from patients with temporal lobe epilepsy (TLE), little information is known about pathological process in the frontal lobe epilepsy (FLE). Objective: Analyze the gene expression of inflammatory-related molecules (Interleukin 1β, Interleukin 6, tumor necrosis factor α, Toll-like receptor, high mobility group box 1, NFκB) and molecules related with nitrosative stress (NOS2 and NOS3) in frontal lobe brain samples. Methodology: Frontal lobe surgical resection tissue (n=4) were obtained from FLE patients and samples from control subjects (n=4) with no neurological disorders were obtained from autopsies at the NINN Hospital in Mexico city. The RNA was isolated using the TRIzol method following manufacturer's protocol and their integrity was achieved by electrophoresis. 1 μg of RNA was reversed transcripted using ReverAid First Strand cDNA synthesis kit. For quantitative PCR assays, we performed SYBR green chemistry using 200 ng of cDNA with specific primers for each gene and normalized with GAPDH gene. We used the Pfaffl method for calculating fold changes in gene expression. Results: Our preliminary data show that there was a high expression level of cytokines genes (TNFα=1682.6, IL-6=1483.4, IL-1β=659.9 folds); together with an increased gene expression of TLR4 and their agonist HMGB1 (2.1 and 2.8, folds respectively). Interestingly, downstream effector of inflammatory cascade such as NFκBp65 (RelA) was also found increased (6.5 fold) in FLE brains samples. Moreover, gene expression of NOS 2/3, enzymes implicated in nitrosative stress, also were upregulated. Conclusion: Our results indicate that there is general increase in gene expression of inflammatory-related molecules and enzymes related with nitrosative stress in brains samples of FLE patients. Although, inflammatory process has been described in other epilepsies (i.e. TLE), we showed for the first time that FLE occurs similar results suggesting a common pathological cascades that contributing to the generation of seizures and lately, a progressive neuronal cell death in both kind of epilepsies

Title: Impact of temporal lobe epilepsy with hippocampal sclerosis upon expression of 5-HT3 receptors: potential novel antiepileptic target

Authors: ***H. A. ALOMAR**[1,2], M. SHEILABI[3], A. PRINCIVALLE[3], A. MASSOURA[1], R. CHELVARAJAH[4], H. PALL[1,5], N. BARNES[1];

Dept., [5]Neurol. Dept., Queen Elizabeth Hosp. Birmingham, Birmingham, United Kingdom

Abstract: Mesial temporal lobe epilepsy with hippocampal sclerosis (mTLE-HS) is a chronic neuropathological disorder affecting primarily the medial part of the temporal lobe, particularly the hippocampus. This disease is characterised by recurrent focal-onset seizures that can be associated with epigastric aura. Of those suffering from this disease, 30% experience pharmaco-resistance to antiepileptic drugs (AEDs), which may necessitate surgical intervention to control their seizures and improve their quality of life. Given the important role of 5-hydroxytriptamine (5-HT) in the hippocampus, we are investigating the expression of 5-HT receptors in resected hippocampi from patients with mTLE-HS relative to post-mortem 'control' hippocampi from donors without a diagnosed neuropathological condition. In this report, we describe the impact of mTLE-HS on the expression of ionotropic excitatory 5-HT3 receptors assessed by immunohistochemistry, qPCR and radioligand binding. Immunoreactivity for the 5-HT3A receptor subunit was increased in surviving neurones, particularly in the CA2 field of the hippocampus, of resected tissues from patients with mTLE-HS compared to control tissue. This finding agreed with the qPCR (quantify the change) and radioligand binding results (homogenate

results; Bmax = 59±8 and 126±10 fmol/mg control and mTLE-HS, respectively), and autoradiography results. In conclusion, our study revealed a significant increase in the expression of the 5-HT3A receptor subunit in the hippocampus of patients with mTLE-HS. The 5-HT3A subunit constitutes the key component the 5-HT3 receptor complex to impart functionality to the receptor. The overexpression of these excitatory receptors is consistent with the enhanced neuronal activity associated with this type of epilepsy and they may represent a novel molecular for antagonists to control seizures in patients with mTLE-HS.

Abstract: Despite the high demand for and potential utility of human primary brain cell cultures in various scientific interests, the methodology has been regarded as extremely difficult to achieve and maintain long-term cultures. With IRB approval, various resected brain tissues, including cortical and hippocampal tissues from different disease cases such as Communicating Hydrocephalus, Epilepsy, Normal Pressure Hydrocephalus and brain tumor, were used for primary brain cell culture. We developed a new methodology for human brain cell culture that allows maintenance of functional brain cells for over 6 months. Briefly, besides the pathological diagnostics of disease, tissues were dissected, followed by enzyme-triggered cell dissociation and plating onto glass coverslips with serum-free media for further experiments. The cellular phenotypes were confirmed by electrophysiology, ion imaging, immunocytochemistry and single

cell transcriptome analysis. Under the established culturing conditions, neurons developed synaptic connections and form neuronal networks. This new culturing protocol allows us to perform long-term experiments on human brain cells including neuron and non-neuronal brain cells with various pharmacological manipulations. This new protocol will open up the possibility for various applications originating from resected human brain tissue for physiology, pharmacology and genomic studies. Funded by: U01-MH-098953

Title: Findings morphological of the cortex on patients with drug-refractory temporal lobe epilepsy: his involvement with the background in childhood

Authors: *J. VILLEDA, SR[1], J. DE JESUS-CARPANTA, Jr[2], F. FERNANDEZ-VALVERDE[3], M. ALONSO-VANEGAS[4];
[1]Home, Mexico Distrito Federal, Mexico; [2]Neuropathology Exptl. and Fac. Of Med., Inst. Nacional De Neurología and the Metropolitan Autonomous Univ., Mexico Distrito Federal, Mexico; [3]Neuropatologia Experimental, [4]Neurosurgery, Instituto Nacional De Neurologia, Mexico Distrito Federal, Mexico

Abstract: Purpose: To assess the morphological findings of the cortex in patients with refractory epilepsy undergoing to surgery of temporal lobe and history of febrile seizures. Method: A retrospective study was performed: Twenty patients with mesial temporal lobe epilepsy (MTLE), four with tumors, two with cortical dysplasias and the average age is 33 years. By prior surgical protocol standardization and candidate's temporal lobectomy and amygdalohippocampectomy are systematically reviewed clinical records with data in Excel. Subsequently the morphological changes was analyzed by histological techniques; H-E, Amino Cupric and PAS and immunohistochemistry technique (anti-GFAP and NeuN). Results: After reviewing MTLE patients; We found five cases with a history of febrile seizures and them a marked loss of pyramidal neurons, a dissociation nucleus-somatic, interstitial edema, cell dysmorphic, in PAS

technique there are accumulation of mucopolysaccharides was observed in the cytoplasm, the aggregates was found with Amino Cupric, the GFAP expression was increased and NeuN was decreased in cortex of this patients. Conclusion: From this study it can be inferred that a first febrile seizure of long time may be an important antecedent to do MTLE, and not only this, but you should think of other antecedents of the childhood that may be the cause of protracted seizure in after time, as they are believed to be generated morphological and functional alterations in cortex and hippocampus since they are developing their brains.

Title: Mutation in mtDNA investigation in children mitochondrial disorders

Authors: ***O. V. GLOBA**[1], L. KUZENKOVA[2], E. KOLESNIKOVA[2], K. SAVOST'YANOV[3]; [2]Neurol., [3]Genet., [1]Scientific Ctr. of Children's Hlth., Moscow, Russian Federation

Abstract: Aim: Mitochondrial diseases represent a heterogeneous group of multisystem disorders which preferentially affect tissues with high energetic demands and associate with stroke, epilepsy and multiorgan damage. Mitochondrial disorders are difficult to diagnose due to extreme genetic and phenotypic heterogeneities. The aim of the study is to examine the clinical spectrum and genetic investigation in children suspected of having mitochondrial disorders. Methods: We analyzed the clinical, electrophysiological, and radiologic data, mitochondria functional tests, systemic biochemical measurements and genomic mtDNA sequencing in 33 of children 6 months-17 years of ages showing the sights of mitochondrial dysfunction. Results: In 24 paediatric patients the mutation in mtDNA was revealed. 10 children had symptomatic focal epilepsy with different types of seizures. 4 patients had ischemic stroke. 4 patients had stroke and epilepsy simultaneously. 3 patients had dilated cardiomyopathy only. In children with stroke 3 patients had mutation in ATPsynthase6 gene, one in 16sRNA, two of children had mutation in ND1c910T>C(4216T>C),related to Leber disease and one had mutations ND1 c910T>C and in ND2c448A>G also usually related to Leber disease, but without visual deterioration. In one girl of 8 years of ages the CYTB c47A>G (14793A>G) which may seen in Leigh disease also

revealed. In contrary in 2 children with high-frequency MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes syndrome), mutation A3243G, A11084G had no stroke, but epilepsy and mental delay. In 2 patients with infantile spasms the ND1c910T>C(Leber mutation) were found, and the same mutation in one boy with ischemic stroke. Three patients with seizures had Leigh disease. In epileptic patients the most common mutations were in ATP6 334 A>G, ND1,ND2 or ND3 340A>G(rare) usually in combination, one patient with epilepsy and stroke had tRNAlys,COX and 16SRNA mutation. The ATP6 mutation was revealed in most of the children (13 patients) with epilepsy, stroke, epilepsy and stroke and dilated cardiomyopathy. The rest of children presented no mutation but polymorphisms Conclusion: The genotype-phenotype correlation in children with mitochondrial mutation are not direct in many cases. Many mutations are not specific to clinical manifestations. But the recognition of mitochondrial origin and initiation of etiological treatment may improve prognosis.

Title: Pharmocogenomics: a new tool to predict efficacy of anti-seizure drug treatment

Authors: *C. J. MARCUCCILLI[1], T. ZEMBLES[3], T. SANDER[4], P. MONRAD[4], D. P. BICK[5], S. O'CONNOR[6], M. ZUPANC[7], A. K. TRYBA[2];
[1]Associate Professor, Dept Pediatrics, [2]Dept Pediatrics, The Univ. of Chicago, Chicago, IL; [3]Pharmacol., [4]Children's Hosp. of Wisconsin, Milwaukee, WI; [5]Genet., Med. Col. of Wisconsin, Milwaukee, WI; [6]Northwestern Univ., Chicago, IL; [7]UC Irvine, Irvine, CA

Abstract: Epilepsy is one of the most prevalent neurological diseases, affecting about 1-3% of the world population. Unfortunately, the mechanisms underlying seizures are not well understood and drug and surgical treatments are unsuccessful in a significant fraction (~33-40%)

of people living with epilepsy. Current standard of care pharmaceutical methods to treat epilepsy typically entail a “try it and see if it works” approach. Most anti-epileptic drugs (AEDs) are metabolized by cytochrome P450 (CYPs) enzymes and single nucleotide polymorphisms (SNP) in CYP enzymes are thought to alter the efficacy of AEDs in terms of preventing seizures. We used genomic testing to identify SNP variants in CYP enzymes of both epilepsy patients and first time seizure clinic patients. We found that pediatric epilepsy patients that carry the CYP2C19*2 allele have seizures that are extremely sensitive to and more frequently controlled by Phenobarbital (PHB), compared to patients with the reference allele (*1) or other alleles (*4, *17), regardless of PHB plasma concentrations, seizure phenotype or cause of their seizures. Approximately 85% of patients with the CYP2C19*2 allele (n=17 of 20 tested) have seizures controlled by PHB compared to 40% of patients with the reference or other alleles (n=14 of 35 tested). Seizure control was defined as being seizure free for at least 6 months or having a greater than 50% reduction in seizure activity. In a test for significance of difference between the two proportions, these results are highly significant ($z=4.53$; $p<0.0001$). In 2 patients with refractory epilepsy, the CYP2C*19 allele was identified prospectively and both patients became seizure free upon initiation of PHB, one for over 2 years. As CYP enzymes control the rate of AED metabolism, SNP variants in CYP genes may cause either slow AED metabolism or rapid AED metabolism. However, the increased efficacy of phenobarbital treatment in patients carrying the CYP2C*19 allele was independent of PHB blood concentrations. PHB is also metabolized by CYP2C9. However, the CYP2C9*2 allele to this gene did not predict efficacy as 6 out of 12 patients with the CYP2C9*2 allele responded to PHB while 24 out of 39 patients with the reference allele or other variants responded to PHB ($z = -1.22$; $p = 0.22$). Thus, we are using genomic approaches to test the hypothesis that epilepsy patients with the CYP2C*19 allele also carry a genetic variant of phenobarbital drug targets (e.g. GABA receptors) that can account for the observed increase in seizure control with PHB treatment. To our knowledge, these are the first data to support the use of a genetic test that could predict AED efficacy.

Abstract: Mesial temporal lobe epilepsy is the most prevalent form of focal epilepsy in adults. The disorder is frequently characterised by hippocampal sclerosis (HS), but many non-lesional MTLE patients (MTLE-NL) have no visible abnormalities on standard MRI. Diagnosis of MTLE-NL is often associated with poor surgical outcome relative to MTLE with HS. Traditional volumetric analyses have identified marginal structural differences in the hippocampus, thalamus and amygdala in MTLE-NL, but gross volumetric measures may overlook subtle or localised effects. We applied a novel shape analysis method in a group of 40 MTLE-NL patients (male/female: 13/27; mean age=33.44 years) and 70 healthy controls (male/female: 40/30; mean age=34.75 years). Using FreeSurfer v5.3.0, we reconstructed 14 major subcortical structures from each patient's T1-weighted image (see Fig. 1A). With a validated surface-based parametric mapping algorithm, we mapped the surface dilation factor (Jacobian determinant) that expresses local area expansions and contractions relative to an average surface. The pointwise Jacobian values of all MTLE-NL patients and controls were predicted from a multiple linear regression model including age, sex, handedness and intracranial volume as covariates. All results were corrected for false discovery rate (q=0.05). MTLE-NL patients showed relative surface area contractions in anterior, medial and posterior portions of the left/right hippocampi, surface area expansions in the medial/anterior hippocampi, surface contractions in the posterior/medial sections of the left/right thalami, and small clusters of surface expansion in the posterior-inferior right thalamus ($p<0.05$, FDR-corrected) (see Fig. 1B-1D). Pharmacoresistant patients also showed surface area contractions in the right accumbens ($p<0.05$, FDR-corrected). This high-dimensional shape mapping technique detects subtle morphometric differences in MTLE-NL that are overlooked using global comparisons. The method offers a sensitive marker of disease burden in epilepsy and other neurological disorders.

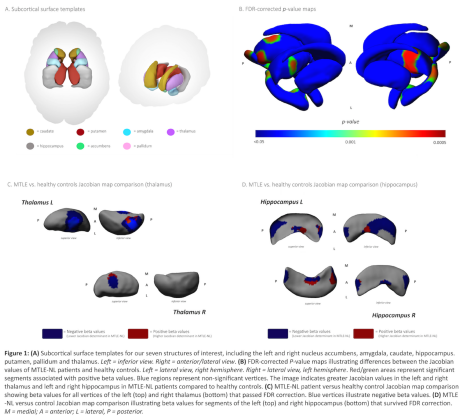

Figure 1: (A) Subcortical surface templates for our seven structures of interest, including the left and right nucleus accumbens, amygdala, caudate, hippocampus, putamen, pallidum and thalamus. *Left = inferior view. Right = anterior/lateral view.* **(B)** FDR-corrected *P*-value maps illustrating differences between the Jacobian values of MTLE-NL patients and healthy controls. *Left = lateral view, right hemisphere. Right = lateral view, left hemisphere.* Red/green areas represent significant segments associated with positive beta values. Blue regions represent non-significant vertices. The image indicates greater Jacobian values in the left and right thalamus and left and right hippocampus in MTLE-NL patients compared to healthy controls. **(C)** MTLE-NL patient versus healthy control Jacobian map comparison showing beta values for all vertices of the left (top) and right thalamus (bottom) that passed FDR correction. Blue vertices illustrate negative beta values. **(D)** MTLE -NL versus control Jacobian map comparison illustrating beta values for segments of the left (top) and right hippocampus (bottom) that survived FDR correction. *M = medial; A = anterior; L = lateral, P = posterior.*

Title: Hippocampal and cortical expression of heat shock proteins in mesial temporal lobe epilepsy and their relation to seizure outcome

Authors: *A. P. NEBREDA-CORONA[1], M. ARROYO-TIBURCIO[1], A. FLEURY[2], M. ALONSO-VANEGAS[3], J. VILLEDA-HERNANDEZ[1];
[1]Exptl. Pathology, [2]Peripheral unit to study neuroinflammation in Neurolog. Pathology INNN - IIB -UNAM, [3]Dept. of Neurosurg., THE NATIONAL INSTITUTE OF NEUROLOGY AND NEUROSURGE, Mexico, Mexico

Abstract: Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures. An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. More than 50 million people worldwide have epilepsy. In most cases, epilepsy can be successfully treated

with anti-epileptic drugs, but many as 20 to 40 percent of patients with epilepsy are likely to have refractory epilepsy. Epilepsy is divided into focal and generalized according to the mode of seizure onset as well as into genetic, structural/metabolic, or unknown according to the underlying cause or etiology. Focal- onset epilepsies account for about 60% of all adult epilepsy cases, and temporal lobe epilepsy (TLE) is the most common type of focal epilepsy referred for epilepsy surgery and often refractory to antiepileptic drugs (AEDs). Heat shock proteins are conserved proteins, some of them are expressed constitutively and some are induced by stressful stimuli such as high temperatures, ischemia and damage. In the nervous system, the HSPs are induced in a variety of pathologic states, including cerebral ischemia, neurodegenerative diseases, epilepsy, and trauma. Expression has been detected in a variety of cell populations within the nervous system, including neurons, glia, and endothelial cells. Several groups using various models (*in vivo* and *in vitro*) of experimental nervous system stress and injury have shown neuroprotective properties of HSPs. In human studies there was found an increase in the Hsp70 levels in CSF depending on the severity of seizures; also this increase was found in key hippocampal subfields and reflects epileptogenicity and poorer outcome of epilepsy surgery. Plasma post-seizure Hsp60 levels in patients were higher than before the seizure and those of controls. We evaluated hippocampus and cortex regions from 14 patients with TLE secondary to temporal mesial sclerosis. The mean age at surgery was 34.57 (19-58) years whereas the mean duration of epilepsy was 27.64 (14-44) years. Seizure frequency varied from 1 to 300 per month. The aim of this study was to find a correlation between the expression of this proteins and the surgical outcome evaluated by ILAE scale (1 to 5, being 5 the worst outcome). We used Spearman´s rho and found negative correlation (-.491 P=0.075) in the expression of Hsp60 and a positive correlation (0.161 P=0.583) in the expression of Hsp70, both in hippocampus. The overview of the data shows us a decreased expression of these HSPs in patients with poor outcome (Hsp70 in smaller proportion) but these results are not significant; this may be due to the small sample size.

Title: The first dedicated epilepsy brain bank in Canada

Authors: *L. E. KALYNCHUK, J. F. TELLEZ-ZENTENO, F. MOIEN-AFSHARI, C. TAGHIBIGLOU, F. CAYABYAB, R. BOROWSKY, H. AFTAB, M. VRBANIC, A. SAAD, C. ROBINSON, M. HIKEN, M. J. MICKLEBOROUGH, R. HUNTSMAN, L. HERNANDEZ RONQUILLO, A. WU;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Basic research in the field of epilepsy lags behind neurodegenerative diseases such as Alzheimer's and Parkinson's disease. One reason for this is the lack of properly stored human epileptic tissue for research. Although there is some history of brain banks containing tissue from epileptic patients in Europe and the United States, this has not been true in Canada. The objective of this initiative was the creation of the first dedicated epilepsy brain bank in Canada. Brain banks typically house post-mortem tissue, but epilepsy is unique among brain diseases in that tissue resection is a therapeutic option for many patients who are treatment refractory. An epilepsy brain bank can therefore include tissue from patients who have experienced such a resection, with the option to follow the patient postoperatively and collect additional data. The Saskatchewan Epilepsy Brain bank is a storage source for brain tissue from epilepsy surgery resections. The tissue is carefully frozen with isopentane and stored at -80 C. Because the tissue it not fixed in formaldehyde, it is available for further research using advanced molecular and genomic methods. An important aspect of our approach is that all patients who donate tissue to the bank participate in a detailed work up prior to surgery, which includes video-EEG, MRI, neuropsychological testing and psychiatric screening, and also possible PET scans and fMRI depending on the case. Patients are then followed after surgery to measure seizure and behavioral outcomes. This provides the opportunity to use the brain bank tissue for studies of the factors that promote behavioral comorbidities in addition to the neural mechanisms of epilepsy and recurrent seizures. To date, we have stored portions of tissue from 5 patients. All patients were assessed by two epileptologists at the Saskatchewan Epilepsy Program. All of them had drug resistant epilepsy and were candidates for epilepsy surgery. The mean age of the patients at the time of surgery was 37.2 $\pm$ 13.8 and two were males. One patient had profound developmental delay and three had psychiatric comorbidities. MRI revealed lesions in three patients. Four patients (80%) had temporal resections and one had a fronto-temporal resection. After six months of follow up all of them were seizure free. We are now using the tissue for a series of basic science experiments using proteomics, immunohistochemistry, and molecular biology. We are also interested in identifying biomarkers of refractory epileptic activity. These biomarkers will be translated into therapeutic targets, which will be tested in animal models to determine efficacy prior to clinical trials.

Abstract: Background: Temporal lobe epilepsy (TLE) has been commonly associated with progressive atrophy in hippocampus and related networks. There is mounting evidence that epileptic seizures are associated with increase in hippocampal neurogenesis. Given the ambiguity of these observations we aimed to answer the question about the trajectory of epilepsy-related hippocampal changes in epilepsy as function of disease progression. Our objectives are to i) detect patterns of structural plasticity in the hippocampus associated with TLE and ii) disentangle how clinical disease characteristics modulate structural plasticity with specific focus on hippocampal morphology. Methods: 128 TLE patients were characterized dependent on the laterality of the epileptogenic focus, on a drug resistance and on the presence or absence of mesial temporal lobe sclerosis (MTS and MRI-) and compared to 120 healthy volunteers. Statistical VBM analysis in the framework of SPM12 is based on T1-weighted MRI data. Patterns of structural plasticity were evaluated using between-groups comparison and correlation with clinical disease parameters including disease duration, age of onset and seizure frequency as

well as hippocampal volume estimates ipsi- or contralateral to the epileptogenic focus. Results:MRI- TLE is associated to bilateral increases of hippocampal and amygdala volume estimates in comparison to estimates of healthy controls, principally in early stages of the disease. In contrast, hippocampal volumes with MTS continuously decline during disease progression ipsilateral to the epileptogenic focus. Structural increments are located in the bilateral hippocampal head, but structural degeneration in the ipsilateral hippocampal body and tail. Drug resistance is characterized by a neurodegenerative process involving the ipsilateral hippocampus and bilateral thalamic structures. In MTS TLE, lower ages of onset are associated to a decreased volume in the left hippocampus and thalamus beside the right inferior temporal gyrus whereas in MRI- TLE, the age of onset is not linked to regional specific structural plasticity. High seizure frequencies favor a volumetric loss in the limbic and associated network marked by different patterns dependent on drug resistance and obvious MTS. Conclusion: Our findings of seizure-induced hippocampal plasticity are clearly linked to the clinical phenotype in TLE. Bidirectional patterns including volume increase and decrease are associated to structural imprinting of disease properties and appear to represent rather a stage within a progressive continuum of structural plasticity than separating different disease entities in TLE.

Title: Effects of Antalarmin treatment on the neuroinflammatory response to hippocampal injury post transient global cerebral ischemia in male rats

Authors: *P. BARRA DE LA TREMBLAYE, K. L. ROSS, H. PLAMONDON; Behavioural Neurosci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The innate immune response to ischemic stroke can exacerbate neuronal injury by further damaging or killing nearby neurons and other cell types, in part through recruitment of cytotoxic immune cells. Previous reports from our laboratory indicate that Antalarmin, a specific

antagonist to corticotropin releasing hormone type 1 receptors (CRHR1) is effective in downregulating post-ischemic elevations in CORT secretion in basal and stress conditions. The current study seeks to determine the relative contribution of CRHR1 receptors in the regulation of the response of two major immune cell-types, astrocytes and microglia, in the hippocampus at a long-term interval post ischemia. It is hypothesized that the CRHR1 antagonist Antalarmin will act as a protective agent by reducing the reactivity of astrocytes and microglia in the hippocampus post ischemia. Wistar rats (N=62) were divided into 5 groups, either ischemic or sham groups, receiving the antagonist or the vehicle, and 1 control group. We used immunohistological analysis to characterize the distribution and density of glial fibrillary acidic protein (GFAP), ionized calcium binding adaptor (IBA1) and tumor necrosis factor α (TNFα) in the CA1, CA3 and Dentate Gyrus (DG) sub-regions 30 days post ischemia. Results from our study indicate that global cerebral ischemia led to a significant lasting increase in astrocytes, microglia and TNFα compared to sham and home-cage controls. The blocking of CRHR1 receptors by Antalarmin led to a partial decrease in IBA1, GFAP and TNFα immunoreactive cells in all subregions of the hippocampus. Antalarmin also conferred significant CA1 neuronal protection positively correlated with attenuation of microglia activation. These findings support moderate neuronal protection by Antalarmin, which are congruent with modulatory effects of CRH on the excitotoxic cascade post ischemia.

Title: Secondary pathology in rat cortical stroke model

Authors: ***J. E. ANTTILA**, T. KUAN-YIN, K. MÄTLIK, M. AIRAVAARA;
Univ. of Helsinki, Inst. of Biotech., Helsinki, Finland

Abstract: Aims Microglia are the immune cells of the brain and are rapidly activated in pathological conditions including ischemic stroke. The aims of the study were to characterize the inflammatory changes in the rat cortical stroke model and to study the role of microglial activation in secondary pathology. Methods A unilateral cortical infarction was induced in adult male Sprague Dawley rats by transiently ligating the distal branch of the right middle cerebral artery with 10-0 suture and occluding both common carotid arteries, followed by release of the ligature after 90 minutes. Immunohistochemistry on sagittal paraffin sections was performed on days 2, 7, 14, 28 and 60 post-stroke to analyze the amount of activated microglia/macrophages in the stroked cortex and in the non-ischemic areas striatum and thalamus. Also neuronal markers were used. Results In the ipsilateral cortex the amount of phagocytic microglia/macrophages was most abundant on day 7 post-stroke. Microglial activation in striatum and thalamus was more delayed, beginning from day 7 post-stroke and persisting several weeks after stroke. The majority of activated microglial cells in striatum and thalamus were phagocytic after day 14. Interestingly, phagocytic microglia in thalamus was associated with neuronal loss. Conclusions In this focal stroke model the infarction area is restricted to cortex. However, activated microglia and neuronal loss was detected also in distal non-ischemic brain regions such as striatum and thalamus. This may be caused by the retrograde and anterograde degeneration of thalamic neurons after injury of the thalamocortical and corticothalamic connections. Secondary thalamic atrophy and microglial activation has been described also in patients suffering from middle cerebral artery infarction. Drug targeting of the secondary affected areas could provide a novel approach for stroke treatment to prevent the neuronal loss.

Title: Pro-inflammatory and anti-inflammatory profile of microglia and macrophages after experimental cerebral ischemia in mice

Authors: *J. G. ZARRUK, S. DAVID;
Ctr. for Res. in Neurosci., McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Microglia and macrophages from the peripheral circulation contribute importantly to the inflammatory response after ischemic stroke. Recent studies have examined macrophage/microglia polarization in brain ischemia, however these studies have not distinguished between the polarization state of microglia and infiltrating macrophages. We have used the LysM-EGFP knockin mouse in which peripheral macrophages and neutrophils are tagged with EGFP to distinguish them from microglia at the site of cerebral ischemia and studied the expression of M1 and M2 polarization markers after a transient Middle Cerebral Artery Occlusion (tMCAO). The middle cerebral artery was occluded in LysM-EGFP mice and reperfusion was allowed 90 minutes later. Animals were trans-cardially perfused and tissue taken at 24h, 72h and 7 days post-tMCAO for immunofluorescence staining. There were very few infiltrating EGFP+ cells in the penumbra or core of the infarct at 24h. Their numbers increased markedly at 72h after reperfusion and comprise of both infiltrating macrophages and neutrophils; and are distributed evenly within the lesion core. At 7 days the EGFP+ cells which at this time point consist mainly of infiltrating macrophages appear to be aggregated and clustered in the core of the infarct. We also did double immunofluorescence labeling for two well established M1 markers (CD86 and CD16/32) combined with Iba-1. Our results show that both CD86 and CD16/32 are mainly expressed in Iba1+ /EGFP- (microglia) but not in Iba1+ /EGFP+ (macrophages) cells. Both markers were found in the border and penumbra regions of the lesion. An additional group of mice was subjected to permanent MCAO and FACS experiments done to characterize the expression of TNF and arginase-1 at 3 and 7 days post-injury. Our results showed that a higher percentage of resident microglia expressed TNF as compared to peripherally-derived macrophages at 3 and 7 days post-ischemia. On the other hand a higher percentage of macrophages expressed arginase-1 at 3 and 7 days after the ischemic insult. These results show that resident microglia become activated and polarized to a predominantly pro-inflammatory M1 state while infiltrating macrophages, which are mainly localized in the core of the lesion appear to be less pro-inflammatory. Additional work is underway to assess the expression of more markers. The use of the LysM-EGFP mice has allowed us to distinguish the differentiation state of microglia and infiltrating peripheral macrophages at the site of cerebral ischemia. Title: Pharmacologically induced hypothermia reduces inflammatory response after ischemic stroke in mice

Authors: ***M. WINTER**[1], J. H. LEE[1], W. CAO[1], Z. Z. WEI[1], X. GU[1,2], L. WEI[1,2], S. P. YU[1]; [1]Anesthesiol., [2]Neurol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Stroke is a leading cause of human death and disability in the US and across the globe, with over 800,000 strokes occurring each year in the US alone. Despite stroke's widespread public health impact, there are very few effective clinical treatments available for acute stroke patients. Preclinical and clinical studies have shown that therapeutic hypothermia is highly protective against ischemic brain injury. Using novel neurotensin receptor 1 (NTR1) agonists, we have previously demonstrated the protective effects of pharmacologically induced hypothermia (PIH) against brain damage after ischemic stroke, hemorrhagic stroke, and traumatic brain injury (TBI) in rodent models. To better understand the mechanism of PIH-induced neuroprotection, we investigated the effect of the NTR1 compound HPI-201 on inflammatory responses following ischemic stroke in mice. Stroke damage increased microglial activation in the penumbra, with peak activation at seven days post-focal ischemia. HPI-201 treatment (2 mg/kg, i.p, 15 min after the onset of ischemia) induced body temperature reduction to 32-34°C in approximately 30 minutes. The hypothermic effect was maintained for 6 hours by additional HPI-201 injections (1 mg/kg). This treatment significantly attenuated microglial activation, and decreased the expression of proinflammatory cytokines, tumor necrosis factor- (TNF-α) and interleukin-1 (IL-1β), 3 days after stroke. Expression of monocyte chemoattractant protein-1 (MCP-1) and macrophage inflammatory protein 1 (MIP-1α), key chemokines in the regulation of monocyte migration and infiltration, were attenuated by the HPI-201 treatment. These findings indicate that pharmacologically induced hypothermia using HPI-201 suppresses the post-stroke neuroinflammatory response, which may contribute to the brain protective effect of PIH therapy.

Title: Protease-Activated anti-inflammatory therapy for ischemic stroke changed distribution and activation of microglia cell

Authors: *S. ZHANG, L. KOJIC, Y. WEN, D. QIANG, F. MORIN, A. O. BEUKERS, K. REN, M. S. CYNADER, W. JIA;
Brain Res. Center, UBC, Vancouver, BC, Canada

Abstract: Regulation of inflammation in the acute stages of stroke is crucial for neuroprotection. We used a genetically engineered AAV that expressed an anti-inflammatory chimeric protein to protect the brain following MCAO. The vector was injected into the brain 4 weeks before the insult and the anti-inflammatory fragment of the chimeric protein was subject to cleavage and release by brain proteases that are activated during ischemic stroke. Lasting and robust neuroprotection was observed in the pretreated rats, and the degree of protection was related to the distance from the center of injection. Here we explore the mechanisms of the anti-inflammatory protection. The expression and distribution of the released protein was examined and we found that our construct was expressed in both neuronal and microglial cells but rarely in astrocytes. The microglial population was strongly affected in ischemic stroke. In the absence of pretreatment, their cell size and density increased markedly in the ischemic area. Pretreatment with the vector largely prevented these changes. These results indicate that our strategy involving prophylactic delivery of an anti-inflammatory construct released by stroke-activated proteases affects activation and behavior of microglia in the ischemic area. The changes in microglia may be at least partly responsible for the neuroprotection observed. Detailed studies are ongoing to examine the signaling pathways in the changed microglia cells.

Title: TREM2 presence in margins of ischemic brain lesions

Authors: C. SEGOVIA[1], C. ZURHELLEN[1], L. BELAYEV[2], *R. C. SWITZER III[1]; [1]NeuroScience Associates, Knoxville, TN; [2]Neurosci. Ctr. of Excellence, Louisiana State Univ. Sch. of Med., New Orleans, LA

Abstract: The microglia cell surface receptor, TREM2 (triggering receptor expressed on myeloid cells 2) has been identified as a marker for an 'anti-inflammatory' state for microglia. Mutations of TREM2 are associated with polycystic disease states (PLOSL) and recently with a small subset of cases with Alzheimer's disease. Lack of TREM2 interferes with the phagocytic role of microglia in the removal plaques in a mouse model of AD. In the role of TREM2 in the removal of apoptotic cells, the sequelae of events depart from those of 'customary' inflammatory means. TREM2 is expressed on microglia cells surface ~300 times more than on astrocytes. In our study to evaluate available antibodies against markers of different activation states of microglia, an anti-TREM2 antibody (Lifespan Biosci.) was applied to brain sections from rats in which the middle cerebral artery had been occluded for 2 hours and then allowed to survive 7 days. At the margin of the ischemic area, where both astrocytes and microglia were prolific and highly hypertrophied, TREM2 positive staining was found as a fibrous meshwork, appearing more astrocyte-like than microglia. Double staining for GFAP and TREM2 displayed co-localization in the TREM2-positive meshwork. That is, TREM2 positive fibers were also positive for GFAP. No TREM2 staining was observed in unaffected regions. Double staining for TREM2 and Iba1 showed cohabitation, but no Iba1 positive profiles were fibrous or co-stained for TREM2. The location of TREM2 at the ischemic zone margin suggests, rather simplistically, a possible merging of phagocytic function of both astrocytes and microglia. In other studies the presence of TREM2 has already been noted in the margin of ischemia/infarction, but not with a co-staining of astrocyte-positive structures. For those studies the TREM2 antibody was from a different source. Other markers associated with TREM2 activation, reactive astrocytes, and microglia should be sought to elucidate this novel appearance of TREM2 immunoreactivity in this model of stroke.

Title: Delayed administration of fingolimod or minocycline attenuates neuroinflammation in a stroke model

Authors: J. KIM[1], M. KAWABORI[1], D. BINGHAM[2], S. WON[1], Z. ZHENG[1], R. BISHOP[1], S. HAWLEY[1], J. LIU[2], R. A. SWANSON[1], *M. A. YENARI[3];
[1]Neurol., [2]Neurosurg., Univ. of California, San Francisco, SAN FRANCISCO, CA; [3]Neurol, Univ. California, San Francisco and San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Stroke is a major cause of long-term disability and death worldwide. Inflammation following stroke has been shown to contribute negatively to stroke outcome. Thus, anti-inflammatory treatments have been studied as a potential therapeutic target. When given within hours of stroke onset, these approaches have been shown in many laboratory studies to be neuroprotective. That is, stroke size and neurological deficits could be improved. Recently, studies have focused on approaches which could be used in the chronic phases of stroke to improve recovery of neurological function (neurorestorative). Here, we studied whether delayed administration of anti-inflammatory agents might prove neurorestorative without being neuroprotective. We first administered two different anti-inflammatory drugs previously shown to be neuroprotective (minocycline and fingolimod) to rats subjected to distal Middle Cerebral Artery Occlusion (dMCAO). Drugs were intentionally delayed by 1 d in order to avoid affecting infarct size (neuroprotection). Behavior tests were performed for 6 weeks after dMCAO to assess changes in motor function. Infarct size was assessed by histology, while immune markers Iba-1 (microglia), CD3 (lymphocytes) and CD11b (microglia) were assessed by immunohistochemistry 4 days after dMCAO. Infarct sizes were not significantly different between vehicle treated and fingolimod and minocycline treated groups. Immunohistochemistry showed reduction in numbers of immune marker positive cells. Numbers of Iba-1 positive cells were decreased by both treatments ($p<0.05$) , CD11b positive cells were decreased in mice treated with fingolimod ($p<0.05$). However, there were no differences in numbers of CD3 positive cells between any of the groups exposed to dMCAO. Behavioral analysis across multiple faculties (sensory, motor, memory) did not show significant improvement in the

minocycline and fingolimod groups. In spite of an anti-inflammatory effect, delayed treatment failed to improve neurological outcome.

Title: Differential roles of microglia and monocytic cells in the ischemic brain

Authors: ***K. GERTZ**[1], N. RICHTER[2], R. UHLEMANN[1], F. KLEMPIN[2], L. STAERCK[2], S. WOLF[2], W. UCKERT[2], H. KETTENMANN[2], M. ENDRES[1], G. KRONENBERG[1]; [1]Charité-Universitätsmedizin Berlin, Berlin, Germany; [2]MDC, Berlin, Germany

Abstract: After brain damage including cerebral ischemia, microglia encounter their peripheral cousins, the monocytes. Despite belonging to the same family, emerging evidence indicates that the one may differ from the other not only in their ancestry but also in their functional characteristics. Here, we set out to study similarities and differences between resident microglia and invading macrophages as regards the brain's longer-term response to ischemia. We used bone-marrow (BM) chimerism and viral vectors to manipulate BM derived cells. CSF-1 receptor-eGFP transgenic mice were used as recipient mice to distinguish resident microglia using green fluorescence. Animals were lethally irradiated and transplanted with red fluorescent BM. After reconstitution BM-chimeric mice were subjected to 30 min middle cerebral artery occlusion (MCAo)/reperfusion. Immunohistological analysis on day 7 after MCAo showed that the contralateral non ischemic hemisphere did not contain any DsRed-labeled cells. Here, resident microglia displayed a typical ramified morphology. By contrast, we found numerous DsRed+ cells and eGFP+ cells within the ipsilateral MCA territory. These cells typically showed an activated morphology with thickening and retraction of branches. Approximately 80% of DsRed+ cells and virtually all eGFP+ cells in the ischemic striatum displayed Iba1 immunoreactivity. Furthermore, we performed patch-clamp recordings of microglia and invading BM-derived cells in the ischemic area. The contralateral side served as control. Interestingly,

intrinsic microglia cells in the stroke area showed an inward current comparable to cultured microglia cells and a very small outward current. The invading red fluorescent cells revealed an additional delayed rectifying outward K+ current after MCAo indicative for a higher activation state. We performed genomic profiling of activated resident microglia and invading macrophages. On day 7 after MCAo, CD11b+ GFP+ microglia and CD11b+ DsRed+ macrophages were extracted from ischemic brain tissue. RNA amplification and microarray analyses were conducted. Statistical analysis yielded 472 transcripts for DsRed>GFP as well as 970 transcripts for GFP>DsRed. Functional grouping analysis using Gene Ontology followed by Fisher's exact test with Benjamini-Hochberg correction was performed. For DsRed>GFP, relevant gene categories included 'innate immunity', 'cell adhesion' and 'T-cell-immunity'. Our data show that the pathogenetic role of brain microglia versus invading monocytic cells diverges markedly after brain ischemia. Invading macrophages show more activation relative to resident microglia.

Title: Post-ischemic tracking and quantification of immune cell migration from the small intestine to lymph nodes and meninges

Authors: *D. BREA, C. BENAKIS, M. MURPHY, C. IADECOLA, J. ANRATHER; Weill Cornell Med. Col., Feil Family Brain and Mind Res. Inst., New York, NY

Abstract: Stroke is an acute neurological disease with a strong inflammatory component. Peripheral immune cells infiltrate the ischemic brain and contribute to stroke pathology. Whereas the identity of brain infiltrating peripheral immune cells has been elucidated, their origin and trafficking after stroke has not been investigated. Given that the intestinal immune system is the largest immune cell compartment in the body, we tested the hypothesis that gut-resident immune cells, specifically lymphocytes, migrate to the brain after ischemic injury. In order to study the trafficking of gut-derived immune cells, we used mice expressing the photoconvertible protein

Kikume Green-Red, which stably shifts its emission from green to red upon exposure to violet light. Mice underwent laparotomy and the distal small intestine (6 cm) was exposed to violet light using a laser light source (405 nm; 4.9 mW). CD45+ immune cells were isolated from the small intestine immediately, 7 and 14 days after photoconversion and analyzed by flow cytometry. Immediately after photoconversion, 33.5±4.2% (n=3) of CD45+ cells expressed the red variant of the protein (KikR). The conversion was equal among different immune cell populations (T cells, B cells, myeloid cells). No CD45+/KikR+ cells were observed in adjacent segments of the small intestine not exposed to violet light and in the peripheral blood. The frequency of CD45+/KikR+ cells decreased at 7 and 14 days (10.5±4.0% and 4.0±0.1% KikR+; n=3). To investigate whether intestinal immune cells traffic to the periphery after cerebral ischemia, we analyzed KikR+ cells in mesenteric and cervical lymph nodes and in the meninges 16 hours after transient middle cerebral artery occlusion. KikR+ B cells, TCRβ T cells and γδT cells were found in the mesenteric, cervical lymph nodes and meninges at days 7 and 14 days after intestinal photoconversion. The frequency of KikR+ cells peaked at day 7 in mesenteric lymph nodes (1.1±0.2% of CD45+, 1.5±0.3% B cells, 0.9±0.2% TCRβ T cells and 0.7±0.3% of γδT cells; n=3) and in cervical lymph nodes (0.9±0.1% of CD45+, 1.3±0.1% of B cells, 0.6±0.1% of T cells and 0.7±0.1% of γδT cells; n=3). Remarkably, the frequency of KikR+ cells was highest in the meninges where 1.2±0.2% of CD45+, 2.5±0.5% of B cells, 0.5±0.1% of TCRβ T cells and 2.1±1.3% of γδT cells were KikR+ 7 days after intestinal photoconversion (n=3). We conclude that the Kikume Green-Red mouse is a useful model to monitor trafficking of intestinal immune cells to secondary lymphoid organs and the CNS. Intestinal B cells, conventional T cells and γδT cells migrate to lymph nodes and to the meninges, where they may play a role in CNS pathologies such as ischemic stroke.

Title: Osteopontin regulates neural stem cells and microglia to support regeneration after stroke

Authors: ***M. RABENSTEIN**[1], S. U. VAY[1], J. HUCKLENBROICH[1], A. WILLUWEIT[2], K.-J. LANGEN[2], G. R. FINK[1], M. SCHROETER[1], M. A. RUEGER[1];

Abstract: Background: Osteopontin (OPN) is a phosphoglycoprotein with important roles in tissue homeostasis, wound healing, immune regulation, and stress responses. It is expressed constitutively in the brain and upregulated during neuroinflammatory responses, e.g. after focal cerebral ischemia. Inflammatory mediators secreted by activated microglia recruit neural stem cells (NSC) towards the ischemic lesion site, thus initiating regeneration. The effects of OPN on both NSC and microglia remain to be elucidated and are, accordingly, subject of this study. We aimed at examining the effects of OPN on fundamental properties of both NSC and microglia. Methods: Primary fetal rat NSC and primary rat microglia were cultured and treated with different concentrations of OPN. Following OPN exposure, both cell types were assessed for survival under (ischemic) stress conditions and for proliferative activity. Further NSC-specific assays included migration and differentiation potential. Microglia were specifically tested for their LPS-induced release of the inflammatory mediators NO, TNF-alpha and IL-6. Results: OPN had positive effects on the survival, proliferation, migration, and neuronal differentiation of NSC. At least in part these effects were mediated via the chemokine receptor CXCR4. In microglia, OPN dose-dependently increased survival under stress conditions, while it did not affect proliferation. Additionally, treatment of microglia with OPN led to a significant reduction of LPS-induced release of NO, TNF-alpha and IL-6. Conclusion: OPN had positive effects on the survival of both NSC as well as microglia under the conditions of (ischemic) stress. At the same time, it promoted neurogenesis from stem cells and reduced the secretion of pro-inflammatory mediators from microglia. Data suggest that OPN regulates both NSC and microglia function to support regeneration after cerebral ischemia.

Title: Age-dependent cytoplasmic TDP- 43 accumulation in cerebral ischemia

Authors: ***S. THAMMISETTY**[1], J. KRIZ[2], F. CALON[3];
[1]faculty of pharmacy, CRIUSMQ, Univ. Laval, Quebec, QC, Canada; [2]Dept. of Psychiatry and Neuroscience,, [3]Fac. of Pharm., Univ. Laval, Quebec, QC, Canada

Abstract: Introduction: The biological role of TDP43 in the brain is not well understood and it has been detected recently in pathological inclusions in the cytoplasm and nucleus of both neurons and glia of ALS and fronto- temporal dementia as well as in Alzheimer's disease suggesting a role in inflammation induced neurodegeneration. Ischemic stroke is the third leading cause of death in western industrialized countries. Experimentally and clinically, stroke is followed by acute and prolonged inflammatory responses. Our initial studies revealed that as in chronic neurodegeneration, ischemic injury is associated with a long term and age-dependent cytoplasmic accumulation of TDP-43. Because stroke represents a major risk factor for development of Alzheimer's style dementia later in the life we propose that TDP-43 may play a role. Methods: We used WT mice as well as transgenic TDP43A315T mice. The stroke was induced by middle cerebral artery occlusion followed by different reperfusion time periods. *In vivo* bioluminescence imaging: The images are taken using IVIS 200 imaging system and 20 min prior to the imaging session mice will administer with luciferine intraperitoneally (150mg/kg body weight). Immunohistochemistry: paraformaldehyde fixed sections are washed with PBS (1X) for 3time, blocked for 1 hr at room temperature and Primary antibody incubation is carried out overnight, followed by an exact Alexa Fluor 488 or 594 secondary antibodies for 2hr at room temperature. Finally sections are observed under microscope. Protein analysis of the brain lysates are carried out by western blot. Results: Immunohistochemistry data and western blot analysis revealed an age-dependent shift of TDP-43 protein into the cytoplasm after stroke in neurons as well as in glial cells. The aging was also associated with an increase in cytoplasmic TDP-35 fragment involved in the formation of aggregates. *In vivo* imaging data showed there is an up-regulation of TLR2 response in TLR2-TDP43A315T double transgenic mice. Conclusion: Our results revealed a long term and age -dependent accumulation of the TDP-43/TDP-35 protein in the cytoplasm of neurons and some glial cells. Further analysis using transgenic models revealed that overexpression of the human TDP-43 leads to an increase in post-ischemic inflammatory and significant increase in ischemic lesions. Taken together our results suggest a role of TDP-43 in modulation of age-dependent neuroinflammation.

Title: Interleukin-4, which promotes alternative activation of microglia, increases neutrophil infiltration and exacerbates neuron damage if injected into the brain at the onset of ischemia

Authors: *S. LIVELY[1], S. HUTCHINGS[2], L. C. SCHLICHTER[1];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Natl. Univ. of Ireland Galway, Galway City, Ireland

Abstract: After stroke, the CNS undergoes a prolonged inflammatory response that involves primarily three innate immune cell types: resident microglia and blood-derived macrophages and neutrophils. In principle, microglia and macrophages can undergo complex activation processes and display a range of functions from cytotoxic to reparative. It is generally thought that an initial pro-inflammatory response is followed by alternative activation processes that reduce inflammation and promote repair. Experimentally, alternative activation is elicited by the cytokine, interleukin-4 (IL-4). Here, we tested the hypothesis that alternative activation will be beneficial at early times after transient focal ischemia. We stereotaxically injected the vasoconstrictor, endothelin-1, into the rat striatum to induce transient focal ischemia, with or without co-injecting IL-4, and then quantified several aspects of inflammation and damage to neurons and white matter in the ischemic infarct at 1, 3 and 7 days. In the damaged ipsilateral striatum, IL-4 increased transcript levels of several genes associated with alternative activation: ARG1, CD163, CCL22, IL-4rα, STAT 6. However, IL-4 treatment did not reduce the extent of white matter injury, which was indicated by reduced myelin basic protein (MBP) staining and increased degraded-MBP staining. Nor did IL-4 reduce the density of activated microglia/macrophages (based on Iba1 staining and morphology) that infiltrated the ischemic core or the proportion that were phagocytic (ED1-labeled). Surprisingly, at 1 day after ischemia, the infarct of IL-4 treated rats had increased numbers of ED1-positive neutrophils (stained for polymorphonuclear leukocyte antigen), which spatially and temporally corresponded with increased neurodegeneration (FluoroJade B labeling). Because VEGF expression increased after IL-4 treatment, we examined blood vessel architecture and BBB breakdown: no differences were apparent in the treated rats. Together, our results suggest that skewing the brain from a pro-inflammatory classical-activation state to an anti-inflammatory alternative-activation state at the onset of ischemia might not be beneficial.

Title: Gestational inflammation and neonatal arterial ischemic stroke, a causal connection?

Authors: *C. GUIRAUT[1], N. CAUCHON[1], M. LEPAGE[1], G. SEBIRE[1,2];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Mc Gill Univ., Montreal, QC, Canada

Abstract: Neonatal arterial ischemic stroke (AIS) affects about 1 out of 3000 newborn per year. It leads to severe complications such as hemiplegic cerebral palsy and/or cognitive impairments. The large cerebral arteries from the anterior system, namely the intra-cranial carotid bifurcation, are the most affected, the ischemic stroke being located in its territory in 85% of cases. The classic pathophysiological hypothesis postulated that the arterial occlusion is caused by emboli from placental origin. However, this pathophysiological mechanism is still unsettled. A new pathophysiological perspective emerged from the epidemiological association between gestational inflammation and neonatal stroke (e.g. prolonged rupture of membrane or chorioamnionitis). We hypothesize that materno-foetal inflammation, induced by gestational exposure to pathogens, leads to a site-specific vasculitis affecting the carotid bifurcation and then triggers a focal thrombosis. Material and methods: Dams were injected with saline or lipopolysaccharide (LPS) from Escherichia coli (200 µg/kg/12h) between gestational day (G) 21 and 22. Brains were harvested at G21, G22 and postnatal day 1 (P1). At P1, a prothrombotic stress (transcutaneous photothrombosis) was applied on middle cerebral arteries to compare its susceptibility to thrombosis between LPS-exposed or unexposed pups. Immunohistochemistry and ELISA detected maternal, placental and fetal/neonatal inflammatory markers. Results: Our results showed a maternal, placental and fetal inflammation mediated by IL-1beta, TNF-alpha and MCP-1. These inflammatory mediators were detected in maternal blood, placentas, fetal blood and fetal cerebral arteries. The arterial wall inflammation correlated with the distribution of human neonatal AIS: intra- vs extra-cranial and anterior vs posterior cerebral arteries showed distinct inflammatory phenotypes. Pups exposed to LPS+photothrombosis are more susceptible to AIS and subsequent motor impairments than those exposed to saline+photothrombosis.

Conclusion: Preliminary results from our new pre-clinical model support our hypothesis of increased susceptibility of anterior cerebral arteries to gestational inflammation, and open a new vasculitic pathophysiological avenue for neonatal stroke.

Title: Salvia miltiorrhiza protects white matter and the hippocampus from damage induced by chronic cerebral hypoperfusion

Authors: ***M.-S. KIM**[1,2], J. BANG[3], J. LEE[1], H. KIM[4], J.-S. HAN[2], W. JEON[1]; [1]KM Convergence Res. Div., Korea Inst. of Oriental Med., Daejeon, Korea, Republic of; [2]Biol. sciences, Konkuk Univ., Seoul, Korea, Republic of; [3]Dept. of Intrnl. Med., Keimyung Univ., Daegu, Korea, Republic of; [4]Col. of Pharm. and Inst. of Pharmaceut. Res., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: ***Ethnopharmacological relevance:*** *Salvia miltiorrhiza* (SM), an herbal plant, is traditionally used in the treatment of cardiovascular and cerebrovascular diseases in Asian countries. SM has multiple biological effects including anti-inflammatory activity. However, no studies have been reported about the anti-inflammatory effects of SM on chronic cerebral hypoperfusion in white matter and the hippocampus. ***Aim of the study:*** The present study is aimed at investigating the effects of SM in rats with chronic cerebral hypoperfusion. ***Materials and methods:*** Chronic cerebral hypoperfusion was induced in male Wistar rats by permanent bilateral common carotid artery occlusion (BCCAo). The rats were divided into 3 groups: sham-control, BCCAo treated with vehicle, and BCCAo treated with SM. Vehicle or SM (200 mg/kg) were administered daily by oral gavage beginning on day 21 after BCCAo and continuing to day

42. Immunohistochemical analyses were used to measure Iba-1-positive microglia and myelin basic protein (MBP) in white matter and hippocampal tissue. In addition, the expression levels of proinflammatory cytokines, including TNF-α, IL-1β and IL-6, and the toll-like receptor (TLR) pathway in the hippocampus, were analyzed by western blot. ***Results:*** Administration of SM attenuated the activation of microglial cells in the white matter and hippocampus after BCCAo. SM also prevented neuroinflammation after BCCAo by reducing hippocampal levels of TNF-α, IL-1β and IL-6, and increasing the reduced levels of MBP in the white matter and hippocampus. Further, the administration of SM alleviated the up-regulation of hippocampal TLR4 and myeloid differentiation primary response gene 88 (MyD88) in rats with chronic BCCAo. ***Conclusions:*** Our findings suggest that SM may be a promising therapeutic candidate in vascular dementia because of its protective effects against damage to the white matter and hippocampus after BCCAo. ***Keywords:*** *Salvia miltiorrhiza*, Chronic cerebral hypoperfusion, Permanent bilateral common carotid artery occlusion, Myelin basic protein, Toll-like receptor

Title: Targeting ischemic brain injury with cocktail drugs during reperfusion ameliorates delayed neuronal cell death following transient global cerebral ischemia

Authors: *I.-C. I. YU[1], J.-H. YEN[1], P.-C. KUO[1], B. C. HONG-GOKA[2], R. D. SWEAZEY[1], F.-L. CHANG[1];
[1]Indiana Univ. Sch. of Med., Fort Wayne, IN; [2]Alzheimer's & Memory Ctr., Univ. of California, San Francisco - Fresno, Fresno, CA

Abstract: Out-of-hospital cardiac arrest (CA) affects approximately 330,000 people annually in the United States. With advanced cardiac interventions, ischemic brain injury has become the major cause of death and disability for victims of CA. CA disrupts global cerebral circulation, which results in damage to neurons. Many CA survivors who remain in comatose states after successful cardiopulmonary resuscitation, suffer severe damage of the forebrain while having relatively preserved brainstem function. Even conscious survivors may experience deficits in memory, attention, or executive function after discharge. These poor neurological outcomes

indicate an urgent need for targeted therapies. Post-CA brain injury is heterogeneous and multifaceted. We hypothesized that simultaneously targeting multiple injury cascades during the acute phase can suppress early deleterious events and alleviate ischemia/reperfusion (I/R) damage to neurons. We induced transient forebrain ischemia in mice and intravenously administered a cocktail of three drugs to target multiple injury cascades during reperfusion. Our results showed that cocktail drug administered during reperfusion suppressed early neuroinflammatory events as early as 6 hours after I/R. The production of pro-inflammatory cytokine, TNFα, was suppressed in the cortex and striatum of cocktail drug-treated mice. The expressions of chemokines, Ccl2, Ccl3, and Cxcl2, which attract peripheral leukocyte infiltration into the brain, were significantly suppressed. Reduced production of brain chemokines was found to decrease the infiltration of CD45high/CD11b+ leukocytes, including macrophages and neutrophils, at later time points. At the cellular level, we found the reduction of CD86 activation marker in microglia cells isolated from cocktail drug-treated mice 6 hours after I/R. The cocktail drug suppressed activation of primary cultured microglia in response to LPS *in vitro*, as shown decreased induction of TNFα and IL-6. Besides inhibiting different steps in neuroinflammation, early cocktail drug treatment was found to reduce induction of oxidative stress sensor, Sestrin 2, in response to excitotoxicity after I/R. Collectively, we found that suppression of multiple deleterious events during the acute phase alleviated damage to hippcampal neurons at 3 days after I/R. In conclusion, the cocktail drug was able to suppress multiple neuroinflammatory and oxidative insults, and to alleviate neuronal cell death when administered early. Our results demonstrate that early targeting of multiple I/R injury cascades during reperfusion has the potential to improve neurological outcomes for victims of CA.

Title: Blood-borne monocytes amplify inflammation and transform into microglia after LPS sensitized hypoxic-ischemic brain injury in rodent neonates

Authors: *Y.-Y. SUN[1], J. LEE[2], C. BRANDON[3], N. ANTHONY[2], C.-Y. KUAN[1];
[1]Dept of Pediatrics (Neurology), [2]Emory Univ. Sch. of Med., Atlanta, GA; [3]The Georgia Inst. of Technol., Atlanta, GA

Abstract: The brain resident microglia have a mesodermal ontogenic origin, but the relationship between microglia and blood-borne monocytes in the neonatal period, with and without injury, remain contentious. Here we use transgenic monocyte- and microglia-reporter mice and adoptive transfer of genetically marked monocytes to study this issue. We hypothesize that (1) monocytes convert to the brain microglial pool prenatally, but stop doing so soon after birth in normal conditions; (2) neonatal infection-sensitized hypoxic-ischemic (HI) injury resurrects the influx of monocytes; (3) these invading monocytes amplify inflammatory responses and transform into the brain resident microglia. We report five sets of results. First, in E17 bitransgenic CCR2-RFP; CX3CR1-GFP embryos, monocytes (RFP+), microglia (GFP+), and RFP/GFP-double-positive cells were readily detected between the choroid plexus and subcortical white matter. Time-lapse imaging in brain slices indicated the monocyte-to-microglia conversion at this stage. Second, in postnatal P6 brains, EdU+ amoeboid microglial cells (AMC) at the classic "fountains of microglia" sites comprised exclusively CX3CR1-GFP+, but not CCR2-RFP-negative cells, suggesting greatly diminished monocyte influx after birth. Third, in P10 bitransgenic mice, a large number of CCR2-RFP+ monocytes and CCR2-RFP+/CX3CR1-GFP+ hybrid cells were found in the ipsilateral hemisphere of LPS (lipopolysaccharide)/HI-injured brains. The monocytes and monocyte-derived cells express pro-inflammatory cytokines (e.g. IL-1β and TNFα). Fourth, deletion or pharmacological inhibition of CCR2 (with RS102895) greatly diminished the influx of monocytes and inflammatory responses to LPS/HI brain injury, leading to greater preservation of the neural tissue. Finally, when actin-GFP+/CCR2-RFP+ monocytes were intravenously transferred to LPS/HI-injured mice, the expression of CCR2-RFP was quickly down-regulated, while GFP+ monocytes transformed into AMC-like cells at 3 day, and microglia-like cells at 7 day recovery. Together, these results suggest that the blood-borne monocytes contribute to inflammatory responses to neonatal infection/HI injury, and likely transform into microglia, whose impacts on neural development are yet to be determined.

Title: Systemic immune responses to cardiac arrest in mice

Authors: N. BRANDON[1], H. DOU[2], *Y. XU[1];
[1]Anesthesiol., Univ. Pittsburgh Sch. Med., Pittsburgh, PA; [2]Dept. of Biomed. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX

Abstract: Systemic immune responses to cardiac arrest and resuscitation have both neuroprotective and neurodegenerative effects. Here we examined the time-dependent immune processes in a mouse model of cardiac arrest and resuscitation to map the immune signals and to understand possible pathways for future therapeutic interventions. We hypothesize that cardiac arrest activates specific components of the immune system in a time dependent manner with measurable quantities, which are correlated with the degree of neuronal damage and consequently with functional and behavioral outcomes. Six-minute cardiac arrest was induced in adult male Balb/c mice (Jackson Labs) by an IV injection of a short acting β-blocker (esmolol) along with asphyxia and reversed by a retrograde arterial infusion of oxygenated blood containing a resuscitation mixture of epinephrine, sodium bicarbonate, and heparin. Sham-operated mice had one of their femoral arteries and veins tied off but did not receive drugs other than anesthesia and analgesia. Surgically naïve mice were also used as controls. Bone marrow, blood, spleen, liver and brain were collected on post-surgical days 1, 3, and 5 for flow cytometry and/or histology analyses. In spleen, CD11b+ cells were continuously increased on days 1, 3, and 5 after resuscitation. The ratio of CD4+ to CD3+ T-cells was decreased from 68% of control to 61.25% and 60.25% on days 3 and 5 after resuscitation, respectively. The sham operation slight increased the ratio of CD4+ to CD3+ T-cells to 71%. In bone marrow, cardiac arrest mice exhibited decreases in CD11c+ cells and increases in CD11b+ cells as compared to the naïve and sham controls. The CD4+ and CD3+ T-cells were clearly increased on post-arrest day 3 but returned to the control levels on post-arrest day 5. In both liver and spleen, cardiac arrest resulted in a depletion of CD3+FoxP3+ and CD8+FoxP3+ T-cells, and a significant increase in CD11b+/Ly6C+ inflammatory monocytes/macrophages and CD11b+/Ly6G+ immune suppressor cells on post-arrest days 3 and 5 as compared to the controls. In addition, the cardiac arrest mice showed decreased CD11b+Ly6C+F4/80+ tissue macrophages in the liver and spleen on post-arrest days 3 and 5. We conclude that specific immune responses to cardiac arrest and resuscitation can be identified, allowing us to design new therapeutic strategies to target immune system as needed. This work was supported by a grant from the NIH (R01GM114851).

Title: Modification of commensal gut bacteria induces protection from ischemic brain injury

Authors: *C. BENAKIS, D. BREA, J. MOORE, M. MURPHY, G. SITA, G. RACCHUMI, C. IADECOLA, J. ANRATHER;
The Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Commensal gut bacteria have a profound impact on the host physiology, metabolism and immune function and influence disease processes affecting a wide variety of organs, ranging from the gut to the brain. Given that intestinal microbiota can impact physiology and pathology of the CNS, we sought to determine whether modification of the intestinal flora affects the outcome of ischemic brain injury in a mouse model of transient middle cerebral artery occlusion (MCAo). To modify the gut microbiota composition, C57Bl/6 male mice received a cocktail of antibiotics in the drinking water that target a broad spectrum of bacteria phyla (ampicillin, metronidazole, neomycin, and vancomycin; AMNV). Four weeks later, fecal bacterial DNA was analyzed by quantitative PCR of the 16S ribosomal RNA gene. To rule out off target effects of antibiotics, their administration was discontinued three days prior to MCAo. Infarct volume was measured 3 days after ischemia in cresyl violet stained brain sections. AMNV treatment resulted in a marked reduction of fecal bacterial DNA ($6x10^8$ vs $2x10^4$ copies/mg fecal mass; n=5-10; $p<0.001$) and a significant decrease of the infarct volume (36±19 mm^3, n=12, mean±SD) compared to control mice (54±21 mm^3, $p<0.05$, n=12). Recolonization of AMNV-treated mice with wild type flora for two weeks reestablished the number of fecal bacterial copies to control levels ($1x10^9$ copies/mg; n=4) and abolished the observed neuroprotection (infarct volume: 72±18 mm^3, $p>0.05$ from controls; n=8). Interestingly, the protective effect was not due to additive effects of different antibiotics, because treatment with V or A alone reduced infarct volume as much as AMNV treatment (controls: 51±24 mm^3, V: 37±23 mm^3, A: 20±7 mm^3; n=15-23/group). The profound neuroprotective effects of intestinal dysbiosis could not be attributed to differences in the levels of cerebral ischemia because cerebral blood flow reduction produced by MCAo was comparable in AMNV-treated mice and controls (controls: 94±2 %, AMNV: 92±2 %, $p>0.05$; n=12/group). Similarly, AMNV-treatment did not reduce the brain lesions produced by neocortical injection of NMDA (20nmol in 140nl) (controls: 3±1 mm^3,

AMNV: 4±1 mm^3, p>0.05; n=5-7/group), suggesting that the reduction of ischemic injury is not mediated by inhibition of excitotoxicity. The composition of intestinal microbiota has a substantial impact on stroke outcome. The mechanisms of the protective effect remain to be defined, but they are unlikely to include vascular effects or protection from glutamate excitotoxicity. Efforts to modify the intestinal flora may provide new preventive approaches to reduce ischemic brain injury in high-risk patients.

Title: Dysregulated cytokine released by activated microglia in the hippocampus of diabetes associated recurrent hypoglycemic rat brain exacerbate ischemic damage

Authors: *V. SHUKLA, A. K. REHNI, K. R. DAVE;
Neurology, Miller School of Medicine, University of Miami, Miami, Fl

Abstract: The Dysregulated innate immune response due to microglial activation in the brain exhibit deleterious effects. Earlier published study from our laboratory demonstrated that recurrent hypoglycemia (RH) in a rat model of insulin-dependent diabetes exacerbates cerebral ischemic damage (Stroke, 42, 2011, 1404). We therefore aimed to determine potential involvement of inflammatory mediators released by activated microglia in cerebral ischemic damage in diabetic rats exposed to RH. Naïve and streptozotocin (Stz) diabetic rats were used for the study. To correct hyperglycemia, a subcutaneous insulin pellet was employed about 2 weeks after injection of Stz. Three experimental groups were examined: (1) naïve (non-diabetics, n = 5), (2) insulin-treated diabetics (ITD, n = 3), and (3) ITD+RH (diabetics on insulin therapy experiencing RH, n = 5). RH was induced once a day for 5 consecutive days. Global cerebral ischemia (8 min, 2VO + hypotension) was induced the day after the last hypoglycemia treatment. Animals were euthanized at 24 h post-reperfusion, brains were excised aseptically, and hippocampus were separated. Hippocampal homogenates were centrifuged at 20,000 × g for 15 minutes. The supernatants were used for the study. Western blot was performed using anti-IL-10,

anti-TNF-α and anti-Iba-1 antibodies. β -actin was used as a loading control. Statistical evaluation of the data was performed using ANOVA followed by Tukey's post hoc test. We observed marked decrease in IL-10 protein level in hippocampus of ITD+RH group compared to ITD (33%) and naïve group (37%). This decline was significant ($p < 0.05$) relative to the naïve group. A significant marked increase (70%) in the level of TNF-α was observed in the hippocampus of ITD+RH group compared to the naïve group. The levels of TNF-α were higher (19%) in ITD+RH group compared with ITD group. However, the difference was not statistically significant. Compared to the naïve group a significant ($p<0.05$) increase in Iba-1 level was observed in the hippocampus of ITD+RH (37%) as well as ITD (42%) group. We are currently increasing number of observations in each specific groups to further confirm our results. The enhanced expression of TNF-α in ITD+RH group might be responsible for exaggerating the ischemic damage in this group. Understanding the mechanism by which recurrent hypoglycemia exposure is involved in post-ischemic dysregulation of cytokines (increased TNF-α production and decreased IL-10 response) may help lower the ischemic damage in diabetes.

Title: Recombinant tissue plasminogen activator promotes, and progesterone attenuates, microglia/macrophage M1 polarization and recruitment of microglia after MCAO stroke in rats

Authors: S. WON[1], J. LEE[2], D. STEIN[3], *L. WEI[1];
[1]Dept. of Anesthesiol., [2]Dept. of Pathology and Immunol., [3]Dept. of Emergency, Emory Univ., Atlanta, GA

Abstract: Background: Tissue plasminogen activator (tPA) is one of the few approved treatments for stroke, but its effects on the phenotype of microglia/macrophages are poorly understood. One of its side effects is an increase in the inflammatory response leading to neuronal cell damage and death in the ischemic cascade after stroke. Injury-induced activated microglia/macrophages can have dual functions as pro-inflammatory (M1) and anti-

inflammatory (M2) factors in brain injury and repair. Recent studies show that progesterone (PROG) is a potent anti-inflammatory agent which affects microglia/macrophage expression after brain injury. Purpose: We examined the interaction of tPA-induced expression of microglia/macrophage phenotypes and PROG's anti-inflammatory effects. Results: tPA treatment increased the recruitment of microglia/macrophages, the polarity of M1 reactions, the expression of MIP-1α in neurons and capillaries, and the expression of MMP-3 compared to vehicle, and PROG modulated these effects. Conclusions: PROG treatment attenuates tPA-induced inflammatory alterations in brain capillaries and microglia/macrophages both *in vivo* and *in vitro* and thus may be a useful adjunct therapy when tPA is given for stroke.

Title: Age-dependent microglial responses to hypoxia-ischemia in the developing brain

Authors: A. WALDMAN[1], V. CHANANA[1], L. COVERT[1], T. DEWALL[1], P. ROWLEY[1], E. UDHO[1], U. CIKLA[1], G. GAVIN[1], D. KINTNER[1], P. CENGIZ[1,2], *P. FERRAZZANO[3,2]; [1]Waisman Ctr., [2]Pediatrics, Univ. of Wisconsin, Madison, WI; [3]Pediatrics, Waisman Ctr., Madison, WI

Abstract: Background: The microglial response plays an important role in injury and recovery after hypoxia-ischemia (HI) in the developing brain. We have previously described regional and age-dependent differences in the microglial response to HI: infant mice (P9) demonstrated a more vigorous microglial activation and proliferation compared to juvenile mice (P30). The aim

of the current study was to assess for differences in the effect of microglial suppression on HI-induced brain injury in P9 and P30 mice. We hypothesized that administration of minocycline after HI would result in suppression of microglial activation in both age groups, and would improve brain injury after HI in younger mice. **Methods**: HI was induced in P9 and P30 mice by unilateral carotid artery ligation and exposure to 10% O2 for 50 minutes. Minocycline or vehicle was administered at 2 hours and 24 hours post-HI. Microglia responses and neuronal injury were characterized using flow cytometry and immunostaining at 2 days and 9 days post-HI. T2-weighted MRI was performed at 9 days and 60 days post-HI to assess for HI-induced cerebral volume loss. HI-induced impairments in memory/learning were assessed using Morris Water Maze testing at 2 months post-HI. **Results**: Minocycline administration effectively suppressed the microglial response in P9 and P30 mice at day 2 post-HI. In contrast, at day 9 post-HI, minocycline-treated P9 mice demonstrated persistent suppression of microglia activation while P30 mice demonstrated a rebound increase in microglial response. P9 minocycline-treated mice demonstrated improved injury at days 2 and 9 post-HI, however no improvement in cerebral atrophy or Morris-Water Maze was seen at 60 days post-HI. Conversely, while minocycline treatment did not improve the early injury in P30 mice, these mice did demonstrate significant improvement in cerebral atrophy and Morris Water Maze performance at 60 days post-HI. **Conclusions**: The effect of microglial suppression on HI-induced brain injury varies with age. Neonatal minocycline-treated mice demonstrate an early improvement in injury which is not sustained out to 60 days post-HI, while P30 treated mice demonstrate sustained improvements in cerebral atrophy and memory. This suggests that the late microglial response seen in P30 mice but not P9 mice is neurotrophic and contributes to the observed improvements in cerebral atrophy and neurologic function. Ongoing studies will assess for age-dependent differences in microglia polarization after HI which may account for developmental differences in susceptibility to HI, and the therapeutic effect of suppressing neuroinflammation after injury in the developing brain.

Title: Eriodictyol improves memory deficits in pMCAO mice by anti inflammatory pathways

Authors: A. P. F. M. MENDONCA[1], E. O. FERREIRA[1], N. M. R. LIMA[1], M. Y. S. D. FERNANDES[2], K. R. T. NEVES[2], A. A. FONTELES[2], F. A. V. LIMA[2], *G. M. ANDRADE[3]; [1]Med. Sci. Dept., [2]Physiol. and Pharmacol. Dept., Federal Univ. of Ceara, Fortaleza, Brazil; [3]Federal Univ. Ceara, Fortaleza- Ceara, Brazil

Abstract: Cerebral Ischemia (CI) is a common disease and one of the greatest causes of death and disability worldwide. The lack of glucose and oxygen to neuronal tissue leads to a series of events inflammations culminating in neuronal death. The use of medicinal plants and flavonoids has been widely spread for the treatment of neurodegenerative diseases. Eriodictyol is a flavonoid isolated from the chinese herb Dracocephalum rupestre with anti-inflammatory property proven. Thus, the present study was designed to explore whether eriodictyol has neuroprotective effects against neuronal damage, motor and memory deficits induced by permanent middle cerebral artery occlusion (pMCAO) in mice. Animals were orally treated with eriodictyol (1, 2 and 4 mg/kg) or vehicle (saline) at 30 min before pMCAO, 2 hours after and daily during 3 days. The parameters studied were infarcted brain area, sensorimotor deficit, exploratory activity, working and aversive memory, TNF-α, iNOS and GFAP immunoreactivity and neuronal viability. In vehicle-treated mice, pMCAO resulted in significant cerebral infarction, higher neurological deficit score, decreased exploratory activity and memory deficits. Also were observed an increase on TNF-α and iNOS positive cells and a significant astrogliosis. The treatment with eriodictyol reduced infarct volume, improved the neurological and memory functions, decreased TNF-α, iNOS and GFAP expression and prevented neuronal death ischemic brain injury. Therefore, the results demonstrated neuroprotective effect of the eriodictyol against permanent focal ischemia-induced memory deficits, by a mechanism that involve this anti-inflammatory properties.

Title: The effect of transcutaneous vagus nerve stimulation on inflammatory markers in acute stroke

Authors: ***I. AY**[1], B. SIMON[2], H. AY[1];
[1]Dept Radiol, Mass Gen. Hosp., Charlestown, MA; [2]electroCore LLC, Basking Ridge, NJ

Abstract: Introduction: Cervical vagus nerve stimulation (VNS) reduces tissue injury after middle cerebral artery occlusion (MCAO) in rats. The exact mechanism of the VNS-induced central anti-ischemic effect is unknown. Systemically, VNS attenuates inflammation via activation of the cholinergic system and concomitant inhibition of pro-inflammatory cytokine production. We hypothesized that in ischemic brain VNS-induced neuroprotection is partly mediated via inhibition of pro-inflammatory cytokines. Methods: Right MCAO was induced by 2 hour filament occlusion in spontaneously hypertensive rats. Ipsilateral VNS (bursts of 1 msec duration, 5kHz sine waves repeated at 25 Hz; 2 min long stimulation, delivered at every 10 min for 1 hour) was initiated 30 min after MCAO using a gammaCore, non-invasive nerve stimulator placed on the skin overlying the vagus nerve in the neck. Animals were euthanized either 3 hours or 24 hours after MCAO. Immunohistochemistry was used to assess brain TNF-α, high mobility group box protein 1 (HMGB1), IL-1β, IL-6, and microglial markers Iba1 and CD68 in control (n=4 per time point) and VNS groups (n=4 per time point). In separate cohorts, we investigated the effect of VNS delivered every 15 min either via right (2 min long; n=8) or right/left (1 min long on each side; n=8) stimulation on infarct volume. In control animals (n=8) the right hindlimb was stimulated. Rats were euthanized 7 days later to determine infarct volume. Results: VNS significantly decreased the ischemia-induced increase in TNF-α staining both at 3 hours and 24 hours ($p<0.05$). VNS significantly increased HMGB1 staining at both time points ($p<0.05$). In control animals, Iba1-positive cells and CD68-positive cells were detectable at 3 hours and 24 hours after MCAO, respectively. VNS decreased the number of Iba1- and CD68-positive cells at 24 hours after MCAO ($p<0.05$). Although there were fewer IL-1β and IL-6 positive cells in nVNS-treated animals, the difference was not significant. Animals treated with 15 min-long nVNS had smaller infarct volumes compared with control; reduction was 29% after right nVNS and 26% after right/left nVNS ($p<0.05$ for both). Conclusion: This study suggests that anti-inflammatory mechanisms via inhibition of TNF-α, HMGB1, and microglia activation play a role in the protective effect of nVNS against ischemic tissue damage.

Title: Examining cannabinoid neuroprotection, inflammation and hippocampal function in a mouse model of stroke

Authors: *D. J. KALAMARIDES, P. B. SIEGELE, K. M. KING, B. K. WELLANDER, R. F. TUMA, S. J. WARD, L. G. KIRBY;
Ctr. for Substance Abuse Res., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Common to many diseases, including stroke, multiple sclerosis, Alzheimer's disease and traumatic brain injury, are pathological inflammatory responses leading to neuronal dysfunction and cell death. We have previously demonstrated that cannabinoid receptor 2 agonists reduce infarct size and microglial activation in a mouse model of stroke, indicating neuroprotective effects on the primary infarct as well as on secondary inflammatory responses. To examine the broader impact of secondary inflammation following stroke, we extended our analysis to include behavioral and electrophysiological measures in the hippocampus, a brain region spared by the primary infarct. C57Bl/6 mice were exposed to a focal photothromotic stroke centered at the primary somatosensory cortex and stroke damage was quantified with tetrazolium chloride staining to determine infarct volume and immunohistochemistry for markers of astrocytes and microglia. Stroked mice showed infarct volumes limited to cortical areas and increased expression of microglia compared to sham surgical controls. In other subjects, hippocampal function was assessed behaviorally two days after the stroke or sham surgery with the spatial object recognition (SOR) test of hippocampal-dependent spatial memory. One to two days after behavioral testing, animals were euthanized and hippocampal slices were prepared for assessment of hippocampal long-term potentiation (LTP), an electrophysiological measure of long-term synaptic plasticity and a cellular correlate of learning and memory. Though the hippocampus was spared by the primary infarct, stroked mice showed both memory impairment in the SOR test and decreased hippocampal LTP. These data indicate that secondary effects of the stroke such as inflammation may produce neuronal damage beyond the infarct zone, impacting hippocampal function. Studies are currently underway to compare these effects of

stroke in wild-type mice to mice with constitutive genetic deletion of cannabinoid receptors and may highlight the cannabinoid system as a potential therapeutic target in a wide range of inflammatory disease states.

Title: Shaoyao-gancao decoction ameliorates neurodegeneration in cerebral ischaemia-reperfusion by inhibiting the inflammation

Authors: Y. ZHANG[1], J. YANG[1], X. JIA[1], H. DING[2], G. YAN[3], Q. LI[1], Z. XU[4], J. WANG[5], *Z.-J. KE[2];

Sch. of Med., Shanghai, China; [4]Shanghai Punan Hosp., Shanghai, China; [5]Shanghai Dahua Hosp., Shanghai, China

Abstract: Stroke rehabilitation is to reduce the neurodegeneration and restore normal life by regaining and relearning the skills of everyday living, which neurogenesis is the key process. Inflammation plays an important role in ischemic stroke-reduced neurodegeneration. Controlling inflammation, ameliorating neuronal death and promoting neurogenesis are important in stroke rehabilitation. Shaoyao-gancao decoction (SGD) consists of Paeonia lactiflora and Glycyrrhiza uralensis, a well-known traditional Chinese medicine prescription, is sourced from the Chinese Medical Classics text_Shanghan Lun, which was used for relieving pain and spasmolysis. Modern pharmacological studies have demonstrated that the main active ingredient of SGD are paeoniflorin and liquiritin, which prevents ischemia-induced loss of neuron, and inhibits activations of microglia and astrocytes in the brain by regulating MAPK and NF-κB signalling pathway. However, little is known about the potential mechanisms of the SGD for stroke rehabilitation, which is used in clinic for Chinese patients. To investigate the mechanism of Shaoyao-gancao decoction in stroke rehabilitation, rats underwent right middle cerebral artery

occlusion for the cerebral ischemia-reperfusion (CI/RP) model. The Bederson scale was used to evaluate behavioral indexes after CI/RP; expression of IL-1β, TNF-α, MCP-1, IL-10, RANTES, VEGF and TGF-β1 were measured by Bio-Plex Magpix System; neurons were stained by Nissl staining and NueN immunohistochemistry staining; Iba1 and GFAP immunohistochemistry staining were used for measuring microglia and astrocytes separately. The results demonstrated that SGD improved the behavioral recovery, increased the number of Neun-positive cells, decreased the number of Iba1- and GFAP-positive cells in brain after CI/RP. These results suggest that Shaoyao-gancao decoction helps stroke rehabilitation by protecting neuron from CI/RP injury, and inhibiting the inflammation.

Title: Targeting thalamic circuits during deep brain stimulation for traumatic brain injury

Authors: ***A. JANSON**[1,2], N. SCHIFF[3], J. BAKER[3], K. PURPURA[3], J. HENDERSON[4], B. RUTT[5], C. R. BUTSON[1,2];
[1]Scientific Computing and Imaging Inst., Salt Lake City, UT; [2]Bioengineering, Univ. of Utah, Salt Lake City, UT; [3]Brain and Mind Res. Inst., New York, NY; [4]Neurosurg., [5]Radiology, Stanford Univ., Stanford, CA

Abstract: Traumatic brain injury (TBI) is a broad term describing an array of complex symptoms and disabilities that can lead to coma or decreased levels of consciousness. Central thalamic deep brain stimulation (DBS) has been demonstrated to modulate arousal in subjects with TBI[1], and the medial dorsal tegmental tract (DTTm) is a specific pathway that has recently been implicated in this response[2]. However, surgical placement of the DBS leads is often guided by anatomical atlases that identify nuclei rather than detailed pathways. The goal of this study is to use computational models to identify DBS lead locations that cause robust modulation of the DTTm. We used computational models to quantify activation of the DTTm using a previously published approach[3]. The original modeling pipeline was adapted to include segmentation of the central lateral (CL) nucleus of the thalamus using a white-matter-nulled MRI sequence, as well as identification of the DTTm using diffusion weighted MRI followed by tractography.

Activation of DTTm was assessed using a finite element model (FEM) of bipolar stimulation between two adjacent electrode contacts on a Medtronic 3387 lead. Activating function density in the DTTm was measured for a range of lead locations. We identified a gradient of DTTm activation that was strongly dependent on electrode location within the CL (Figure 1). The most robust activation occurred for anterior lead locations where the DTTm fibers converge. We anticipate that analysis of fiber activation and lead location will guide future preoperative planning and postoperative DBS programming to treat TBI. Further, we anticipate that a combination of modeling and *in vivo* testing will elucidate the mechanisms of DBS in ways that were not previously possible.

Deleted: *in vivo*

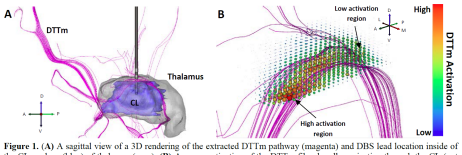

Figure 1. (**A**) A sagittal view of a 3D rendering of the extracted DTTm pathway (magenta) and DBS lead location inside of the CL nucleus (blue) of thalamus (grey). (**B**) Average activation of the DTTm fiber bundle projection through the CL (not shown) with respect to lead location. Each sphere in the image represents a single lead location with 0.5mm resolution. Both the size and color of each sphere indicate the degree of DTTm activation according to the colorbar.

Title: Circuit-level modulation of arousal using central thalamic deep brain stimulation

Authors: ***C. R. BUTSON**[1,2], A. JANSON[2], A. QUINKERT[3], J. BAKER[4], K. PURPURA[4], N. SCHIFF[4], D. PFAFF[3];
[1]Neurol. & Neurosurg., Univ. of Utah, Salt Lake City, UT; [2]Scientific Computing & Imaging (SCI) Inst, Univ. of Utah, Salt Lake City, UT; [3]Rockefeller Univ., New York, NY; [4]Weill Cornell Med. Col., New York, NY

Abstract: Deep brain stimulation (DBS) of the central thalamus (CT) has been shown to be promising for the treatment for traumatic brain injury (TBI) (Schiff et al, 2007). However, we do not yet have a detailed understanding of the mechanisms of CT-DBS or the stimulation targets. Previous studies have examined changes in behavior in both mouse and primate models. Bilateral CT-DBS has been performed in both intact (non-injured) and TBI mice (Quinkert & Pfaff, 2012; Quinkert et al, 2010). In tandem with these experiments, non-human primate studies have been conducted to identify neural circuits that robustly modulate arousal during CT-DBS. Studies in both animals have demonstrated that CT-DBS can regulate arousal, and the primate studies suggested that the degree of arousal is modulated by stimulation of the specific fiber pathways including the medial dorsal tegmental tract (DTTm) (Baker et al, submitted). In this study we used computational models to identify circuits that mediate behavioral improvement in the mouse. Behavior was measured using counts (whole body movement, measured as a changing field strength between the subcutaneous transmitter and the receiver beneath the mouse's cage), horizontal activity (fidgeting, all infrared beam breaks in the horizontal plane), and total distance (ambulation, non-repeating beam breaks in the horizontal plane). Stimulation location is a synergistic combination of electrode location, which was determined from post-mortem histology, and stimulation parameters. We used previously published computational modeling methods to predict the volume of tissue activated (VTA) during CT-DBS for each brain hemisphere in each animal (Butson et al, 2007). We then combined the animal-specific models with behavioral outcomes to generate a probabilistic stimulation atlas (PSA) as previously described (Butson et al, 2011). The purpose of the PSA is to identify regions where DBS-induced activation is significantly correlated with changes in behavioral outcome. Lastly, we used the Allen Connectivity Atlas to identify projections that passed through the regions that where stimulation was most strongly correlated with behavioral improvement. We found that those with the largest projection volumes were primary and secondary motor areas, somatosensory cortex and nucleus accumbens. Our results suggest that stimulation location can play an important role in outcomes for CT-DBS, information that may be useful in further development of human therapy for TBI. Further, our approach can enable quantitative comparison of stimulation targets across multiple species including mice, non-human primates and humans.

Title: Sex-dependent changes in depression and facial allodynia in the chronic period following mild TBI in the mouse

Authors: S. ECKERT, J. SHAW, S. KODURI, A. HERMANN, R. PRASAD, R. ESPANA, *R. RAGHUPATHI;
Drexel Univ. Col. Med., Philadelphia, PA

Abstract: Patients who have sustained a mild TBI suffer from both somatic (headache, dizziness, nausea, fatigue, sleep disturbances) and neuropsychiatric (cognitive deficits, anxiety, depression) symptoms. The effect of gender on response to and outcome after TBI has not received substantive attention both in clinical studies and in pre-clinical animal models. Importantly, a recent study suggested that men and women exhibit different behavioral deficits following sports-related concussions. In the present study, we used a well-established mouse model of mild TBI and assessed facial allodynia and depressive behavior at 4 and 8 weeks post-injury in male and female C57Bl/6 mice. Compared to their sham-injured counterparts, brain-injured male mice exhibited depressive-like behavior (using the forced swim test) at 4 and 8 weeks post-injury (Injury effect, $p<0.001$); female brain-injured mice were not different from their sham-injured counterparts. To test whether altered dopamine signaling may be the basis for this depression-like behavior, fast scan cyclic voltammetry was used to determine dopamine release kinetics in the nucleus accumbens following stimulation of the ventral tegmental area. Whereas baseline evoked dopamine release was not affected in either brain-injured male or female mice compared to sham-injured mice, cocaine-stimulated dopamine concentration in the nucleus accumbens was greater in the brain-injured male mice compared to their sham-injured counterparts ($p<0.01$), suggestive of a decreased functionality of the dopamine transporter.

Female brain-injured mice exhibited increased sensitivity to periorbital stimulation (using the von Frey filament test) compared to sham-injured mice at both 4 and 8 weeks post-injury (injury effect, $p<0.001$), suggestive of post-traumatic headache; male brain-injured mice were not different from their sham-injured counterparts. Together, these data are indicative of sex-dependent differences in the response to mild TBI and underscore the importance of evaluation of behavioral and biochemical measures in the chronic post-traumatic period.

Title: Determining mean heart rate at symptomatic threshold in post-concussion syndrome

Authors: ***M. LETOURNEAU**[1], C. ALARIE[2], D. MOORE[2], D. ELLEMBERG[2]; [1]Kinesiology, Neurodevlab, Univ. of Montreal, Montreal, QC, Canada; [2]Kinesiology, Univ. of Montreal, Montreal, QC, Canada

Abstract: Recent research demonstrates that aerobic exercise protocols are promising for rehabilitating individuals suffering from post-concussion syndrome. However, exercise protocols usually include the frequent triggering/exacerbating of symptoms in order to track progress and adjust exercise intensity. Unfortunately, triggering/exacerbating symptoms can impede recovery and deter adherence. Therefore, we sought to provide a less traumatic, more efficacious and therapeutic use of exercise by establishing the threshold at which symptoms are triggered/exacerbated. Doing so will enable the avoidance of exercise induced symptoms and allow the personalization of aerobic exercise protocols. Eighteen concussed individuals (25.8yrs, ± 10.2) reporting persisting symptoms at rest (m=91.6 ± 78.0 days) completed a graded exercise test (GXT) on a stationary bike until symptoms were triggered/exacerbated. Participants had a mean resting heart rate of 75.7 bpm (± 9.0). We observed that symptoms were triggered/exacerbated at a mean heart rate of 123,6 BPM (± 23.7), which corresponded to 42.0 % (± 18.95) of the heart rate reserve and 65.5% (± 12.2) of maximal theoretical heart rate. Interestingly, neither age at injury nor number of injuries was correlated with symptomatic

threshold ($p > 0.05$). These results help determine the symptom threshold in concussed individuals, which can be used to implement a less traumatic exercise protocol, while enhancing rehabilitative efficacy by not voluntarily triggering/exacerbating symptoms. Thus, our data suggest that individuals experiencing persistent symptoms after a concussion would benefit from initiating physical activity by starting at an intensity below aforementioned symptomatic thresholds.

Title: Delayed thymosin beta 4 treatment improves functional recovery via neurovascular remodeling in rats after traumatic brain injury

Authors: ***Y. XIONG**[1], Y. ZHANG[1], Y. MENG[1], Z. LIU[2], D. C. MORRIS[3], Z. G. ZHANG[2], A. MAHMOOD[1], M. CHOPP[2,4];
[1]Neurosurg., [2]Neurol., [3]Emergency Med., Henry Ford Hlth. Syst., Detroit, MI; [4]Dept. of Physics, Oakland Univ., Rochester, MI

Abstract: Object. Our previous studies demonstrate that thymosin beta4 (Tβ4) significantly improves functional recovery in rats after traumatic brain injury (TBI). Here, we investigated potential mechanisms underlying the Tβ4 therapeutic effect in rats after TBI. Methods. Adult male rats subjected to TBI induced by controlled cortical impact received saline or Tβ4 (6 mg/kg, RegeneRx Biopharmaceuticals Inc, Bethesda, MD) ip starting 24 hr post injury and then every third day for 2 weeks. We evaluated functional outcome after different treatments. We injected biotinylated dextran amine before injury into the contralateral intact cortex for anterogradely labeling corticospinal track (CST). Animals were sacrificed at 35 days post injury. Their spinal cords were processed for measurement of midline-crossing axons. Immunostaining with brain sections was performed for assay of angiogenesis and neurogenesis. A set of rats were sacrificed at 2 days after TBI for assay of Angiopoietin 1 (Ang1), Ang1 receptor Tie2, Akt, and cAMP responsive element-binding protein (CREB) expression. Results. Tβ4 treatment significantly improved spatial learning and sensorimotor functional recovery, promoted angiogenesis and neurogenesis, as well as increased expression of Ang1, Tie2, p-Akt, p-CREB in the injured cortex and hippocampus compared to saline treatment ($p<0.05$). Tβ4 administration

significantly promoted axonal sprouting from the intact side into the denervated side in both the cervical and lumbar enlargements in TBI rats compared to saline controls ($p<0.05$). The number of axons crossing at the cervical ($p<0.001$) and lumbar ($p<0.001$) spinal cord was highly and inversely correlated to the incidence of forelimb and hindlimb footfaults examined at Day 35 after TBI. The total number of axons crossing was highly and inversely correlated to the mNSS score assessed at Day 35 after TBI ($p<0.05$). Conclusions. Our data indicate that promotion of neurovascular remodeling through activation of Ang1/Tie2/Akt signaling pathway may contribute to the therapeutic effect of Tβ4 after TBI.

Title: Deletion of aquaporin-4 is neuroprotective during the acute stage of micro traumatic brain injury in mice

Authors: ***Z. PEI**[1], F. LIANG[1,2], C. LUO[2];
[1]The First Affiliated Hospital, Sun Yat-Sen Univ., Guangzhou, Guangdong, China; [2]State Key Lab. of Quality Res. in Chinese Medicine, Inst. of Chinese Med. Sciences, Univ. of Macau, Macau, China

Abstract: Micro traumatic brain injury (TBI) is the most common type of brain injury, but the mechanisms underlying it are poorly understood. Aquaporin-4 (AQP4) is a water channel expressed in astrocyte end-feet, which plays an important role in brain edema. However, little is known about the role of AQP4 in micro TBI. Here, we examined the role of AQP4 in the pathogenesis of micro TBI in a closed-skull brain injury model, using two-photon microscopy. Our results indicate that AQP4 deletion reduced cell death, water content, astrocyte swelling and lesion size during the acute stage of micro TBI. Our data revealed that astrocyte swelling is a decisive pathophysiological factor in the acute phase of this form of micro brain injury. Thus, treatments that inhibit AQP4 could be used as a neuroprotective strategy for micro TBI.

Title: The use of the dig task to explore the effectiveness of magnesium on recovery of function after traumatic brain injury

Authors: *J. YOUNG, M. R. HOANE;
Psychology: Brain and Cognitive Sci., Southern Illinois Univ., Carbondale, IL

Abstract: Currently, an effective pharmacological treatment after traumatic brain injury (TBI) that returns a patient to a normal level of functioning is nonexistent. In order to better examine the effectiveness of a drug treatment after TBI, tasks that assess all aspects of cognitive function are needed. Discrimination tasks, such as the dig task, can be used to examine cognitive deficits after an experimental TBI in rodents. The dig task is a two-choice scent discrimination task that can effectively assess the cognitive abilities of the rat after a TBI has been induced. The task can be used to determine if the pharmacological treatment is improving the rat. A pharmacological treatment of magnesium has been previously shown in other studies to be a viable treatment for the recovery of cognitive and motor function after TBI. Magnesium plays an important role in the pathophysiological processes after insult and can help to promote cognitive function if delivered correctly. For this reason, a study will be conducted in order to further evaluate the effectiveness of magnesium after a TBI using the dig task. 30 male Sprague Dawley (Harlan, Indianapolis, IN) will be used and separated into either MAG/TBI, VEH/TBI, or VEH/Sham groups. Before induction of a bilateral frontal injury, rats will be pre-trained on the dig task as well as the locomotor placing task. After surgery, rats will receive either an intraperitoneal injection of 2 mmol/kg magnesium chloride or 0.1% phosphate buffer solution (PBS). Magnesium injections will occur 4 hours post-surgery then at 24 hours and again at 72 hours. After 10 days of recovery rats will begin testing on the dig task. The dig task includes two scent pairings; basil (baited) versus coffee, then the reversal, cocoa (baited) versus cumin, and then the reversal. The locomotor placing task will also be conducted in order to assess for the recovery of motor function after TBI. Ideally the results of this study will demonstrate that magnesium is an effective treatment after a traumatic brain injury. It is expected that the dig task will assess acute and prolonged cognitive deficits following the frontal brain injury. It is also expected that the locomotor placing task will assess for any motor deficits.

Title: Restoration of enzymatic activity of energy related proteins in traumatically brain injured rats following the administration of gamma-glutamylcysteine ethyl ester

Authors: *T. T. REED, B. B. RICE;
Eastern Kentucky Univ., Richmond, KY

Abstract: Biochemical processes such as the glycolytic pathway and Kreb's cycle are important in producing ATP for the brain. Without a sufficient supply of glucose for energy metabolism, the brain cannot efficiently regulate or coordinate the actions and reactions of the body. The disruption of brain function resulting from an external force, such as a bump, is known as traumatic brain injury (TBI). Symptoms of TBI range from physical to psychological while effects are indicative of the severity of injury experienced. TBI is associated with reduced energy metabolism, as studies have demonstrated that protein nitration is consequential of TBI through the production of reactive oxygen/nitrogen species (ROS/RNS). Antioxidants, such as glutathione (GSH), combat the deleterious effects of oxidation by scavenging ROS/RNS, inhibiting propagation, and removing neurotoxic byproducts. Gamma-glutamylcysteine ethyl ester (GCEE) is an ethyl ester moiety of gamma-glutamylcysteine that exhibits antioxidant activity by increasing GSH production. Previous studies have demonstrated that the administration of GCEE following TBI has protective effects against protein nitration through the elevation of glutathione. This study investigates the enzymatic activity of energy related proteins that have been identified as nitrated in moderate TBI treated Wistar rats. To test the hypothesis that the elevation of GSH production upon administration of GCEE will normalize enzymatic activity post-TBI, adult male Wistar rats were equally divided into three groups: sham, saline, and GCEE. Rats in all groups (except sham) were subjected to a craniotomy and a moderate TBI via cortical contusion. Post-TBI rats treated with saline or GCEE groups received 150 mg/kg of saline and GCEE, respectively. Upon sacrifice, brains were harvested and enzymatic activity was measured spectrophotometrically. Preliminary results demonstrate an increase in enzymatic activity upon GSH elevation via GCEE administration in several key enzymes, thereby indicating GCEE is a potential therapeutic strategy to restore energy related proteins in the brain post-TBI via GSH elevation.

Title: Etifoxine reduces neuroinflammation in a model of traumatic brain injury in rats

Authors: E. SIMON O'BRIEN, D. GAUTHIER, *V. RIBAN, M. VERLEYE;
Biocodex, Compiegne, France

Abstract: Traumatic brain injury (TBI) results in important neurological impairments which occur through a cascade of deleterious physiological events over time. No effective treatment exists to prevent these consequences. Etifoxine (EFX) is a non-benzodiazepine compound exhibiting anxiolytic properties in the treatment of adjustment disorders with anxiety (1). An enhancement of GABAergic neurotransmission underlies its anxiolytic profile directly after binding on the $GABA_A$ receptor, or indirectly, involving the activation of translocator protein 18 kDa (TSPO) that leads to an increase in the synthesis of neuroactive steroids (2). EFX displays potent regenerative and anti-inflammatory properties, promotes functional recovery in experimental models of traumatic peripheral nerve injury, and reduces brain edema in rats (3-5). TBI is followed by a profound reorganization of the GABAergic system, a dysregulation of TSPO levels (6), and a dramatic inflammatory response characterized by the release of pro- and anti-inflammatory cytokines. In previous studies, we studied the effects of EFX treatment in a model of mild TBI induced by controlled cortical injury (CCI) in rats, and showed that EFX treatment improved sensorimotor recovery (7). In the present study, we assessed the effect of EFX on CCI-induced neuroinflammation. Male SD rats were subjects to sham surgery or CCI and sacrificed at 6 hours. EFX (50 mg/kg, i.p.) or vehicle was administered 30 minutes after injury. We measured several cytokines levels in the ipsi and contralateral cerebral cortex of rats and looked at the effects of EFX treatment on inflammation markers. Compared to injured vehicle treated rats, EFX treatment reduced pro-inflammatory cytokines levels, without affecting anti-inflammatory cytokines levels. Altogether, these results suggest that in mild TBI CCI model, post injury treatment with EFX is effective in reducing neuroinflammation and improves functional recovery. These findings suggest that EFX may have a therapeutic potential in the treatment of TBI. The effect of EFX on neuronal death, astrocytes and microglia activation is currently being investigated in our model. 1. Nguyen *et al.*, *Hum Psychopharmacol.* 21, (2006).

Title: A “neet” target for traumatic brain injury: pioglitazone and mitoneet interactions improve tbi related mitochondrial dysfunction

Authors: *H. M. YONUTAS[1], J. PANDYA[2], A. SEBASTIAN[2], W. GELDENHUYS[3], R. CARROLL[3], P. G. SULLIVAN[1];
[1]Spinal Cord and Brain Injury Res. Center/Anatomy and Neurobio. Dept., [2]Spinal Cord and Brain Injury Res. Ctr., Univ. of Kentucky, Lexington, KY; [3]Col. of Med. and Pharm., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Traumatic Brain Injury (TBI) is difficult to treat due to the complicated secondary injury cascade that is activated post-injury. The most promising therapeutics are multi-targeted, improving neuroinflammation, ROS production and mitochondrial dysfunction. Pioglitazone, an

FDA approved drug for Type 2 Diabetes and a known PPAR agonist, has shown promise in altering neuroinflammation and decreasing ROS production. Work from our lab found that pioglitazone can increase mitochondrial bioenergetics within the first 12 hours of injury leading to improved cortical sparing and functional recovery. This effect seems to be too rapid for PPAR activation alone and may be due to its ability to bind a novel mitochondrial protein called mitoNEET. We hypothesize that targeting mitoNEET with a mitoNEET ligand, such as pioglitazone, leads to improved tissue and functional recovery. To test this hypothesis we used a severe Controlled Cortical Impact (CCI) injury model, mitoNEET null and wild-type mice, pioglitazone and a novel mitoNEET ligand called NL-1, which has a similar structure to pioglitazone however contains no PPAR binding region. In a simulated excitotoxicity experiment, *ex vivo* mitochondrial studies show that pioglitazone and NL-1 can increase bioenergetics in isolated cortical mitochondria with and without Ca2+ insult. An in-vivo pioglitazone and NL-1 dose-response study was then preformed in wild-type mice post-injury. The dosages which provided the greatest amelioration of mitochondrial dysfunction were used in wild-type and mitoNEET null mice subjected to sham or severe CCI surgery. Pioglitazone lost its ability to increase mitochondrial respiration and provide neuroprotection in mitoNEET null mice. Additionally, the mitoNEET specific ligand, NL-1, increased cortical sparing and functional recovery and decreased MRI T2-weighted hyperintensity at the injury site. These results support the role of mitoNEET in the neuropathological sequelae of brain injury and as a crucial target for pioglitazone mediated neuroprotection following TBI.

Title: Minocycline plus N-acetylcysteine have a clinically useful therapeutic window in two animal models of traumatic brain injury

Authors: ***M. A. SANGOBOWALE**, N. M. GRIN'KINA, K. WHITNEY, P. J. BERGOLD; Pharmacol. and Physiol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: There are presently no drugs to treat traumatic brain injury (TBI). We have previously shown that the combination of the FDA-approved drugs minocycline (MINO) and N-acetylcysteine (NAC) synergistically improved cognition and memory, modulated inflammation, limited grey matter injury and induced remyelination when dosed 1 hour after injury in a rat controlled cortical impact model (CCI) of TBI. MINO plus NAC retained similar efficacy in a mouse closed head injury (CHI) model of TBI. The CHI model was then used to determine the lowest dose of both drugs that retained full efficacy. When dosed at one hour after CCI or CHI, the optimized MINO plus NAC dose modulated neuroinflammation and induced remyelination in the injured brain. We now report that this optimized dose of MINO plus NAC improved cognition and memory when dosed 6 hours after injury in the rat CCI and mouse CHI models. This therapeutic window was assessed using an active place avoidance task with high cognitive demand. MINO plus NAC, however, no longer improved cognition in the rat CCI model when dosed 12 hours after injury. We are testing whether the 6-hour therapeutic window of MINO plus NAC may be longer when tested using Barnes maze, a behavioral task that likely has a lower cognitive demand than active place avoidance. We are also testing whether the 6-hour dosing of MINO plus NAC modulates inflammation, limits grey matter injury and induces remyelination. These data suggest that MINO plus NAC limits brain injury with a clinically useful therapeutic window in two TBI models and in two species. These preclinical studies provide further evidence that that MINO plus NAC has sufficient potency and safety to be tested against clinical TBI.

Title: Multi-modal interventions for improving recovery after TBI assessed by a data-driven multivariate approach

Authors: ***J. HAEFELI**[1], A. R. FERGUSON[1], D. BINGHAM[2], A. ORR[2], S. WON[2,1], T. I. LAM[2,1], J. SHI[2,1], S. HAWLEY[2], J. LIU[2,1], R. A. SWANSON[2,1], S. M. MASSA[2,1]; [1]UCSF, San Francisco, CA; [2]San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Traumatic brain injury (TBI) causes a complex cascade of events involving primary cell death, secondary injury, and chronic inflammation, all of which work in concert to impact recovery, leading to a highly complex syndrome. Due to growing evidence that combinatorial therapies might have cumulative effects, a combination of neuroprotective drug interventions including minocycline and LM11A-31 (a small molecule p75 neurotrophin receptors modulator), and physical therapy (i.e., conventional or botulinum toxin-induced constraint movement therapy) were applied in a controlled cortical impact (CCI) TBI model in rats. To remain sensitive to multimodal changes induced by the combinatorial interventions, we took a data-driven multivariate approach to leverage the full set of outcome measures ranging from cellular to long-term motor and cognitive behavior. The interaction effects (i.e., synergistic and counteracting) of different drug interventions and physical therapies were assessed using a linked analytical workflow involving principal component analysis followed by a linear mixed model (PCA-LMM). The linear mixed model was used to test the effect of drug intervention and physical therapy on principal components scores extracted from functional outcome measures and brain markers. This analytical workflow was applied to a prospectively collected database including 202 animals (79 shams, 123 TBI animals). Both sham and TBI rats received minocycline, LM11A-31, physical therapy and constraint-induced movement therapy delivered alone or in combination. Animals were assessed with an extensive functional outcome battery (i.e., forelimb use asymmetry, vermicelli handling, Morris water maze and sticky label tests) and cortical lesion volume and glial activation were evaluated. Results revealed a significant benefit of LM11A-31 on multidimensional recovery after TBI ($F=14.05$, $p<0.001$). This effect depended on the type of physical therapy intervention applied ($F=9.77$, $p<0.001$). Further, LM11A-31 and minocycline had a synergistic effect on multidimensional learning and memory outcomes ($F=5.41$, $p=0.022$). This data provides evidence of combinatorial effects of drug and physical therapy interventions on multidimensional outcomes following experimental TBI in a large-scale dataset.

Title: effect of aspirin and clopidogrel on bleeding, platelet aggregation, and neuronal damage following traumatic brain injury

Authors: *F. H. KOBEISSY[1], M. NASSER[2], D. SERHAN[3], F. DAKROUB[2], Z. DALLOUL[2], E. HAMADE[4], K. ZIBARA[4], H. DARWICHE[2];
[1]Dept of Psychiatry, Univ. of Florida, Gainesville, FL; [2]Bichemistry, [3]American Univ. of Beirut, Beirut, Lebanon; [4]Lebanese Univ., Beirut, Lebanon

Abstract: Background: Traumatic brain injury (TBI) often referred to as the “silent epidemic,” is a non-degenerative non congenital insult to the brain due to a blow or penetrating object that disrupts the function of the brain leading to permanent or temporary impairment of cognition, physical and psychosocial functions . Antiplatelet agents such as clopidogrel and Acetyl-Salicylic Acid- ASA (aspirin) inhibits the formation of blood clot by inhibiting platelet aggregation and activation and are essential adjuncts to the medical care of patients with cardiovascular disease and had been co-administered in elderly patients, Clinical studies show that patients taking anti platelets before head trauma are at an increased risk to develop serious intra cranial hemorrhage when compared to untreated patients. Aims: In this study, we will assess the different aspects of systemic changes (bleeding, platelets activation and thromboxane levels) as well as different bio-markers of brain injury after co-administration of clopidogrel and aspirin after experimental model of brain injury and in control group. Methods: Rats were divided into five groups (control, TBI , TBI +Aspirin 20 mg/kg ip , TBI+ clopidogrel 10 mg / kg , TBI +Combination) treatments were given for 2 days and sacrifice was done 48 hours post injury .Western blotting was performed on brain samples to assess the changes in the levels of different proteins (spectrin , Gfap and transferrin) . Immunofluorescence (IF) was also performed on different proteins notably Gfap and Neun . Finally, ELISA and EIA were used to find relevant serum proteins associated to brain injury and inflammation (IL6 , IL10 , tnfα and thromboxane) . Results : Aspirin and Clopidogrel inhibited platelet aggregation alone and in combination also Thromboxane (TXB2) whose level is indicative of activated platelets ,increased after TBI when compared to control group however its level in all treated groups was comparable to control . WB data confirmed that spectrin cleavage (an early marker of necrotic and apoptotic cell death

following TBI) increased in TBI when compared to control groups. and in rats treated with combination, spectrin cleavage is highest among all groups

Title: Galantamine as an effective co-adjuvant medical countermeasure to counter the delayed neurotoxic effects of the organophosphorus compound sarin

Authors: *E. F. PEREIRA[1], Y. ARACAVA[1], J. D. PESCRILLE[1], D. CARTER[1], L. RICHARDSON[1], D. MCKOY[1], L. MCCOWAN[1], E. ALEXANDROVA[1], N. PHAM[1], E. LUMSDEN[1], R. CLARK[1], J. MAMCZARZ[1], S. XU[1], R. P. GULLAPALLI[1], M. LANE[1], I. MERCHENTHALER[1], G. W. BASINGER, Jr.[2], E. X. ALBUQUERQUE[1];
[1]Div. of Translational Toxicology, Dept Epidemiol Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Countervail Corp, Charlotte, NC

Abstract: The acute toxicity of OP compounds, including the nerve agent sarin, results primarily from the irreversible inhibition of acetylcholinesterase (AChE). While conventional antidotal therapy consisting of atropine (to block overactivation of muscarinic receptors), oximes (e.g. 2-PAM, to reactivate OP-inhibited AChE), and benzodiazepines (to halt convulsions) helps mitigate the acute signs of OP intoxication, they do not adequately prevent long-term neurotoxic effects [J Pharmacol Exp Ther 350: 313-321, 2014]. Here, we used a multi-disciplinary translational approach to: (i) assess the delayed neurotoxicity of 1.2xLD50 sarin (108 µg/kg, sc) in rats treated with atropine (0.5 mg/kg, im)-plus-2-PAM (25 mg/kg, im) administered 1 min post-sarin with or without diazepam (0.72 mg/kg, im, at onset or 20 min after onset of convulsions), and (ii) evaluate the benefits of using galantamine (0.3-3.0 mg/kg, im, 6 h post-sarin) as a co-adjuvant therapy. Between 3 and 5 months after the exposure to sarin, rats treated with atropine-plus-2-PAM with or without diazepam, administered 20 min post-onset of convulsions, presented significant spatial learning and memory deficits in the Morris water maze.

Between 2 and 6 months after the injection of sarin, the total EEG power and the power of individual EEG frequencies in these rats were also higher-than-normal. Diazepam given at onset of convulsions to sarin-exposed rats prevented the learning impairment and the changes in EEG activity, but not the memory deficits. *In vivo* imaging revealed that, between 2 and 6 months after the injection of sarin followed by treatment with atropine-plus-2-PAM, diazepam (at onset or 20 min after onset of convulsions), rats presented significant metabolic and structural alterations in areas of the brain that are known to play an important role in controlling cognitive function, including the hippocampus, thalamus, and striatum. Finally, immunohistochemistry revealed significant and persistent neuronal loss in the hippocampus and lateral amygdala of sarin-injected rats that were post-treated with atropine-plus-2-PAM with or without diazepam (administered at onset or 20 min after onset of convulsions). Inclusion of galantamine in the post-treatment regimen effectively countered the behavioral deficits as well as the electrical and structural alterations in the brain of sarin-exposed rats, with the most effective dose of galantamine being 3 mg/kg. In conclusion, using various metrics, the present study demonstrates the beneficial effects of the use of galantamine as a co-adjuvant medical countermeasure to mitigate the delayed neurotoxic effects of OP compounds.

Title: Efficacy of oral galantamine pre-treatment against soman toxicity in guinea pigs

Authors: *Y. ARACAVA[1], J. D. PESCRILLE[1], D. CARTER[1], R. CLARK[1], L. RICHARDSON[1], M. LANE[1], E. F. PEREIRA[1], E. X. ALBUQUERQUE[1], G. W. BASINGER, Jr.[2];
[1]Div. of Translational Toxicology, Dept Epidemiol Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Countervail Corp, Charlotte, NC

Abstract: Previous studies from several laboratories have assessed the effectiveness of numerous medical countermeasures as pre-treatments against the acute toxicity of nerve agents [e.g., PNAS 103:13220, 2006; Neurotoxicology 23:1, 2002]. Because absorption of a drug delivered intramuscularly, particularly to laboratory animals, is more consistent than the absorption of drugs delivered orally, the preferred route of administration of the medical countermeasures in the majority of those studies was the intramuscular route. Yet, the variety of dose forms, in addition to the convenience and safety of use, make the oral route the preferred route for human use. For example, pyridostigmine has been approved by the FDA for oral use by the military personnel at risk of exposure to soman [Neurologist 13:20, 2007]. In recent years, galantamine emerged as an effective medical countermeasure against OP poisoning. Thus, the present work was designed to determine the effectiveness of orally delivered galantamine as a pre-treatment to reduce the acute toxicity and lethality induced by soman in guinea pigs. To this end, male and female guinea pigs were treated orally with galantamine HBr (8, 10, or 12 mg/kg), pyridostigmine HBr (1.9 mg/kg), or vehicle and injected 30 min later with 1.0x or 2.0xLD50 soman (1.0xLD50 = 28 µg/kg). Animals that were injected with 2.0xLD50 soman were also treated 1 min later with atropine (0.5 mg/kg, im)-plus-2-PAM (25 mg/kg, im) and 5 min after onset of convulsions with midazolam (2.8 mg/kg, im). Survival was significantly greater among soman (1.0xLD50)-challenged guinea pigs pre-treated orally with galantamine (8, 10, or 12 mg/kg) than among those pre-treated with pyridostigmine or saline. In male and female guinea pigs challenged with 2.0xLD50 soman, pre-treatment with 12 mg/kg galantamine in association with post-treatment with conventional antidotes afforded significantly greater survival than conventional antidotes in association with pre-treatment consisting of pyridostigmine or vehicle. Oral pre-treatment with galantamine was also significantly superior to pre-treatment with pyridostgimine in reducing neuronal cell death in the brains of guinea pigs challenged with 2.0xLD50 soman and post-treated with standard care and in the brains of guinea pigs challenged with 1.0xLD50 soman and provided with no additional supportive post-treatment. Compared to saline and pyridostigmine, galantamine reduced by more than 25% the neuropathology in the brain of soman-injected guinea pigs. In conclusion, oral galantamine emerged as a better pre-treatment than oral pyridostigmine in countering the acute toxicity of soman.

Title: Pharmacokinetics of galantamine following oral administration to guinea pigs

Authors: W. P. FAWCETT[1], R. H. COOMBES[1], Y. ARACAVA[1], J. D. PESCRILLE[1], G. W. BASINGER, Jr.[2], E. F. PEREIRA[1], *E. X. ALBUQUERQUE[1];
[1]Div. of Translational Toxicology, Dept Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Countervail Corp, Charlotte, NC

Abstract: Galantamine, a drug approved to treat Alzheimer's disease, has emerged as an effective medical countermeasure against organophosphorus (OP) intoxaition [PNAS 103:13220-13225, 2006]. Here, we examined the pharmacokinetic profile of galantamine following its oral administration to guinea pigs and the corresponding degree of blood AChE inhibition. To this end, galantamine was dissolved in pharmaceutical grade saline (0.9%) and an adequate volume of the solution was administered together with an equal volume of a vegetable juice to the animals. A 1-ml disposable syringe was used to deliver orally 8, 10, or 12 mg/kg galantamine to the animals. Plasma galantamine levels were measured using an HPLC coupled to a UV detector, and blood AChE activity was measured using a radiometric assay. Time to reach maximal plasma concentration was approximately 1 h, indicating that in guinea pigs, as in humans, oral galantamine is quickly absorbed. Maximal plasma concentrations of galantamine (Cmax) and area-under-the-curve of plasma concentrations of galantamine over time (AUC) were linearly correlated with the test doses. The degree of blood AChE inhibition changed with time following oral administration of galantamine HBr to guinea pigs as anticipated by the pharmacokinetic profile of the drug. Maximal degree of AChE inhibition (Imax) and the area-under-the-curve of AChE inhibition over time were significantly correlated with Cmax and area-under-the-curve of plasma concentrations of the drug over time. The pharmacokinetics of orally administered galantamine and the degree of AChE inhibition produced by each dose were comparable between males and females. The absolute oral bioavailability of galantamine in male and female guinea pigs was found to be approximately 50%. The lower bioavailability of galantamine in rodents than in humans may be accounted for by species-specific metabolism. Although rodent models can be used to predict oral drug absorption in humans, they are generally poor predictors of drug metabolism or oral bioavailability in humans [Pharm Res 23:1675-1686, 2006]. The maximal degrees of AChE inhibition attained following oral treatment of guinea pigs with the test doses of 8, 10, and 12 mg/kg galantamine HBr ranged from 40% to 55%, which are within the range of AChE inhibition measured in the blood of humans treated with approved doses of the drug [Clin Pharmacol Ther 50: 420-428, 1991]. In conclusion, the pharmacokinetic profile and the degree of AChE inhibition resulting from oral treatment of guinea pigs with doses of

galantamine in the range of 8 to 12 mg/kg indicate that these doses of galantamine will convert to oral doses that are safe for human use.

Title: Hyperbaric oxygen therapy as a potential treatment for traumatic brain injury

Authors: ***C. G. PICK**[1], R. BARATZ-GOLDSTEIN[1], V. RUBOVITCH[2], S. TOUSSIA-COHEN[2];
[2]Anat., [1]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Introduction: Traumatic brain injury is a common health problem with significant effect on quality of life. Hence, TBI is a major social problem and economic burden. The major causes are motor vehicle crashes, falls, and violence. Mild traumatic brain injury (TBI) accounts for 80-90% of total brain injuries. mTBI may lead to short- and long-term cognitive, emotional, and behavioral deficits. As yet, there is no effective treatment or cure for patients with mTBI. Hyperbaric oxygen therapy (HBOT) is a treatment by which 100% oxygen is administered at a pressure greater than atmospheric pressure at sea level (one atmosphere absolute, ATA). This involves placing the patient in an airtight vessel, increasing the pressure within that vessel, and administering 100% oxygen for respiration. In this way, it is possible to deliver a greatly increased partial pressure of oxygen to the tissues. HBOT has been shown to decrease cerebral edema, normalize water content in the brain, decrease the severity of brain infarction, and maintain blood-brain barrier integrity. Methods and Results: Mice were subjected to closed head weight-drop injury with 70 g weight. Mice were treated with hyperbaric oxygen for 1 hour at 2 ATA for 4 consecutive days starting from 3 hours post injury. 7 days post injury mice were assessed in 2 behavioral paradigms: Y-Maze and Novel Object Recognition test. Mice exhibited a lower learning ability following mTBI in both the Y-Maze and Novel Object Recognition test. The cognitive impairments were ameliorated in mice treated with HBOT. Brains (from another group) were remove 72 hours post last HBO treatment. mTBI group had decrease in myelin basic

protein. Furthermore, we found increase in neuronal loss and in astrocyte reactivity post brain injury. These changes were abolished in mice that were treated with HBOT. Conclusions: These findings may suggest a new therapeutic strategy to treat damages induced by mTBI. The mechanisms underlie this improvement may be related to reducing inflammation and preventing de-meyelinization.

Title: Wnt3a protects against autophagic cell death after traumatic brain injury

Authors: *J. Y. ZHANG, J. LEE, S. P. YU, L. WEI;
Emory Univ., Decatur, GA

Abstract: Traumatic brain injury (TBI) is the leading cause of morbidity and mortality in children and young adults, including soldiers and athletes. However, there are currently no effective pharmacological therapies for TBI. Wnt proteins are a family of signaling ligands that are critical for many aspects of development, including cell division, differentiation, and migration, cell fate specification, and axis formation. In adults, Wnt ligands still play major roles in multiple organ systems. In the adult brain, canonical Wnt ligands, such as Wnt3a, mediate endogenous neural stem cell (NSC) proliferation and differentiation, which is an important component of tissue repair. We expected that supplementation of recombinant Wnt3a following TBI would increase endogenous neurogenesis. While our previously reported results supported our original hypothesis, we now report on the novel discovery of a protective effect of Wnt3a that acts through a mechanism independent of neurogenesis. Specifically, Wnt3a is able to directly attenuate autophagic programmed cell death that results from TBI. The whisker barrel pathway provides a useful serial system for studying both the functional deficits and recovery

following TBI on a systems and behavioral level. Focal injury to the barrel cortex disrupts the pathway's connectivity and signal transduction, resulting in delayed transneuronal degeneration in areas even outside of the contusion region, such as the thalamus. Therefore, promoting cell survival and functional outcomes requires neuroprotective strategies and re-establishment of the original pathway through endogenous neurogenesis. We delivered a focal injury to the barrel cortex of young adult mice using the well-established controlled cortical impact model of TBI. Wnt3a was administered intranasally once at 1 hr post-injury. At 24 hours post-injury, mice were sacrificed to collect tissue for Western blotting, and at 2 days post-injury, mice were sacrificed for immunohistochemistry. To assess the extent of autophagy, we performed Western blots for Beclin-1 and LC3, two components of the autophagic pathway. Furthermore, we used Beclin-1 and LC3 to immunofluorescently label cells around the peri-contusion region in cryosectioned brains. Our findings suggest that Wnt3a is able to ameliorate cell death by reducing the susceptibility of injured cells to autophagy. These results demonstrate the efficacy of Wnt3a as a treatment during the acute stage of TBI, as well as uncover a novel mechanism of action of Wnt3a that can synergize with its neuroregenerative effects.

Title: Acute intrathecal baclofen (ITB) and therapeutic exercise provide effective rehabilitation for TBI-Induced spasticity without adversely affecting cognitive performance

Authors: ***F. J. THOMPSON**[1,2,3], J. HOU[1,2], R. NELSON[1], G. MUSTAFA[1,2], A. SINHAROY[1], R. PANDEY[4], Z. WILKIE[1], S. TSUDA[1,2], L. PAGE[6], P. BOSE[1,2,5];
[1]Brain Rehabil. Res. Ctr., North Florida/South Georgia Veterans Hlth. Abstract: Spasticity is a major health problem for patients with moderate to severe traumatic brain injury (TBI). Current federal guidelines preclude the use of ITB therapy during the first year following TBI due to insufficient data to determine potential risk associated with early therapies on cognitive function, balance, and motor recovery. To address some of these challenges, there were two objectives of the present series of studies. The first was to provide a comprehensive evaluation of dose response using three ITB doses: low (0.4µg/hr), medium (0.8µg/hr), and high (1.6µg/hr) (Lioresal® baclofen injection), initiated at 1 week post injury, and continued for 1 month, on the long-term outcome of spasticity, cognition function, and balance recovery. Our data to date indicate that compared with time-matched data obtained from untreated TBI animals, ITB treatment significantly reduced spasticity in a dose-dependent manner. The higher dose (1.6 µg/hr) blocked the early (tested at post-ITB treatment week 1) and late onset (tested at post-ITB treatment week 3) spasticity with no negative impact on cognitive performances. However, animals receiving the highest dose, exhibited balance test deficiencies. In contrast, the medium dose blocked the early onset spasticity, significantly attenuated the late onset spasticity, and produced no negative impact on balance and cognitive performances. The lowest dose mildly attenuated early and late onset spasticity with no adverse impact on balance and cognitive performances. The second objective was to use the optimal therapeutic dose in an experimental rehabilitation program that combined ITB and locomotor exercise. In these studies ITB and treadmill locomotor (Tm) exercise were initiated at one week after TBI and continued for 4 more weeks. These studies compared tests of lower limb spasticity, balance, serial learning, and anxiety function in normal, TBI-saline treated, TBI-ITB treated, and TBI-ITB plus Tm animals. One month of ITB treatment using the medium dose (0.8µg/hr) combined with a Tm locomotor training protocol produced the most significant reduction in spasticity without detectable impact on cognitive, balance, and anxiety recovery. These observations indicated that initiating ITB at one week post-TBI was safe, feasible and effective, and in combination with a Tm locomotor therapeutic exercise training protocol provided the most effective rehabilitation. These studies also indicate that progressively, a broad spectrum of comprehensive data will reinforce confidence in the safety, feasibility, and efficacy of early intervention treatments with locomotor therapy for TBI-spasticity.

Title: Post-traumatic pain in a rodent model of mild-traumatic brain injury (mTBI) and treatment with transcranial magnetic stimulation (TMS)

Authors: *G. MUSTAFA[1,2], J. HOU[1,2], S. TSUDA[2], R. NELSON[1], R. M. CAUDLE[3], J. K. NEUBERT[4], F. J. THOMPSON[1,2,5], P. BOSE[1,2,6];

Abstract: Pain is a major complaint in patients after traumatic brain injury and ranges from acute to chronic forms of neuropathic, central, and thalamic pain. It is known that the prevalence of chronic pain is higher (72%) in mild TBI than severe TBI (32%). Although only limited fundamental neurobiological details of TBI-induced pain are available, the causes of pain in mild TBI patients has been attributed to TBI induced neuroplasticity, such as alteration in neurotransmitter signaling in central pain pathways. Accordingly, specific insights into TBI-induced changes in transmitter signaling in pain pathways could direct the development of more effective TBI pain therapies. To obtain a broader understanding of pain in mTBI, we used a rodent model of closed head mTBI (modified Marmarau's model, 450 g X 1.25 m, anesthetized helmeted adult Sprague Dawley rats). We measured thermal sensitivity in hind-paws and orofacial regions using a conventional hot plate assay and an orofacial pain assessment device respectively before and after mTBI. Our data to date indicate that animals with mild TBI exhibit significant increases in thermal sensitivity starting at 4 weeks post-TBI; this increased sensitivity was enduring and was prominent when the testing was repeated at post-TBI week 8. In parallel with these changes in behavior, significant alterations of key neurotransmitters (eg. 5-HT, GABA, NE and substance P receptors (NKR1)) were found in the sensory cortex, ventral posteromedial thalamic nucleus and nucleus caudalis (trigeminal pathway) and also in dorsal root ganglia. Treatment of post TBI animals with a regimen of TMS therapy produced significant decreases in the thermal sensitivity in both facial and peripheral regions. These findings suggest an encouraging potential for TMS in pain management. Accordingly, we propose a working hypothesis that includes TMS as an effective therapy to deal with the alteration of neuromodulators in the pain processing pathway following mTBI.

Title: Altered noradrenergic innervation in the amygdala-bed nucleus of the stria terminalis and the ventral subiculum-paraventricular nucleus of hypothalamus anxiety pathways following closed-head traumatic brain injury in rats

Authors: *S. TSUDA[1], J. HOU[1,2], R. NELSON[1], G. MUSTAFA[1,2], Z. WILKIE[1], F. J. THOMPSON[1,2,3], P. BOSE[1,2,4];
[1]Malcom Randal VA Med. Ctr., Gainesville, FL; [2]Dept. of Physiological Sci., [3]Dept. of Neurosci., [4]Dept. of Neurol., Univ. of Florida, Gainesville, FL

Abstract: In the United States, each year approximately 1.7 million people experience traumatic brain injuries (TBIs). The majority of these injuries are closed-head TBIs (cTBIs) which often lead to long-term anxiety disorders. Critical questions remain regarding the neurobiology of these disorders, and, accordingly, there has been no established treatment for this morbidity. It is understood that several interconnected brain regions, such as the medial prefrontal cortex (mPFC), amygdala (AMG), the bed nucleus of the stria terminalis (BNST), ventral hippocampus (vHPC), and hypothalamus work in concert to regulate anxiety. Although dysregulation of the central noradrenergic (NA) system has been correlated with anxiety, few studies have specifically reported alteration in the NA innervation (NAI) to known essential mood regulating neural substrates following cTBI. The purpose of this study was to identify chronic TBI-induced changes in the locus coeruleus (LC) neurons (LC supplies NA projections to extensive regions of the central nervous system), TBI-associated changes in the NAI pathways, and NA expression in several mood regulating neural substrate regions. Post-fixed coronal brain sections of animals in which anxiety-like behaviors were detected 5-6 months after cTBI (modified Marmarou TBI

Model, 450g x 1.25 m) were immunofluorescently stained with dopamine -hydroxylase (DH) and norepinephrine (NE). NA fiber density was determined by unbiased stereological analysis using the Petrimetrics method with the StereoInvestigator software (MicroBrightField). Compared with time-matched normal controls, significantly fewer immunoreactive (IR-) NA cells were detected in the LC. Moreover, significantly fewer IR-NA fibers were detected in the dorsal NA projection pathway as well as the central nucleus of amygdala. In contrast, significantly elevated IR-NA fibers were detected in specific regions of the BNST, subiculum (Sub), and dorsomedial hypothalamic nucleus (DMH). These results suggest that cTBI-induced enduring anxiety disorder may, in part, be related to significant alterations in central NA projections to and within mood regulating neural substrates. Accordingly, these studies provide new information for understanding the anxiety-related cTBI neurobiology, which in turn may provide insights for targeted therapies of cTBI-induced anxiety disorders.

Title: New therapy in experimental TBI-induced motor (e.g. spasticity and balance), cognitive and anxiety disorders

Authors: *J. HOU[1,2], R. NELSON[1], Z. WILKIE[1], G. MUSTAFA[1,2], S. TSUDA[1,2], R. J. BERGERON, Jr.[3], P. BOSE[1,2,4], F. J. THOMPSON[1,2,5];
[1]NF/SG Veterans Hlth. Syst., Gainesville, FL; [2]Dept. of Physiological Sci., [3]Dept. of Medicinal Chem., [4]Dept. of Neurol., [5]Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Traumatic brain injury (TBI) can produce life-long disabilities including motor, anxiety and cognitive deficits. Development of safe and effective therapies for these long-term disabilities is urgently needed. Here, we evaluated the therapeutic potential of two treatments

individually: a) transcranial magnetic stimulation (TMS), and b) an iron chelating agent (HBED, mono-sodium salt). We used a rodent model of mild/moderate TBI (modified Marmarou closed head TBI model: 450 g/1.25 m); we recently reported that enduring spasticity, balance, anxiety and cognitive deficits were observed and quantitated in this TBI model (Bose et al., 2013). The TMS treatments were applied 3 times/week for one month and consisted of 75 single pulses delivered to the surface of the cranium through a 25 mm figure of 8 coil using an intensity ladder protocol that we recently reported (Hou et al., 2014). The velocity-dependent ankle torques and time-locked triceps surae EMGs were recorded as a measure of spasticity. Anxiety behavior, balance, and cognitive performance were measured using an elevated plus maze (EPM), rotorod, and Morris water maze (MWM), respectively. Compared to untreated TBI controls, four weeks of TMS treatment resulted in an 87.28% reduction in spasticity, a 25.71% reduction in anxiety score, a 17.67% reduction in balance disability, and a 78.71% increase in serial learning performance. Interestingly, significant therapeutic effects on spasticity reduction (90.05%) and balance improvement (21.14%) persisted for more than 3 months following cessation of TMS treatment. In a different cohort of animals, iron chelator (HBED) treatment (s.q.100 mg/kg/day, twice a day for 10 days, started immediately following the TBI) effectively blocked the development of spasticity and improved the balance performance. These therapeutic benefits were still evident when tested at 4 months following cessation of treatment. No changes were detected in EPM (anxiety) and MWM (learning) performance following chelator treatment. Our data to date indicate that compared with untreated TBI controls, TMS treatments induced significant improvements in cognitive performance and significant reductions in anxiety, balance disability, and spasticity. Chelator treatments blocked the development of motor and balance disabilities. In both treatments, the therapeutic benefit for motor and balance persisted when tested 3 or 4 months after cessation of treatments. Further studies are in progress to understand the role of chronic neuro-inflammation and oxidative stress on these differential therapeutic benefits.

Title: Neurobiological markers of aberrant aversive learning in the traumatic brain injury rodent model

Authors: ***R. P. MEARS**[1], H. C. CROMWELL[4], P. K. BOSE[5,2,3], F. J. THOMPSON[5]; [1]Dept. of Psychology, [2]Dept. of Physiological Sci., Univ. of Florida, Gainesville, FL; [3]Univ. of Florida, Department of Neurology, FL; [4]Dept. of Psychology, Bowling Green State Univ., Bowling Green, OH; [5]Brain Rehabil. Res. Ctr. (151), North Florida/South Georgia VA Hlth. Syst., Gainesville, FL

Abstract: Traumatic brain injury (TBI) is accompanied by increased risk of PTSD, persistent anxiety, and dysphoria. Closed head traumatic brain injury (CH-TBI) in the rat model produces emotional dysregulation and anxiety. Diffuse axonal injury in the CH-TBI model accompanies disruption of neuromodulation of prefrontal cortex. Inhibitory gating (IG) deficits coincide with cognitive and emotional dysfunction in a variety of neuropsychiatric disorders. Persistent IG occurs in rat prelimbic medial prefrontal cortex (mPFC), a crucial site for modulating emotional learning. Here we hypothesized that IG would be disrupted in the CH-TBI animal model. Closed head TBI (CH-TBI) rats were assessed in order to identify biological markers of anxiety and disrupted fear conditioning. To investigate the interaction of affect and IG, we recorded local field potentials (LFP) directly from prelimbic mPFC and examined the influence of tone-shock fear conditioning (FC) on IG. In an auditory cue discrimination paradigm, one tone co-terminated with footshock and the other did not. Subjects were tested immediately after and one day after fear conditioning. Behavioral reactions during IG were observed before and after FC, and increase of orienting response after FC indicated induction of tone-shock association. After FC, some components of LFP response exhibited short-term weakening of IG. On a subsequent day of recording, IG strengthened for all LFP components in control animals. These findings will permit further definition and expansion of non-invasive, neuro-diagnostic markers of traumatic brain injury that might significantly improve early detection of TBI associated disorders.

Title: Role of d-serine in nadph oxidase-induced oxidant/antioxidant imbalance in early stage vascular dementia

Authors: ***N. LI**[1], W. ZHANG[1], Y. ZHU[1,2], D. BRANN[2], R. WANG[1];
[1]Neurobio. Inst. of Med. Res. Center,, North China Univ. of Sci. and Technol., Hebei, China;
[2]Med. Col. of Georgia, Department of Neuroscience and Regenerative Medici, GA

Abstract: Glutamate excitotoxicity and NADPH oxidase-derived reactive oxygen species (ROS) are important pathological components in neurodegenerative diseases. In the current study, we examined the role of D-serine, a co-agonist at the NMDA class of glutamate receptors, in the early pathogenesis of vascular dementia (VD). Chronic hypoperfusion induced by bilateral common carotid artery occlusion (BCCAO) in the rat was used as the animal model for vascular dementia. The results of our study revealed that a profound oxidant/antioxidant imbalance occurs in hippocampal CA1 neurons at 7d and 21d after BCCAO. For instance, antioxidant factors such as NF-E2-related factor 2 (Nrf2) and its downstream anti-oxidative enzymes (HO-1, SOD2) were significantly decreased after BCCAO, while oxidant factors (O2-) and oxidative stress markers (4-HNE and 3NT) were markedly increased. The elevation of O2- and oxidative stress was likely due to enhanced NADPH oxidase, as in-situ hybridization and activity assays revealed NADPH oxidase expression and activity was significantly enhanced at 1h, 1d, 7d and 21d after BCCAO. The increase of NADPH oxidase appears to involve mediation by D-serine, an NMDA receptor co-agonist, as expression of serine racemase (SR), an enzyme that forms D-serine from L-serine, was significantly increased from 1h to 21d after BCCAO. Furthermore, continuous central administration of antisense oligonucleotides (AS) of SR not only markedly attenuated the activity of NADPH oxidase, 4HNE and 3NT, but also up-regulated the protein expression of the anti-oxidant enzymes Nrf2, HO-, and SOD2, as compared to the BCCAO 21d group. Of significant interest, both SR knockdown and gp91ds-tat, a specific inhibitor of NADPH oxidase, perfectly prevented early ultrastructural damage in hippocampal CA1 neurons at 21d after BCCAO. Taken as a whole, the results suggest that up-regulation of endogenous D-serine in the hippocampal CA1 region plays an important role in the NADPH oxidase induction and antioxidant/oxidant imbalance that occurs during early stage BCCAO.

Title: Role of oxidative cysteine protein modification in Amphetamine induced neurotoxicity

Authors: V. BHARTI, H. TAN, Z. ZHOU, Y. WANG, *J.-F. WANG;
Dept. of Pharmacol. & Therapeutics, Fac. of Medicine, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Amphetamine is a highly abused psycho stimulant that can lead to dopaminergic neuron degeneration and increased the risk for neurodegenerative diseases with advanced age upon long term consumption. Many studies have shown that oxidative/nitrosative stress contributes significantly to AMPH-induced toxicity. Thiols of cysteine residues in many proteins are very susceptible to attack by reactive oxgen/nitrogen species H2O2 and NO•, subsequently inducing sulfenylation and nitrosylation. In this study, we analyzed the effects of amphetamine on H2O2 induced sulfenylation and NO• induced nitrosylation in rat brain using biotin switch method following by immunoblotting analysis. We found that repeated amphetamine treatment increased total sulfenylation and nitrosylation of proteins in rat frontal cortex. Vesicular monoamine transporter 2 (VMAT2) is mainly responsible for packaging of monoamine neurotransmitters and play an important role in neurotransmission. We found that VMAT2 can be sulfenylated and nitrosylated, and that repeated amphetamine treatment increased sulfenylation of VMAT2. Our finding suggested that nitrosylation and sulfenylation of proteins including VMAT2 may interrupt normal regulation of neurotransmission and lead to neurotoxicity

Title: Neuroprotection by valproic acid and spermidine in a mouse model of normal tension glaucoma

Authors: ***T. HARADA**, A. KIMURA, T. NORO, X. GUO, K. NAMEKATA, C. HARADA; Visual Res. Project, Tokyo Metropolitan Inst. of Med. Sci., Setagaya-Ku, Tokyo, Japan

Abstract: Glaucoma is characterized by progressive degeneration of retinal ganglion cells (RGCs) and their axons, together with visual field loss, which are usually associated with elevated intraocular pressure (IOP). Normal tension glaucoma (NTG) is a subtype of glaucoma that presents with statistically normal IOP. We previously reported that loss of glutamate transporters (EAAC1 or GLAST) in mice leads to RGC degeneration that is similar to NTG (***J Clin Invest*** 117:1763-70, 2007). These mice show elevated glutamate neurotoxicity and oxidative stress, which have been proposed to contribute to human glaucoma. Valproic acid (VPA) is widely prescribed for treatment of epilepsy, mood disorders and migraines. It modulates multiple mechanisms including glutamate neurotransmissions, activation of pro-survival protein kinases and inhibition of histone deacetylase. Herein, we show that VPA (300 mg/kg) treatment prevented RGC death and visual disturbance in GLAST knockout (KO) mice without affecting IOP. We found that VPA reduces oxidative stress induced in the GLAST KO retina and stimulates the cell survival signalling pathway associated with extracellular-signal-regulated kinases (ERK). Polyamines, such as spermidine, are organic cations required for cell growth, cell differentiation, and synthesis of DNA, RNA, and proteins. Spermidine plays key roles in mediating protection against oxidative damage. We show that spermidine, at 30 mM in drinking water, prevented retinal degeneration and improved visual function in EAAC1 KO mice without affecting IOP. Spermidine alleviated the severity of the glaucoma-like phenotype by acting as an antioxidant. Our findings raise intriguing possibilities that the widely prescribed drug VPA and oral spermidine administration could be useful for treating retinal degenerative disorders including glaucoma. In addition, our NTG models are available to test the effect of a variety of therapeutic interventions including novel and existing drugs, particular foods, and gene therapy, in a short period.

Title: Molecular mechanisms activated by iron in neuroblastoma SH-SY5Y cells

Authors: *E. BAUTISTA, P. VERGARA, J. SEGOVIA-VILA;
CINVESTAV, Mexico City, Mexico

Abstract: Iron is essential for proper neuronal functioning; however, excessive accumulation of brain iron is reported in Parkinson's, Alzheimer's, Huntington's diseases and amyotrophic lateral sclerosis. This indicates that dysregulated iron homeostasis is involved in the pathogenesis of these diseases. In this work, we examined the molecular mechanisms activated by iron in neuroblastoma SH-SY5Y cells. We found that iron induced apoptotic cell death in SH-SY5Y cells in a concentration-dependent manner. Detection of iNOS and nitrotyrosine confirms the presence of increased reactive oxygen and nitrogen species. Furthermore, we found a decrease of catalase and protein arginine methyl-transferase 1 (PMRT1). Interestingly, iron increased the activity of ERK and AKT and reduced DyrK1B. Moreover, after FeCl2 treatment, the transcription factors c-Jun and pSmad1/5 were activated. These results indicate that the presence of high levels of iron increase the vulnerability of neurons to oxidative stress

Title: Acute binge ethanol exposure induces brain proinflammatory cytokines, NADPH oxidase, microglial activation and neurodegeneration

Authors: *L. QIN, F. T. CREWS;
Bowles Ctr. Alcohol Studies, Univ. North Carolina, Sch. Med., Chapel Hill, NC

Abstract: Binge drinking levels of alcohol increase endotoxin and innate immune signaling molecules in blood. In previous studies we found that 10 days of ethanol treatment of mice activated blood and brain innate immune gene induction including proinflammatory cytokines and NADPH oxidase (NOX) that forms reactive oxygen species (ROS) that lead to neurodegeneration. We investigated acute binge alcohol drinking responses in brain using male C57BL/6J mice treated with 1 oral binge dose of ethanol (6 g/kg, i.g., 25% ethanol w/v). We determined mRNA and protein levels of TNFα, IL-1β and MCP1 as well as NOX and ROS using real-time PCR, immunohistochemistry and hydroethidine histochemistry. Acute binge ethanol treatment increased activated caspase-3 +IR cells in the entorhinal cortex and reduced neurogenesis (i.e. doublecortin immunoreactivity) in the dentate gyrus 24 hours after ethanol treatment, consistent with increased cell death. Iba1+IR indicated activated morphology of microglia with increased NOX gp91phox expression 24 hours after ethanol exposure that remained elevated for at least 1 week after exposure. Ethanol increased gp91phox expression coincided with increased production of O2- and O2--derived oxidants. Diphenyleneiodonium (DPI), a NOX inhibitor, reduced brain gp91phox gene expression, release of ROS and microglial activation. Acute ethanol increased HMGB1 and TLR4 immunoreactivity 24 hours after ethanol treatment. Inhibition of HMGB1 by Glycyrrhizin, a HMGB1 inhibitor, decreased ethanol-induced gp91phox and ROS, as well as microglial activation. These results suggest that HMGB1 is associated with up-regulation of NOX and release of ROS after acute ethanol treatment. Further, acute ethanol induction of NOX and production of ROS may contribute to “hangover-like” acute ethanol withdrawal responses as well as long lasting microglial activation and neurodegeneration.

Title: Novel function of amyotrophic lateral sclerosis-associated fus in oxidative dna damage repair by enhancing the ligation activity of ligase iii

Authors: *H. WANG[1], T. ALAN E.[2], P. HEGDE[1], S. MITRA[3], M. HEGDE[4];
[1]Houston Methodist Hosp. Res. Inst., Houston, TX; [2]Univ. of New Mexico Cancer Center,University of New Mexico, Albuquerque, NM; [3]Houston Methodist Res. Inst., Houston, TX; [4]Houston Methodist Res. Inst., Housotn, TX

Abstract: The RNA/DNA-binding protein named Fused in Sarcoma/Translocated in Sarcoma (FUS/TLS) has been etiologically linked to the initiation and progression of motor neuron degenerative disorder, amyotrophic lateral sclerosis (ALS). While the molecular basis for many sporadic forms of ALS is unknown, the others result from hereditary mutations in the FUS/TLS gene that leads to cytoplasmic aggregation of the polypeptide. Recent studies, showing ATM-mediated phosphorylation of FUS and the latter's interaction with DNA single-strand break marker protein PARP1, suggested its role in DNA damage response. However, direct involvement of FUS in DNA repair and its pathological implications in motor neuron death in ALS is still unexplored. Furthermore, significantly higher DNA damage observed in the motor cortex and other affected brain regions of familial ALS patients harboring FUS mutations than in the control, warrants investigation of the role of FUS in DNA damage repair. Here we have observed that FUS's specific in-cell complex with XRCC1 and Ligase III but not with XRCC4 and Ligase IV, the association increased after oxidative stress in SH-SY5Y cells as well as in human motor neural cells derived from neural stem cells (hNSC line). *In vitro* co-elution analysis revealed that FUS physically interacts with both XRCC1 and Ligase III, which significantly stimulates SSBR efficiency by enhancing the catalytic activity of ligase III, an essential enzyme that ligates DNA nicks. Furthermore, sh-RNA-mediated FUS knock-down sensitized neurons to oxidative stress. Taken together, our data suggest that FUS is required for oxidative DNA damage repair via its functional regulation of DNA ligase III activity. Together with nuclear clearance of FUS in both sporadic and familial ALS, our data provides clues of how FUS mutation negatively affects oxidative damage repair in the genome and thus could open up new avenues for therapeutic intervention in ALS. Title: Sirt3-mediated deacetylation of SOD2 contributes to neuronal survival during excitotoxicity

Authors: *C. C. ALANO, S. KIM;
NEUROLOGY, VAMC/UCSF, San Francisco, CA

Abstract: Sirt3 is a major NAD-dependent deacetylase in mitochondria, and has been shown to regulate energy metabolism and oxidative stress response. In our previous study, we showed that Sirt3 plays a direct role in protecting neurons from NMDA-induced excitotoxicity. However, the mechanism by which Sirt3 mediates neuroprotection in mitochondria during excitotoxicity is not clear. Here, we show that Sirt3 deacetylates SOD2, which reduces mitochondrial ROS production upon NMDA-induced excitotoxicity. An increase in Sirt3 correlated with SOD2 deacetylation during NMDA-induced excitotoxicity. Acetylated SOD2 was not reduced in Sirt3-KO neurons under excitotoxic condition, whereas SOD2 was more deacetylated in NMDA-treated WT neurons. Neurons from Sirt3-KO had a larger increase in reactive oxygen species (ROS) production than the wt neurons after exposure to excitotoxic insult. Neurons from Sirt3 KO mice showed a decrease in mitochondrial respiration and ATP production compared to wt neurons under either control or excitotoxic conditions. NMDA-induced neuronal death was higher in neurons from Sirt3 KO mice than WT mice, which was attenuated by SOD2 mimetics. Our study demonstrates that Sirt3-mediated deacetylation of SOD2 contributes to neuroprotection from ecitotoxicity.

Title: Neuronal activity and the astrocytic Nrf2 pathway cooperate to provide neuroprotection against oxidative stress

Authors: *N. M. MARKUS[1], K. F. S. BELL[1], P. S. BAXTER[1], B. AL-MUBARAK[1], M.-A. MARTEL[1], N. WHEELAN[1], S. MCKAY[1], R. F. DEIGHTON[1], P. HASEL[1], S. CHOWDHRY[2], P. J. MEAKIN[2], A. M. KAINDL[3], R. H. SCANNEVIN[4], D. J. A. WYLLIE[1], J. D. HAYES[2], G. E. HARDINGHAM[1];

Abstract: Nuclear factor erythroid 2-related factor 2 (Nrf2) is a master regulator of antioxidant genes, and its activation in astrocytes is known to provide non cell-autonomous neuroprotection against oxidative insults. However, the capacity for dynamic regulation of Nrf2 target genes in neurons, and their role in boosting intrinsic antioxidant defences, is poorly understood. We examined the contributions of Nrf2 target genes in neurons and astrocytes in providing neuroprotection. We found that, in contrast to astrocytes, the Nrf2 pathway is inactive in neurons due to the Nrf2 promoter being epigenetically silenced during early development. However, this did not mean that Nrf2 target gene expression could not be controlled. Known Nrf2 target genes, including genes involved in the glutathione antioxidant system, were induced in neurons following neuronal activity. However, this gene induction was found to be independent of Nrf2, being observed in Nrf2-deficient neurons. Since neuronal activity is associated with higher metabolic activity and ROS production, and higher glutathione usage, this gene induction serves to tune the neuron's defences to reflect higher requirements of an active cell. Of note, we found that neuronal activity and astrocytic Nrf2 activation were additive in promoting neuroprotection against oxidative insults and sustaining neuronal glutathione levels, demonstrating the importance of both autonomous and non-cell autonomous pathways. To conclude, despite having a non-functional Nrf2 pathway, neuronal activity can promote the expression of many known antioxidant Nrf2 target genes to modify intrinsic antioxidant defences.

Title: TGF-β1 upregulates system xc- through ERK mediated increased oxidative stress

Authors: ***R. ALBANO**, J. HJELMHAUG, D. LOBNER;
Marquette Univ., Milwaukee, WI

Abstract: System x_c-, the cystine/glutamate exchanger located on the cell membrane, mediates the transport of one cystine molecule into the cell in exchange for the release of one glutamate molecule into the extra extrasynaptic space. Through providing cystine to the cell system x_c- regulates the levels of cellular glutathione (GSH), the main endogenous intracellular antioxidant, and in this way may protect cells against oxidative stress. However, by releasing glutamate, it can increase extracellular glutamate levels and potentially cause excitotoxicity. Due to this dual nature, system x_c- likely plays an important role in regulating neuronal survival and death. In order to better understand the role system x_c- plays in neuronal survival and death how it is regulated must be understood. We have found that transforming growth factor β1 (TGF-β1), which is involved in many cellular processes, increases cystine uptake through system x_c- in both a concentration and time-dependent manner in murine primary cortical cultures, with the effect being specific to astrocytes. TGF-β1 treatment also induced an early increase in oxidative stress (1 and 3 hours). The ERK antagonist, U0126, blocked both the early increase in oxidative stress and the upregulation of system x_c-, suggesting that both are downstream of ERK activation. The antioxidant allopurinol also decreased the TGF-β1 induced increase in system x_c-. Together the data suggest that the upregulation of system x_c- by TGF-β1 occurs through an early ERK-dependent increase in oxidative stress. Since system x_c- regulates the amount of GSH in cells and the TGF-β1 induced increase in oxidative stress was back to control levels by 24 hours, we hypothesized that the upregulation of system x_c- by oxidative stress increased intracellular GSH levels. Interestingly, we found that TGF-β1 did not change GSH in mixed (neural and glial) cultures. However, it decreased levels of GSH in pure glial cultures, but increased the amount of

GSH in the media. In pure neuronal cultures TGF-β1 decreased GSH levels both in the cells and in the media. We hypothesized that TGF-β1 was causing glial cells to export GSH, so that it can be taken up by and used to protect neurons. To test this we used a cell culture insert system that allowed us to co-culture glial cells and pure neurons together, but then separate them to assess GSH levels in each of the cell types separately. In this system TGF-β1 still decreased GSH levels in glial cells, however, GSH levels were maintained in the neurons. This data supports our hypothesis that glial cells are exporting GSH, which is being taken up by neurons, even to the detriment of the glial cell antioxidant defenses.

Title: Effect post-lesion of curcumin on quinolinic acid-induced dysregulation of MAPK pathway signaling in a model of striatal neurodegeneration

Authors: ***R. A. SANTANA MARTINEZ**[1], D. BARRERA[2], P. D. MALDONADO[1]; [1]Natl. Inst. of Neurol. and Neurosurg., Mexico, Mexico; [2]Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Quinolinic acid (QUIN), an endogenous competitive agonist of NMDAr, is considered an excitotoxin and its intrastriatal administration to rats has been used to reproduce some biochemical, behavioral and morphological alterations similar to those observed in some neurodegenerative disorders. QUIN induces selective neuronal death in the striatum due to overactivation of NMDAr (excitotoxicity), which has been related to acute oxidative stress. It has been checked that the oxidative stress-induced MAPK signaling pathway activation is often dysregulated in pathological conditions. Oxidative stress activates in some cases MAPK signaling to further the survival cell, but also the activation of the same pathway, promotes cell death. Emerging evidence suggest that some naturally occurring antioxidants exert their health-promoting effects by activating one or more adaptive cellular stress response pathways. Curcumin (CUR), a polyphenol derived from the rhizome of Curcuma longa is highly lipophilic and its biological properties as direct (free radical scavenger) and indirect (Nrf2 inducer)

antioxidant are well known. In this study, we evaluate the role of CUR on activation or inactivation on MAPK kinases pathway induced by QUIN and its protective effect on QUIN-induced morphological and behavioral alterations. Animals were intrastriatally infused with QUIN (30, 60, 120 and 240 nmol/µl) and after 24 h, received CUR (400 mg/kg, i.g.) daily during 6 consecutive days. CUR decreased the histological damage and number of neurons positive to FJ-B (7 days post-lesion) as well as QUIN-induced behavioral alterations in doses-dependent manner. We found that QUIN (120 and 240 nmol/µl) significantly decreased the level of phospho-ERK1/2 respect to control at 7 day. Stress-activated signaling pathway JNK and p38 were activated by QUIN at highest doses. The impairment in phospho-ERK1/2 could be related to decrease in BDNF (brain-derived neurotrophic factor) and TrkB (BDNF-receptor) levels, at same doses of QUIN. So far, our results suggest that QUIN turn off the survival-related signaling pathways and turn on death-related signaling pathways, possibly by oxidative stress. Further studies are needed to elucidate the effect of CUR and precise its mechanism action to explain the toxic paradigm induced by QUIN on MAPK signaling pathways.

Title: The impact of reactive oxygen species (ROS) on mitochondrial transport in axons

Authors: *P.-C. LIAO, P. J. HOLLENBECK;
Biol. Sci., Purdue Univ., West Lafayette, IN

Abstract: Mitochondria are the source of aerobic ATP production for the cell and also contribute to calcium (Ca^{2+}) homeostasis. To maintain cellular function and survival in neurons, mitochondria are transported along the axon between different domains, and accumulate in regions with high demand for their functions. But mitochondria are also a major source of reactive oxygen species (ROS) production, which can induce oxidative damage. Both oxidative stress and abnormal mitochondrial axonal transport induce neurodegenerative disorders. However, we know little about the connection between oxidative stress and mitochondrial transport. Here we used primary *Drosophila* neuronal cell culture and the third instar larval

Deleted: *Drosophila*

nervous system as *in vitro* and *in vivo* models, respectively, to study mitochondrial transport under oxidative stress conditions. In primary neuronal cell culture, hydrogen peroxide treatment resulted in reduced mitochondrial length and diminished membrane potential, judged by ratiometric imaging with tetramethylrhodamine methyl ester (TMRM). Both *in vitro* and *in vivo*, we found that ROS treatment inhibited several parameters of mitochondrial transport including flux, percentage of moving mitochondria, velocity, duty cycle, and run length. Furthermore, these defects were rescued by the overexpression of superoxide dismutase 1 (SOD1). Our findings indicate that oxidative stress not only affects mitochondrial morphology and membrane potential, but also reduces their axonal transport both *in vitro* and *in vivo*. To further understand the mechanisms behind these results, we activated the JNK pathway, which has been shown both to respond to oxidative stress and to inhibit fast axonal transport. JNK activation yielded reduced mitochondrial flux and velocities in both directions. In addition, JNK knockdown partially rescued defects in mitochondrial transport under oxidative stress conditions, suggesting that the JNK pathway plays a role in regulation of mitochondrial transport in response to ROS. In addition, we found higher Ca^{2+} levels, which has been shown to abolish mitochondrial transport, under oxidative stress conditions by using genetically encoded Ca^{2+} indicator (GCaMP6). These results suggest that in addition to the JNK pathway, Ca^{2+} levels are involved in regulation of mitochondrial transport in the presence of ROS.

Title: Inhibition of HDAC6 protects neuronal cells against oxidative stress-induced cell death

Authors: ***L. MA**, Y. HU, C. A. GRETZULA, S. NIROOMAND, J. J. RENGER, S. M. SMITH;
Dept. of Neurosci., Merck Res. Labs., West Point, PA

Abstract: Histone deacetylase 6 (HDAC6) plays a central role in α-tubulin acetylation, axonal transport, and neuronal oxidative stress. Inhibition of HDAC6 shows neuroprotective effects by increasing the acetylation of α-tubulin, resulting in a subsequent improvement of axonal transport of mitochondria and reversing axonal loss. Genetic deletion and inhibition of HDAC6 also delays disease progression in symptomatic deficits in neurodegenerative disorders and

motor neuron diseases. Furthermore, HDAC6 is involved in deacetylation of antioxidant enzymes peroxiredoxin-1 (Prx-1) and peroxiredoxin-2 (Prx-2), both of which primarily function to reduce hydrogen peroxide levels in the cell. Evidence shows that HDAC6 inhibition reduces oxidative stress through acetylation of the peroxiredoxins. Therefore, genetic and pharmacological inhibition of HDAC6 has the potential to be a novel therapeutic for the treatment of neurodegenerative disorders associated with oxidative damage. Here we report that the HDAC6 inhibitor Tubastatin A protects rat B35 neuroblastoma cells from L-homocysteic acid (HCA) and hydrogen peroxide induced oxidative stress in a dose dependent manner. This protective effect is also observed with oxidative stress induced apoptotic cell death. Furthermore, Tubastatin A protects primary hippocampal neurons from hydrogen peroxide induced oxidative stress demonstrating efficacy in a native system. Further study reveals that one possible mechanism for Tubastatin A's neuroprotective properties is its ability to significantly decrease peroxiredoxin superoxidation as demonstrated in hydrogen peroxide treated B35 cells. Since acetylation of Prx increases reductive properties and resistance to superoxidation, HDAC6 inhibition enhances the antioxidant properties of B35 cells by preventing deacetylation of Prx under extreme oxidative stress conditions. Taken together, inhibition of HDAC6 is a very promising novel therapeutic approach to treating oxidative stress associated neurodegenerative diseases.

Title: Inorganic mercury-mediated cytotoxicity and oxidative injury in human astrocytes

Authors: *D. OSPONDPANT[1], P. CHIVICHIT[1], N. SIBMOOH[1], S. SOODVILAI[2], P. VIVITHANAPORN[1];
[1]Pharmacol., [2]Physiol., Fac. of Science, Mahidol Univ., Bangkok, Thailand

Abstract: Mercury is a highly neurotoxic heavy metal, leading to brain injury and neurological disorders including Alzheimer′s disease. However, its toxic effects on human astrocytes, major glial cells, remain unclear. In the central nervous system, methyl mercury, a common form of organic mercury, can be demythylated and became inorganic divalent mercury, a mercuric form. This study, we aimed to compare the toxic effects of inorganic mercury, mercuric chloride, on human astrocyte cells with human neuronal cells and investigate the mechanism underlying its toxicities. Cell viability was evaluated by MTT reduction assays. Surprisingly, our finding demonstrated that mercuric chloride was toxic to human astrocytoma U373, U-87 MG and A172 cells at concentrations similar to the toxic concentration on human cortical neuronal HCN-2 cells. At 6 hours post-exposure, the median toxic concentration (TC50) values were ranged from 10.1-13.9 μM in human astrocytes and 14.3 μM in human neurons. We further studied the effects of mercuric chloride on reactive oxygen species (ROS) levels and lipid peroxidation production in human astrocytes using dichlorofluorescein (DCF) and thiobarbituric acid reactive substances (TBARs) assays, respectively. Our finding showed that mercuric chloride, 10-100 μM, increased DCF fluorescence intensity at 1 hour post-exposure and malonaldehyde levels at 24 hours post-exposure, indicating that inorganic mercury promote ROS and lipid peroxidation formation. Taken together, these data suggested that inorganic mercury-induced toxicity in human astrocytes was associated with oxidative stress. The toxicities of inorganic mercury to human astrocytes could contribute to pathophysiology of mercury-mediated neurodegeneration.

Title: Hippo/MST1 signaling regulates neuronal cell death and microglial activation

Authors: *Z. YUAN, S. ZHAO, L. ZHOU, R. WU;
Inst. of Biophysics, Beijing, China

Abstract: Oxidative stress influences neuronal cell survival and homeostasis, but the mechanisms underlying the biological effects of oxidative stress remain to be elucidated. We have shown that protein kinase Hippo/MST1 plays a major role in oxidative stress-induced cell death in primary mammalian neurons and the protein kinase c-Abl phosphorylates MST1 at Y433, which triggers the stabilization and activation of MST1, thereby activating the MST1-FOXO signaling pathway, leading to cell death in both primary culture neurons and rat hippocampal neurons. Microglial activation has been implicated as a secondary and detrimental cellular response for neuronal cell death in neurodegenerative diseases. Recently we found that MST1 is also involved in the microglial activation through directly phosphorylating IkappaB as to initiate the immune response. We further identified that Src kinase functions as the upstream of MST1-IkappaB signaling during microglial activation. Taken together, we demonstrated that Hippo/MST signaling plays a critical role in both neuronal cell death and microglial activation upon oxidative stress, with the implication of a therapeutic target for the neurodegenerative diseases.

Title: Maternal vitamin B12 deficiency is associated with increased oxidative stress and DNA damage in brain regions of C57BL/6 mouse offspring

Authors: *S. GHOSH, J. K. SINHA, M. RAGHUNATH;
NATIONAL INSTITUTE OF NUTRITION, HYDERABAD, India

Abstract: Maternal micronutrient deficiencies are predominant in developing countries. Vitamin B12 deficiency is common in women especially during child-bearing age. Maternal vitamin B12 deficiency is known to have profound impact on the developing fetus and programs it to a

number of complex adult-onset disorders like cardiovascular diseases, diabetes, neurological disturbances, etc. We hypothesized that increased oxidative stress and reduced activity of antioxidant enzymes along with DNA damage are associated with the etiology of these complications. As little is known about the effects of maternal vitamin B12 restriction on brain regions of the offspring, we have focused particularly on cerebral cortex and hippocampus in our study. Female, weaning C57BL/6 mice received ad libitum for 4 weeks a control diet (American Institute of Nutrition-76A) or the same with restriction of vitamin B12. After confirming the deficiency, the mice were allowed to breed with control males to obtain the F1 generation offspring. The different parameters related to oxidative stress and DNA damage were assessed at 3 months age of the offspring. Interestingly, offspring born to mice fed on vitamin B12 restricted diet had significantly higher degree of oxidative stress in both cerebral cortex and hippocampus as reflected by their increased levels of lipid peroxidation and protein oxidation. Also, the activity of antioxidant enzymes (superoxide dismutase and catalase) was diminished in both the brain regions of offspring born to mice fed on vitamin B12 restricted diet. DNA damage in the form of single and double stranded DNA breaks were also increased in the cerebral cortex and hippocampus of mice offspring born to vitamin B12 restricted dams. To conclude, maternal vitamin B12 deficiency is associated with increased oxidative stress in the brain of young offspring, which further leads to DNA damage in brain.

Title: Flavanoid (-)-epicatechin inhibits hemoglobin-induced oxidative stress in astrocytes via nrf2 and ap1 pathways

Authors: *X. LAN, J. WANG;
Johns Hopkins, Baltimore, MD

Abstract: (-)-Epicatechin (EC) is a natural flavonoid extracted from cocoa and green tea. Our previous studies have shown that EC improves early intracerebral hemorrhage (ICH) outcomes by modulating redox oxidative stress via the NF-E2-related factor (Nrf) 2 pathway. In this study, we cultured astrocytes from wild-type (WT) and Nrf2 null ($Nrf2^{-/-}$) mice to explore the effects and molecular mechanisms of EC on reactive oxygen species (ROS) production. In astrocytes from WT mice, EC (100 μM) significantly increased Nrf2 translocation after hemoglobin stimulation and upregulated its downstream target protein expression, including SOD1 and NQO1. However, (-)-epicatechin tended to decrease heme oxygenase 1 (HO1) expression in WT astrocytes exposed to hemoglobin. In $Nrf2^{-/-}$ astrocytes exposed to hemoglobin, (-)-epicatechin did not affect SOD1 or NQO1 protein expression, but it reduced HO1 protein expression. Furthermore, it protected WT and $Nrf2^{-/-}$ astrocytes, increased their viability after hemoglobin stimulation, and decreased ROS production in a dose-dependent manner. The IC50 of EC for inhibition of ROS production was 52.5 μM and 44.1 μM, in WT and $Nrf2^{-/-}$ astrocytes, respectively. These data indicate that the effect of EC on ROS production is not totally Nrf2-dependent. Moreover, we found that in $Nrf2^{-/-}$ astrocytes, EC inhibited translocation of activator protein-1 (AP1 [c-jun and c-fos]), which might control the transcription of HO1. Together, these data suggest that EC inhibits hemoglobin-induced ROS production in astrocytes via Nrf2 and AP1 pathways and that AP1 could be a new molecular target for treating ICH. **Keywords**: (-)-Epicatechin, redox oxidative stress, NF-E2-related factor 2; activator protein-1

Title: Characterization of the Nrf2 activation pathway, independent of oxidative stress

Authors: *C. A. SILVA[1], P. MALDONADO[2];
[2]Vascular Cerebral Patology, [1]Natl. Inst. of Neurol. and Neurosurg., Mexico City, Mexico

Abstract: Excitotoxicity is an event that occurs in neurodegenerative disorders involving overactivation of NMDAr, which increase the intracellular calcium and generate an acute state of oxidative stress. Quinolinic acid (QUIN) is a selective agonist of NMDAr capable of inducing an oxidative/nitrosative state in the cell, so its intrastriatal administration has been used as an excitotoxic/pro-oxidant model to study both events. The cells counteract the oxidative stress by activation of Nrf2 factor, a master regulator of the cellular antioxidant responses. The canonical pathway of Nrf2 activation involves the oxidation of the some Keap1 cysteins (protein that retains Nrf2 in the cytoplasm), subsequent dissociation of the complex Keap1-Nrf2 and the Nrf2 translocation to the nucleus. However, a not canonical pathway has been reported *in vitro* recently. This pathway involves the disruption of Keap1-Nrf2 complex by direct interaction of some proteins with Keap1 or Nrf2, so in this work we propose to evaluate the effect of different doses of QUIN in an *in vivo* model, on Nrf2 factor activation and these proteins, and its relationship with the state of oxidative stress in the rat striatum. We administrated 1 µL of isotonic saline or QUIN (15, 30, 60, 120 and 240 nmol) in the right striatum of male Wistar rats (260-300 g) and then we sacrificed the animals at 30 min after injection. The Nrf2 activation was measured using an ELISA kit in nuclear extract, the oxidative stress level was evaluated by GSH/GSSG levels and the lipid oxidation by TBARS assay, and finally we evaluated the enzymatic activity of GR, GST, GPx, GCL, G6PDH and CAT like a cellular redox state. The activation of Nrf2 increased 30 min after the QUIN administration in a dose-response manner. The lipid oxidation and the levels of GSH/GSSG showed not changes, but the administration of 120 and 240 nmol of QUIN slightly increased the levels of GSSG. Finally, the enzymatic activity showed no changes with all doses of QUIN. These results suggest that at 30 min, the oxidative stress is not involved in the activation of Nrf2 induced by QUIN administration *in vivo*.

Title: The ketone body b-hydroxybutyrate (BHB) reduces the production of reactive oxygen species and prevents neuronal death induced by glucose deprivation in cortical cultured neurons

Authors: *T. MONTIEL, E. SOTO TINOCO, C. GERONIMO-OLVERA, S. FLORES, L. MASSIEU T;
Inst. de Fisiologia Celular, MEXICO, D.F., Mexico

Abstract: Glucose is the most important energy source in brain and whenever its concentration in blood decreases to less than 20 mg/dl, neuronal death can take place. The mechanisms leading to neuronal death during glucose deprivation have not been completely elucidated but the role of reactive oxygen species (ROS) has been suggested. Under certain conditions the brain can consume alternative substrates to glucose, such as the ketone bodies (KB), beta-hydroxybutyrate (BHB) and acetoacetate (AcAc). KB blood levels substantially increase (from 0.1 mM to 1-8 mM) during the ketogenic diet, prolonged fasting and sustained hypoglycemia. It has been shown that the ketogenic diet reduces the number of seizures in epileptic patients and BHB administration prevents neuronal death induced in models of brain ischemia, trauma and neurodegenerative diseases. We have investigated if BHB can prevent neuronal death induced by glucose deprivation (GD) in cortical neurons and whether this effect is related to the decrease in reactive oxygen species (ROS). Primary cortical cultures obtained form E17 embryos were exposed at 8 DIV to GD during 1-2 h to GD followed by glucose reintroduction (GR). ROS production was assessed by the oxidation of the fluorescent dye, dihydroethidium (DHE), ATP levels measured by the luciferin-luciferase determination kit and cell viability assessed by the MTT reduction and the LDH release assays. Results show that D-BHB reduces 50-60% ROS generated during GD and GR, partially prevents the decline in ATP levels and reduces 50-70% neuronal death. D-BHB was effective when administered either only during GD or only during GR. The non-physiological isomer of BHB, L-BHB was less efficient preventing neuronal death as compared with D-BHB, but also effectively reduced ROS generated during GR. Results suggest that protection by BHB, results from its metabolic action combined with its capability to reduce ROS levels, probably due to its contribution to the maintenance of mitochondrial activity. They also suggest that BHB may be a good candidate for the treatment of ischemic and traumatic injury. This work was supported by IN204213 PAPIIT (UNAM) grants to LM.

Title: Novel acrolein scavenger dimercaprol mitigates acrolein-mediated PC-12 cell death, reduces acrolein concentration and offers neuroprotection in a rat contusive spinal cord injury model

Authors: *R. TIAN[1], R. SHI[2];
[1]Dept. of Biol. Med. Sciences, Weldon Sch. of Biomed. Engin., [2]Dept. of Biol. Med. Sciences, and Weldon Sch. of Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Acrolein is one of the most toxic byproducts of lipid peroxidation with a highly electrophilic chemical structure. Acrolein can react with many nucleophilic biomacromolecules including proteins, lipids and DNA, resulting in their dysfunction. As both the product and catalyst of lipid peroxidation, acrolein perpetuates oxidative stress (OS) and OS-related damages in spinal cord injury (SCI). As such, acrolein is believed to play a critical role in neuronal degeneration, particularly the expansion and worsening pathology during secondary injury, which ultimately leads to functional loss after SCI. Therefore, inhibition of secondary injury processes, particularly acrolein-mediated damage, may be an effective means to halt degeneration after SCI. In this regard, utilizing acrolein scavengers to neutralize acrolein has shown some promising results including the reduction of post-SCI damage and additional neuroprotective effects. Aiming to improve the efficacy of several known scavengers, such as hydralazine and phenelzine, we have identified dimercaprol, a FDA approved drug for metal poisoning, as an alternative acrolein scavenger. Unlike hydralazine and phenelzine, which possess hydrazine groups, dimercaprol has thiol functional groups that could bind and trap acrolein. In this study, we have confirmed that dimercaprol can indeed react with acrolein through thiol groups in a non-biotic condition using Nuclear Magnetic Resonance (NMR) spectra. In fact, dimercaprol possesses two thiol groups with the potential for binding acrolein at the carbon-carbon double bond and the aldehyde group. The acrolein-scavenging ability was further examined *in vitro* on a PC-12 cell line. Dimercaprol at non-toxic concentrations could offer dose-dependent alleviation of acrolein-mediated PC-12 cell death based on WST-1, LDH and trypan blue cell viability assays. Interestingly, the necessary dosage of dimercaprol required to reduce cell death by 50 percent is substantially less than that of hydralazine, indicating it offers a higher efficacy for acrolein scavenging. This is also consistent with the fact that dimercaprol possesses two acrolein binding groups while hydralazine only has one. In addition, we have also shown that dimercaprol, at a safe dose of 5 mg/kg, can significantly lower acrolein levels in damaged spinal cord tissue in a rat contusive SCI model. Furthermore, dimercaprol application mitigated both motor deficits based on BBB score and sensory dysfunction based on Von Frey mechanical stimulation assessment. Taken together, these data suggest that dimercaprol may be an effective acrolein scavenger and neuroprotective agent in neuronal trauma.

Title: Deleting PDE11A4 improves efficacy of the mood stabilizer lithium

Authors: *M. P. KELLY[1], B. IBRAHIM[2], K. BISHARA[2], W. CAPELL[2], J. FISHER[2], N. PATEL[2], G. PATHAK[2];
[1]Pharmacology, Physiol. & Neurosci., [2]Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Lithium is a first line mood stabilizer for patients with bipolar disorder, but for unknown reasons approximately half of all patients do not respond to lithium. Lithium responsiveness has been genetically associated with single nucleotide polymorphisms (SNPs) in Phosphodiesterase 11A (PDE11A), a unique enzyme that breaks down cAMP and cGMP and is enriched in the hippocampus. These PDE11A SNPs are intronic, which suggests they may influence expression levels. Therefore, we determined if decreasing expression of PDE11A4, the isoform in brain, was sufficient to increase lithium responsivity in mice. Here, we show that BALB/cJ mice, which respond poorly to lithium, have significantly increased PDE11A4 protein expression relative to C57BL/6J mice, which respond well to lithium. This elevation in PDE11A4 protein occurs within both cytosolic and membrane compartments of dorsal hippocampus (DHIPP) but only the membrane compartment of ventral hippocampus (VHIPP). This compartment-specific difference in PDE11A4 expression appears to be related to a nonsynonymous coding SNP at amino acid 499, which falls within the PDE11 GAF-B protein-protein binding domain. *In vitro* studies conducted in COS1 cells show that, relative to the C57BL/6J 499A sequence, the BALB/cJ 499T sequence promotes aggregation of PDE11A4 (a putative readout of homodimerization). Further, relative to 499A, 499T shifts PDE11A4 from the cytosol to the membrane (a putative readout of binding partner interactions), perfectly replicating the differences in PDE11A4 expression noted within the VHIPP of BALB/cJ vs. C57BL/6J

Deleted: In vitro

mice. To determine if decreasing PDE11A4 expression is sufficient to increase lithium responsiveness, we tested the effect of chronic lithium treatment in PDE11A wild-type (WT) and knockout (KO) mice. Consistent with the fact that lower PDE11A4 expression correlated with better lithium responsiveness across mouse strains, we found that PDE11A KO mice given 0.4% lithium chow for 3 weeks exhibited greater lithium responsivity relative to WT littermates in tail suspension, an anti-depressant predictive assay, and in amphetamine hyperlocomotion, an anti-manic predictive assay. The ability of PDE11A4 to regulate lithium responsiveness may be related to IL6, a pro-inflammatory cytokine that has been implicated in mood disorders. C57BL/6J and PDE11A KO mice demonstrated elevated IL6 protein expression in hippocampus relative to BALB/cJ and PDE11A WT mice, respectively. Together, these findings show that PDE11A negatively regulates lithium responsiveness, suggesting that genetic associations found in patients with bipolar disorder may be functionally relevant.

Abstract: The serine/threonine kinase Glycogen Synthase Kinase-3 beta (GSK3), part of the WNT signaling pathway, has been implicated in multiple human disorders including

neurological and psychiatric disorders. A growing number of direct genetic associations for WNT signaling have been established in bipolar disorder, schizophrenia and autism. In addition, a clear role for GSK3 in neuronal cell development and neuroplasticity has also been demonstrated by several groups. Importantly, in pre-clinical studies, the rapid anti-depressant effects of ketamine depend on GSK3β signaling, suggesting a therapeutic potential for GSK3β inhibitors in an acute setting in treatment resistant depression. It was also demonstrated in pre-clinical studies that potent GSK3β inhibitors may be efficacious in models of lithium insensitivity. These data suggest therapeutic potential of GSK3β inhibitors across a number of indications. While numerous GSK3α/β inhibitors are reported, none possess a desirable kinome-wide selectivity profile nor single isoform selectivity and suitable pharmacokinetic properties required of a CNS drug. Moreover, GSK3 inhibitors are known to increase β-catenin levels which has oncogenic potential. Therefore, we set out to identify small-molecule isoform selective GSK3α and GSK3β inhibitors to delineate the biological function of each isoforms and their potential use in a variety of disorders including psychiatric and neurological disorders.

Abstract: Schizophrenia is a devastating disease that affects 1-2% of the world's population with limited progress in the development of new therapeutics. Current antipsychotic drugs all target the dopamine D2 receptor (D2R) as part of their pharmacology. D2R belongs to the superfamily of G-protein coupled receptors (GPCRs) and signal through the second messenger cAMP in a GPCR dependent manner and also through b-arrestin in a GPCR independent manner. All current antipsychotic drugs antagonize the D2R/b-arrestin pathway, while demonstrating mixed pharmacology at the D2R cAMP pathway (i.e. agonist (Aripiprazole) or antagonist (Clozapine)). Recent evidence suggests that the antagonist activity at b-arrestin is responsible for the antipsychotic effect while modulation of the cAMP pathway could be responsible for extrapyramidal side effects. Amphetamine induced hyperactivity (AIH) studies recently reported by the Caron lab (successfully reproduced in our lab) suggest that the psychotic phenotype is dependent on b-arrestin2 and support the development of b-arrestin biased D2R antagonists for the treatment of schizophrenia. We have now developed a toolkit of b-arrestin biased antagonists that will help us investigate the contribution of each signaling pathway downstream of D2 on both antipsychotic efficacy and motoric side effects.

Title: Limbic regulation of prefrontal glutamate and dopamine release is mediated by stimulation of cortical alpha7 nicotinic receptors

Authors: *V. VALENTINI[1,2,3], D. M. BORTZ[4], V. PERRA[1], G. P. PIETRO[1], D. PHENIS[4], G. DI CHIARA[1,2,3,6], J. P. BRUNO[4,5];
[1]Univ. of Cagliari-Dept. Biomed. Sci., Cagliari, Italy; [2]Natl. institute of Neurosci., Cagliari, Italy; [3]Ctr. of Excellence for the Neurobio. of Addiction, Univ. of Cagliari, Cagliari, Italy; [4]Dept. of Psychology, [5]Dept. of Neurosci., The Ohio State Univ., Columbus, OH; [6]Natl. Res. Council of Italy, Inst. of Neurosci., Cagliari Section, Italy

Abstract: Dysregulations within a neural system containing the nucleus accumbens (NAC), basal forebrain (BF), medial dorsal thalamus, and prefrontal cortex (PFC) contribute to the cognitive deficits seen in several neuropsychiatric disorders (e.g. schizophrenia, ADD, drug addiction). Previously we demonstrated that stimulation of the NAC shell with NMDA evoked ACh release in PFC and that this release was cognitively beneficial, increasing resistance to distractors in a sustained attention task. We also demonstrated, using a biosensor with sec-to-sec resolution, that NMDA activation elevates both PFC choline and glutamate levels. Here we determined if a) NAC-evoked glutamate levels were also seen using more traditional microdialysis methods; b) NAC activation also increased DA release in PFC; and c) the relative contributions of nicotinic receptor subtypes to glutamate and DA release. Rats were implanted with an infusion cannula into the NACshell and either a biosensor or microdialysis probe in the ipsilateral mPFC. NMDA was infused and extracellular levels of glutamate and DA were measured. In a separate group, the role of nicotinic (α7, α4β2) receptors in this stimulated release was determined following local perfusions (1.0 or 10.0 μM) of mecamylamine (MEC), α-bungarotoxin (α-BGT), DHβE, or galantamine (3.0 mg/kg). The TTX (0.1 μM) dependency of basal and evoked glutamate and DA release was also determined. Infusions of NMDA (0.05, 0.15, 0.30 μg/0.5 μL) produced dose dependent increases in glutamate as measured with the sensor (2.01$\pm$ 0.32, 3.34 $\pm$ 0.37, and 4.56 $\pm$ 0.42 μM above baseline for each of the 3 doses, respectively). The evoked glutamate signal was rapidly cleared to basal levels in ~30 sec. Microdialysis-based measures also revealed an NMDA (0.30 μg) stimulation of glutamate efflux in PFC (75% increase). These levels were not cleared to baseline until 20 min later. Intra-NAC NMDA also increased prefrontal DA levels in PFC (100% increase). Evoked levels of glutamate and DA efflux (microdialysis) were dependent upon activation of nicotinic receptors (α7) as MEC or α-BGT blocked the increases. Blockade of α4β2 receptors resulted in partial reductions. Finally, TTX blocked stimulated release of glutamate and DA but only affected basal DA. The results confirm, using two methods, the limbic stimulation of prefrontal glutamate release. The difference in clearance times suggest different pools of glutamate may be sampled by the MEA vs the dialysis probe. Activation of NAC also stimulates DA release in PFC. Evoked release of glutamate and DA are secondary to the release of ACh and a subsequent activation of local nicotinic (α7) receptors on glutamate and DA terminals.

Title: Positive allosteric modulators of the alpha7 nicotinic acetylcholine receptor potentiate glutamate levels in prefrontal cortex *in vivo*

Authors: ***D. M. BORTZ**[1], B. A. UPTON[1], J. D. MIKKELSEN[2], J. P. BRUNO[1,3];
[1]Dept. of Psychology- The Ohio State Universit, Columbus, OH; [2]Neurobio. Res. Unit, Univ. Hosp. Copenhagen, Copenhagen, Denmark; [3]Dept. of Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Positive allosteric modulators (PAMs) of the alpha7 nicotinic acetylcholine receptor (α7nAChR) may have potential as cognition-enhancing drugs. PAMs better preserve the nature of endogenous cholinergic transmission than direct agonists because agonists stimulate receptors independent of presynaptic activity. PAMs' effects depend upon cholinergic activity, with the extent of potentiation interacting with levels of ACh/choline in cellular models. Since this effect has only been demonstrated *in vitro*, we determined if it would hold true *in vivo* by using an assay designed to a) dose-dependently evoke glutamate and choline release in PFC from awake rats and b) improve rodent performance on an attention task. Importantly, the glutamate release depends upon cholinergic activity at the α7nAChR. We tested the hypothesis that two α7nAChR PAMs (type I and II) would potentiate glutamate release in the PFC, *in vivo*, following afferent stimulation but not under basal conditions, and that the magnitude of this potentiation would vary as a function of PAM type and choline levels in PFC. Adult male Wistar rats received infusion cannulae into their nucleus accumbens shell (NaccSh) and a choline- or glutamate-sensitive biosensor in their ipsilateral medial prefrontal cortex (mPFC). On each of 3 consecutive test days, rats were infused with NMDA (aCSF, 0.05, or 0.30 µg/0.5 µL) 40 minutes after a systemic injection of either AVL3288 (type I, 5% DMSO vehicle, 1, or 3 mg/kg) or PNU120596 (type II, 5% DMSO vehicle, 3, or 9 mg/kg), and extracellular levels of glutamate were measured. Infusion of aCSF into NaccSh did not evoke choline release in mPFC, and neither PAM potentiated glutamate under these conditions. The low dose of AVL3288 (1 mg/kg) potentiated glutamate release after both the low (0.05 µg; 24.2% increase) and high (0.30 µg; 84.7%

Deleted: *in vivo*

Deleted: in vitro

Deleted: in vivo

Deleted: in vivo

increase) doses of NMDA, relative to NMDA + vehicle. The high dose of AVL3288 (3 mg/kg) had no effect on the low dose of NMDA, and inhibited glutamate release after the high dose of NMDA (64.2% decrease). The low dose of PNU120596 (3 mg/kg) failed to significantly potentiate either dose of NMDA. The high dose of PNU120596 (9 mg/kg) potentiated glutamate release after the low dose of NMDA (211%), relative to vehicle, but had no effect on the high dose of NMDA. These *in vivo* data extend previous *in vitro* results by revealing that the extent of PAM potentiation depends upon level of afferent activity at local α7nAChRs, and that there are important differences in the potentiation of type I vs. II PAMs. Thus, PAMs have potential as replacements for agonists, but comparisons in behavioral studies are needed to determine whether type I or II PAMs effectively enhance cognition.

Title: Dose dependent effects of delta-9-tetrahydrocannabinol on correlates of schizophrenia in the sub-chronic PCP rat model

Authors: ***A. SEILLIER**, S. A. PEREZ, A. A. MARTINEZ, D. J. LODGE, A. GIUFFRIDA; Pharmacol., UTHSCSA, San Antonio, TX

Abstract: The “cannabinoid hypothesis” of schizophrenia postulates that an over-active endocannabinoid system may contribute to the etiology of this pathology. However, we recently challenged this hypothesis by showing that social withdrawal, a behavioral correlate of the negative symptoms of the disease, resulted from deficient, rather than over-active, endocannabinoid transmission. This discrepancy might arise from the divergent effects of cannabis, which negatively affects the course and expression of psychosis, versus those of endocannabinoids. In this study, we tested whether the beneficial effects of endocannabinoid-mediated CB1 activation on social withdrawal in phencyclidine (PCP)-treated Wistar rats (5 mg/kg, b.i.d. for 7 days, followed by a washout period) could also be observed after administration of the psychoactive ingredient of the Cannabis plant, delta-9-tetrahydrocannabinol

(THC). To determine whether these observations could be generalized to positive symptoms, we also assessed the effects of THC (0, 0.1, 0.3, 1.0 mg/kg, i.p.) on: 1) motor activity induced by d-amphetamine (0.5 mg/kg, i.p.), and 2) dopamine neuron population activity in the ventral tegmental area (VTA). The brains from d-amphetamine-treated animals (immediately after the motor activity test) were further processed for endocannabinoid measurements. Systemic administration of THC reversed PCP-induced social withdrawal at the lowest dose tested, whereas it significantly reduced social interaction in saline-treated rats (at all the doses tested with the exception of 0.3 mg/kg). Although PCP-treated rats did not differ from saline-treated controls in the motor response elicited by d-amphetamine (irrespective of THC treatment), they showed a 2.3 fold increase of anandamide (AEA) levels in the nucleus accumbens. This AEA elevation was completely reversed by THC (at all the doses tested), which had no effect per se in saline-control rats. Interestingly, we found a robust decrease in the number of VTA dopamine neurons firing spontaneously in PCP-treated rats. THC at the lowest, but not highest, dose was able to normalize this effect in PCP-treated rats, but produced a deficit on its own at the lowest dose in saline-treated rats. Taken together, these data suggest that in contrast to high doses, low doses of THC have beneficial effects on correlates of both negative and positive symptoms of schizophrenia. This observation might shed some light on the controversial hypothesis of marijuana use as self-medication in schizophrenia patients. Supported by RO1MH91130.

Title: The effects of PDE4 and PDE10 inhibition on auditory processing in mice

Authors: ***L. SCOTT**[1], C. BUZBY[2], Z. HUGHES[1];
[1]Pfizer, Cambridge, MA; [2]Northeastern Univ., Boston, MA

Abstract: Sensory processing abnormalities have been observed in numerous psychiatric diseases, including schizophrenia. Auditory-evoked potentials (AEPs) have been used to assess these sensory processing deficits in schizophrenia patients as well as in rodent models of schizophrenia. In the present study AEPs were recorded from the frontal cortex of freely moving adult male C57BL/6J mice, using a paired pulse paradigm. Utilizing a within subject crossover

design, the effects of the novel PDE4 inhibitor, ABI-4 on AEPs were assessed and compared to those of the clinically prescribed antipsychotics, risperidone and haloperidol. The failed clinical candidate PDE10 inhibitor, PF-02545920 was included as a putative negative control compound. The PDE4 inhibitor ABI-4 (0.01-1.0 mg/kg, s.c.) caused a dose-dependent increase in the AEP in response to the first tone of each pair presented (S1) while also decreasing the response to the second tone presented (S2), resulting in enhanced auditory gating (vehicle S2/S1= 0.41 ± 0.04 ; ABI-4 (0.1 mg/kg, s.c.) S2/S1 = 0.26 ± 0.02; P<0.001). Fast Fourier transform (FFT) also revealed a dose-dependent decrease in EEG power across all frequency bands. Similarly to PDE4 inhibitors, risperidone (1.0-3.0 mg/kg, s.c.) and haloperidol (1.0-3.0 mg/kg, s.c.) were also shown to increase auditory gating in a dose-dependent manner, however this increase in gating was mediated through an increase the S1 AEP while the S2 response was unchanged (vehicle S2/S1= 0.43 ± 0.02 ; risperidone (3.0 mg/kg, s.c.) S2/S1 = 0.34 ± 0.02 ; haloperidol (3.0 mg/kg, s.c.) S2/S1 = 0.29 ± 0.02). Risperidone and haloperidol also cause a decrease in delta (1-4Hz) and theta (4-12Hz) power, but did not affect gamma (30-100Hz) power. The PDE10 inhibitor PF-02545920 had no effect on either the S1 or S2 AEP or EEG power across any frequency band. Finally, the ability of PDE10 and PDE4 inhibition to enhance risperidone-induced increases in sensory processing was also assessed. This study increases confidence that this assay may prove useful in supporting other pre-clinical programs targeting sensory processing deficits, as well as supporting the use of AEP as an electrophysiological end-point in clinical proof of mechanism and potentially proof of concept studies.

Title: Phosphorylation of Heterochromatin Protein 1 (HP1gamma) and H3S10 by antipsychotics

Authors: ***B. M. FEINER**[1], K. A. CHASE[1,2], J. MELBOURNE[1], C. ROSEN[1], R. P. SHARMA[1,3];

[1]Psychiatry, UIC Psychiatry, Chicago, IL; [2]Human Genet., Univ. of Chicago, Chicago, IL; [3]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL

Abstract: Background: Global levels of different epigenetic modifications have been found to be altered in patients with schizophrenia. We have previously reported altered levels of histone acetylation and methylation in schizophrenia subjects. However, most psychotropic drugs such as antipsychotics act through membrane receptors that are commonly linked to kinase cascades, which reach into the nucleus and phosphorylate nuclear proteins such as histones, transcription factors and heterochromatin proteins. Heterochromatin protein 1 (HP1) is proposed to encourage the spreading of restrictive chromatin domains through the binding of methylated H3K9, and acts as a bridge to adjacent nucleosomes, either binding to itself or through interplay with other stabilizing heterochromatic factors. However, phosphorylation of the γ isoform of HP1 causes it to disengage and encourages disassembly of heterochromatin, resulting in a transcriptionally facilitative environment. Methods: Human SW872 cells, selected for their expression of D2 receptor protein and mRNA, were cultured in the presence of Clozapine, Haloperidol or Forskolin for 40 and 120 minutes, at which point their proteins were extracted in the presence of phosphatase inhibitors. Levels of phosphorylated HP1γ and H3S10 were then determined via Western blot and normalized to β-actin. Results: We found that treatment with forskolin increases the levels of HP1γ, as would be predicted by its effects on cAMP levels and PKA pathway. Clozapine and Haloperidol increase levels of both HP1γphos and H3S10phos. We can demonstrate a dose and duration effect. Discussion: Phosphorylation events, while transient and reversible, upon repetition can eventually lead to long-term changes in the cell. For example, treatment with Clozapine has been shown to increase levels of phosphorylated MEK in the prefrontal cortex of rats. The MEK/ERK pathway is well-characterized, and includes a myriad of acute and long-term neuronal effects, such as potassium channel activation in the acute phase and transcription factor activation in the longer term. Acute activation of kinase cascades such as MEK/ERK could lead to lasting alterations in neuronal function that could explain the efficacy seen in antipsychotic drugs only after weeks of treatment.

Title: Glycinamide blocks MK-801-induced hyperlocomotion in an inverted U-shaped fashion in an animal model of positive-like symptoms of schizophrenia

Authors: *E. BASURTO, K. L. HOFFMAN, O. GONZALEZ-FLORES;
Univ. Autónoma de Tlaxcala - CINVESTAV, Tlaxcala, Mexico

Abstract: Experimental evidence suggests that hypofunction of the NMDA receptor participates in the pathophysiology of schizophrenia. Pharmacological attempts to enhance NMDA receptor activity involve the obligate co-agonists glycine, D-serine and D-cycloserine, which bind at the glycine modulatory site (GMS) of this receptor. In many, but not all studies, these compounds show antipsychotic effects. Inconsistent effects of these compounds might be explained by their low ability to cross the blood-brain barrier (BBB). Glycinamide is a synthetic precursor of glycine that readily crosses the BBB. In previous studies in the rat and rabbit, we demonstrated that glycinamide prevented MK-801-induced hyperlocomotion and deficits in object recognition memory. In order to characterize dose-dependent effects of glycinamide, in the present study we examined the effects of three doses of glycinamide (37, 56, 112 mg/kg, ip.) on MK-801-induced hyperlocomotion in rats, an animal model that resembles positive symptoms of schizophrenia.

Title: NSX-0527: A novel M1/M4 selective muscarinic agonist with antipsychotic and cognition-enhancing properties

Authors: J. C. OCKULY, J. D. BECK, S. A. HANSON, *M. L. HENDRICKSON;
Neurosci., NeuroSolis, Inc., Madison, WI

Abstract: Schizophrenia affects nearly 2.5 million Americans, comprising 1.1% of the adult population. Many treatments are approved, but pharmacotherapy of the disease remains problematic. Antipsychotics do provide some benefit in mitigating the positive symptoms of the disease (delusions and hallucinations), but have little effect on the negative symptoms (emotional blunting) and cognitive symptoms (impaired learning and memory). However, these compounds produce drowsiness, weight gain, and metabolic disruption, which can lead to significant morbidity and contribute to decreased medication adherence. Research into muscarinic agonists has suggested that pharmacologically balancing dopaminergic and cholinergic activity via stimulation of M4 muscarinic receptors may be as effective in treating schizophrenia as currently approved therapies. Several muscarinic agonists have been investigated in early clinical trials with the target indication of Alzheimer's disease. One of these, the M1/M4-preferring agonist xanomeline showed efficacy in AD patients. Interestingly, in addition to cognitive benefits, the compound reduced vocal outbursts, suspiciousness, delusions, agitation, and hallucinations. NSX-0527 is an M1/M4-selective orthosteric muscarinic agonist showing good bioavailability (~75%) and brain penetration (~60%), excellent metabolic stability, and a half-life of approximately one hour in rats. It was investigated in three behavioral antipsychotic assays: reversal of apomorphine-induced climbing, reversal of MK-801- and amphetamine-induced hyperlocomotion, and inhibition of conditioned avoidance response. NSX-0527 compared favorably to xanomeline as well as olanzapine without producing the classic antipsychotic side effect of hyperprolactinemia. NeuroSolis has also developed an NSX-0527 formulation that minimizes the peripheral effects of high doses. Finally, mice dosed with NSX-0527 demonstrated improved memory in the novel object recognition test, suggesting that NSX-0527 has the potential to be a first-in-class treatment that both reduces positive symptoms and enhances cognition.

Title: Pharmacological blockade of Lingo-1 in combination with olanzapine administration reverses phencyclidine induced effects on dendritic morphology, cognitive performance and locomotor activity

Authors: *J. L. ANDREWS[1,2,3], R. P. SULLIVAN[4], K. A. NEWELL[1,2,3], X.-F. HUANG[1,2,3], F. FERNANDEZ-ENRIGHT[1,3,5];

Inst., Sydney, Australia; [4]ARC Ctr. of Excellence for Electromaterials Science, Intelligent Polymer Res. Inst., University of Wollongong, Australia; [5]Sch. of Psychology, Fac. of Social Sci., University of Wollongong, Australia

Abstract: Background and Aims: Myelination dysfunction is one of the strongest hypotheses implicated in schizophrenia pathophysiology. Interestingly, myelination peaks during late adolescence, coinciding with the onset of schizophrenia. Lingo-1, a transmembrane signal-transducing molecule expressed on oligodendrocytes and neurons, is a potent negative regulator of oligodendrocyte differentiation, axonal growth and myelination. Since myelination and neuronal outgrowth disturbances lead to cognitive dysfunction, and considering the involvement of Lingo-1 in these events, we have investigated the effects of pharmacological inhibition of Lingo-1 as a novel treatment for schizophrenia in these processes. Methods: Adolescent male Sprague Dawley rats (4 weeks) were injected subcutaneously with either saline vehicle or PCP (10 mg/kg, Sigma) for a total of 8 days. On the third day, rats (n=12/group) were concurrently treated for 5 days with either olanzapine (Olz) (oral administration by cookie dough 1 mg/kg/day, 3 times/day), vehicle cookie dough and/or an anti-Lingo-1 functional antibody ab23631 (Abcam, UK), (intracerebroventricular injection: i.c.v), or saline (i.c.v), with surgery for intracranial cannula implantation performed one week prior. Behavioral testing (locomotor activity and novel object recognition) was performed prior to sacrifice. Dendritic morphology (assessed by Golgi staining) and protein expression levels of Lingo-1, and myelination marker myelin basic protein (MBP) were examined within the prefrontal cortex of the treated rats. Results: Locomotor activity was significantly increased in PCP treated rats ($p=0.044$) and both preference index and dendritic spine density were significantly reduced in PCP treated rats ($0.006<p<0.014$). Behavior and spine density were restored to near control levels in anti-Lingo-1/Olz treated rats ($0.001<p<0.004$). While Lingo-1 protein expression was increased by PCP

administration (p=0.019), the combined anti-Lingo-1/Olz treatment had no effect of normalizing Lingo-1 protein levels (p=0.325). Myelination as measured by MBP levels, were not significantly altered by any of the treatments (p>0.05). Conclusions: This is the first study to show that increased locomotor activity, decreased preference index and decreased dendritic spine density, all induced by PCP can be reversed by a combined anti-Lingo-1/Olz therapy. We suggest that Lingo-1 may be a suitable target for the development of new future therapeutic treatments targeting the cognitive deficits of schizophrenia.

Title: Pharmacotherapeutic potential of disrupting neuromodulation of hyper-dopaminergic neural activity in the co-morbid expression of schizophrenia and drug addiction

Authors: *T. COOMER, J. GALLEGOS, N. RAUSCHER, P. ELLO, K. SANDERS, R. DAS, E. OLESON;
Univ. of Colorado Denver, Denver, CO

Abstract: Schizophrenia is a debilitating psychopathology that is exacerbated by patients showing a predilection for addictive behavior. The high co-morbidity between schizophrenia and drug addiction theoretically arises from a hyper-dopaminergic state in schizophrenia, pre-sensitizing the neural mechanisms that invigorate drug seeking. Due to recent technical advances, we can now directly test this theory by assessing the causal role of heightened dopamine (DA) release in behaviors relevant to the co-morbid expression of schizophrenia and addiction. Our research attempts to establish the causality of DA in eliciting a pro-psychotic response in a conditioned avoidance task, which is a classical screen with high predictive validity for determining the efficacy of anti-psychotic drugs. We then attempt to counteract that response pharmacologically. Historically, both typical and atypical antipsychotics target the dopamine D2 receptor, but a number of issues exist with these pharmacotherapies that result in poor compliance. We propose an alternative method of treatment that targets upstream modulators of

dopaminergic neurons in the mesocorticolimbic pathway that will potentially ameliorate both the schizophrenic symptoms, and drug-seeking behaviors. To achieve this, our group artificially induces a hyper-dopaminergic state in transgenic rats by utilizing Gq-coupled DREADD virus technology. We then systemically administer antagonists of the cannabinoid CB1 receptor and orexin OX1 receptor, which we have previously demonstrated to modulate DA neural activity. Preliminary results show a DREADD-induced hyper-dopaminergic state evokes a pro-psychotic response in a classic pharmacological screen, as well as increases locomotor activity and motivation for cocaine; whereas, an anti-psychotic response and reduced motivation for cocaine is observed when either the CB1 or OX1 antagonist drug is administered. Additionally, we have found that both of these effects can be amplified when the two drugs are administered concurrently. These results show promise for targeting upstream modulators of DA function in the treatment of co-morbid diagnoses of schizophrenia and drug addiction.

Title: Positive allostery: A new approach to the treatment of schizophrenia

Authors: ***R. P. DAYA**[1], J. K. BHANDARI[1], S. K. KOONER[1], R. L. JOHNSON[2], R. K. MISHRA[1];
[1]McMaster Univ., Hamilton, ON, Canada; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Antipsychotic medications are the first line of defense against schizophrenia and other severe neuropsychiatric illnesses. Unfortunately, antipsychotic treatments control only a subset of the symptoms and induce adverse side effects that can be more severe than the illness itself. It is clear that a new approach to treatment is needed to better treat and manage the symptoms of this complex neuropsychiatric illness. We have investigated the use of a positive dopamine D2 receptor allosteric modulator (PAOPA) in regulating receptor expression as a new approach to

ameliorating the positive, negative, and cognitive symptoms of schizophrenia. In contrast to current forms of antipsychotic medication, which antagonize dopamine binding, PAOPA enhances binding to the dopamine D2 receptor. Our previous studies suggest that positive allosteric modulation with PAOPA leads to subsequent receptor internalization of the dopamine D2 receptor, ultimately decreasing dopaminergic neurotransmission and regulating aberrant receptor expression. In the present study, PAOPA was tested for its therapeutic efficacy across a battery of tests (hyperlocomotion, social withdrawal, sensorimotor gating, novel object recognition, brain metabolic activity, 5-choice serial reaction time task) in the phencyclidine and amphetamine induced rat models of schizophrenia. PAOPA showed therapeutic efficacy in behavioural paradigms representing the positive, negative, and cognitive symptoms of schizophrenia. Interestingly, some behavioural indices that were ameliorated in the amphetamine model were not ameliorated in the PCP model, suggesting that the deficits induced by amphetamine and PCP--while behaviourally and phenotypically similar--are mechanistically different and that PAOPA's effects are limited to certain mechanisms and systems. These studies provide insight into the use of positive allostery for the safe and effective treatment of schizophrenia.

Title: The ergoline 2-bromoterguride produces antipsychotic-like effects and mild hyperprolactinemia in rats

Authors: *J. BROSDA[1], E. A. TARLAND[1], R. T. FRANKE[1], H. H. PERTZ[2], H. FINK[1]; [1]Inst. of Pharmacol. and Toxicology, Sch. of Vet. Med., [2]Inst. of Pharmacy, Dept. of Biology, Chemistry, and Pharm., FU Berlin, Berlin, Germany

Abstract: Objectives: The therapy of schizophrenic patients with currently available antipsychotic drugs is of limited efficacy. 2-Bromoterguride, a dopamine D2 receptor partial agonist, has previously been shown to have antipsychotic-like activity in rats (reversal of

amphetamine-induced locomotion) without inducing adverse side effects (no changes in body weight/body fat composition and cataleptic behavior, respectively) [1]. The conditioned avoidance response (CAR) and the prepulse inhibition (PPI) of the acoustic startle response were conducted to verify the antipsychotic potential of 2-bromoterguride. In addition, the effect of 2-bromoterguride on prolactin release was investigated to screen for further potentially adverse side effects. Methods: In male Sprague-Dawley rats aged 10-15 weeks, the effects of 2-bromoterguride (0.1 and 0.3 mg/kg; i.p.) on (1) the avoidance behavior in the CAR test (two-way avoidance paradigm) 30, 90, 270min and 24h post-injection and on (2) apomorphine- or phencyclidine (PCP)-induced PPI-deficits were investigated. (3) At various time points after injection of 2-bromoterguride (1, 2, 4, 8h; 0.1 and 0.3 mg/kg; i.p.), the plasma prolactin concentration was determined by enzyme-linked immunosorbent assay (ELISA). Established antipsychotics (haloperidol, clozapine, aripiprazole) were used as positive controls. Results: Preliminary results show that 0.3mg/kg 2-bromoterguride significantly decreased CAR at 30 and 90min post-injection in a comparable manner to haloperidol and aripiprazole. Furthermore, 0.3mg/kg 2-bromoterguride antagonized apomorphine- but not PCP-induced sensorimotor gating deficits in the PPI-paradigm. 2-bromoterguride (0.3mg/kg) triggered a reduced prolactin release compared to the D2 receptor antagonist haloperidol (0.5 mg/kg). Conclusions: In the present study, the CAR test revealed that 2-bromoterguride, haloperidol and aripiprazole decreased avoidance levels, which is indicative of antipsychotic activity. Additionally, 2-bromoterguride ameliorated PPI-deficits induced by the D2 agonist apomorphine but not those induced by the non-competitive NMDA antagonist PCP, which is in agreement with the effect of various atypical antipsychotics on drug-induced PPI-deficits. Besides, the mild hyperprolactinemia indicates the drugs´ effect on the pituitary, which is not as distinct as the effect of the full D2 antagonist haloperidol. Due to the *in vitro* properties [1] and the *in vivo* antipsychotic-like effects of 2-bromoterguride, the terguride derivative may be a promising candidate for the treatment of schizophrenia with a low risk to induce adverse side effects.

Title: Effects of chronic haloperidol treatment on the nigrostriatal dopamine system

Authors: D. GROOS[1], *F. ZHENG[2,1], C. P. MÜLLER[3], C. ALZHEIMER[1];
[1]Dept. of Physiol. and Pathophysiology, [3]Dept. of Psychiatry and Psychotherapy, [2]Univ. of Erlangen-Nürnberg, Erlangen, Germany

Abstract: Haloperidol is a widely used, typical antipsychotic drug, whose therapeutic benefits and side effects in schizophrenic patients have been both linked to D2 dopamine receptor antagonism in different brain regions. In previous animal studies on chronic effects of haloperidol, the drug was typically given daily via intraperitoneal injection. Here, we re-evaluated the effect of chronic haloperidol on the nigrostriatal dopamine system in mice by taking advantage of subcutaneously implanted osmotic mini-pumps as a reliable method to achieve sufficiently high drug levels comparable to those of chronically treated patients. Adult C57Bl6 mice received haloperidol (0.5 mg/kg/d) or vehicle for 6 and 14 days, corresponding to the time points when the drug was effective or already fading, respectively. To determine the impact of chronically administered haloperidol on the electrical activity of dopaminergic neurons and on one of their target regions, we prepared brain slices from treated animals and performed whole-cell recordings from substantia nigra pars compacta (SNc) dopaminergic neurons as well as field potential recordings in dorsal striatum (DS). Chronic haloperidol treatment for 14 days reduced the intrinsic excitability of SNc dopaminergic neurons, as indicated, firstly, by an increased number of silent dopaminergic neurons, with resting membrane potentials shifted to more negative values, and, secondly, by a reduced firing frequency in neurons displaying spontaneous activity. The action potential waveforms of spontaneously active dopaminergic neurons from haloperidol-treated mice showed a significantly stronger afterhyperpolarization when compared to that of neurons from vehicle-treated mice. Interestingly, the synaptic field potentials in the DS, the major projecting area of SNc dopaminergic neurons, displayed time-dependent changes in basal transmission, with a reduction after 6 days and an enhancement after 14 days of haloperidol treatment. Independent of the duration of its application, haloperidol markedly enhanced the use-dependent inhibition of synaptic field potentials during trains of 40 stimuli at 25 Hz. Our data show that chronic haloperidol exerts a dampening effect on the nigrostriatal dopamine system in that it reduces the number of spontaneously active neurons and slows their firing rate. Furthermore, chronic haloperidol appears to have complex actions on basal and plastic synaptic properties in the DS, some of which appear to critically depend on the length of drug application.

Title: Green tea polyphenol, EGCG, attenuates phencyclidine-induced HSP70 expression and hyperlocomotion in the rat

Authors: *A. S. DARVESH[1], W. J. GELDENHUYS[1], P. SADANA[1], C. PAXOS[1], A. PRUS[2], H. BERGSTROM[3], C. K. MESHUL[4], S. P. BERGER[5];

Abstract: Noncompetitive N-methyl-D-aspartate (NMDA) antagonists such as phencyclidine (PCP) and ketamine produce psychotic behavior in humans and are used extensively as pharmacological models of schizophrenia in rodent pre-clinical studies. NMDA antagonists induce behavioral effects such as ataxia and hyperlocomotion. NMDA antagonists also produce neuronal injury and increase expression of heat shock protein 70 (HSP70), a marker for cellular injury and neurotoxicity, in the rat cingulate cortex. It has been hypothesized that neuronal circuits and biochemical mechanisms that clinically mediate PCP-induced psychotic behavior may be similar to those involved in the neurotoxic and behavioral effects of NMDA antagonists. Oxidative stress, produced by both reactive oxygen and nitrogen species, as well as inflammation, have been strongly implicated in the pathophysiology of schizophrenia. Thus both antioxidants and anti-inflammatory agents are being investigated for their therapeutic potential in schizophrenia. The present study investigated the effects of epigallocatechin-3-gallate (EGCG), a polyphenol present in green tea, which has potent antioxidant and anti-inflammatory properties, as well as the ability to inhibit the enzyme inducible nitric oxide synthase (iNOS), on PCP-induced HSP70 expression and hyperlocomotion. We also investigated the effect of aminoguanidine (AG), a selective iNOS inhibitor, on the aforementioned PCP effects. Adult, male, Sprague-Dawley rats showed a dose-dependent and significant ($p<0.05$) increase in HSP70 expression in the cingulate cortex, 24 hrs after PCP (10, 20, 30 mg/kg, i.p.) administration as measured by western blot analysis. Pre-treatment with EGCG (100 mg/kg, i.p.) or AG (100 mg/kg, i.p.) 30 min earlier, significantly ($p<0.05$) attenuated the PCP (30 mg/kg, i.p.)-induced HSP70 expression. PCP (5 mg/kg, i.p.)-induced hyperlocomotion in rats, measured for 60 min, was significantly ($p<0.05$) blocked by EGCG (100 mg/kg, i.p.) or AG (100 mg/kg, i.p.) pre-treatment, 30 min prior to PCP administration. These results support the hypothesis that iNOS mechanisms contribute to the acute neurotoxic and behavioral effects of PCP. These results also suggest that the iNOS inhibitory effect of tea polyphenols may contribute to their potential antipsychotic properties. It has also been hypothesized that naturally occurring dissociative episodes in post-traumatic stress disorder (PTSD) occur by mechanisms similar to those produced by dissociative drugs such as PCP. Thus the aforementioned results may be relevant to PTSD therapy as well.

Title: Effects of tianeptine on adults offspring rats exposed prenatally stressed rats: evaluation prenatally preventive antipsychotic and antidepressant drug treatment

Authors: H. LEE, H. WON, J. IM, H.-K. KIM, J.-T. KWON, *H.-J. KIM;
Dept. of Clin. Pharmacol., Soonchunhyang Univ., Cheonan, Korea, Republic of

Abstract: Exposing a pregnant female to stress during the critical period of fetal brain development is a risk factor for the development of psychiatric disorders in offspring. In this study, a repeated variable stress paradigm was applied to pregnant rats during the last week of gestation. The effects of the antidepressant tianeptine on prenatally stressed (PNS) rats were investigated in terms of behavioral and protein expression analyses. Many of the forced-swimming, open-field, and social interaction test parameters decreased in the PNS rats compared with those in non-stressed offspring, but the behavioral changes recovered after tianeptine treatment. Western blot and immunohistochemical analyses of the prefrontal cortex revealed that downregulation of several neurodevelopmental genes in the PNS rats recovered after tianeptine treatment. These findings demonstrate that downregulation of several genes in the PNS rats may have affected the subsequent behavioral changes, and that these phenomena recovered following tianeptine treatment. Our results suggest that tianeptine may reduce the incidence of prenatal stress related-psychiatric disorders, such as depression and schizophrenia.

Title: Embryonic stem cell transplants as a therapeutic strategy in a rodent model of schizophrenia

Authors: ***J. J. DONEGAN**[1], J. TYSON[2], S. ANDERSON[2], D. LODGE[1];
[1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [2]Psychiatry, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Schizophrenia is a devastating psychiatric disorder characterized by positive symptoms, such as delusions and hallucinations, negative symptoms, like reduced social interaction and anhedonia, and cognitive deficits. The dopamine hypothesis of schizophrenia suggests that enhanced activity in the mesolimbic dopamine system underlies symptoms of the disorder. However, no primary pathology exists in the dopamine system of schizophrenic patients and currently prescribed antipsychotic medications, which target dopamine receptors, only alleviate positive symptoms of the disorder. Previously, our lab and others have demonstrated that hyperactivity in brain regions upstream of the dopamine system, such as the ventral hippocampus (vHipp), are responsible for the increase in dopamine cell activity and schizophrenia-like symptoms in the methylazoxymethanol acetate (MAM) model of schizophrenia. Schizophrenic patients show increased vHipp activity and reduced parvalbumin (PV) and somatostatin (SST) interneurons in this brain region. Therefore, we hypothesized that restoring interneuron function in the vHipp would reverse schizophrenia-like deficits in the MAM model. To test this hypothesis, we used a mouse embryonic stem cell line containing dual reporters (Lhx6::GFP and Nkx2.1::mCherry) to grow interneuron populations enriched for either PV or SST subtypes. Cells were sorted using flow cytometry, then injected into the vHipp of MAM rats. After 30 days, a sufficient time for the cells to migrate and integrate into the existing circuitry, we performed a battery of behavioral assays to measure positive, negative and cognitive symptoms, including latent inhibition, social interaction, and attentional set-shifting. In addition, we used *in vivo* extracellular recordings to assess pyramidal cell firing in the vhipp and dopamine population activity in the ventral tegmental area (VTA). We found that SST-positive interneurons attenuate deficits in reversal learning and reduce dopamine population activity. Excitingly, the PV-positive transplants also improve reversal learning and normalize dopamine cell activity in MAM rodents, but also reversed deficits in extradimensional set-shifting and

Deleted: in vivo

social interaction. These results suggest that PV interneuron transplants may be an effective treatment strategy for the positive, negative and cognitive symptoms of the disorder.

Title: The glutathione cycle: an access point to target neural glutamate and oxidative stress

Authors: ***T. W. SEDLAK**, M. KOGA, C. HIGGS, P. TALALAY, A. SAWA;
Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Glutathione is the principal cellular antioxidant and alterations, predominantly decreases, are found in a variety of neuropsychiatric conditions including schizophrenia and Alzheimer's disease. Glutathione, is one third glutamate and present at 0.5-3 millimolar intracellular concentrations in brain, participating in antioxidant defense and drug detoxification. We find that glutathione is a physiologically relevant reservoir of glutamate, and increasing or decreasing liberation of glutamate from the glutathione cycle can, respectively, increase or decrease miniature excitatory post synaptic potential (mEPSC) frequency in rat primary cortical neurons. Sulforaphane, a plant derived isothiocyanate, augmented protein expression of GCL, the rate limiting enzyme of the glutathione cycle, and increased glutathione levels in cultured neurons. In a translational study in human subjects, sulforaphane demonstrated increases in monocyte intracellular glutathione ($p=0.08$, $n=7$). Our findings bridge independent findings of glutathione and glutamatergic dysfunction in neuropsychiatric disorders, and suggest tools with which glutathione and glutamate levels might be targeted.

Title: A stimulus-invariant threat encoding in human sensory cortex

Authors: *M. STAIB, D. R. BACH;
Univ. of Zurich, Zürich, Switzerland

Abstract: Fear learning entails establishing an association between a neutral stimulus (conditioned stimulus, CS) and an aversive event (unconditioned stimulus, US), and this alters the neural representation of the CS. Rodent studies have suggested that neurons in auditory cortex shift their tuning curves towards the frequency of a sound associated with threat, implying a stimulus-specific threat representation. However, human research has hinted towards a stimulus-unspecific representation of threat associated with complex visual objects in humans. Here, we seek to elucidate whether the encoding of a threat associated with a CS is linked to specific features. To do so, we defined stimulus sets in each of which CS+ and CS- are distinguished by different features. In two studies, healthy participants underwent a differential delay fear conditioning paradigm in a reinforcement context where the CS+ was probabilistically paired with electrical shock, while the CS- was never paired. In a non-reinforcement context, different sets of sounds were always presented alone (neutral sounds, NS). High-resolution functional MRI was recorded to measure blood-oxygen-level dependent (BOLD) signal associated with the presentation of sounds. Using multivariate pattern analysis (MVPA) of BOLD patterns in superior temporal sulcus (STS), we show that CS identity (CS+ or CS-) can be decoded from neural activity, within each stimulus set, over and above the differences between NS. However, while the identity of the stimulus can be reliably decoded within CS- and NS, responses to the CS+ from the different sets cannot be discriminated. This result is supported by a representational similarity analysis (RSA) revealing formation of a new category defined by threat level. Our results suggest a stimulus-unspecific representation of threat in sensory cortex. This could imply that threat-associated changes in sensory cortex are not simply retunings of receptive fields but crucially involve a new threat encoding.

Title: Increase thalamic modulation of cortical targets in obsessive-compulsive disorder: Network dysfunction as a basis for obsessive-compulsive symptoms

Authors: *H. PAREKH[1], D. BATTEPATI[2], A. BURGESS[2], C. RIX[2], P. ARNOLD[3], G. HANNA[4], D. ROSENBERG[2], V. A. DIWADKAR[2];
[1]Wayne State Univ., Sterling Heights, MI; [2]Wayne State Univ., Detroit, MI; [3]Univ. of Toronto, Toronto, ON, Canada; [4]Univ. of Michigan, Ann Arbor, MI

Abstract: Background: Aberrant cortical-striatal-thalamic circuitry is a fundamental pathophysiologic mechanism in obsessive-compulsive disorder (OCD, Arnold et al., 2009). OC symptoms occur when an aberrant positive feedback loop develops in the reciprocally excitatory thalamic neuronal interchanges (Modell,1989). Evidence from resting state studies suggest reduced functional connectivity within cortical-thalamic circuits, but basic cognitive challenges appear to induce task-driven hyper-modulation by regions such as the dorsal anterior cingulate (Diwadkar et al., 2015). Here we assessed task-active modulation by the thalamus of cortical targets in a large group of youth with OCD and controls. **Methods:** fMRI data were collected in 27 typical controls (age: 12-21, mean = 17.1; 18 males) and 31 OCD youth (age: 13-22, mean = 19.2; 12 males). Subjects underwent fMRI (3T Siemens Verio) using an established verbal working memory paradigm (0-back, 1-back; 30 s epochs, interspersed with 20 s rest epochs). fMRI data were analyzed in SPM8 using typical methods. Psychophysiological interaction was employed to assess contextual modulation by the thalamus of cortical targets (Friston et al., 1997). Time series from the thalamus ($p<.05$, effects of interest) were convolved with the contrast of interest (1back > 0back). The resultant first level maps representing the modulatory effect, were submitted to second level random-effects analysis to identify between group-differences. **Results:** Relative to typical controls, OCD were characterized by significantly increased modulation of the basal ganglia (Putamen, $t=2.15$, x = 21, y= 12, z = 6), and dorsal prefrontal cortex ($t = 2.63$, x = 22, y = 33, z = 30). **Conclusion:** Our results complement previous studies by suggesting that dysfunctional inputs from the thalamus may exacerbate frontal-striatal circuit dysfunction in OCD. Exaggerated intra-network modulation within the cortical-striatal-thalamic circuit may impede dynamic transitions in network function that are needed to sustain adaptive behavior. Our ongoing network-based assessments of fMRI signals are designed to experimentally address this question.

Title: Racial differences in the emotional response to aversive threat

Authors: *N. G. HARNETT[1], J. C. LADNIER[1], M. D. WHEELOCK[1], K. H. WOOD[1], M. A. SCHUSTER[2,3], M. N. ELLIOT[4], S. TORTOLERO[5], S. MRUG[1], D. C. KNIGHT[1]; [1]Psychology, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Pediatrics, Harvard Med. Sch., Boston, MA; [3]Pediatrics, Boston Children's Hosp., Bostom, MA; [4]RAND, Santa Monica, CA; [5]Hlth. Sci. Ctr., Univ. of Texas, Houston, TX

Abstract: Caucasian-American individuals tend to experience internalizing disorders, such as anxiety and depression, at a higher rate than African-American individuals. However, the neural mechanisms mediating these differences are not clear. Anxiety and depression appear to be mediated in part by a network that includes the prefrontal cortex (PFC) and amygdala, wherein altered network activity in these brain regions leads to emotion dysregulation. Pavlovian fear conditioning is often used to investigate neural processes that mediate emotional learning, expression, and regulation. Recent work has demonstrated that the unconditioned response (UCR) elicited by an innately aversive stimulus (unconditioned stimulus; UCS) is diminished when preceded by a warning cue (conditioned stimulus; CS) compared to presentation of the UCS alone (Dunsmoor et al., 2008; Knight et al., 2011; Wood et al., 2012). However, relatively little research has investigated racial differences in the brain regions that mediate conditioned diminution of the UCR. Understanding these differences may provide insight into racial differences in emotion processes related to susceptibility to anxiety and depression. The current study investigated differences in brain (i.e., BOLD fMRI) and behavioral (i.e., SCR and EMG) responses to predictable and unpredictable threat between Caucasian and African-American individuals. We observed diminished brain (e.g., dorsomedial PFC (dmPFC), dorsolateral PFC (dlPFC), inferior parietal lobule (IPL), posterior cingulate cortex, and insula) and behavioral (e.g., SCR) responses to predictable compared to unpredictable threat, consistent with prior conditioned UCR diminution research (Dunsmoor et al., 2008; Wood et al., 2012). However, African-American participants demonstrated diminished threat-elicited responses (independent

of threat predictability) in the dmPFC, dlPFC, ventromedial PFC, IPL, and amygdala compared to Caucasian-American participants. Thus, both groups display conditioned UCR diminution, but African-American participants showed a diminished response to both predictable and unpredictable threat. Follow-up analyses investigated the relationship between the neural response to threat and violence exposure, social support, socioeconomic status, and anxiety. Our findings suggest that socioeconomic status, social support, and anxiety may partially mediate the observed racial differences in the neural activity within these brain regions. The present findings suggest individual differences in socioeconomic status, social support, and anxiety may, in part, account for racial differences in emotional function.

Title: Deconstructing white matter connectivity of human amygdala and thalamus subdivisions *in vivo*

Deleted: *in vivo*

Authors: ***A. ABIVARDI**, D. R. BACH;
Psychiatrische Universitätsklinik Zürich, Zurich, Switzerland

Abstract: Objective: Subcortical amygdalo-thalamic circuits have been suggested to play an important role in early processing of sensory information. In particular, an involvement of a direct pulvinar-amygdala pathway, and more recently an interaction between amygdala and the paraventricular thalamus, has been implicated in processing visual threat information. Such connections have been revealed in non-human animals by semi-quantitative and qualitative tracing methods. However evidence concerning direct subcortical connectivity in humans is still sparse and non-systematic. Here we sought to investigate structural amygdalo-thalamic connections on a subnucleus level by means of probabilistic tractography. Methods: Amygdala parcellation into deep and superficial nucleus groups was implemented in 10 datasets from the human connectome database using a previously established protocol (Bach et al. 2011). This approach is based on voxel-to-voxel connectivity with two distinct cortical areas and uses k-means clustering. Connectivity-based segmentation of the thalamus was based on voxel-to-

region connectivity with frontal, parietal, occipital, temporal, motor and somatosensory cortex. Probabilistic tractography was then performed between these individual amygdala and thalamus segmentations excluding cortical tracts. Results: Among amygdalo-thalamic connections, both amygdala subdivisions showed highest probability of connecting with the temporal parcellation of the thalamus. This corresponds to the dorsal part of the pulvinar and partially to the paraventricular thalamus. Intermediate probabilities of connection, in descending order, were found for the occipital (middle pulvinar regions), parietal (anterior pulvinar) and frontal (MD, VA, VLa, anterior complex) thalamic parcellations. Motor (VLp) and somatosensory (LP, VPL) segments showed low connectivity with the amygdala. Stronger connections with the anterior pulvinar were observed in the deep amygdala nucleus group as well as marginally higher connectivity with the temporal thalamic segmentation for the superficial amygdala. Conclusion: Substantial connectivity between the amygdala and subdivisions of the pulvinar could be shown. Furthermore we found evidence of subcortical connections from the amygdala to paraventricular nuclei. Deep and superficial amygdala nuclei proved to have similar connectivity profiles to the thalamus. Our results consolidate and expand existing evidence of direct anatomical interaction between amygdala and the thalamus in humans and may be used as a guide for functional and pathophysiological neuroimaging studies.

Title: Meta-analysis of sex difference in human amygdala volume

Authors: D. MARWHA, M. HALARI, *L. S. ELIOT;
Dept. Neurosci., Rosalind Franklin Univ., North Chicago, IL

Abstract: Statistically-speaking, men and women differ in various measures of social-emotional behavior, including face perception, emotion recognition, fearfulness, and aggression. Each of these behaviors engages the amygdala, a limbic structure that has been proposed to differ both structurally and functionally between males and females. The amygdala has also been found to be reduced in volume in certain CNS disorders that show differential prevalence between sexes,

including borderline personality disorder, PTSD, and unmedicated unipolar depression. We therefore set out to test whether the amygdala is sexually dimorphic, using meta-analyses of amygdala volumes from MRI studies of matched healthy male and female groups of all ages. Using four search strategies, we read 872 unique studies to identify 45 total MRI studies from which we could extract effect sizes for the sex difference in amygdala volume. Among these reports, 35 studies reported raw or uncorrected amygdala volumes from 71 matched samples of males and females, and 13 studies reported data from 29 matched samples in which amygdala volumes were corrected for individual differences in in intracranial volume (ICV) or total brain volume (TBV). All data were converted to Hedges g values and pooled effect sizes were calculated using a random-effects model. Each dataset was further meta-regressed against study year and average participant age. We found that uncorrected amygdala volume is about 10% larger in males, with pooled sex difference effect sizes of 1.044 for left amygdala (k=28), 0.880 for right amygdala (k=29), and 0.774 for bilateral amygdala (k=14) volumes (all p values < 0.001). This difference is comparable to measures of both ICV (g=1.108, p<.001, 11.6% larger in males, k=10) and TBV (g=1.268, p<0.001, 10.0% larger in males, k=6) reported in subsets of the same studies, suggesting the sex difference in amygdala volume is a product of larger brain size in males. Among the studies reporting amygdala volumes that were corrected for ICV or TBV, effect sizes were small and not statistically significant, ranging from g=0.257 for bilateral volumes (p=0.131, k=5,) to g=0.230 for the left amygdala (p=0.105, k=12) and g=0.136 for the right amygdala (p=0.380, k=12). These values correspond to about 5% larger corrected left amygdala volume, and less than 0.1% larger corrected right amygdala volume, in males compared to females. In summary, males of all ages exhibit larger amygdala volume than females, but adjusting for individual variation in TBV or ICV statistically eliminates this difference, especially in the right amygdala.

Title: Contextual fear conditioning in humans using painful laser

Authors: J.-H. CHIEN[1], F. A. LENZ[1], A.-C. SCHMID[1], J.-H. KIM[3], D. T. CHENG[2], W. S. ANDERSON[1], *C.-C. LIU[1];
[1]Neurosurg., [2]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Korea Univ. Guro Hosp., Seoul, Korea, Republic of

Abstract: Contextual fear conditioning has been used in human neuroimaging studies to reveal the underlying neural mechanisms of learning and memory. During conditioning the unconditioned stimulus (US) is repeatedly paired with conditioned stimulus (CS+) in a particular environmental context (CX+). After repeated pairing, prior to US onset, an elevated skin conductance response (SCR) can be observed and is considered an indication of learning the CS-US association. To date, the functional neuroanatomy underlying the production of SCR is still largely undetermined. Traditional neuroimaging and non-invasive electrophysiological techniques do not provide sufficient spatial-temporal resolutions for studying the neuronal mechanisms underlying the changes of SCR during learning. Earlier human studies of fear conditioning often used highly annoying but not painful electric shocks as US. Less studies incorporated painful stimulus modality as US, and thus the role of US modality in such a conditioning paradigm remains unclear. In the proposed study, we aim to test the hypothesis that elevated SCRs are related to the neuronal mechanisms in the brain, and can be observed during contextual fear conditioning in humans when painful laser is used as US and repeatedly paired with CS+ in CX+. In a group of 9 healthy subjects (2 females; age 23-58 years), we used a 3D display for CSs and CXs presentations and recorded SCR during the entire experiment. The painful laser level (i.e. US) was adjusted to product a level of 5/10 on the pain rating scale. The conditioning phase consisted of 20 CS+ and 20 CS− trials, all presented within CX+. The entire trial was 21s, and the US was delivered 3s following CS+ offset in 80% of the trials. The extinction phase consisted of 20 trials in total, 10 CS+ and 10 CS- trials, all presented within CX-. Our results showed that the SCR was significantly larger comparing CS+ versus CS- during acquisition ($p=0.006$, Wilcoxon signed-rank test). The significant SCR differences between CS+ and CS- vanished at the end of extinction ($p > 0.05$). The presented results provide the initial evidence for the applicability of painful laser during the contextual fear conditioning. Our future work is to compare the neural basis of SCR between nonpainful electric shock and painful laser using high-resolution electrophysiological recordings in patients who are admitted in the epilepsy monitoring units following intracranial depth electrode implantations, and such a study may potentially advance our understanding of the brain mechanisms underlying mental conditions such as PTSD, depression and anxiety.

Title: Biases guiding preference between painful sequences

Authors: ***J. S. WINSTON**[1], C. NORD[1], K. OHRNBERGER[1], Y.-C. TSENG[1], R. B. RUTLEDGE[1], G. REES[1], I. VLAEV[2], R. J. DOLAN[1];
[1]Univ. Col. London, London, United Kingdom; [2]Warwick Business Sch., Univ. of Warwick, Warwick, United Kingdom

Abstract: When asked to report on hedonic experiences that extend over time, humans and other animals show reliable biases. Two specific heuristics that have been identified as disproportionately affecting self-reports are (i) the hedonic "peak" of the experience (the best or worst part) and (ii) how it ends; these features have been shown to impact judgments about experiences of durations between 1 minute and several years. In a series of experiments on healthy human volunteers, we explored whether such biases extend to short-lasting (6-12s) sequences of cutaneous pain, delivered by electrical stimulation. We found that judgments about painful experiences were influenced by simple heuristics, despite the short timescale. Specifically, evaluation of the overall experience was influenced more by the intensity of stimulus onset than other stimulus components. Intensity at the end of the sequence also exerted an independent bias on evaluation. The relative influence of onset and offset were strongly influenced by the introduction of a concurrent working memory task. Under working memory load, the influence of the stimulus amplitude at onset was diminished while the influence of the end of the sequence was enhanced. Overall, the findings support the idea that mnemonic limitations bias judgments of aversive experiences, even when these unfold over short timescales.

Abstract: Social anxiety disorder (SAD) is a chronic psychiatric disorder characterized by fear and avoidance of actual or anticipated social situations. The core of the disorder lays in dysfunctional beliefs concerning oneself or the way one is supposed to behave in public that triggers a feeling of being threatened by social situations. According to psychological models, SAD may result from both cognitive factors such as irrational thoughts and an attentional bias towards negative, threatening information. Exploring how SAD patients process face and expressivity from faces is crucial in understanding the pathophysiology of SAD. Emotional face processing bias may explain not only the onset of SAD, but also the persistence of SAD in the clinical population. This study investigated the time course of emotional face perception in SAD patients using EEG. Thirteen SAD outpatients and thirteen control subjects were presented with emotional faces during EEG recording. A block design was used to explore the processing of angry versus neutral faces on the one hand, and happy versus neutral faces on the other. The EEG response pattern of SAD patients was altered relative to control subjects at all processing stages, in response to both angry, happy and neutral faces. In the earliest stages of face processing, around 100 ms after stimulus, activity in the visual cortex was higher in the SAD group than in the control group, whatever the emotional expression presented. This result is compatible with a hypervigilance toward faces, irrespective of its expression during stages of attentional orientation. On the other hand, around 150 ms after stimulus, during face identity processing stage, SAD patients had a decreased activity in the right hemisphere in response to neutral, angry and happy faces as well. At later stages of information processing, around 500 ms after stimulus, the SAD group failed to show modulation of cortical activity by emotion, though the control group did. SAD patients display face processing abnormalities across the entire time range, from perceptual coding to more integrative stages of face and emotional processing. A hypervigilance to faces is then followed by a lowered coding of the structure of faces. Later still, cortical activity is decreased in the SAD group, with less sensitivity to the affective dimension of faces. This last result should be considered in the context of reduced processing of faces.

Title: The tipping point: anterior cingulate and gating of human approach-avoidance decision making

Authors: *M. W. SCHLUND[1], A. T. BREWER[2], S. MAGEE[1], D. M. RICHMAN[3], S. DYMOND[4];
[1]Univ. of North Texas, Denton, TX; [2]Florida Inst. of Technol., Melbourne, FL; [3]Texas Tech. Univ., Lubbock, TX; [4]Swansea Univ., Swansea, United Kingdom

Abstract: A wide variety of neurophysiological investigations highlight a central role for the anterior cingulate in arbitrating conflict. In approach-avoidance (AA) decision-making, conflict arises when there is a strong competition between available reward and prevailing threat, making cost-benefit analyses difficult. In this functional neuroimaging investigation, an AA conflict task was employed to examine whether the anterior cingulate simply responds to the presence of conflict (binary response) or tracks reward-threat differences (parametric response) in a way consistent with reward-threat arbitration and gating of AA decision making. Thirty healthy adults completed an AA task where monetary reward was fixed ($0.10) but threat ($1 loss) intensity was varied probabilistically (0.0 to 1.0) across trials. Each trial offered a choice to approach a reward in the presence of a CS+ intensity level displayed on a 'threat meter' or to avoid. The meter had ten CS+ threat intensities, where low levels were safe (CS-) and higher levels were paired with a greater probability of aversive US delivery. Approach produced the reward and a probabilistic US. In contrast, avoidance reduced threat to a safe CS- level and prevented US delivery. The parametric increase in CS+ threat intensity eventually led to a conflict and a switch from approach to avoidance (the AA transition threshold). Behavioral results showed increasing CS+ threat produced significant increases in ratings of fear, US expectancy, decision times and revealed the AA transition threshold. Imaging results showed increasing CS+ threat was associated with an inverted U-shaped response in pregenual and dorsal anterior cingulate and inferior frontal cortex and a U shaped response in ventromedial prefrontal cortex. For both response profiles, peak activation occurred at a lower threat level than the actual AA transition threshold and well below the uncertainty threshold (where p of loss was .50). Our findings highlighting a parametric response in the anterior cingulate suggests a role in tracking relative

differences between threat and reward information in a way consistent with reward-threat arbitration and gating of AA decision making in humans.

Title: Use of a control task battery to control for pharmacological fMRI investigation of pain responses

Authors: *L. DEMETRIOU[1], M. B. WALL[1], E. CONSTANTINOU[2], M. ANTONIADES[2], J. HOWARD[1], P. D. WHITE[2], E. A. RABINER[1], J. BOURKE[2];
[1]Imanova, London, United Kingdom; [2]Ctr. for Psychiatry, Wolfson Inst. for Preventive Med., Queen Mary Univ. of London, London, United Kingdom

Abstract: The interpretation of fMRI BOLD response relies on a cascade of cellular events, assuming its relationship with cerebral vasculature is intact; 'neurovascular coupling' (NVC). phMRI involves measuring BOLD response combined with a pharmacological agent to measure further neurochemical responses. The use of drugs may disrupt NVC and result in over/underestimations of effects. Separate placebo scans enable robust comparisons of drug effect but do not account for global effects specific to the drug used, independent of the task of interest. A region specific approach allows the use of a control task that activates regions unrelated to the task of interest. The absence of observable effects to the control task in placebo/drug scans suggests that region-specific alterations cannot be accounted for by global vascular effects. We present pilot data examining the efficacy of a brief task battery in assessing for NVC effects in a phMRI study of dopamine and opioid responses to pain in healthy controls and chronic pain patients. Seven controls (mean age 36) and five patients (mean age 39) were recruited. BOLD response was measured during 3 separate fMRI scans paired to oral placebo (always on first scan), naltrexone (NT - 50mg) and amisulpride (AMI - 400mg), separated by

one week. A brief (5 minute) task battery was developed, which included auditory, calculation, language, motor and visual stimuli presented in an event-related design with 3s trials and 10 conditions presented in a pseudo-random order. A pressure-pain paradigm was then used to examine BOLD responses to pain under drug conditions. Data was available for 12 placebo, 11 NT and 10 AMI scans. Both drug conditions (relative to placebo) produced clearly dissociable group effects on pain responses in key brain regions; generally increasing pain responses in the control group and decreasing them in the patients. However, a region of interest analysis on the control task battery data revealed only an effect in the AMI condition on the auditory component. This effect was present in both participant groups; there was no interaction with the between-subjects group variable. NT also had no effect on responses to the control task battery. The effect of AMI on the auditory task alone may represent a combination of the scanner environment and the fact that dopamine differentially modulates neural activity in auditory processing. The use of such control tasks is simple and improves the validity of phMRI studies, potentially filling the gap between fMRI and positron emission tomography (PET) methodologies on the frontier of behavioral research.

Title: Human fear conditioning follows ideal bayesian learning

Authors: ***A. TZOVARA**[1], D. R. BACH[2];
[1]Psychiatric Hospital, Univ. of Zurich, Univ. of Zurich, Zuerich, Switzerland; [2]Dept. of Psychiatry, Psychotherapy, and Psychosomatics, Univ. of Zurich, Zurich, Switzerland

Abstract: Using environmental cues to predict threat is crucial for survival, particularly in dynamic environments, where associative learning is required. Models of aversive learning propose different mechanisms, based on signed or unsigned prediction errors (Rescorla-Wagner -RW- and Pearce-Hall -PH- models, respectively), or on integrating prior expectations with

incoming evidence (Bayesian Learning models -BL-). These different models try to explain the same behaviour but give rise to different and often opposing predictions in terms of how instructive signals are computed and passed in neural networks. Here, we capitalised on Bayesian model selection to arbitrate between different learning models based on activity of the parasympathetic nervous system. In a delay fear conditioning experiment, healthy volunteers were presented with two neutral conditioned stimuli (CS+/-), one of which was paired with an aversive unconditioned stimulus (US) in 50% of trials. Threat prediction on each trial was inferred from phasic sympathetic responses, estimated from skin conductance responses in a dynamic causal model. We implemented three different families of learning models, following the RW, PH and BL rules, each including models with different levels of complexity (i.e. number of free parameters), and one family which assumed that no learning took place (NL). Model evidence was quantified as Bayesian information criterion (BIC), calculated from residual error. We used fixed and random effects analysis (FFX/RFX) for a formal model comparison. Results showed strong evidence of learning, indexed by significantly higher Bayes factors (FFX) and exceedance probabilities (RFX) for learning vs. non-learning model families. Within the learning models, model evidence was clearly in favor of BL compared to RW and PH. Among two implementations of the BL model, significantly stronger evidence was found for the less complex one, assuming uninformative beta priors for CS+/CS-. Our results suggest that ideal Bayesian learning best explains sympathetic conditioned responses during delay fear conditioning. This result crucially constrains the search for a neural implementation of delay fear conditioning in terms of aversive instructive pathways. Further studies will investigate whether other forms of conditioning, such as trace conditioning also conform to ideal Bayesian learning.

Abstract: The “need to belong” is an important evolutionary motivation for humans. Social rejection has been associated with a host of psychological and physiological morbidities including major depressive disorder (MDD). Once MDD develops, abnormal responses to social rejection or acceptance may reinforce symptoms and contribute to poor treatment outcomes. The present study compared neural responses to social rejection and acceptance in patients with MDD to a matched group of healthy controls. Participants were 18 medication-free female patients with current MDD (30 ± 10.8 years) and 19 healthy female controls (31.4 ± 12.0 years). MDD patients were diagnosed by structured clinical interview, with an average score of 17 on the 17-item Hamilton Depression Rating Scale, and were free of antidepressant medication for at least six months at the time of the study. Subjects rated online profiles of preferred-sex individuals with whom they were most likely to form a close relationship. During functional magnetic resonance imaging (fMRI) they were given feedback that they were liked or not liked by their highest-rated profiles. A priori regions of interest (ROIs) included areas within the “social pain-matrix” including the dorsal anterior cingulate cortex (dACC) and the anterior insula (AI) for rejection, and reward regions including the nucleus accumbens (NAcc) and amygdala. In both healthy controls and depressed subjects, acceptance trials corresponded to increased activation in the NAcc. Furthermore, rejection trials increased activity in the “pain-matrix” (dACC and AI) in depressed subjects, but not in healthy controls. These results indicate that there are systematic differences in how depressed individuals process social feedback.

Title: Simultaneous appetitive and aversive classical conditioning: an fMRI study

Authors: *D. TALMI[1], R. HOSKIN[2];
[1]Sch. of Psychological Sciences, Univ. of Manchester, Manchester, United Kingdom; [2]Sch. of Psychological Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: Being able to attenuate fear by using information about the long-term reward associated with a scary prospect is a key aspect of emotional intelligence. Our goal here was to elucidate the neural correlates of this emotion regulation skill. Emotion regulation has often been studied in the laboratory with re-appraisal paradigm, where participants are asked to re-appraise stimuli that have been paired with aversive outcomes in a positive manner. For example, participants may be asked to use the color of a fear-conditioned stimulus to trigger an image of a relaxing scene. However, because the re-appraisal paradigm is open-ended, we know little about how re-appraisal instructions were implemented at a mechanistic level. Here we used joint appetitive-aversive classical conditioning paradigm to study this mechanism. As in previous research, participants learned to fear inherently neutral stimuli by taking part in a classical conditioning paradigm with a 2 (threat anticipation: yes/no) x 2 (reward anticipation: yes/no) design. Participants learned about the value of four different stimuli during the course of the experiment. Two images predicted physical pain, and two predicted safety. One of the stimuli that predicted pain and one that predicted safety also predicted that monetary reward will be added to participants' account, and paid at the end of the experiment. The other two predicted that no reward will be delivered. The value of the reward was titrated individually so that it was equivalent to the (aversive) value of the painful stimulus, using the Becker-DeGroot-Marschak method. We found that the interaction between threat and reward anticipation was expressed in the inferior frontal cortex, where activation for the conflict-ridden condition (pain and reward anticipation) was stronger than the activation for the pain only or the reward only conditions.

Title: A genome-wide association study of the long-term clinical response to SSRI or SSRI with antipsychotics in obsessive-compulsive disorder in the Japanese population

Authors: *H. UMEHARA[1], S. NUMATA[1], A. TAJIMA[2,3], A. NISHI[1], I. IMOTO[2], S. SUMITANI[1], T. OHMORI[1];
[1]Tokushima Univ. Grad. Sch., Toskushima, Japan; [2]Dept. of Human Genet., Inst. of Biomed. Sciences, Tokushima Univ. Grad. School,, Tokushima, Japan; [3]Dept. of Human Genet., Grad. Sch. of Med. Sciences, Kanazawa Univ., Ishikawa, Japan

Abstract: Object: Obsessive-compulsive disorder (OCD) is a neuropsychiatric disorder with a prevalence of approximately 2%. Selective serotonin reuptake inhibitors (SSRI) are well-established first-line pharmacological treatments for OCD, and antipsychotics are used as an augmentation strategy for SSRI in SSRI-resistant patients with OCD. The purpose of the present study is to identify genetic variants and pathways which are associated with the long-term clinical response to SSRI or SSRI with antipsychotics in OCD. Methods: We performed a genome-wide association study in 93 OCD patients. The patients were divided into three groups according to pharmacological response, as evaluated by the Yale Brown Obsessive-Compulsive Scale (Y-BOCS): group A, responders to a SSRI (n=54); group B, responders to a SSRI with an atypical antipsychotic (n=22); and group C, non-responders to a SSRI with an atypical antipsychotic (n=17). Patients who showed a >35% decrease on the Y-BOCS after treatments were considered responders. These patients were evaluated at baseline and at the end of 6- to 36-month treatment (mean follow-up duration: 13.1 ± 8.1 months). To evaluate the effect of each SNP on the clinical response (SSRI response (group A vs. group B plus C) or the response to a SSRI with antipsychotics (group B vs. group C)), logistic regression analysis was performed using the PLINK software with adjustment for covariates sex, age, onset age and Y-BOCS baseline score. A pathway-based analysis was conducted by Improved Gene Set Enrichment Analysis for Genome-wide Association Study (i-GSEA4GWAS). Results: We didn't reveal any genetic variants associated with clinical responses to SSRI or SSRI with an atypical antipsychotic at genome-wide significance. However, we identified 8 enriched pathways in the SSRI treatment response and 5 enriched pathways in the treatment response to SSRI with an antipsychotic medication (FDR < 0.05). Conclusion: Our results may provide the clues of the mechanisms of treatment response in OCD.

Title: Computer-based “avatar” to assess avoidant behaviors in participants with symptoms of posttraumatic stress disorder (PTSD)

Authors: ***C. E. MYERS**[1,2], Y. T. EBANKS-WILLIAMS[1], M. L. RADELL[1], K. D. BECK[1,2], M. W. GILBERTSON[3];
[1]Dept. of Veterans Affairs, New Jersey Healthcare Syst., East Orange, NJ; [2]Dept. of Pharmacology, Physiol. & Neurosci., Rutgers-New Jersey Med. Sch., Newark, NJ; [3]Dept. of Veterans Affairs, Manchester VA Med. Ctr., Manchester, NH

Abstract: Symptoms of posttraumatic stress disorder (PTSD) include cognitive and behavioral avoidance of reminders of a traumatic event. PTSD symptoms can be assessed through clinical interview as well as via self-report questionnaires, such as the PTSD Checklist (PCL), which queries for frequency of specific PTSD-related symptoms. The PCL is well-validated and highly predictive of clinical PTSD, but like all self-report questionnaires it can be subject to demand characteristics as well as vulnerable to unawareness of deficit. It would therefore be useful to have a behavioral tool for the assessment of avoidant behavior, which generates scores correlated with PTSD symptomatology. A viable approach may be virtual environments, in which participants guide avatars through a series of on-screen events that simulate real-world situations. We have been developing such a tool, where participants select avatars to represent themselves and then guide the avatars through several simulated scenarios, such as attending a party or helping out at a volunteering event. At each choice point, participants are asked what the avatar would do next, and can select from predefined response options corresponding to avoidant, non-avoidant, or neutral behaviors. In an initial sample of putatively healthy young adults (college students), scores on the avatar task were strongly predictive of the personality trait of behavioral inhibition (BI), a tendency to withdraw from or avoid novel situations that is a risk factor for PTSD and anxiety disorders. The relationship between performance and BI held regardless of participant gender or prior experience with computer games. Here, we considered a sample of veterans and community civilian controls (mean age 52 years), assessed for PTSD symptoms via the PCL. Over half of the sample met symptom criteria for PTSD based on PCL. Results show a strong correlation between task scores and PCL scores; additionally, subjects reporting diagnosed PTSD scored significantly higher on the task than those reporting no PTSD or anxiety disorders. Importantly, the relation between PTSD symptoms and task performance held even though the task did not specifically invoke trauma-related imagery or events, but rather simply scored how the avatar behaved in various social situations. These results suggest that virtual environments may hold promise as alternative formats for observing, rather than merely querying, avoidant behaviors related to PTSD symptomatology, and also add to a growing literature documenting that avoidant behaviors in those with PTSD symptoms may represent a general cognitive bias not limited to trauma-related situations.

Title: Gender differences in avoidance behavior in individuals with post-traumatic stress disorder (PTSD) symptoms

Authors: ***M. L. RADELL**[1], J. SHEYNIN[2,3], K. D. BECK[1,4], K. C. H. PANG[1,4], C. E. MYERS[1,4];
[1]VA New Jersey Hlth. Care Syst., East Orange, NJ; [2]Veterans Affairs Ann Arbor Healthcare Syst., Ann Arbor, MI; [3]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI; [4]Dept. of Pharmacology, Physiol. & Neurosciences, New Jersey Med. Sch., Newark, NJ

Abstract: Women are more likely to be diagnosed with post-traumatic stress disorder (PTSD), and exhibit differences in symptom presentation and course, compared to men. Exaggerated avoidance is a prominent feature of PTSD and potential differences in how men and women learn to avoid aversive events could, in part, underlie the observed gender differences in vulnerability. Therefore, understanding gender differences in PTSD might provide the opportunity to tailor treatment to the individual and improve clinical outcomes. Previously, we examined avoidance learning in putatively healthy young adults using a computer-based task and found that women acquired avoidance behavior to a greater degree than men. Here, we examined avoidance learning in veterans and civilians (mean age 53 years) with self-reported PTSD symptoms in a similar task. Participants could learn to shoot an enemy spaceship to earn points and hide their own spaceship from an enemy to avoid losing points. On each trial, a warning signal predicted subsequent point loss caused by an enemy firing at the participant's spaceship. Subjects could move their spaceship into safe areas to completely avoid losing points, or to escape from enemy fire, terminating ongoing point loss. While there was a conflict between approach and avoidance in our previous study, here, we limited the opportunity to earn points to a safe intertrial interval. PTSD symptoms were also quantified via the PTSD Checklist (PCL), a well-validated self-report questionnaire predictive of clinical PTSD. Subjects were split into low

PTSD symptom (low PTSS) and high PTSD symptom (high PTSS) groups based on PCL scores (<50 or 50+, respectively). While most subjects learned to escape, a subset did not, and this included more “low PTSS” women. Among subjects who did learn to escape, “low PTSS” women escaped less than “high PTSS” women, and less than men regardless of PTSS. Finally, in contrast to our study in young adults, the results so far show that “low PTSS” women also tended to avoid less. Age differences between the studies could account for this discrepancy. Since approach-avoidance conflict was removed from the current study, associations with gender may also depend on the presence of competing responses, i.e. where the ability to obtain reward precludes avoidance. Finally, the results suggest that women with more PTSD symptoms are, as expected, more susceptible to avoidance than women with fewer symptoms, even in non-trauma-related situations. It remains unknown if this is due to preexisting differences in associative learning that confer vulnerability to PTSD in women who will later experience trauma or results from developing the disorder.

Title: Differential effects of us alone trials: pre-exposures, but not interpolated trials, disrupt acquisition of conditioned eyeblinks in anxiety vulnerable individuals

Authors: *T. ALLEN[1,2], D. P. MILLER[3,2], R. J. SERVATIUS[4,2];
[1]Sch. Psych Sci., Univ. Northern Colorado, Greeley, CO; [2]Stress and Motivated Behavior Inst., Syracuse, NY; [3]Neurosci., Carthage Col., Kenosha, WI; [4]Syracuse Veterans Affairs Med. Ctr., Syracuse, NY

Abstract: Behavioral inhibition (BI), defined as a temperamental tendency to withdraw from or avoid novel social and non-social situations, enhances acquisition of conditioned eyeblink responses (CRs). Holloway et al. (2012) reported enhanced proactive interference of eyeblink

conditioning following US alone or CS alone pre-exposures in individuals with high trait anxiety. More recently, acquisition of CRs did not differ between a partial reinforcement protocol with 50% US alone (corneal air puff) trials as compared to 100% CS-US (tone-air puff) trials (Allen et al., 2014). This was surprising given the reduction in paired trials in the 50% US alone. Previously, Kimble et al. (1955) tested a protocol with an interpolated block of 20 US alone trials during CS-US training and reported that CRs did not differ from those receiving 100% paired trials. We sought to extend the work with US alone training both when pre-exposed and interpolated into training sessions include behavioral inhibition. Undergraduates completed personality inventories including the Adult Measure of Behavioural Inhibition (AMBI). All participants received 60 acquisition trials. Acquisition consisted of either 100% CS-US training, 20 CS-US trials followed by 20 US alone trials, followed by 20 more CS-US trials or 30 US alone pre-exposures followed by 30 CS-US trials. BI individuals exhibited more CRs than non-inhibited individuals in the 100 % CS-US training protocol and the Kimble et al., protocol. The interpolated US alone trials did not disrupt CRs which replicated the findings of Kimble et al. The US alone pre-exposures disrupted acquisition of eyeblink CRs which replicated the findings of Holloway et al. In addition, US alone pre-exposures eliminated the enhanced acquisition normally observed in BI individuals. The effects of unpredicted aversive stimuli on learning and anxiety will be discussed in the light of uncertainty, learned helplessness, and cue salience.

Title: Assessing behavioral flexibility in anxiety vulnerable rats using of a novel aversive strategy shifting task

Authors: *J. E. CATUZZI[1,2], K. C. H. PANG[1,3], K. D. BECK[1,3];
[1]Dept. of Veterans Affairs, NJHCS, East Orange, NJ; [2]Grad. Sch. of Biomed. Sci.,
[3]Pharmacology, Physiol. & Neurosci., Rutgers Univ., Newark, NJ

Abstract: Behavioral flexibility is the ability to alter learned behaviors in response to unexpected changes in the environment, and is dependent on the ventromedial prefrontal cortex (vmPFC). Several psychiatric disorders, including anxiety disorders, are associated with vmPFC dysfunction and exhibit a lack of behavioral flexibility. Strategy shifting tasks used to assess behavioral flexibility have traditionally employed appetitive motivation, whereas tasks used to assess anxiety employ aversive motivation. In this study we sought to determine whether behavioral flexibility in anxiety vulnerable rats differs between appetitive and aversive motivated strategy shifts. Anxiety vulnerable Wistar Kyoto (WKY) rats naturally exhibit inflexible behavior in the form of perseverative avoidance. In the first experiment, WKY and Sprague Dawley (SD) rats were tested in an appetitive maze-based strategy shifting task. In this task, rats were presented with two stimulus domains (color and texture) with only one domain predictive of reward. WKY rats acquired the initial discrimination faster than SD rats. Both strains expressed similar performance during reversal learning (intra-domain change), but, WKY rats acquired extra-domain shifts faster than SD rats. In a second experiment, WKY and SD rats will be tested in a novel, aversive operant-based strategy shifting task. In this task, rats will be presented with two stimulus domains (lever-location or light-location) with only one domain capable of terminating shock. We predict that WKY rats will again acquired initial discrimination faster than SD rats and both strains will express similarities in reversal learning. In contrast to the appetitive strategy shifts, we predict that WKY rats will have more difficulty in aversive strategy shift compared to SD rats. These results would provide a novel way to assess the negative bias underlying anxiety disorders.

Abstract: Anxiety disorders interfere with individuals' ability to perform daily tasks, and are often associated with specific decision-making biases. For instance, loss aversion is a well-documented human tendency - defined as a willingness to sacrifice attainable gains in order to avoid equivalent potential losses. Data suggest that loss aversion is increased in anxiety, but studies have rarely examined clinical populations across the full range of anxiety disorders. Here, we investigated the influence of anxiety disorders on variables that shape decision-making under risk, using the Cumulative Prospect Theory framework (Tversky & Kahneman; 1992). Eighty-seven patients recruited from an academic Anxiety Disorders Clinic and 20 control subjects were given a battery of self-report clinical and personality measures and completed a computerized decision-making task. The task required a series of decisions in which subjects chose preferred gambles based on varying probabilities of winning or losing varying amounts of points. We employed the two key elements of the Prospect Theory: (1) Utility function, which models the diminishing sensitivity for increasing gains/losses, as well as the loss-aversion phenomenon; (2) Probability function, which models the tendency to over-weight small probabilities and under-weight moderate and high probabilities. Parameters were estimated for each subject to generate a close fit of subject's performance on each trial of the task. Preliminary findings suggest that anxious individuals, across multiple diagnoses, have altered processing of the value of gains and losses, consistent with evidence of similar disruptions in post-traumatic stress disorder. This investigation will shed light on anxiety-related decision making biases involving approach and avoidance tendencies, and examine differences across various anxiety disorders. Such biases may contribute to sub-optimal decision making and maladaptive behavior in patients with anxiety. (JS and SAG have equally contributed to this work.)

Title: Functional changes in brain activity in response to recent traumatic experiences: a trauma specific fMRI study

Authors: *A. S. NILSEN[1], I. BLIX[1], S. LEKNES[2], T. HEIR[1];
[1]Norwegian Ctr. For Violence and Traumatic Stress, Oslo, Norway; [2]Intervention Ctr., Oslo Univ. Hosp., Oslo, Norway

Abstract: Exposure to traumatic events such as assault, injury, combat, accidents and death, can develop into Post-Traumatic Stress Disorder (PTSD). The past 20 years an increasing number of studies have focused on the neurobiological mechanisms of PTSD, however, short term neurobiological changes of trauma exposure, pre-PTSD diagnosis, are not well understood. We employed fMRI to investigate functional changes in response to trauma specific, threatening and neutral visual stimuli (images selected from the IAPS database). Twenty three trauma exposed participants (females=5, age=40.1±12.5) who were recently (within 3 weeks) involved in serious traffic accidents, performed a standardized picture task including road traffic accidents (trauma specific), violence (threatening) and neutral pictures. The trauma exposed group was matched on gender, age and education with 21 healthy controls (females=7, age=36.9±9.2). We analyzed functional blood oxygenation response between conditions and groups while controlling for symptom severity as measured by the PTSD checklist (PCL). Based on the existing literature of fMRI studies of negative emotional stimuli in trauma exposed participants with PTSD, we hypothesized that trauma exposed participants without PTSD would show higher activation of amygdala and reduced activation of medial prefrontal cortex, during viewing of trauma specific and/or threatening images relative to neutral images. A secondary hypothesis was that activation patterns in these regions would reflect symptom severity, as measured by the PCL. Contrary to the main hypothesis, preliminary results indicate no significant hyperactivation in amygdala or hypoactivation in medial prefrontal cortex when watching trauma specific or threatening stimuli in trauma exposed participants, as compared to the control group. Furthermore, the activation patterns were not significantly modulated by symptom severity. Compared to controls, participants who had recently been involved in a traffic accident did show significantly higher activation in the visual system along the dorsal and ventral visual streams, including bilateral superior colliculi, fusiform cortex and parahippocampal gyrus during viewing of trauma specific images. These results are consistent with an increased perceptual sensitivity to trauma specific material in this group at ~3 weeks after the traumatic event. We discuss these findings as potential early indications of risk of (or protection against) development of PTSD.

Title: Time-dependent changes induced by acute stress in function and architecture of excitatory synapses in prefrontal and frontal cortex

Authors: ***M. POPOLI**[1], L. MUSAZZI[1], P. TORNESE[1], N. SALA[1], G. TRECCANI[1,2], C. BAZZINI[1], G. WEGENER[2], J. NYENGAARD[3], N. NAVA[3,2];

Abstract: Stressful life events impact on brain and bodily function and represent major risk factors for stress-related neuropsychiatric disorders. The response to stressful events can promote adaptive plasticity and improved cognition, when the physiological stress response is efficiently activated and inactivated in due time, or maladaptive and harmful effects, when the response is overused or dysregulated. In turn, the outcome of a maladaptive stress response can be associated with the triggering of brain, systemic and metabolic disorders. Chronic stress has been shown to induce reduction of density of synapses and dendrites in prefrontal and frontal cortex (PFC/FC), with concomitant impairments in neuronal activity and cognitive functions. Instead, the early and rapid effects of acute stress on synaptic function and plasticity are often opposite, with enhancement of glutamate release/transmission, increased number of spines and synapses, enhancement of synaptic strength. However, the delayed effects of acute stress have not been investigated, although this could give crucial information on the time-dependent changes in the brain stress response. We have previously characterized the synaptic effects of acute footshock (FS)-stress, which induces enhancement of glutamate release/transmission in PFC/FC, due to the increase of the readily releasable pool (RRP), in turn mediated by rapid non-genomic corticosterone action at synapses (Mol. Psy., 19:433-443, 2014). Here we have analyzed the effects of acute FS-stress in the PFC/FC of rats at different times after completion of the stress protocol. We found that acute stress induced early and sustained increase of RRP over time in excitatory perforated synapses, while the number of non-perforated and axo-spinous synapses

was increased (without changes in vesicle pools). The total number of synaptic spines was increased up to 24 h, while apical dendrites showed decreased density 2 weeks after acute stress (with no significant changes at earlier times). In behavioral tests for working memory, FS-stress improved performance 2 h after stress and impaired it after 24 h. Changes in glutamate release, RRP, number of synapses and spines are blocked or attenuated by prior chronic treatment with the antidepressant desipramine. The different glutamatergic modifications in functional and morphological plasticity suggest a bi-phasic process, during which the stress response in PFC/FC may turn from early increased excitatory activation into its opposite. The identification of these points and the players involved in the switch are crucial for the understanding of the dynamics of stress-related pathology.

Title: Transcriptomic ‘hyper-maturity’ of the hippocampus in mice

Authors: ***H. KOSHIMIZU**[1,2], H. HAGIHARA[1,2], K. OHIRA[1,2], K. TAKAO[3,2], T. MIYAKAWA[1,2,3];
[1]ICMS, Fujita Hlth. Univ., Toyoake, Japan; [2]CREST, JST, Kawaguchi, Japan; [3]Ctr. for Gene. Anal. of Behav.,NIPS, Okazaki, Japan

Abstract: The development and maturation of the brain has long been believed to be a one-way process. In previous studies on mouse models of psychiatric disorders, we showed the existence of pseudo-immature brain cell states as intermediate phenotypes in these disorders. Recent studies, including our own, have shown that some brain cells repeatedly undergo rejuvenation and maturation in response to changes in the external environment, such as treatment with antidepressant [fluoxetine (FLX)], pilocarpine-induced seizure, and physiological stimulation. Maturation failures in the brain have also been identified in some regions and cell types in

patients with psychiatric disorders, including schizophrenia and bipolar disorder. Overexpression of glucocorticoid receptor (GR) in the forebrain during early life and throughout the lifetime causes increased depression-like and/or anxiety-like behaviors in mice, suggesting that mice overexpressing GR (GRov mice) represent a potential animal model for mood disorders, such as depression and anxiety disorder. Overexpression of GR has been shown to cause an aging-like neuroendocrine phenotype and mild cognitive dysfunction in young mice, raising the possibility that GRov mice may have an "hyper-matured" brain status. In this study, to assess whether cellular maturity of brain cells in the mice is altered, we compared genome-wide gene expression in the DG of GRov mice with those of the corresponding regions in normally developing brains of wild-type (WT) mice by using a bioinformatics tool, NextBio. The DG of GRov mice exhibited an opposite expression pattern of immaturity and maturity marker genes when compared to the developing DG in WT mice. We further tried to find microarray data sets that have statistically significant similarity in their gene expression patterns to those in GRov mice among more than 56,900 publicly available microarray data sets. Hippocampal gene expression patterns in the glutamate dehydrogenase 1 (Glud1) transgenic (Tg) mice, which shows aging-related biochemical and physiological phenotypes, and in the mice treated with PF-04447943, a selective phosphodiesterase-9 inhibitor, were significantly similar to those in the DG of GRov mice. These mice also displayed contrasting gene expression patterns in the hippocampus to those in developing DG in WT mice. These observations indicate that maturation status of the hippocampal cells might be altered toward ‘hyper-maturity’ in GRov mice, Glud1 Tg mice, and PF-04447943-treated mice, suggesting that cellular hyper-maturation is a common phenomenon shared by a certain type of state in the brain induced by some genetic or pharmacological manipulations.

Title: Paternal transmission of stress-induced phenotypes are transmitted via male germ cells

Authors: *D. M. WALKER, M. A. DOYLE, R. C. BAGOT, D. BUREK, E. J. HARRIGAN, G. E. HODES, J. RABKIN, E. S. CALIPARI, H. M. CATES, O. ISSLER, M. E. CAHILL, B. LABONTE, E. A. HELLER, J. FENG, C. J. PENA, E. RIBEIRO, O. ENGMANN, Z. LORSCH, P. J. HAMILTON,, E. J. NESTLER;

Abstract: Depression is caused by a combination of genetic and environmental factors. In addition, it has been proposed that epigenetic mechanisms may also contribute to the risk for depression. Recent evidence suggests that the offspring of males who are susceptible to chronic social defeat stress (CSDS) display increased depressive- and anxiety-like behaviors but only after the fathers are exposed to stress. The mechanisms by which such parental experience influences stress susceptibility of their offspring are poorly understood. We tested the hypothesis that changes in sperm cells during CSDS are responsible for encoding increased susceptibility to stress in F1 and F2 offspring. Male mice were exposed to 10 days of CSDS and subjected to social interaction testing to assess paternal phenotype. Males identified as resilient or susceptible to CSDS, as well as control F0 males, were allowed to mate 30 days after the stress, to allow the sperm exposed to the stress to mature. One week following natural mating, those same F0 males were euthanized and their sperm was collected for artificial insemination and snap frozen for epigenetic analysis. At ~P60, 1 male and 1 female in each litter was exposed to subthreshold unpredictable stress and depression- and anxiety-like behaviors were assessed. Each animal was compared to an unstressed littermate of the same sex to control for litter effects. Additionally, phenotypes of offspring produced via natural mating and artificial insemination were compared between litters sired by the same father to investigate if the phenotype was passed via the paternal germ cells. Preliminary evidence suggests that F1 offspring of defeated fathers produced by natural mating or by artificial insemination display altered phenotypes, with opposite effects seen in males and females. Paternal stress augmented stress susceptibility of F1 males, while reducing it in F1 females. These data suggest that there are changes in sperm during CSDS that encode altered depressive- and anxiety-like phenotypes in their offspring. Transgenerational inheritance is currently being investigated by assessing similar outcomes in the F2 generation, and epigenetic changes are being investigated in the sperm of the F0 fathers to identify the molecular mechanisms of this paternal transmission.

Title: Dissociative depression-related behavioral effects of cholinergic signaling in the ventral tegmental area versus the nucleus accumbens

Authors: *K. M. SMALL, E. J. NUNES, N. A. ADDY;
Dept. of Psychiatry, Yale Univ., New Haven, CT

Abstract: Preclinical studies report that cholinergic signaling in both the ventral tegmental area (VTA) and the nucleus accumbens (NAc) is involved in regulating depression-related behaviors. Cholinergic receptors on multiple neuronal populations in the VTA and NAc can robustly alter dopaminergic activity that is known to mediate susceptibility to stress. However, it remains unclear whether cholinergic mechanisms in the VTA and NAc similarly or distinctly mediate behavioral responses to stress and anxiety that are implicated in depression. Thus, the goal of the present study was to determine whether an increase in cholinergic tone in the VTA or the NAc would similarly modulate various depression-related behaviors. Adult Sprague-Dawley male rats, were surgically implanted with a bilateral cannula into the VTA or NAc. After a recovery period of one week, we examined whether pharmacological manipulation of VTA and NAc cholinergic tone altered responding in the forced swim test (FST) and the sucrose preference test. We found that VTA administration of the acetylcholinesterase inhibitor, physostigmine (0, 1, or 2 μg/side), increased immobility time in the forced swim test and decreased sucrose preference in a dose-dependent manner. In contrast, physostigmine (0, 1, or 2 μg/side) administered into the NAc dose-dependently decreased immobility time in the forced swim test but had no effect on sucrose preference. The physostigmine effects in the VTA suggest susceptibility to stress while the effects in the NAc are suggestive of an antidepressant-like response. These findings provide new insight into the role of cholinergic activity in the mesolimbic circuitry in depression-related behavior.

Title: Antidepressant screening of a novel glun2b-specific n-methyl-d-aspartate receptor antagonist ro 8-4304

Authors: ***N. PROWSE**, K. FARMER, S. HAYLEY;
Carleton Univ., Ottawa, ON, Canada

Abstract: The Canadian Mental Health Association estimates that major depression affects approximately 8% of Canadians at some point in their lives, and up to 30% of those affected do not respond to traditional therapeutics. Low doses of ketamine, a N-methyl-D-aspartate (NMDA) receptor antagonist, have been found to alleviate depressive symptoms more rapidly than conventional anti-depressants particularly in treatment-resistant patients. Recent research suggests that the anti-depressant effect of ketamine is specific to NMDA receptors containing the GluN2B subunit. In this study, we ran an antidepressant screening of the novel GluN2B-specific antagonist Ro 8-4304 hydrochloride to determine if the drug could reduce immobility time in the Porsolt Forced Swim Test (FST); a traditional preclinical screening test of potential anti-depressant medications. 20 male Balb/c mice were divided into 4 groups and were given intraperitoneal injections of saline, 5mg/kg, 10mg/kg, and 15mg/kg of Ro 8-4304, respectively. All mice were tested one hour post-injection using the FST. The 15mg/kg group exhibited a statistically significant trend towards reduced immobility in the FST. While low dose ketamine treatment has been found to produce an increase in brain-derived neurotrophic factor (BDNF) in the hippocampus, our study did not find significant increases in BDNF in any of the treatment groups. These findings are sufficient to suggest that a dose of 15mg/kg of Ro 8-4304 may have antidepressant effects, and therefore should be studied more extensively using a chronic mild stress paradigm to determine its full treatment potential and to elucidate its mechanisms of action.

Title: Mechanism of lithium-induced recovery of memory and emotional impairment in DGKbeta KO mice

Authors: *W. OKIMOTO[1], M. ISHISAKA[2], H. NAKANISHI[3], S. UEDA[1], M. YAMANOUE[1], T. SASAKI[3], H. HARA[2], Y. SHIRAI[1];
[1]Kobe Univ., Kobe, Japan; [2]Gifu Pharmaceut. Univ., Gifu, Japan; [3]Akita Univ., Akita, Japan

Abstract: Diacylglycerol kinase (DGK) converts diacylglycerol to phosphatidic acid. To date, 10 mammalian subtypes of DGK have been identified. Among them, DGKβ is enriched in neuron. We have developed DGKβ knockout (KO) mice to investigate function of DGKβ in nervous system, and revealed that they have emotional and memory disorder with decrease of spine density. Interestingly, both disorders were rescued by 10 days lithium treatment [1,2]. However the mechanism is still unknown. Therefore, to elucidate the mechanism, we measured spine density after the lithium treatment, and found that, spine density in KO mice was recovered with lithium, indicating that spine density is a key for both impairment and recovery of memory and emotion of the KO mice. And now, we are investigating changes in lipid metabolism in neurons from the KO mice before and after the lithium treatment.

Title: Interpeduncular nucleus neurons innervate dorsal raphe nucleus serotonergic neurons preferentially

Authors: ***Y. LI**[1], X. LI[2];
[1]Zhejiang Univ., Zhejiang, China; [2]Zhejiang Univ., Hangzhou Zhejiang, China

Abstract: Dorsal raphe nucleus (DRN) is a hindbrain structure located below the aqueduct. It consists 2/3 of serotonergic neurons, and is important to regulating emotion-related behaviors. It has been proved that DRN receive dense inputs from interpeduncular nucleus (IPN). However, the circuit between IPN and DRN is poorly investigated. Here we injected Cre-dependent rabies virus in DRN of GAD2-Cre and ePet 1-Cre mice respectively in order to trace the monosynaptic inputs of DRN GABAergic and serotonergic neurons retrogradely. Results showed that IPN neurons were strongly labeled in ePet 1-Cre mice, in contrary, a handful of IPN neurons were labeled in GAD2-Cre mice. Immunohistochemistry results showed that the neurons projecting from IPN to DRN labeled by rabies virus were mostly CaMKII positive. Taken together, these results showed that IPN CaMKII positive neurons project to DRN, and target serotonergic neurons preferentially.

Title: Pre-existing variability in functional connectivity predicts behavioral response to acute social defeat in mice

Authors: ***Y. GROSSMAN**, D. DUMITRIU;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Depression is a neuropsychological disorder that affects millions of people. There are currently no predictors for susceptibility to depression and a large proportion of afflicted individuals are resistant to available treatments. The ability to predict selective psychosocial vulnerability and resilience to stress holds great promise in preventing this debilitating disorder. Social defeat (SD) is a highly validated mouse model of depression. In order to elucidate the pre-existing neurocircuitry involved in the establishment of socially avoidant (susceptible) and resilient behavioral phenotypes, we developed an acute model of SD (ASD) that closely correlates with chronic SD. Using this behavioral model in conjunction with cFos immunohistochemistry, whole slice imaging and semi-automated detection of fluorescent puncta,

we quantified the cellular activation in 49 brain regions one hour after ASD in behaviorally characterized mice (18 control, 15 resilient, 21 susceptible). Post-hoc region-to-region and global network analyses revealed that resilient animals exhibit higher correlative inter- but not intra-network activity compared to susceptible animals. Overall, our data suggests that there is pre-existing variability in functional connectivity contributing to divergent behavioral phenotype following ASD.

Title: Behavioral and physiological effects of oxytocin treatment in a rat model of post-traumatic stress disorder

Authors: ***D. P. DABERKOW**, M. D. RENICKER, N. G. CYSEWSKI, S. M. PALMER, D. V. NAKONECHNYY, A. J. KEEF;
Biol., Eastern Washington Univ., Cheney, WA

Abstract: Post-traumatic stress disorder (PTSD) is characterized by anxiety, hyperarousal, flashback memories and avoidance of reminders of the traumatic event. Dysregulated fear and stress responses put an individual at an increased risk for developing PTSD. Oxytocin has been suggested to reduce certain PTSD-like behaviors and resulting cognitive functional impairments. The objective of this study was to investigate the effects of oxytocin treatment on electric shock-induced PTSD-like symptoms. METHODS: Oxytocin treatments were accomplished by intranasal administration of oxytocin (0.1 µg/kg) or natural oxytocin release as a result of massage-like stroking. PTSD-like symptoms were induced via inescapable foot shock in a fear conditioning chamber (26 cm x 26 cm). Adult, male Sprague Dawley rats (n=24) were divided into four groups (n=6, per group): control (no shock treatment and intranasal administration of saline), PTSD-control (exposed to foot shock and intranasal administration of saline), PTSD-stroke (exposed to foot shock and administered massage-like stroking to evoke natural oxytocin release), and PTSD-oxytocin (exposed to foot shock and intranasal administration of oxytocin). One week post fear conditioning, exposed rats and controls (not exposed to foot shock) were evaluated behaviorally and physiologically using a range of tests including: freezing when re-exposed to the fear conditioning chamber, anxiety assessment in elevated zero maze, spatial

learning in Morris water maze, heart rate and hematocrit. RESULTS: Relative to controls, oxytocin treated rats showed significantly less conditioned fear (periods of watchful immobility when re-exposed to the foot shock chamber), significantly less anxiety-related behaviors in the elevated zero maze (time in walled off areas), significant improvement in spatial learning measures in the Morris water maze (time to reach the hidden platform), significantly lower resting heart rate and hematocrit levels. CONCLUSIONS: The results of this study suggest that oxytocin treatment reduces anxiety, improves learning and physiological measures related to stress. Therefore, these data support further investigation of oxytocin administration in the prevention of PTSD induction.

Title: Comparison of behaviors under Light versus Dark conditions in the neoclomipramine rodent model of Obsessive Compulsive Disorder (OCD)

Authors: L. S. LAIKS[1,2], A. M. BARNES[1], E. C. GRONSETH[1], A. M. SOLIN[1], L. BURKE[1], L. J. KASPARSON[1], C. MATTHIJSSEN[1], A. SCALZO[1], *D. S. KREISS[1,3];
[1]Psychology and Neurosci. Dept, Colgate Univ., Hamilton, NY; [2]Neurosci., Texas A & M Inst. for Neurosci., College Station, TX; [3]Psychology Dept, Neurosci. Program, Ithaca Col., Ithaca, NY

Abstract: Obsessive Compulsive Disorder (OCD) is characterized by persistent, anxiety producing thoughts accompanied by overwhelming urges to perform repetitive, ritualistic behaviors. Current pharmacological treatments for OCD are only effective in 40-60% of patients and have an 8-10 week delayed onset. The current study provides further evaluation of a new animal model of OCD based upon neonatal exposure to an uptake inhibitor of both serotonin and norepinephrine, clomipramine. Prior studies conducted by Anderson et al., 2010 and at Colgate (SFN & FUN abstracts, 2013 and 2014) have demonstrated that the neoclomipramine model has both face and predictive validity for behaviors in the Hole-Board, Marble Arena, and Elevated

Plus Maze. A major limitation of prior studies of the neoclomipramine model is that the behaviors were assessed in the Light, a factor known to increase anxiety in nocturnal species. For the first time, head dips, holes poked, marbles buried, marbles checked, and marbles carried were measured in the Dark - in both control and experimental neoclomipramine rats. Male Sprague-Dawley rats were administered either clomipramine (15 mg/kg, “neoClom,” n=23) or saline (“neoSal”, n=28) twice daily from postnatal Day 9 through Day 16. Behaviors were first assessed at Day 68-85 and again at Day 172-184 under standard Light conditions. After a 2-week adjustment period to a reverse light-dark cycle, the rats were assessed under Dark conditions (using red lamps). In accordance with prior studies conducted in the Light, neoClom rats buried, checked, and carried more marbles than the neoSal rats both at Day 68-85 and at Day 172-184. When these behaviors were assessed in the Dark at Day 206-213, neoSal animals exhibited a REDUCTION of pokes/hole, repeated pokes, marbles carried, and marbles carried - and, unexpectedly an ENCHANCEMENT of marbles buried. In contrast, expression of behaviors of neoClom rats in the Dark was NOT different from the neoClom’s behaviors in the Light. In the Dark, neoClom rats continued to exhibit higher values of marbles buried, checked, and carried as compared to their control counterparts. These results strengthen the face validity of hole-poke, marble checking and marble carrying behaviors in the neoclomipramine model, yet challenge the proposition that marble burying is a valid measure of “OCD-like” behavior. Furthermore, this study contributes to the growing evidence that behavioral observations in animal models of anxiety-related disorders exhibit higher face validity if conducted under Dark conditions.

Title: Behavioral effects of enhancing GABAergic neurotransmission through disinhibition of somatostatin-positive interneurons in mice

Authors: *S. J. JEFFERSON[1], T. FUCHS[1], A. HOOPER[3], J. MAGUIRE[3], B. LUSCHER[2]; [2]Dept Biol, Dept Biochem & Mol, [1]The Pennsylvania State Univ., University Park, PA; [3]Dept Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Clinical evidence suggests that Major Depressive Disorder (MDD) is associated with reduced concentrations of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) in certain brain regions[1,3], reduced expression of GABA type A ($GABA_A$)[4] receptors and reduced expression of the inhibitory neuron marker somatostatin (SST)[2]. Consistent with a causal role of GABAergic deficit in the etiology of MDD, reduction of GABAergic neurotransmission in mice through global heterozygous deletion the γ2 subunit of the $GABA_A$ receptor results in an anxious-depressive-like phenotype that is normalized by chronic but not acute treatment with the antidepressant desipramine[5]. These data suggested that modest GABAergic deficits may be causal for depressive disorders and, conversely, that chronic antidepressants act over time to enhance GABAergic transmission. Accordingly, we hypothesized that increasing the excitability of somatostatin (SST)-positive GABAergic interneurons would result in an antidepressive phenotype. To generate mice with increased excitability of SST^+ interneurons we inactivated the γ2 subunit gene (*gabrg2*) selectively in SST^+ interneurons (SST-Cre x $\gamma2^{f/f}$). To facilitate recordings from SST^+ interneurons we further crossed these mice with a Rosa26-YFP Cre-reporter (SST-Cre x $\gamma2^{f/f}$ x Rosa26-YFP). Consistent with increased excitability of SST^+ neurons, the input resistance and number of action potentials observed following current injection into SST^+ cells of SST-Cre x $\gamma2^{f/f}$ x Rosa26-YFP neurons was increased compared to SST-Cre x $\gamma2^{f/+}$ x Rosa26-YFP controls. Conversely, analyses of pyramidal cells in L2/3 of the cortex and CA1 region of the hippocampus by voltage clamp revealed an increased frequency and amplitude of IPSCs, as predicted. Behaviorally, SST-Cre x $\gamma2^{f/f}$ mice showed an anxiolytic and antidepressive phenotype characterized by reduced time spent in the open arms of an elevated plus maze, reduced latency to feed in the novelty suppressed feeding test, decreased immobility in the forced swim test and fewer escape failures in the learned helplessness test. Finally, SST-Cre x $\gamma2^{f/f}$ mice showed brain region-specific biochemical changes indicative of antidepressant drug action, including decreased phosphorylation of eEF2. Collectively, the results suggest that enhancing GABAergic inhibition of forebrain principal cells by increasing the excitability of SST^+ GABAergic interneurons confers an anxiolytic and antidepressive phenotype.

Title: Adult neurogenesis in the hippocampus is responsible for the transition from depressive to manic behavior

Authors: ***S. KIM**, J.-M. LEE, D. GEUM;
Korea Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Recently, it has been reported that adult neurogenesis in the hippocampus is involved in not only learning and memory but also mood regulation. In the present study, we generated Nestin-CreER;Rosa26-FloxedlacZ-DTa (Nestin-DTa) mice whose nestin-positive adult neural stem cells (aNSCs) were ablated by tamoxifen treatment, and we evaluated the function of hippocampal neurogenesis on the depressive and manic behavior. Five-consecutive daily injections of tamoxifen (5mg/injection) ablated aNSCs, and resulted in the decrement of nestin positive cells and BrdU-positive proliferating cells to 50% in Nestin-DTa mice. Four weeks after tamoxifen injections, when new born neurons matured and were integrated into neural circuits, behavior tests such as learned safety, open field test (OFT), elevated plus maze (EPM) and forced swimming test (FST) were performed. The Nestin-DTa mice could not learn safety learning, which clearly shows the ablation of hippocampal neurogenesis. The Nestin-DTa mice spent less time in the center of the open field during OFT, and stayed longer in closed arms in EPM than those of control mice, which demonstrated the higher anxiety level. The Nestin-DTa mouse also showed depressive behavior such that they exhibited more immobilization time during FST. However, eight weeks after tamoxifen injections, the higher anxiety level shown in Nestin-DTa mice was recovered to that of control level. More interestingly, 8 weeks after tamoxifen injections, Nestin-DTa mice showed manic like behavior during FST. We also analyzed the population of aNSCs, proliferating cells, immature neuroblasts and mature neurons in Nestin-DTa mice with immunohistochemistry. Four weeks after tamoxifen injections, BrdU positive newly born mature neurons that were incorporated into the circuit were decreased. However, proliferating cells (PCNA+) and immature neuroblasts (Dcx+) were repopulated in spite of the loss of sox2 positive stem cells. Eight weeks after tamoxifen injections, proliferating cells and immature neuroblasts were re-populated in Nestin-DTa mice. Interestingly, however, newly born mature neurons were over-populated than control mice. Behavior tests in concordance with histological analyses suggest that the population of newly born mature neurons in the hippocampus that may incorporate into the neural circuit is important for the mood regulation such as depressive and manic behavior. Key words: Hippocampus, Neurogenesis, Depressive behavior, Manic behavior.

Title: A depressive-like brain state caused by GABAergic deficits involves a homeostatic adaptation of glutamatergic synapses that is normalized by ketamine

Authors: Z. REN[1], H. PRIBIAG[4], M. SHOREY[2], T. FUCHS[3], D. STELLWAGEN[4], *B. LUSCHER[3];

Abstract: Mechanisms underlying major depressive disorder (MDD) are increasingly recognized to involve deficits in GABAergic and glutamatergic synaptic transmission. To elucidate the relationship between these phenotypes we here made use of GABAA receptor (GABAAR) γ2 subunit heterozygous (γ2+/-) mice, which have previously been established as model with construct, face and predictive validity for MDD. Cortical cultures derived from γ2+/- embryos showed reduced cell surface expression of NMDA and AMPARs along with the synaptic cell adhesion protein neuroligin 1 (NL1), as well as reduced density of glutamatergic synapses. All these phenotypes were restored to wild-type (WT) levels by 3-6 h treatment of γ2+/- cultures with 10 μM ketamine. Cell surface NMDARs and NL1 but not AMPARs were also reduced *in vivo* as shown for hippocampus and medial prefrontal cortex of γ2+/- mice. Functionally, glutamatergic inputs to CA1 pyramidal cells of γ2+/- mice were reduced mainly due to functional impairment of temporoammonic-CA1 synapses; however, Schaffer collateral-CA1 synapses were also affected. A single subanesthetic dose of ketamine given to γ2+/- mice resulted in enduring normalizatin of NMDAR cell surface expression and function of glutamatergic synapses in slices harvested and analyzed 24h post treatment of mice. Moreover, ketamine had more modest effects in WT than γ2+/- mice. The amplitude of miniature inhibitory postsynaptic currents was reduced in CA1 neurons of γ2+/- compared to WT mice and remained functionally constrained in slices of ketamine treated γ2+/- mice. Collectively these results newly

Deleted: in vivo

define depressive-like brain states as GABAergic deficit-induced homeostatic adaptations of glutamatergic synapses that are reversible enduringly by ketamine.

Title: Voluntary wheel running alters intermittent swim stress-induced ultrasonic vocalizations

Authors: *R. C. DRUGAN, I. STRIBLING, N. P. STAFFORD;
Dept Psychology, Univ. New Hampshire, Durham, NH

Abstract: Exercise has been shown to impart resilience in animal stress paradigms. The typical exercise protocol involves 6-8 weeks of voluntary running in the home cage. We have recently reported that certain rats exposed to intermittent swim stress (ISS) emit ultrasonic vocalizations (USVs). The rats that emit USVs during ISS later show stress resilience when tested on both anxiety and depression measures. In the current study, we sought to determine if rats given the opportunity to engage in voluntary exercise for 6 weeks would show enhanced USVs during ISS and show the expected resilience in a subsequent forced swim test (FST). Preliminary results indicate that certain rats given the opportunity to exercise emit more USVs than the sedentary controls and show commensurate resilience in the FST.

Title: Left cortical activity modulates stress effects on social behavior

Authors: *J. HONG[1], S. CHAE[1], E. LEE[1], Y.-G. PARK[1], K. KANG[2], Y. KIM[3], D. KIM[1]; [1]KAIST, Taejon-City, Korea, Republic of; [2]Dankook Univ., Chungnam, Korea, Republic of; [3]Rockefeller Univ., New York, NY

Abstract: In response to chronic stress, some individuals develop maladaptive symptoms while others retain normal behavior. The functional hemispheric asymmetry of medial prefrontal cortex (mPFC) is known to be implicated in control of stress responses. Despite the potential importance of mPFC, the contribution of each hemisphere of mPFC in mediating stress resilience remains unclear. To elucidate the specific role of each hemispheres, we investigated the neural activity and gene expression profiles of mPFC in social defeat stress model. In the left mPFC, mice expressing social avoidance showed depressed neural activity, while resilient mice showed normal firing rates. The neural activity stimulation of left mPFC optogenically leads to social behavior change. The same photomodulation has no effect on the right mPFC. From the analysis of microarray data in each mPFC hemispheres, we discovered that the genetic changes in the left cortices determines the adaptive behavior upon social defeat stress. Evidenced together with the neural activity, we conclude that it is the activity of left mPFC plays critical role in behavioral expression of stressed mice.

Title: Behavioral differences due to recent de novo mutations among C57BL/6 and C57BL/10 mouse substrains

Authors: *C. ST. PIERRE, N. M. GONZALES, A. A. PALMER;
Univ. of Chicago, Chicago, IL

Abstract: C57BL/6 (B6) mice are the most widely used inbred strains in biomedical research. Several B6 substrains exist that have been maintained as isolated breeding populations for several decades. These B6 substrains are known to exhibit numerous of behavioral differences. In addition, C57BL/10 (B10) mice have also given rise to a number of substrains, which are most commonly used for immunological rather than behavioral studies. We subjected a panel of 13 different B6 and B10 substrains to a battery of behavioral tests relevant to addiction and psychiatric disorders. The panel included eight C57BL/6 strains (C57BL/6J, C57BL/6NJ, C57BL/6JBomTac, C57BL/6NTac, B6N-TyrC/BrdCrlCrl, C57BL/6NCrl, C57BL/6ByJ, and C57BL/6NHsd) and five C57BL/10 strains (C57BL/10J, C57BL/10ScCr, C57BL/10ScSnJ, C57BL/10SnJ, and C57BL/10ScNHsd). We found significant differences in the behavior of the substrains in the open field test, locomotor response to cocaine, fear conditioning, prepulse inhibition, and Porsolt forced swim test. Our results show a divergence of behavioral performance within these substrains, suggesting that recent de novo mutations that alter disease-relevant CNS pathways have accumulated since the strains were separated. We are currently re-sequencing individuals from each substrain in an effort to identify causal polymorphisms.

Title: Effect of amygdaloid kindling and administration of fluoxetine in the rat forced swim test

Authors: *A. DÍAZ, A. VALDÉS-CRUZ, D. U. GONZÁLEZ-MÉNDEZ, J. D. AYALA-RODRÍGUEZ, L. A. MARTÍNEZ-MOTA, S. ALMAZÁN-ALVARADO, R. FERNÁNDEZ-MAS;
Inst. Nacional De Psiquiatría Ramón De La Fuen, Mexico, Mexico

Abstract: Depression represents one of the most common comorbilities of epilepsy. However, causes and mechanisms of depression associated to epilepsy remain poorly understood. It has

been suggested that shared biological factors might both cause seizures and lead to affective disturbances. Experimental models have shown that antidepressants, such as fluoxetine (FLX) affect excitability in short time scales which may lead to changes in epilepsy severity. Amygdaloid kindling (AK) is a model of epilepsy characterized by sustained increase in seizure susceptibility. Furthermore AK allows temporal control over both seizure generation and severity. Thus, it appears to be particularly suitable for epilepsy-associated depression models that results from neuronal plastic changes. Therefore, the goal of the present study was to examine AK epileptogenesis with behavioral correlates of depression in the rat forced swim test (FST) as well as the effects of FLX on seizure susceptibility and depressive behaviors. Male Wistar rats (280-320 g) were used. Tripolar electrodes were placed in the basolateral nucleus of left temporal lobe amygdala (P: 2.8, L: 5.0, H: 8.5) and both frontal cortices. AK was induced by daily electrical stimulation (1 s train, 1 ms pulses, 60 Hz, 250-500 μA) until AK stage V (tonic-clonic seizure) was achieved for three consecutive days. One hour after last seizure, FST sessions were conducted by placing rats in individual glass cylinders (46 cm height; 20 cm diameter, water at 25-28 °C). An initial FST of 15-min (termed pre-test) was performed and after 24 h, a 5-min test was completed. A 10 mg/kg of fluoxetine hydrochloride (2 ml/kg) dose was administered following a sub-acute schedule, three injections administered between pre-test and test sessions (21 h, 5 h, and 1 h before test session). Rats were assigned to four experimental groups: K-Flx (n=7), in which AK, FST and FLX injections were applied; K-Vh (n=6) AK, FST and vehicle (saline solution 0.9%); Sham-Vh (n=6) FST and vehicle and Control (C) (n=7) solely with FST. Immobility time in FST and seizure susceptibility on test stimulations of post stage V were assessed. We found a decrement in immobility time in the FST on all groups compared with C ($p< 0.001$), whereas both K-Vh and K-Flx groups exhibited an increase in seizure susceptibility ($p< 0.001$), nevertheless no difference between groups was observed. Our results suggest that the FLX has no effects on seizure susceptibility, thus the neuronal plastic changes associated with limbic system, particularly with the amygdala, could be interfereds by the development of depressive behavior.

Title: Cannabinoid receptor 1 blockade in the lateral habenula exerts anxiolytic effects in sprague dawley rats

Authors: *A. BERGER[1], A. M. WILLIAMS[1], R. J. MCLAUGHLIN[2];
[1]Psychology, [2]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Clinical and preclinical research has identified the lateral habenula (LHb) as a key structure regulating motivated and stress-related behaviors, such as anxiety, in part through its strong inhibitory effects on midbrain monoaminergic nuclei. Extensive research has also established the endocannabinoid (eCB) system as an important regulator of stress responsiveness and emotional behavior. Despite this overlap, very little research has evaluated the role that eCBs play in the LHb in the context of anxiety. The goal of this study was to examine the role of the eCB system in the lateral habenula with respect to anxiety-like behavior. Adult male Sprague Dawley rats were surgically implanted with bilateral cannulae aimed at the LHb. Following recovery from surgery, animals were subjected to the elevated plus maze and novelty suppressed feeding paradigms, which are both measures of anxiety-like behavior in rodents. Animals were pretreated with the CB1R inverse agonist rimonabant (0.3µg/side), a cocktail of baclofen and muscimol (75ng/side), or vehicle infusion. Compared to vehicle infusions, animals receiving rimonabant unexpectedly exhibited a significant increase in open arm exploration in the elevated plus maze, indicative of reduced anxiety, as well as a trend for decreased time to consume a palatable food item in the novelty suppressed feeding paradigm. Animals receiving the baclofen/muscimol cocktail exhibited a non-significant increase in open arm exploration in the elevated plus maze and did not show altered behavior in the novelty suppressed feeding paradigm. These findings are indicative of anxiolytic properties of CB1R antagonism in the LHb and contribute to our understanding of how signaling in the LHb influences anxiety-like behaviors. This data also points to the LHb as the potential site of action for the anxiolytic effects of CB1R blockade.

Title: Sex specific stress regulation of the microRNA transcriptome in mouse nucleus accumbens

Authors: *M. L. PFAU, G. E. HODES, I. PURUSHOTHAMAN, J. FENG, S. A. GOLDEN, H. M. CATES, H. ALEYASIN, M. FLANIGAN, L. SHEN, S. RUSSO;
Fishberg Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Adult women are twice as likely as men to develop major depression, although the precise molecular mechanisms underlying sexual dimorphism in depression susceptibility are unknown. We have developed a stress paradigm--subchronic variable stress (SCVS)--to mimic these sex differences in mice. Female mice subjected to SCVS exhibit depression-like behavior after 6 days of stress exposure, whereas male mice exhibit this behavior only after chronic stress exposure (21 days, but not 6 days, of SCVS). Thus, this model is a valid recapitulation of the sexual dimorphism characteristic of the human population. We profiled sex differences in gene expression and transcriptional regulation in the mouse nucleus accumbens (NAc), an essential structure in the processing of reward and motivation, using next generation mRNA and small RNA sequencing. Both types of sequencing were performed on the same NAc tissue from reproductively intact male and female mice subjected to SCVS. Bioinformatic analysis was used to determine differential mRNA and microRNA (miR) expression patterns, predict miR targets, create miR-gene networks and identify biological pathway enrichment. We find very little overlap in stress-regulated mRNA and miR profiles between male and female mice. miR target, network and pathway analyses revealed evidence for sex differences in regulation of molecular processes related to stress vulnerability in males and females. Our results demonstrate that male and female mice initiate fundamentally different transcriptional responses to stress. These transcriptional profiles correlate with behavioral susceptibility or resilience to stress. Our findings provide insight into the molecular underpinnings of enhanced female susceptibility to stress.

Title: Underlying molecular circuitry of miR-124-mediated glutamatergic pathway regulation by corticosterone: role in stress-related pathophysiology

Authors: *B. ROY[1], R. C. SHELTON[1], G. TURECKI[2], Y. DWIVEDI[1];
[1]Psychiatry and Behavioral Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL;
[2]Douglas Mental Hlth. Res. Inst., Montreal, QC, Canada

Abstract: Imbalance in Cortisol- or Corticosterone-mediated delicate regulation of limbic-hypothalamic-pituitary-adrenal axis can induce physiological stress, a critical factor in inducing stress-related disorders, including major depression. Understanding the underlying neuro-molecular circuitry of stress response reveals a complex set of biological mediators involving both genetic and epigenetic candidates in prefrontal cortex, amygdala and hippocampus. In recent years, microRNA (miRNA or miR) has established its potential role as epigenetic master regulator of gene expression in central nervous system by affecting genes involved in neurotransmission and synaptic plasticity. In this study a chronic paradigm of 50 milligram corticosterone (CORT) administration in rat model exhibited increased expression of a brain enriched miR-124 in prefrontal cortex. Underpinning the molecular nature of this miRNA unveiled an intricate switch involving CORT-mediated post transcriptional regulation of a candidate gene Gria4, earlier reported to be a subunit of AMPA receptor family in glutamatergic pathway. The concomitant CORT-mediated downregulation of Gria4 was substantiated by the observation of similar transcriptional repression in prefrontal cortex of depressed subjects. In-vitro target validation models established Gria4 3'UTR as direct target of miR-124 using luciferase and miRNA oligo transfection assays. This observation was further supported by RNA-Induced Silencing Complex (RISC)-mediated immuno enrichment study of endogenous miR-124 seed binding with Gria4 mRNA 3'UTR. Interestingly, our observation of high miR-124 abundance in serum samples of patient population suffering from major depression potentially consolidated the role of miR-124 as a biomarker for MDD and established a strong relationship

with impaired Gria4 expression possibly translating its role in the pathophysiology of depression. As an additional layer of transcriptional regulation on miR-124 expression, the upstream proximal promoter was found to be populated with two CpG islands. Exploring a significant hypomethylation status of the miR-124 promoter under chronic stress correlated well with the observed transcriptional upregulation of miR-124 expression. Altogether the present study exhibits a molecular switching mechanism induced by corticosteron leading towards transcriptional upregulation of miR-124 with a possible disruption in glutamatergic pathway by post transcriptional silencing of Gria4 transcripts, which could potentially be important in the pathophysiology of stress-related disorders.

Title: Differential impact of maternal protein insufficiency on 5-HT1A receptor function in adult offspring: increased risk for affective disorders?

Authors: ***W. YE**[1], B. J. THOMPSON[2], J. G. HENSLER[3];
[1]Physiol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [2]Biomed. Sci., Oakland Univ. Sch. of Med., Rochester, MI; [3]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Genetic programming and pharmacological manipulation of serotonin1A (5-HT1A) receptors have been associated with anxiety. Protein insufficiency, without caloric restriction, during pregnancy leads to elevated anxiety in female but not male adult offspring. However, the underlying neural mechanisms are unclear. In rats, we examined 5-HT1A receptor function in adult offspring of mothers that were free-fed standard (20%) or low (10%) protein isocaloric chow during pregnancy, which models protein intake patterns in the US. Importantly, the maternal low protein diet did not affect the body weight of mothers or offspring. Preliminary data indicate that the maternal low protein diet does not alter the number of 5-HTergic cell bodies in the dorsal and median raphe, or 5-HT content or turnover in the forebrain of offspring. At P110-117, 5-HT1A receptor agonist 8-OH-DPAT (0.01-1mg/kg, ip)-induced stereotypic

behaviors were measured. The potency of 8-OH-DPAT to induce flat body posture and lower lip retraction was reduced in female offspring, as indicated by rightward shifts (~3 fold) in the dose-response curves. In littermates, we used quantitative autoradiography to measure the capacity of 5-HT1A receptors to activate G proteins. The maternal low protein diet resulted in a (50%) decrease in 8-OH-DPAT (1μM)-stimulated [35S]GTPYS binding in hippocampus of female offspring, with no change in frontal cortex, suggesting a region-specific down-regulation of postsynaptic 5-HT1A receptor function. 8-OH-DPAT (1μM)-stimulated [35S]GTPYS binding was increased (54%) in dorsal raphe of female offspring, suggesting enhanced inhibition of serotonin neuronal activity. By contrast, no significant change in 5-HT1A receptor function was observed in male offspring. Both *in vivo* and *ex vivo* data indicate that maternal protein insufficiency causes profound region-specific and sex-dependent changes in 5-HT1A receptor function. As improperly balanced diets and nutritional insecurity remain considerable problems in developed countries, including the US, these findings have important implications for understanding why some individuals are at greater risk for affective disorders.

Title: Characterizing rat model of post-traumatic stress disorder using neuroimaging approaches

Authors: ***P. D. PEREZ**, J. RUDDY, Y.-K. YAM, J. KUHN, N. ZHANG;
Biomed. Engin., Pennsylvania State Univ., University Park, PA

Abstract: Chronic stress-related disorders can develop when a situation overwhelms the physical and/or emotional resources of the individual. A single life threatening experience, in the event of a posterior maladaptation, can develop into disorders such as post-traumatic stress disorder (PTSD), excessive anxiety and phobias. PTSD is a complex disorder that is poorly

understood. Furthermore, there is heterogeneity in the response to traumatic stress and its eventual development in a chronic disorder. Most studies in humans have focused on restricted populations that had already been exposed to traumatic stress months or years ago, such as veterans and accident and crime victims. The use of an animal model allows for investigating the development of PTSD before the stress exposure, which is extremely difficult in humans. We use a rat model of PTSD where we expose rats to a single life threatening situation (predator odor) in an inescapable environment. Using a combination of behavior and awake resting-state functional magnetic resonance imaging (rsfMRI) experimental techniques, we can study the effect of single-episode traumatic stress in neuroplasticity at the circuit level. Furthermore, we investigate how single traumatic stress affects fear conditioning and fear extinction learning which are suspected to be staples of chronic stress disorders. We use rsfMRI to study the function of neural circuits critical to anxiety disorders. We complement rsfMRI with behavior techniques to evaluate the efficacy of the stressor and anxiety levels. Our study has multiple goals. We present a longitudinal set of experiments where we can first study the onset of chronic disorder, then its impact in fear conditioning circuits and finally in fear extinction circuits. Furthermore, we observe a segregation of resilient and vulnerable populations. By looking at differences between these two populations at different stages, we investigate the existence of vulnerability markers to PTSD at the circuit level with non-invasive techniques. Understanding and detecting this vulnerability has great importance in prevention and treatment, and it opens the way for later extending this knowledge to human studies.

Title: Neuronal features involved in depresive disorders are found in CB1receptor knockout mice

Authors: *H. A. BRUSCO, D. SORIANO, F. CONDE, L. CALTANA;

Abstract: Endocannabinoid system (CB1 and CB2 receptors, endogenous ligands, and the synthesis and metabolism associated enzymes) plays a fundamental role during development of nervous system. CB1R is expressed mainly in the central nervous system, is located at presynaptic level and is the main responsible for the effects produced by cannabinoids in the brain. It regulates physiological processes such as appetite, memory, pain regulation, humor and learning among others. It plays a key role in the neuromodulation of synaptic activity, neurogenesis and synaptogenesis. It has been proven that the absence of the CB1 receptor, in experimental mice, as well as the use of antagonist drugs to that receptor in humans, generates behavioral states similar to depression, stating its presence and involvement as a key element for the proper functioning of the nervous system. The aim of this work is to analyse the neuronal morphology (cytoskeletal organization in axons and dendrites, and synaptic contact ultrastructure) as well as the serotonergic system in CB1R knockout mice. The changes observed in these parameters are in accord with the alterations observed in depressive disorders. Funding: UBACYT 20020130100258BA (HAB), 20020130300033BA (LC), PIP CONICET 00269

Title: Modeling the role of Akt kinase in resilience to stress

Authors: C. D. WILLOCK[1], N. C. BERDUX[1], *T. F. FRANKE[2];

Abstract: Background: Akt kinase plays a key role in neuronal cell function and survival. Biochemical studies on postmortem brains from suicides define the importance of Akt signaling in mood regulation. Human genetic studies provide evidence that AKT1 mutations are a liability in neurodevelopmental disorders with high incidence of suicide such as schizophrenia. Our project builds on these remarkable findings to examine tractable genetic mouse models of altered Akt signaling that “reverse-translate” changes in human Akt to determine their impact on anxiety- and depression-like behaviors. Methods: To define the physiological involvement of Akt signaling on the processing of emotional stimuli, we used Akt knockout mouse strains to study Akt-dependent behavioral and biochemical phenotypes, and structural neuroplasticity. To address the contribution of Akt in defined brain areas, we employed Cre-dependent recombination to ablate Akt expression in the frontal cortex and mesolimbic system. Genomic and brain area-specific conditional knockout mice were exposed to acute and chronic stress, and assessed for anxiety- and depression-like behaviors and treatment response to antidepressant treatment. Results: Akt-deficient mice differed significantly in the acquisition of fear memories. Consistent with changes in fear memory acquisition, Akt KO mice exhibited decreased synaptic plasticity. Acute stress exposure of Akt KO mice resulted in a transient depression-like phenotype. Chronic exposure to social defeat uncovered a reduced resilience to stress. Ablation of Akt expression specifically in the frontal cortex also decreased resilience of mutant mice when compared to littermate controls. Treatment of chronically-stressed mice with antidepressants reversed the depression-like phenotype in control mice but failed to ameliorate depression-like behaviors in Akt-mutant mice. Discussion: Our results in Akt-mutant mice converge with biochemical and genetic findings of Akt dysfunction in neuropsychiatric patients and confirm a critical requirement for Akt signaling in mood regulation. Decreased Akt function in the frontal cortex of mice increased the susceptibility to chronic stress and occluded reversal of depression-like behaviors by antidepressants. Our data validate the utility of Akt-mutant mice as experimental model to study gene-environment interactions governing the susceptibility to stress and development of depression-like behaviors later on in life. A mechanistic understanding of the role of fronto-cortical Akt signaling in stress resilience will help to develop new diagnostic markers and therapeutic interventions.
