Title: Long-lasting alterations in microglial HMGB1 expression correlates with increased vulnerability to depressive-like behaviors after chronic unpredictable stress

Authors: *T. C. FRANKLIN, E. S. WOHLEB, R. S. DUMAN;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Long-lasting alterations in microglial HMGB1 expression correlates with increased vulnerability to depressive-like behaviors after chronic unpredictable stress. T.C. Franklin; E.S. Wohleb; R.S. Duman Major Depressive Disorder (MDD) is a recurrent mental health illness with more than half of affected patients relapsing after their initial episode. High levels of psychological or environmental stressors are associated with the initial development of MDD and may play a role in recurrent episodes. To better understand these processes it is important to study stress-associated mechanisms that promote depressive-like behavior. Various stress paradigms have been used to model the molecular, cellular and behavioral effects of depression. For instance, several reports support the hypothesis that repeated stress exposure increases neuroinflammation, which contributes to the development and persistence of depressive-like behaviors. In this study, we identified long-lasting microglial changes that corresponded with development and recurrence of MDD using a chronic unpredictable stress (CUS) model in rodents. Following CUS exposure, microglia in the prefrontal cortex and hippocampus displayed robust morphological changes indicative of an activated phenotype. Gene expression analyses of enriched hippocampal microglia showed elevated levels of several inflammation-associated genes, including HMGB1 mRNA levels after CUS, and increased HMGB1 expression in microglia overlapped with the development of depressive-like behaviors during stress exposure. To determine if stress-induced microglia alterations persisted after CUS, additional studies were performed in which rats were exposed to CUS then allowed to recover for 4 weeks. Here we show that microglia morphological alterations along with elevated HMGB1 expression are present 4 weeks after CUS cessation. Furthermore, changes in microglia were associated with recurrence of depressive-like behaviors during the recovery period. Specifically, exposure to short-term unpredictable stress during the recovery period caused recurrence of anhedonia in rats previously exposed to CUS. Importantly, short-term unpredictable stress did not cause significant behavioral changes in naïve rats. Taken together, these data suggest that initial CUS exposure can evoke alterations in microglia HMGB1 signaling that may contribute to increased vulnerability to depressive-like behaviors following subsequent stress exposure. Studies are being conducted to directly test this hypothesis.

Title: Anhedonia in the Chick Anxiety-Depression Model

Authors: ***A. L. SALMETO-JOHNSON**[1], M. K. JOURDAN[2], K. J. SUFKA[2];
[1]Psychology, Graceland Univ., Lamoni, IA; [2]Psychology, Univ. of Mississippi, Oxford, MS

Abstract: Anhedonia, the loss of pleasure in previously pleasurable activities, is one of the cardinal features of depression. To further validate the chick anxiety-depression model as a neuropsychiatric simulation, we sought to quantify this behavioral endophenotype as well as its pharmaceutical reversal. Assessment of anhedonia involved measures of social reinstatement in a straight alley maze, which had a mirror at the end to simulate the presence of another chick. A baseline measure was taken for all chicks. The next day chicks were tested again (No Test), or exposed to a test apparatus for 90 min either with 2 conspecifics and mirrors (Social) or individually (Isolated) to induce a depression-like state, prior to straight-alley maze testing. In general, both start and goal latencies were delayed in the Social and Isolated groups compared to the No Test group. Planned comparisons demonstrated a significant delay in start latency in the Isolated group compared to the No Test group ($p = 0.029$) and appeared delayed in Isolated compared to the Social group. Experiment 2 assessed the impact of Imipramine (0, 10, 15 mg/kg) administered prior to isolation apparatus exposure to alleviate the display of anhedonia as assessed in the straight alley maze. In general, start latency increased in all groups compared to the No Test group and was decreased in the Imipramine groups compared to the Vehicle group. Planned comparisons showed a significant decrease in start latency in the 15 mg/kg ($p = 0.014$) and approached significance with the 10 mg/kg Imipramine groups ($p = 0.077$) compared to the Vehicle group. Goal latency increased in all groups compared to No Test and was deceased in the Imipramine groups compared to Vehicle. Planned comparisons showed a decrease in the 15 mg/kg Imipramine group compared to the Vehicle group ($p = 0.032$), which is interpreted as a reduction in anhedonia. Results suggest the ability to assess anhedonia in chicks and that Imipramine is capable of alleviating the expression of anhedonia as assessed in this paradigm.

Title: Light modulates spatial learning and memory in an animal model of SAD

Authors: *J. E. SOLER, T. IKENO, L. YAN;
Michigan State Univ., East Lansing, MI

Abstract: Light has profound effects on brain and behavior, which are best exemplified in Seasonal Affective Disorder (SAD). SAD is a major depressive disorder; SAD patients experience recurring symptoms i.e. depressed mood, anxiety and cognitive impairments during the fall and winter when there is less sunlight. The symptoms can be alleviated by bright light therapy before full remission takes place in spring and summer. The neural mechanisms mediating the effects of light on mood and cognition are not well understood. Our previous work has developed an animal model of SAD utilizing the diurnal Nile grass rats (*Arvicanthis Niloticus*) (Leach et al, 2013; Deats et al, 2014). We have found that grass rats show increased depression- and anxiety-like behaviors in a winter-like 12:12 hr Dim Light-Dark (DLD) condition compared to those in a summer-like Bright Light-Dark (BLD) cycle. The objective of the present study was to enhance the face validity of this model of SAD and to explore the neural substrates underlying photic modulation of mood, anxiety and cognition. Specifically we examined spatial learning abilities, as well as structural and functional changes in the hippocampus. Spatial learning and memory was assessed in animals housed in either BLD or DLD conditions using two hippocampal-dependent tasks: Novel Place Preference (NPP) and the Morris Water Maze (MWM). The results revealed that, although short-term spatial learning and memory were not affected by lighting conditions in both tasks, long-term spatial memory in the MWM was significantly impaired in grass rats housed in DLD. In the hippocampus, we found that the expression of brain-derived neurotrophic factor (*bdnf*) mRNA was significantly lower in DLD compared to BLD animals. In addition to the functional changes in the hippocampus, morphological changes are also being analyzed using Golgi staining. The behavioral data provide further evidence for the claim that light affects mood and cognition in the diurnal grass rats in a way similar to that seen in diurnal humans. The data on hippocampal function and morphology will provide a starting point for determining how light affects synaptic plasticity and neuronal morphology in this structure to modulate learning and memory in a diurnal species.

Title: Serotonergic markers clustering in blood lymphocytes from animals exposed to corticosterone parallels the alterations found in depressed patients

Authors: ***E. Y. FENTON**[1], R. ROMAY-TALLON[2], M. A. MITCHELL[3], T. RIVERA-BALTANAS[5], K. LEBEDEVA[3], L. E. KALYNCHUK[4], J. OLIVARES[5], H. J. CARUNCHO[2]; [1]Project Search and Evaluation, Ctr. for Drug Res. and Develop., Vancouver, BC, Canada; [2]Col. of Pharm. and Nutr., [3]Dept. of Psychology, [4]Col. of Med., Univ. of Saskatchewan, Saskatoon, SK, Canada; [5]Meixoeiro Univ. Hosp., Vigo, Spain

Abstract: Depression is a severe neuropsychiatric illness that affects roughly 16% of the population. Despite its high prevalence, the complex etiology and symptomatology of depression make understanding and treating it particularly difficult. As such, a great deal of effort has been placed on identifying new biological mechanisms of antidepressant efficacy, and biomarkers to help guide diagnosis and treatment. Two proteins of particular interest in this regard are the serotonin transporter (SERT) and the serotonin 2A receptor (5HT2AR), as they facilitate serotonin neurotransmission, they are primary targets of antidepressant medication and alterations in their expression and activity have been documented in depressed patients. We have recently shown that patients showing the greatest reduction in depressive symptoms after pharmacological treatment have larger SERT and 5HT2AR protein clusters per blood lymphocyte, compared to controls and other depressed patients. These patients also show a normalization of SERT and 5HT2A clustering, whereas other depressed patients do not. In light of this evidence, the aim of the current study was to identify whether similar alterations in SERT and 5HT2A clustering occur in a well-established rodent model of depression. To examine this, 40 male rats (20 for the SERT study and 20 for the 5HT2AR study) were administered the stress hormone corticosterone (CORT; 40mg/kg) for 21 days and depressive-like behaviour was assessed using the forced swim test. Blood was collected via cardiac puncture and

immunocytochemistry was used to examine SERT and 5HT2AR protein clusters in lymphocytes. As expected, CORT-treated animals showed a significant increase in depressive-like behaviours. Interestingly, the size of SERT and 5HT2AR clusters was increased significantly by 13% and 7% respectively, while the number remained unchanged. Moreover, a significant positive correlation was found between depressive-like behaviour and cluster size and a negative correlation was found between depressive-behaviour and cluster number. Together with our previous findings, these data suggest that SERT and 5HT2AR may be important biomarkers of depression, and that our rodent model of the disorder is a reliable way for us to examine this relationship more closely.

Title: Neural circuitry underlying the ketamine-like antidepressant effect of infralimbic prefrontal cortex optogenetic stimulation

Authors: ***A. M. THOMAS**[1], E. S. WOHLEB[2], R. J. DILEONE[2], R.-J. LIU[2], G. K. AGHAJANIAN[2], R. S. DUMAN[2];
[2]Dept. of Psychiatry, [1]Yale Sch. of Med., New Haven, CT

Abstract: Ketamine is an antidepressant that promises to be more effective and faster-acting than any of the currently available depression pharmacotherapies, but its clinical use is limited by side effects. It is thus important to understand how ketamine acts in the brain in order to develop new therapies that utilize its mechanism of action. One key aspect of its mechanism that

is not well understood is the neural circuitry underlying its effects. Ketamine is known to increase glutamate release in the rodent medial prefrontal cortex (mPFC), which is critical to its antidepressant action. Part of the rodent mPFC, the infralimbic cortex (IL), is thought to correspond to the human anterior cingulate and ventromedial PFC, which have been shown through functional brain imaging to be differentially active in depressed patients compared to controls. Consistent with these data, our lab has demonstrated an antidepressant effect similar to that of ketamine by optogenetically inducing glutamatergic activity in the IL. Specifically, a single, one-hour 10-Hz laser stimulation of IL excitatory neurons infected with an rAAV2-CaMKIIα-ChR2(H134R)-EYFP construct produces an antidepressant effect lasting up to 2 weeks, as measured by the forced-swim test (FST) and novelty-suppressed feeding test (NSFT), which are measures of depression and anxiety. The effect is specific to the IL, as stimulation of the nearby prelimbic cortex does not produce an antidepressant effect. Using these optogenetic manipulations, we have sought to further characterize the circuitry underlying this antidepressant effect. Three brain areas in particular, the dorsal raphe, lateral habenula, and nucleus accumbens, have robust connections to the IL and are involved in the development of depressive features in rodents. Ongoing studies are assessing the importance of the IL projections to each of these brain areas, and how they relate to the observed antidepressant effect of IL stimulation, by analyzing the behavioral effects of optogenetic stimulation of light-sensitive axon terminals in each region after injection of the viral channelrhodopsin construct into the IL. Molecular studies are also being conducted to characterize changes in activity in these regions and to determine which cell types are the target of these projections. Title: Role of neuronal vascular endothelial growth factor signaling in the actions of antidepressants

Authors: *S. DEYAMA, X.-Y. LI, E. S. WOHLEB, S. DUTHEIL, A. BECKER, R. S. DUMAN;
Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Growing evidence demonstrates that growth factors play a significant role in the pathophysiology and treatment of mood disorders. Our previous work has shown that vascular endothelial growth factor (VEGF) signaling contributes to the behavioral and neurogenic actions of typical antidepressants, notably the monoamine reuptake inhibitors. VEGF is a pleiotrophic growth factor expressed by neurons and glia, as well as vascular endothelial cells, and it is possible that the antidepressant actions of VEGF are mediated by one or more of these cell types. Here we examine the role of neuronal VEGF signaling by generating conditional deletion of either VEGF or Flk-1 (VEGF receptor 2) in neurons. CaMKII-Cre mice were bred with homozygous Flk-1 (VEGF receptor 2) or VEGF floxed mice. The resulting neuronal specific deletion of Flk-1 (Flk-$1^{NEURON-/-}$) and VEGF ($VEGF^{NEURON-/-}$) were tested in antidepressant responsive behavioral models, including the forced swim test (FST). The antidepressant effect of repeated desipramine (DMI) was blocked in Flk-$1^{NEURON-/-}$ or $VEGF^{NEURON-/-}$ mice. In addition, the antidepressant responses to chronic fluoxetine (FLX) or a single dose of ketamine were blocked in Flk-$1^{NEURON-/-}$ mice ($VEGF^{NEURON-/-}$ have not yet been tested). The locomotor response was not altered in either mutant line, indicating that the observed effects are not due to a general effect of neuronal Flk-1 or VEGF deletion on ambulation. These results indicate that neuronal VEGF signaling in the forebrain, the region where CaMKII drives expression of Cre, contributes to the actions of both typical and rapid acting antidepressants. To further define the forebrain region underlying these effects and to test the role of VEGF release, we have examined the medial prefrontal cortex (mPFC), a region implicated in the actions of ketamine, by intra-mPFC infusion of a VEGF neutralizing antibody (nAb). Infusion of the VEGF nAb into the mPFC significantly blocked the antidepressant effects of ketamine in the FST and in the novelty-suppressed feeding test, indicating that VEGF signaling in the mPFC plays an important role in antidepressant actions of ketamine. We are currently developing an approach to examine the effects of Flk-1 knockdown in CaMKII+ neurons in the mPFC via viral mediated expression of floxed Flk-1 shRNA in CaMKII-Cre mice. Together these studies will further characterize the cellular mechanisms underlying the antidepressant actions of VEGF signaling.

Title: Effect of repeated restraint stress on depression-like behavior and protein level of FKBP5 in the amygdala in rats

Authors: *T. IZUMI, R. GHEBREAB, C. WANG, Y. OHMURA, T. YOSHIDA, M. YOSHIOKA;
Hokkaido University, Col. of Med., Sapporo, Japan

Abstract: Major depression is a life threatening psychiatric disorder, and hyperactivation of HPA axis is one of the pathophysiological changes of it. The hippocampus and the medial prefrontal cortex inhibit the HPA axis, besides the amygdala activates it. Binding of FKBP5 decreases glucocorticoid receptor (GR) sensitivity to its ligand and alters intra-nuclear translocation. Here we investigated the effect of single and repeated restraint stress (RS) (3 hr/day) on depression- and anxiety-like behaviors using forced swimming test (FST) and elevated plus maze test (EPM) in rats. Moreover, we assessed the effect of repeated RS on the serum corticosterone by EIA, and on the GR and FKBP5 in the medial prefrontal cortex, hippocampus and amygdala by Western blotting. We performed above these assessments 2 weeks after repeated stress. Seven times RS increased depression-like behaviors (immobilization in FST) ($P< 0.017$). Locomotor activity and anxiety assessed by EPM were no change. Serum corticosterone was increased by seven times RS ($P< 0.017$). Protein level of GR was not changed, but that of FKBP5 was increased in the amygdala by seven times RS ($P< 0.05$). Hyperactivation of HPA axis and increase of FKBP5 in the amygdala may be related to RS-induced depression-like behaviors.

Title: NR2B-containing NMDA receptors on prefrontal cortex interneurons and the rapid antidepressant effects of ketamine

Authors: *D. M. GERHARD[1], E. S. WOHLEB[2], K. T. OTA[2], S. R. TAYLOR[2], M. R. PICCIOTTO[2], R. S. DUMAN[2];
[1]Psychology, [2]Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: Major depressive disorder (MDD) is a growing public health concern with widespread effects on personal welfare, the economy and society. Recent efforts have focused on the therapeutic benefits of ketamine, an NMDA receptor antagonist that produces rapid and sustained antidepressant effects in treatment resistant patients. Rodent studies show that ketamine rapidly increases glutamate release, activates mTORC1 signaling and increases translation of synaptic proteins in the medial prefrontal cortex (mPFC) shortly following acute treatment. Additional studies suggest that ketamine exerts behavioral effects through blockade of NR2B-containing NMDARs. Selective NR2B antagonists activate mTORC1 signaling and produce antidepressant-like behavioral effects comparable to ketamine. Collectively, these studies point to blockade of NR2B-containing NMDARs as the critical mediator for the rapid antidepressant effects of ketamine. NR2B is expressed by excitatory glutamate expressing (CaMKII+) pyramidal neurons as well as inhibitory GABA-expressing (GAD67+) interneurons in the mPFC. To determine if ketamine exerts rapid antidepressant effects via blockade of NR2B on glutamatergic (CaMKII+) pyramidal neurons or GABAergic (GAD67+) interneurons in the mPFC we developed a viral construct that expresses a short-hairpin RNA targeting NR2B in a Cre-dependent manner. Preliminary results demonstrate that this shRNA construct reduces NR2B expression in cultured cells in a Cre-dependent manner. Moreover, we have found that viral-mediated NR2B knockdown in GAD67-Cre mice produces an antidepressant response and occludes the antidepressant effects of ketamine in the forced swim test. In contrast, preliminary studies indicate that the NR2B knockdown in CaMKII-Cre mice does influence immobility or block the actions of ketamine, although additional studies are needed. Immunohistological studies of subtypes of GABAergic interneuron show that parvalbumin (PV)- and somatostatin (SST)-expressing interneurons have varied distribution of NR2B expression in the mPFC, with lower levels of NR2B on PV neurons. Studies are currently being conducted to determine if NR2B knockdown in SST-Cre and PV-Cre lines blocks the on the antidepressant actions of ketamine.

Title: Ketamine reverses helpless behavior in rats exposed to acute mild stress

Authors: ***D. LOPRESTO**, T. C. FRANKLIN, M. J. GIRGENTI, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Ketamine, a noncompetitive N-methyl-D-aspartate (NMDA) glutamate receptor antagonist, produces rapid antidepressant effects in treatment resistant depressed patients. Molecular studies show that ketamine rapidly induces synaptogenesis and reverses stress-induced synaptic deficits by stimulating postsynaptic AMPA receptors and raising BDNF levels. This is thought to occur via blockade of GABAergic interneurons that results in a transient burst of glutamate. At the behavioral level, acute ketamine administration has been shown to produce robust antidepressant effects after chronic unpredictable stress exposure as well as in animals that have undergone intracranial surgery, another form of stress. Ketamine is also reported to produce antidepressant actions in naïve rodents in drug screening models, notably the forced swim test (FST). However, our recent FST studies of ketamine in naïve animals have been inconsistent, possibly due to environmental stressors resulting from different vendors, transport, or vivarium conditions. This discrepancy suggests that acute mild stress could provide a better, more consistent model to study the antidepressant effects of ketamine. To test this hypothesis, we determined if exposure to acute mild foot shock stress could unmask ketamine's antidepressant properties. A 2 x 2 experimental design was used, where male Sprague-Dawley rats were exposed to mild foot shocks, which causes a two-fold increase in serum corticosterone levels, or remained in their home cage and received either vehicle or a single dose of ketamine (10 mg/kg, i.p.). The actions of ketamine were subsequently examined 24 hr later in a well-established

antidepressant model, the FST, a measure of behavioral despair that is reversed by acute antidepressant administration. Our results demonstrate that exposure to acute mild foot shock stress increases immobility time in the FST, and a single dose of ketamine significantly reverses immobility time and latency to immobility to levels in control, unstressed rats. Importantly, in agreement with our recent studies ketamine showed no antidepressant effects in naïve, unstressed rats in the FST, either in immobility time or in the latency to immobile posture. In conclusion, ketamine was able to reverse helpless behavior in the FST in rats exposed to mild foot shock stress but had no effect in naïve rats. Based on these findings, we conclude that prior exposure to a mild stressor provides a more consistent approach to uncover the antidepressant behavioral actions of ketamine.

Title: Chronic corticosterone-mediated dysregulation of microrna network in prefrontal cortex of rats: relevance to depression pathophysiology

Authors: *Y. DWIVEDI[1], B. ROY[1], G. LUGLI[2], H. ZHANG[2], H. RIZAVI[2], N. SMALHEISER[2];
[1]Dept of Psychiatry, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Stress plays a major role in inducing depression, which may arise from interplay between complex cascades of molecular and cellular events that influence gene expression leading to altered connectivity and neural plasticity. In recent years, microRNAs (miRNAs) have

carved their own niche owing to their innate ability to induce disease phenotype by regulating expression of a large number of genes in a cohesive and coordinated manner. In this study, we examined whether miRNAs and associated gene networks play a role in chronic corticosterone (CORT; 50 mg/kg x 21 days)-mediated depression in rats. Rats given chronic CORT showed key behavioral features that resembled depression phenotype. Expression analysis revealed differential regulation of 26 miRNAs (19 upregulated, 7 downregulated) in prefrontal cortex of CORT-treated rats. Interaction between altered miRNAs and target genes showed dense interconnected molecular network, in which multiple genes were predicated to be targeted by the same miRNA. A majority of altered miRNAs showed binding sites for glucocorticoid receptor element, suggesting that there may be a common regulatory mechanism of miRNA regulation by CORT. Functional clustering of predicated target genes yielded disorders such as developmental, inflammatory, and psychological that could be relevant to depression. Prediction analysis of the two most prominently affected miRNAs miR-124 and miR-218 resulted into target genes that have been shown to be associated with depression and stress-related disorders. Altogether, our study suggests miRNA-mediated novel mechanism by which chronic CORT may induce depression phenotype in rats.

Title: Efferents of the mouse anterior cingulate cortex

Authors: *P. VEINANTE, C. FILLINGER, M. BARROT, I. YALCIN;
INCI CNRS UPR3212, Strasbourg Cedex, France

Abstract: The anterior cingulate cortex (ACC) is known to be involved in chronic pain and depression in human and rodent. While the connectivity of ACC has been studied in primate and rat, a complete mapping of its efferents is still missing in the mousewhich is a relevant model for preclinical studies. Thus, we analyzed the efferents of the mouse ACC by injecting anterograde tracers (biotin dextran amine, BDA, and Phaseolus vulgaris leucoagglutinin, PhaL) in the rostral and caudal parts of the dorsal (Cg1) and ventral (Cg2) quadrants of the ACC. As a whole, ACC was found to project strongly to cortical areas, thalamus, basal ganglia and associated structures, midbrain and pons. In addition to specific intra-ACC connections, main cortical targets included orbital, retrosplenial, associative parietal and secondary visual areas. A light projection was identified to the dorsal subiculum and postsubiculum. Subcortical forebrain projections were dense in the dorsal striatum and the claustrum, and moderate in the basolateral amygdaloid nucleus, lateral septum and medial septum/diagonal band. Main thalamic targets were the anteromedial, interanterodorsal, laterodorsal, mediodorsal, ventromedial, paracentral and reuniens nuclei; lighter projections occurred in centromedial, ventral anterior and rhomboid nuclei. The dorsal zona incerta was also strongly innervated by ACC. In the hypothalamus, a moderate projection was found in lateral and posterior areas. ACC projections to the midbrain were dense in the pretectal nuclei, superior colliculus, dorsolateral PAG, ventral tegmental area and substantia nigra. The anterograde labeling was further identified caudally in paramedian, median and dorsal raphe, oral pontine reticular nucleus, laterodorsal tegmental nucleus, ventromedial medulla and gigantocellular nucleus. Several differences in topography and/or labeling density were observed between Cg1 and Cg2 along the rostrocaudal axis, especially in cortical, striatal and thalamic targets, as well as in midbrain and pontine projections. While most of forebrain and thalamic efferents were reciprocal, excepted to the striatum, the extensive pontomesencephalic ACC projection appeared mostly unidirectional. These results disclose the organization of ACC outputs in mice and, along with our companion study of ACC inputs, emphasize its position at the center of a circuit relevant for pain and depression.

Title: Rapid acting antidepressants cause activity dependent release of BDNF and stimulate mTORC1 signaling in primary neuronal cultures

Authors: *E. BANG, A. E. LEPACK, M. FUCHIKAMI, J. M. DWYER, A. TROG, M. BANASR, R. S. DUMAN;
CMHC S310, Yale Univ., New Haven, CT

Abstract: Clinical studies have demonstrated that a single low dose of ketamine, a non-competitive NMDA receptor antagonist, can elicit rapid and long lasting antidepressant effects in treatment resistant depressed patients. Our lab has demonstrated that ketamine rapidly activates the mammalian target of rapamycin complex 1 (mTORC1) pathway in the medial prefrontal cortex (mPFC) of rodents, which is required for the synaptogenic and behavioral actions of ketamine. In addition, activation of mTORC1 and the antidepressant behavioral effects of ketamine are blocked by pretreatment with an AMPA receptor antagonist, indicating that neuronal activation is required. A role for BDNF is supported by studies demonstrating that the behavioral actions of ketamine are blocked by infusion of an anti-BDNF antibody into the mPFC and that the response to ketamine is blocked in Val66Met knock-in mice, which have impaired activity dependent release of BDNF (Liu et al., 2012). Taken together, these findings indicate that the behavioral responses to ketamine are mediated by activity dependent release of BDNF and activation of mTORC1 signaling. The aim of the present study was to directly test if ketamine increases BDNF release and activates mTORC1 signaling in primary neuronal cultures. The results demonstrate that ketamine produces a rapid (15 - 30 min) and dose dependent (10 to 500 nM) increase in mTORC1 signaling and BDNF release, and that these effects are dependent on activation of AMPA receptors. Moreover, preliminary studies demonstrate that other rapid acting antidepressants, including scopolamine (a muscarinic receptor antagonist), LY341495 (an mGluR2/3 receptor antagonist), and GLYX13 (a glycine site partial inverse agonist) also increase BDNF release and increase mTORC1 signaling in primary cultures, and that these effects are dependent on AMPA receptor activation. Finally, incubation with ketamine increases the complexity of dendrites in primary neuronal cultures, possibly as a result of increased BDNF release. Studies are being conducted to test the actions of the other rapid acting agents on dendrite morphology, and to test the role of AMPA receptor activation and BDNF signaling. Together these studies demonstrate that ketamine and rapid acting antidepressants cause activity dependent release of BDNF that leads to synaptogenic responses.

Title: Transcriptional networks of resilience in a mouse model of depression

Authors: *Z. S. LORSCH[1], R. C. BAGOT[1], I. PURUSHOTHAMAN[1], J. SCARPA[2], B. LABONTÉ[1], P. J. HAMILTON[1], D. WALKER[1], C. J. PEÑA[1], M. WANG[1], L. SHEN[1], A. KASARSKIS[2], B. ZHANG[2], E. J. NESTLER[1];

Abstract: Major Depressive Disorder (MDD) is one of the most debilitating psychiatric disorders worldwide. Despite this, our understanding of the underlying mechanisms of MDD is far from complete. While genetics is believed to confer up to 40 percent of the risk for developing MDD, no genetic loci have emerged as genome-wide significant from a multitude of GWAS studies. Animal models of MDD, such as chronic social defeat stress (CSDS) in mice, have been successful in identifying molecular determinants of susceptibility and resilience to stress, but experiments to date have primarily focused on single genes and biochemical pathways as opposed to gene networks. Consequently, development of targeted antidepressants has been limited and a large portion of MDD patients fail to respond to currently available therapeutics. As such, a more comprehensive network-based approach to studying MDD is needed. In this study, we performed differential expression and Weighted Gene Co-Expression Network Analysis on transcriptional profiles obtained from key depression-related brain regions (nucleus accumbens, prefrontal cortex, basolateral amygdala, and ventral hippocampus) following 10-day of CSDS. We identified seven gene networks that show differential connectivity between mice resilient to CSDS and mice susceptible to CSDS. Four of these gene networks are also enriched for genes differentially expressed between resilient and susceptible mice. We have characterized key drivers within these four networks and identified upstream regulators of the networks that are putative master-regulators of resilience to CSDS. Furthermore, by assessing enrichment of known pharmacologic transcriptional signatures within these resilient-specific modules, we have generated predictions for novel therapeutic applications of existing drugs that may produce antidepressant effects by regulating network-level gene expression.

Title: Inhibitory modulation of orbitofrontal cortical activation on medial prefrontal cortex-amygdala information flow: Implication of interacting systems of obsessive-compulsive disorder and major depressive disorder

Authors: ***C.-H. CHANG**, A. A. GRACE;
Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: One to two thirds of patients with obsessive-compulsive disorder (OCD) display depressive symptoms. Consequently, major depressive disorder (MDD) is considered to be the major psychiatric comorbidity in OCD. The pathophysiology of OCD includes hyperactivity of the orbitofrontal cortex (OFC)-related circuitry, and it has been suggested that MDD arises due to dysfunction of the medial prefrontal cortex (mPFC)-amygdala pathway. However, how the OFC interacts with mPFC-amygdala information flow is largely unknown. In this study, we used *in vivo* extracellular single-unit recordings combined with local drug infusion in anesthetized rats to examine how OFC activation modulates amygdala neurons that fire in response to mPFC activation. Neurons in the amygdala that were responsive to mPFC stimulation (~50% evoked spikes) were first recorded for 10 min for baseline (BL; total 300 trials at 0.5 Hz stimulation rate), followed by intra-OFC local infusion of N-Methyl-D-aspartate (NMDA; 0.75µg/0.5µl), NMDA antagonist (2R)-amino-5-phosphonopentanoate (APV; 5µg/0.5µl), or vehicle (VEH; 0.5µl). All neurons (n = 8 in each group) were then recorded for another 40 min. We found that OFC activation with NMDA significantly decreased the ability of the mPFC to drive amygdala neurons immediately following local drug infusion ($p < 0.05$; first 5-min time block), while APV or VEH did not change the evoked probability compared to BL at all time points. We next assessed how neurons in the amygdala responded to mPFC electrical stimulation (BL; ~50% evoked spikes in 50 trials) with OFC stimulation preceding mPFC stimulation (50 trials each; OFC-mPFC stimulation delay: 10, 20, 30, 40, 50, and 100 ms). OFC modulatory gating was

Deleted: in vivo

tested in naive and OFC tetanized animals (200 trials at 20Hz). We found that OFC activation had a significant inhibitory gating (changes in evoked probability > 15% relative to BL) on mPFC-amygdala evoked response in the majority of the amygdala neurons recorded (n = 20 out of 23) at all latency delays relative to BL (all ps < 0.05), which was totally abolished with OFC tetanus (n = 8). Our results suggest that OFC activation exerted an inhibitory modulation of the mPFC-amygdala pathway. Potentiation of the OFC-related pathways, if such a condition is present in OCD, could result in a loss of OFC control over the mPFC-amygdala pathway, and thus may contribute to depressive-like symptoms.

Title: Norepinephrine regulates hippocampal gene expression after acute stress

Authors: *J. BOHACEK[1], M. ROSZKOWSKI[1], F. MANUELLA[2], L. VON ZIEGLER[1], I. M. MANSUY[1];
[1]ETH Zurich, Zurich, Switzerland; [2]Univ. Zurich, Zurich, Switzerland

Abstract: Acutely stressful experiences can trigger or exacerbate neuropsychiatric disease in humans, including post-traumatic stress disorder and anxiety disorders. The ability of stress to elicit such profound behavior changes depends on its ability to regulate gene expression in various brain regions. Indeed, acute stress elicits a highly complex, tightly orchestrated neuronal response involving multiple brain regions and various stress-signals, including neurotransmitters and hormone systems. How these stress-signals contribute to the transcriptomic response, however, remains poorly understood. To address this issue, we first established a mouse model in which a brief cold swim challenge induces strong anxiety on the elevated plus maze. Then, we assessed the transcriptomic profile in response to stress in the hippocampus, a key region involved in cognitive function, mood as well as stress-axis regulation. We find strong, genome-wide changes in gene expression involving signaling networks critical for neuronal function.

Using pharmacologic tools, we determined that the majority of the top-regulated genes is dependent on noradrenergic signaling, while none of these genes depends on the classic stress-hormones corticosterone and corticotropin releasing hormone. This demonstrates that norepinephrine plays a key role in regulating gene expression following acute swim stress exposure and suggests that it may be involved in the stress-induced increase in anxiety.

Title: Electrophysiological changes in the anterior cingulate cortex in neuropathic pain-induced depression

Authors: *J. SELLMEIJER[1], F. BARTHAS[1], M. BARROT[1], A. AERTSEN[2], P. VEINANTE[1], I. YALCIN[1];
[1]UPR3212 CNRS Inst. Des Neurosciences Cellulaire, Strasbourg, France; [2]Bernstein Ctr. Freiburg, Freiburg, Germany

Abstract: Clinical research has shown that suffering from chronic pain makes patients prone to develop mood disorders such as depression and anxiety. While the comorbidity of chronic pain and depression is well established in clinical research, the underlying mechanisms and involved brain regions are yet to be elucidated. The anterior cingulate cortex is among the candidate brain regions as it is known to be involved in the processing of both pain and affective processing. In this study, we identified electrophysiological alterations within the ACC in a model of chronic-

pain induced depression. Neuropathic pain was induced by cuffing the right sciatic nerve in male C57BL/6J mice. Anxiodepressive-related behaviors were evaluated through the novelty suppressed feeding, marble burying, splash and forced swimming tests. Mechanical thresholds were determined using von Frey filaments. We performed *in vivo* electrophysiological single unit recordings and local field potential recordings in the ACC. Recorded neurons were filled with neurobiotin to allow histological analysis. Cuff animals displayed an ipsilateral mechanical allodynia, and developed anxiodepressive-like behaviors with time. Interestingly, mice spontaneously recovered from the mechanical allodynia after 3 months, but still presented the anxiodepressive-like phenotype. Recordings from animals with depression-like behavior show increases in overall firing rate and in the number of bursting events in the ACC. This effect was observed independently from the presence or recovery from the neuropathic allodynia. These findings are supportive of long-term physiological alterations within the ACC with chronic pain-induced depression.

Title: GLYX13 increases mTORC1 signaling and synaptogenesis in the prefrontal cortex

Authors: ***C. H. DUMAN**[1], D. LOPRESTO[1], R.-J. LIU[1], R. TERWILLIGER[1], E. BANG[1], S. DUTHEIL[1], J. DWYER[1], A. BECKER[1], J. BURGDORF[2], J. R. MOSKAL[2], G. K. AGHAJANIAN[1], R. S. DUMAN[1];
[1]Dept. of Psychiatry, Yale Univ., New Haven, CT; [2]Naurex Inc, Evanston, IL

Abstract: Studies demonstrating rapid antidepressant actions of NMDA receptor antagonists, notably ketamine, in treatment resistant depressed patients represent the most significant advances in the field of depression over the past 60 years. This work has stimulated research and drug development to identify additional novel agents with less side effects and abuse potential. Studies by Moskal and colleagues demonstrate that GLYX13, a partial agonist of the glycine site of the NMDA receptor, produces rapid antidepressant actions in rodent models and also in depressed patients but without the psychotomimetic and dissociative side effects of ketamine. Electrophysiological studies also demonstrate that GLYX13, like ketamine increases synaptic plasticity in rodent models. In the current study, we examined the influence of GLYX13 on signaling pathways and synaptic responses in the prefrontal cortex (PFC), effects that have been identified to play a significant role in the antidepressant behavioral actions of ketamine. The results demonstrate that a single dose of GLYX13 increases signaling molecules in the mechanistic target of rapamycin complex 1 (mTORC1) pathway, including increased levels of the phosphorylated and activated form of p70S6K1, as well as increased levels of phospho-ERK in the PFC. In addition, a single dose of GLYX13 increased the number and function of spine synapses in layer 5 pyramidal neurons in the PFC. In these studies, GLYX13 administration increased the frequency of hypocretin-induced excitatory postsynaptic currents (EPSCs), and increased the number and head diameter of dendritic spines on layer 5 neurons. Elevation of the hypocretin response, which is mediated by thalamocortical terminal projections, would be expected to enhance attention and cognitive behaviors that are subserved by these connections. GLYX13 administration did not increase 5-HT-induced EPSCs. The results demonstrate that the actions of GLYX13 overlap with those of ketamine, as well as other rapid acting agents (i.e., scopolamine), although there are also differences that could potentially be related to the lack of psychotomimetic or dissociative side effects. Studies are being conducted to further characterize the type of spines that are influenced by GLYX13 and examine the thalamocortical inputs to these layer V postsynaptic elements.

Title: Afferents to the mouse anterior cingulate cortex

Authors: ***C. FILLINGER**, M. BARROT, I. YALCIN, P. VEINANTE;
Cnrs - Upr3212 (inci), Strasbourg Cedex, France

Abstract: Depression is the most common mood disorder estimated to become the foremost contributor to the worldwide burden of disease by 2030. Because mechanisms underlying depression are not well understood, there is a need to investigate in greater detail the anatomical circuitry of the depression. The anterior cingulate cortex (ACC) is known, in human and rodent, to play a major role in depression. The connectivity of ACC has been studied in primate and rat, but a complete mapping is still missing in the mouse. Thus, we analyzed the afferents to the mouse ACC by injecting retrograde tracers (Fluorogold, FG, and the beta-subunit of the choleric toxin, CTb) in the rostral and caudal parts of the dorsal (Cg1) and ventral (Cg2) quadrants of the ACC. This allowed us to highlight five principal groups of structures projecting to the ACC: (1) cortical areas, with numerous retrogradely labeled neurons principally in orbital, medial prefrontal, retrosplenial, parietal associative, primary and secondary sensory areas and hippocampus; (2) basal forebrain with a dense labeling found in the basolateral amygdaloid nucleus, the claustrum and the diagonal band of Broca (HDB); (3), the hypothalamus with moderate labeling in the lateral area and a denser one in premamillary region;(4), thalamus with labeled neurons found principally in anterior medial, lateral mediodorsal, central lateral, central medial and reuniens/rhomboid nuclei; and (5) the brainstem with a retrograde labeling exclusively located in monoaminergic centers. In most cases, the ipsilateral staining was more important than the controlateral one, excepted in the thalamus where no controlateral labeling was observed. Only few differences in afferents were found among the four ACC quadrants, especially in the orbital cortex and dopaminergic centers. Comparing FG and CTb results, some staining differences in density were found brainstem centers. Reciprocal anterograde tracing was performed with biotine dextran amine (BDA), to confirm retrograde labeling and further investigate the laminar organization of inputs from selected afferents: the HDB, the substantia

nigra pars compacta, the median raphe, and the locus coeruleus. Finally, the neurochemical nature of inputs coming from HDB and brainstem centers was investigated by a double-labeling procedure, showing that only a part of these afferents were cholinergic or monoaminergic. These results highlighted specific inputs to the ACC and replace it in a circuit which may be a new target for the study of the depression.

Title: Comparison of intermittent and continuous swim stress-induced behavioral depression: a levels of analysis approach

Authors: ***N. P. STAFFORD**[1], K. M. SPENCER[1], M. R. ARNOLD[3], N. J. PAGLUICA[1], D. H. TOWNSON[2], C. A. LOWRY[3], R. C. DRUGAN[1];
[1]Psychology, [2]Mol. and Cell. Biol., Univ. of New Hampshire, Durham, NH; [3]Integrative Physiol., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Prior exposure to inescapable stressors produces a depression of normal active behaviors (i.e., behavioral depression) in response to subsequent stress treatment. Swim stress paradigms (particularly cold-water swim) have been widely validated as models of behavioral depression, with the key endpoint being increased immobility during a forced swim test (FST). This phenomenon of behavioral depression is mediated in large part by serotonergic (5HT) and noradrenergic (NE) systems. The pattern of stressor administration (i.e., intermittent or continuous) is known to differentially recruit 5HT and NE. Intermittent swim stress (ISS) and continuous swim stress (CSS) in cold-water enhance behavioral depression in response to a subsequent FST, indicated by increased immobility. ISS typically exposes rats to 100 5-second forced swims (total swim of 8-min at 15°C water), while CSS typically exposes rats to 15-min forced swimming (19°C water). Total water exposure differences, coupled with differential water temperature makes direct comparisons between ISS and CSS paradigms difficult to interpret. Furthermore, the neurobiology of CSS has been examined at length, while only indirect evidence exists to describe the role of 5HT and NE systems in ISS-induced behavioral despair. Therefore,

the current experiment examined the effects of ISS and an equivalent (8-min) CSS on subsequent FST reactivity. Behavioral (immobility), endocrine (corticosterone), and molecular (c-Fos expression in 5HT and NE neurons) markers were assessed in order to provide a levels of analysis view. Treatment with either ISS or CSS resulted in enhanced immobility. Interestingly, prior exposure to CSS, but not ISS, resulted in an increase of FST-induced CORT release and LC activity. Both ISS and CSS pretreatment resulted in enhanced double-immunostained 5HT neurons in the caudal region of dorsal raphé, but not in other subregions. Overall, the data demonstrate that ISS and CSS result in differential physiological and equivalent behavioral responses to a subsequent FST.

Title: Development of the rat late-onset depression model related to white matter lesion

Authors: ***H. ONO**[1], H. IMAI[1], S. MIYAWAKI[1], S. MIYATA[2], H. NAKATOMI[1], M. MIKUNI[2], M. FUKUDA[2], N. SAITO[1];
[1]Dept. of Neurosurgery, Grad. Sch. of Medicine, The Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Psychiatry and Neuroscience, Gunma Univ. Grad. Sch. of Med., Maebashi, Japan

Abstract: [Background] Late onset depression (LOD) gets familiar with growing aged society and a significant contributor to the global burden of disease. The occurrence of white matter hyperintensities on T2-weighted magnetic resonance images is more frequent in patients with LOD, compared with early-onset depression. This fact indicates that white matter lesions (WML) may provoke some stress vulnerability leading to depression. In this study, we have developed a selective WML rat model with restraint stress (RS) to evaluate the correlation between the WML and depression. [Method] Sprague-Dawley rats (302-380g, n=108) were used in this study. Selective WML was induced under general anesthesia with bilateral endothelin-1 injection. Animals were randomly assigned to 4 groups: WML with RS (group 1); sham operation with RS

(group 2); WML no RS (group 3); sham operation, no RS (group 4). Two weeks after surgery, group 1 and 2 animals received 2 hours of RS a day, for 13 days. Some animals in group 1 and 4 received escitalopram along the protocol. Body weight (BW) was recorded daily and blood samples were collected at three time points along the protocol. Animals underwent a forced swimming test (FST) on the day following the 13th RS day. Animals were euthanized after the FST, and brain sections analyzed. [Result] Conventional histopathology of the operated rat brain revealed the selective damage of the internal capsule. RS significantly suppressed weight gain in groups 1 and 2 compared with non RS groups. Moreover the change in BW over time in group 1 was significantly different from group 2. The body weight reduction in group 1 reversed with the administration of escitalopram. The corticosterone levels were elevated at the seventh stress day and returned to basal levels at the thirteenth day in group 1 and 2. The immobility time on the FST for group 1 was longer than that of other groups. [Discussion] Accompanied with WML, repeated RS induced a reduction in weight gain and prolongation of immobility time in FST. These results provide preliminary evidence that WML could influence stress vulnerability leading to depression. Additionally, selective serotonin reuptake inhibitor reversed the weight gain reduction. In order to use this model as depression rat model, further behavioral tests need to be added, but it is considered that this model represents some aspects of the depression related to the WML, and may have a potential to contribute to the near future aging society.

Title: Behavioral changes in a neuroprogression model for bipolar disorder

Authors: *M. R. PITCHER, A. N. SHARMA, G. R. FRIES, G. Z. REUS, T. BARICHELLO, J. C. SOARES, J. L. DE QUEVEDO;
Univ. of Texas Hlth. Sci. Ctr. at Houst, Houston, TX

Abstract: People with bipolar disorder (BD) have recurrent affective mood episodes that feature manic or depressive behavior. Clinicians have observed differences in people with early-stage

and late-stage BD and have attributed the changes to neuroprogression. Neuroprogression in BD is characterized by a progressive increase in the frequency of affective episodes, decreased response to medications, development of systemic inflammatory and oxidative stress markers, and decline in cognitive function. A relevant preclinical model of BD neuroprogression could offer insight into the pathophysiologic mechanisms underlying the progressive change in symptoms. To this end, we have modeled recurrent affective episodes in young adult male rats using multiple day exposure to D-amphetamine followed by drug-free intervals. To model a single mania episode and recovery period, we treated rats with D-amphetamine for 7-days, followed by a 7-day drug-free period. To model neuroprogression, we exposed rats to two, three, four, or five of these mania episodes, separated by recovery periods. Rats that experienced increased numbers of mania episodes had increased spontaneous locomotor activity and abnormalities in habituation memory, compared to rats that experienced fewer mania episodes. These findings demonstrate that this model may have face validity to neuroprogression in BD.

Title: Differential effects of corticosterone on the colocalization of reelin and neuronal nitric oxide synthase in the adult hippocampus in wild type and heterozygous reeler mice

Authors: *R. ROMAY-TALLON[1], T. RIVERA-BALTANAS[4], L. E. KALYNCHUK[2], H. J. CARUNCHO[3];
[1]Dept. of Pharm. and Nutr., [2]Col. of Med., [3]Col. of Pharm. and Nutr., Univ. of Saskatchewan, Saskatoon, SK, Canada; [4]Dept. of Psychiatry, Meixoeiro Univ. Hosp., Vigo, Spain

Abstract: Repeated corticosterone (CORT) treatment induces a deficit in dentate gyrus subgranular zone reelin-positive cells, in maturation of newborn neurons, and results in a consistent depressive-like behavior. However, the molecular mechanisms underlying these

processes are not known in detail. The purpose of the present study was to characterize the effect of three weeks of 20mg/Kg CORT injections in the number of reelin and neuronal nitric oxide synthase (nNOS), as well as their colocalization, in hippocampal regions in wild type (WTM) and heterozygous reeler mice (HRM). ANOVA analysis shows a CORT x genotype interaction in the density of reelin+ cells co-localizing nNOS in the dentate subgranular zone and stratum-lacunosum moleculare, and in the density of nNOS+ cells in the hilus. There is a main effect of CORT in the density of both reelin+ and nNOS+ cells in the dentate subgranular zone and hilus, and in reelin+ cells in the molecular layer and CA3 stratum radiatum; and a main effect of genotype on the co-localization of both markers in the dentate subgranular zone, and in the density of reelin+ cell sin the stratum lacunosum moleculare. These alterations suggest a possible interconnection between reelin and nNOS expression that is altered by repeated CORT treatment.

Title: The involvement of NOX1/nicotinamide adenine dinucleotide phosphate, reduced form oxidase in anxiety- and depressive-like behaviors induced by stress

Authors: *M. IBI, J. LIU, C. YABE-NISHIMURA;
Kyoto Prefectural Univ. Med., Kyoto, Japan

Abstract: While the involvement of reactive oxygen species (ROS) in neural functions has been reported, the source of ROS in the nervous system has not been clearly identified. In addition to mitochondria, nicotinamide adenine dinucleotide phosphate, reduced form oxidase (NADPH oxidase) is a major source of ROS generated in the nervous system. It is a superoxide-generating flavoenzyme composed of the catalytic subunit, NOX. Several homologues of NOX have recently identified including NOX1, a nonphagocytic form of the enzyme. We previously

reported that NOX1-derived ROS affect pain signaling under pathological conditions (J Neuroscience 28:9486-9494, 2008; J Neuroscience 31:18094-18103, 2011). However, the functional significance of NOX1 in brain function have not been elucidated. This led us to examine the role of NOX1 in a broad range of behaviors using mice deficient in *Nox1* (Nox1-KO). There was no difference in the social behavior between wild-type mice (WT) and Nox1-KO. When the spatial memory was evaluated in the Morris water maze test, there was no difference between the genotypes. Nox1-KO did not show the impairment of memory consolidation in contextual and cued fear conditionings. No difference in spared nerve injury (SNI)-induced tactile allodynia was demonstrated between the genotypes. On the other hand, the SNI-induced anxiety-like behavior in elevated plus-maze (EPM) test was suppressed in Nox1-KO. When the anxiety-like behavior was evaluated in intact mice, both genotypes showed similar anxiety levels in EPM and open-field tests. However, increased anxiety-like behaviors demonstrated in WT following acute or chronic two hour-restraint stress, were markedly ameliorated in Nox1-KO. In the Porsolt forced swim test and tail suspension test in intact mice, both genotypes showed the similar immobility time. When mice were subjected to chronic social defeat stress or chronic corticosterone administration, the social behavior was significantly decreased in WT, but not in Nox1-KO. Interestingly, decreased level of BDNF mRNA in prefrontal cortex of WT following corticosterone administration was significantly suppressed in NOX1-KO. Taken together, ROS derived from NOX1/NADPH oxidase may play a key role in anxiety- and depressive-like behaviors induced by stress.

Title: Lysine-specific demethylase1 modulates anxiety-related behavior regulating stress-evoked transcription of immediate early genes

Authors: ***F. S. RUSCONI**[1], B. GRILLO[1], L. PONZONI[1], S. BASSANI[3], E. TOFFOLO[1], L. PAGANINI[1], A. MALLEI[2], D. BRAIDA[1], M. PASSAFARO[3], M. POPOLI[2], M. SALA[1], E.

Abstract: Stress-related brain plasticity contributes to environmental adaptation. However, chronic stress can elicit maladaptive neuronal responses linked to mood and anxiety disorders. Epigenetic modulation of stress-evoked transcription has been suggested to play a critical role in translating stressful stimuli into anxious phenotype. Here we demonstrate the involvement of transcriptional corepressor Lysine-specific demethylase 1 (LSD1/KDM1A) and its dominant-negative splicing isoform neuroLSD1, in the modulation of epigenetic mechanisms underlying the acquisition of normal anxiety-related phenotype. We show that in mouse hippocampus LSD1 and neuroLSD1 interact with the transcription factor SRF, setting the basal chromatin state of the SRF-targeted immediate early genes egr1 and c-fos. Indeed, we found that in mice complete lack (neuroLSD1KO mice) or reduction (neuroLSD1HET mice) of neuroLSD1 expression resulted in a low anxiety-like behavior. On a molecular point of view, neuroLSD1 mutant mice display reduced levels of positive histone marks at the egr1 and c-fos promoters dampening their stress-induced transcription. Interestingly, systemic administration of HDAC inhibitor SAHA to neuroLSD1KO mice restored egr1 and c-fos promoter chromatin structure as well as the normal behavioral phenotype. Therefore, proper IEGs transcriptional response to stress is instrumental to shaping the physiological anxiety profile. Remarkably, LSD1 expression itself is acutely increased by stress, involving LSD1 not only as a molecular transducer of stress stimuli, but also as a stress-response modifier. Our data provide a rationale to use LSD1 as a pharmacological target in the treatment of mood and anxiety disorders.

Title: High fat food induces anxiety and anhedonia: first steps towards identifying the common neural pathological mechanisms linking type 2 diabetes and depression in rat models

Authors: *S. DUTHEIL, K. T. OTA, E. S. WOHLEB, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: According to the World Health Organization, type 2 diabetes (T2D) and depression will have the greatest health care burdens worldwide by 2025. Increasing evidence suggests the existence of a bidirectional relationship, but the pathological cross-signaling underlying the increased risk of developing these two disorders remain unknown. In this regard, the current study seeks to identify important genes and intracellular cascades that work in concert under a chronic high fat diet (HFD) exposure, mimicking T2D in a rat male model. The results show that chronic HFD intake leads to glucose intolerance and alterations of the mammalian target of rapamycin complex 1 (mTORC1) pathway. The mTORC1 pathway integrates signaling from growth factors, energy, and nutrient levels to regulate translation and new protein synthesis. Such alterations under HFD exposure suggests that protein synthesis may be affected and could contribute to behavioral impairments. Interestingly, animals exposed to HFD develop anxiety-like, anhedonia and cognitive deficits that are similar the effects of chronic stress models of depression. We also found increased neuronal and peripheral corticosterone levels, enhanced pro-inflammatory cytokines levels (i.e. TNFα, IL-1β, IL-6), and alterations of Toll-Like receptor expression in the hippocampus of HFD rats. Hence, our findings provide a coherent picture showing how chronic HFD exposure causes multiple complications in the brain, thereby affecting intracellular signaling and gene expression that underlie behavior. We will also present data using pharmacological approaches to decrease the immune response via blockade of the purinergic receptors or to test the ability of the rapid acting antidepressant ketamine to reverse the behavioral and inflammatory effects elicited by HFD. This study is a first step towards understanding the mechanisms linking diet-induced diabetes to depression and should help to narrow the range of risk factors serving as a bridge between these two devastating disorders. In the future, early interventions targeting these disrupted pathways could help to decrease the prevalence of mood disorders in diabetic patients and reciprocally, then minimizing the burden associated with these two conditions.

Title: Treatment with the rapid acting antidepressant ketamine accelerates fear extinction in rodents

Authors: *M. J. GIRGENTI[1], D. LOPRESTO[2], J. R. TAYLOR[2], R. S. DUMAN[2];
[1]Physiol. and Neurobio., [2]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Impaired fear extinction contributes to the persistence of post-traumatic stress disorder (PTSD) symptoms. To date, few pharmacotherapies have demonstrated sufficient efficacy in PTSD. As such, the development of novel agents that improve the extinction of fear memory is warranted. There is mounting evidence for the role of glutamate in mediating stress responsiveness, the formation of traumatic memories, and the pathophysiology of PTSD, raising the possibility of identifying novel therapeutic interventions for this disorder. In this regard, recent clinical studies demonstrate that infusion of the rapid acting antidepressant ketamine, a glutamate NMDA receptor antagonist, rapidly and significantly reduces symptom severity in PTSD patients. Here, we used a rodent model of fear conditioning to test the effects of ketamine on the rate of fear extinction as well relapse and to study the underlying neurobiology of this response. Rats received ketamine (10 mg/kg; i.p.) or saline twenty-four hours after fear conditioning (foot shock paired with an auditory cue) and the next day were subjected to an extinction-training paradigm (exposure to auditory cue without foot shock). We found that ketamine treatment did not influence conditioned freezing responses during the initial extinction training, but that freezing behavior was significantly lower the next day during the extinction recall session. We also observed that a combination of ketamine treatment and extinction training caused activation of cFos in the medial prefrontal cortex (mPFC) and a subsequent decrease in cFos in the amygdala after the second day of extinction recall. In addition, the enhancement of extinction learning with ketamine is associated with activation of mTORC1 signaling in mPFC. The enhancement in fear extinction recall parallels earlier work showing that ketamine induces synaptogenesis and plasticity in the mPFC- a brain region instrumental in the acquisition and retrieval of extinction. Taken together, our findings support the hypothesis that the formation of new neuronal circuits by ketamine enhances the recall of extinction and could represent a novel approach for the treatment of PTSD and other fear disorders.

Title: Social bonds, cardiac function, and serotonin: An investigation using the prairie vole

Authors: ***N. MCNEAL**, A. DAGNER, E. IHM, M. WOODBURY, W. COLBURN, J. WARDWELL, A. J. GRIPPO;
Psychology, Northern Illinois Univ., Dekalb, IL

Abstract: Social relationships positively influence psychological and biological function in humans and other mammals. The disruption of an individual's social environment can adversely impact mental and physical health. The prairie vole is a useful laboratory model to investigate the neurobiological mechanisms linking social stress to deleterious changes in health because these animals form monogamous pair bonds, and display cardiac and hormonal regulation in a manner similar to humans. Male-female prairie vole bond disruption induces depression-relevant behaviors and disrupted regulation of the cardiovascular and endocrine systems. We hypothesized that antidepressant drug treatment (sertraline; Zoloft) would buffer the deleterious changes in behavioral and cardiac function during social isolation from an opposite-sex partner. To investigate this, adult male prairie voles were implanted with wireless transmitters for electrocardiographic recordings. Following recovery, male prairie voles were paired with an unrelated female partner for 5 days, followed by isolation from the female for 20 days. After 5 days of isolation, males received either sertraline or vehicle treatment for the remaining 15 days of the experiment. Finally, measures of depressive behaviors were conducted 24 hours apart on the final 2 days of the experiment. Preliminary results indicate drug treatment was limited in its ability to buffer the negative cardiac and behavioral changes associated with social stress. All male prairie voles (regardless of drug treatment) displayed a significant ($P<0.05$) increase in heart rate during isolation. Drug treatment tended to decrease the depression-relevant behavior and cardiac function in the tail-suspension test; however, during the forced swim test this pattern was reversed. These results demonstrate that disruption of social bonds in prairie voles deleteriously influenced neurobiological regulation of behavior and cardiac function, but that

sertraline was not entirely effective in ameliorating social isolation-induced negative changes. Continued use of this rodent model will improve our understanding of the associations among negative social experiences, depressive behaviors, and physiological health.

Title: Circuit-wide transcriptional profiling reveals opposing prefrontal cortical and ventral-hippocampal gene co-expression networks regulating depression susceptibility in mice

Authors: ***R. C. BAGOT**[1], H. M. CATES[1], I. PURUSHOTHAMAN[1], Z. S. LORSCH[1], D. M. WALKER[1], C. J. PEÑA[1], I. S. MAZE[1,2], E. A. HELLER[1], M. A. DOYLE[1], O. ISSLER[1], X. LIU[1], J. L. Abstract: Recent functional studies suggest that opposing alterations in prefrontal cortex (PFC) and ventral hippocampus (VHIP) neuronal activity regulate susceptibility to chronic social defeat stress (CSDS) (Bagot et al., Nat Commun, in press), a highly validated mouse model of depression. However, the molecular mechanisms mediating depression-associated functional alterations in these brain circuits are largely unknown. We performed RNA-sequencing on multiple brain regions, including PFC and VHIP, from control animals and mice susceptible or resilient to CSDS at multiple time points after defeat. We employed an intersectional bioinformatics approach combining differential expression analysis with weighted gene co-expression network analysis and key-driver analysis to identify novel transcriptional networks regulating depression susceptibility. We used viral-mediated over-expression of identified

network hub-genes in mice exposed to CSDS and assessed effects on depression associated behavioral assays. We identified two susceptible-specific gene co-expression networks that exhibited significant enrichment of oppositely regulated differentially expressed genes in PFC versus VHIP. Both networks were significantly enriched for neuronal-specific genes and gene ontology analysis indicated relevant functions including synaptic transmission and cell-adhesion. Viral-mediated over-expression of hub genes in each network confirmed bioinformatic predictions, inducing increased defeat-elicited social avoidance in VHIP and reduced social avoidance in PFC. These results demonstrate that opposing regulation of gene co-expression networks in PFC and VHIP mediates susceptibility to social defeat stress. Moreover, *in vivo* validation of bioinformatically predicted hub-genes validates the utility of a systems biology approach in identifying novel transcriptional mechanisms that mediate depression-like behavior.

Title: Exposure to a novel environment inhibits nucleus accumbens dopamine response to palatable food in mice

Authors: ***S. A. ROBINSON**, T. E. HILL-SMITH, I. LUCKI;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Exposure to a novel environment inhibits nucleus accumbens dopamine response to palatable food in mice Shivon A. Robinson[1], Tiffany E. Hill-Smith[2], and Irwin Lucki[2,3] Departments of Neuroscience[1], Pharmacology[2], and Psychiatry[3] University of Pennsylvania, Philadelphia, PA, 19104. Anhedonia is a hallmark symptom of several psychiatric disorders, including depression, schizophrenia and post-traumatic stress disorder. Though the term

encompasses both consummatory and motivational components, clinical studies indicate that anhedonic patients display greater deficits in motivational behaviors as opposed to perception of pleasure. Given the high presentation of anhedonia in stress-related psychiatric disorders, we were interested in investigating the effects of stress on motivational drive for obtaining natural rewards. In these studies we implemented the use of C57BL/6J (C57) mice in assessing the neurochemical correlates underlying approach behavior for palatable food. Previous studies in our lab have found that in contrast to rats, C57 mice are neophobic and do not immediately approach palatable food. Instead, these mice require repeated exposures in a controlled environment to exhibit approach behavior and consume the food. Using *in vivo* microdialysis, we characterized the effect of palatable food exposure on dopamine release in the nucleus accumbens (NAc), a region known to play a prominent role in food reward behavior. We found that animals trained to consume food in the testing chamber exhibited a significant 30% elevation in dopamine release in the NAc when food was presented ($p < 0.05$). However, if a bright light and novel scent was presented during food exposure, dopamine release in response to the food reward was blocked. Furthermore, animals in this condition took longer to approach the food compared to animals in the non-aversive condition. Lastly, among the animals there was a significant correlation between dopamine release and latency to approach the food ($r = -0.6358$, $p < 0.05$), but not with amount of food consumed. Together, these data indicate that in C57 mice, the mild stress of exposure to novelty reduces motivational drive to approach palatable food via alterations in NAc dopamine responsiveness to the food reward. Thus, stress-induced dysregulation of dopaminergic activity in response to natural rewards may be an underlying cause of anhedonia. Title: Altered dendritic spine plasticity in a mouse depression model

Authors: ***L. H. L. NG**[1], R. C. C. CHANG[2], C. S. W. LAI[1];
[1]Depratment of Physiol., [2]Depratment of Anat., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Structural atrophy and functional deficit of prefrontal cortex (PFC) have been consistently reported in patients of major depressive disorder. In animal models of depression, chronic stress reduced both the complexity and density of dendritic spines in PFC, which can be reversed by antidepressants treatment. It has been found that ketamine, a NMDA receptor blocker, can exert rapid antidepressant effect at a single, sub-anaesthetic dose. Ketamine can also reverse chronic stress-induced spine loss through the induction of synaptogenesis in animal depression models. Nevertheless, data on the immediate and long-term effect of ketamine in dendritic spine plasticity is lacking. On the other hand, previous report showed ketamine increased cortical excitability through the disinhibition of pyramidal neurons by preferential suppression of cortical interneurons. However, the involvement of cortical interneurons in the antidepressant effect of ketamine remains elusive. In this study, we used *in vivo* two-photon transcranial imaging of 1 month-old male *Thy1*-YFP H line mice to investigate the dendritic spine plasticity in the chronic restraint stress (CRS) depression model. We found that CRS altered dendritic spine plasticity of layer V pyramidal neurons and reduced parvalbumin (PV) interneurons immunoreactivity in the frontal cortex. We will further investigate the short-term and long-term effect of ketamine on the dendritic spine plasticity, and the potential involvement of PV interneurons in the CRS depression model.

Title: M1-type muscarinic acetylcholine receptors on prefrontal cortex interneurons mediate the rapid antidepressant effects of scopolamine

Authors: ***E. S. WOHLEB**, K. T. OTA, D. M. GERHARD, J. M. DWYER, S. R. TAYLOR, M. R. PICCIOTTO, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Major depressive disorder (MDD) is a recurring psychiatric illness that causes significant health and socioeconomic burden. Clinical reports revealed that the muscarinic acetylcholine receptor antagonist, scopolamine, produces rapid antidepressant effects in individuals with MDD. Moreover, studies in our lab show that the antidepressant behavioral effects of scopolamine are due to increased glutamate release, activation of mTORC1 signaling, and enhanced dendritic spine density on pyramidal neurons in the medial prefrontal cortex (mPFC). Further studies in the lab suggest that scopolamine exerts behavioral effects through blockade of M1-type muscarinic acetylcholine receptors (M1-AChR). For instance, antagonists selective for M1-AChR activate mTORC1 signaling and promote antidepressant responses comparable to scopolamine. These findings indicate that the cellular trigger for the rapid antidepressant effects of scopolamine is blockade of M1-AChR in the mPFC. M1-AChR is expressed by excitatory, glutamate-expressing (CaMKII+) pyramidal neurons along with subsets of inhibitory, GABA-expressing (GAD67+) interneurons in the mPFC. To determine if scopolamine exerts rapid antidepressant effects via blockade of M1-AChR on CaMKII+ or GAD67+ neurons in the mPFC we developed a viral construct that expresses a short-hairpin RNA targeting M1-AChR in a Cre-dependent manner. Here we show that viral-mediated M1-AChR knockdown in GAD67-Cre, but not CaMKII-Cre, mice blocks the antidepressant effects of scopolamine in the forced swim and novelty suppressed feeding tests. Closer examination of GAD67+ interneuron subsets through immunohistology showed that parvalbumin (PV+) and somatostatin (SST+) interneurons have varied distribution and M1-AChR expression in the mPFC. Furthermore, viral-mediated M1-AChR knockdown in SST-Cre mice promoted a pro-depressive behavioral response and M1-AChR knockdown in SST, but not PV, interneurons of the mPFC attenuated the rapid antidepressant effects of scopolamine. These data indicate that M1-AChR on SST+ interneurons play a pivotal role in the rapid antidepressant actions of scopolamine. Supported by NIMH Grants MH045481 and MH093897, and the State of CT.

Title: "Nature and nature" in a genetic model of depression

Authors: ***N. S. MEHTA**, S. L. WERT, C. MORLEY, E. N. GRAF, E. E. REDEI; Northwestern Univ., Chicago, IL

Abstract: "Nature and nurture" in a genetic model of depression Neha S. Mehta, Stephanie L. Wert, Claire Morley, Evan N. Graf, Eva E. Redei In this study, we sought to discover whether nurture in the form of environmental enrichment (EE) could overcome the negative effects of nature: the genetic causes of depressive behavior in a rat model of depression. This genetic rat model was developed in our lab from an accepted animal model of depression, the Wistar Kyoto (WKY) rat strain. Selective breeding of WKYs, based on immobility extremes in the forced swim test (FST), led to the Wistar Kyoto Less Immobile (WLI, control) and the Wistar Kyoto More Immobile (WMI, depression model) inbred strains, currently at their 35th generation. These strains contributed significantly to the discovery of blood transcriptomic markers of major depressive disorder (MDD). The thereby developed blood transcriptomic markers discriminated adolescent and adult subjects with MDD from their matched controls. In the current study, adult male WMIs and WLIs were either provided EE for 30 days or kept in their regular laboratory environment. Depression-like behavior decreased in both strains by EE, as measured by reduced immobility in the FST, with no change in anxiety-like behavior in the OFT. Nevertheless, WMIs still showed greater despair-like behavior post-EE, when compared to WLIs. Blood and hippocampal levels of transcripts that discriminated MDD subjects from controls in the clinical studies changed more in the WLIs than in WMIs. EE-induced changes in blood transcript levels of *Ras association and pleckstrin homology domains 1* (*Raph1*), and hippocampal expression of *Adenylate cyclase 3* (*Adcy3*) and *Family with sequence similarity 214, member B* (*Kiaa1539*) paralleled the changes in FST behavior post-EE in both strains. We propose that the maintained greater immobility of the WMIs post-EE is solely due to genetic factors. FST itself is a behavioral measure, but also an acute stressor. Indeed, FST altered the expression of several genes in the blood and in the hippocampus of WMIs and WLIs compared to those in behaviorally naïve animals. Thus, the attenuated immobility in both strains could be due to the EE-induced reduction of the FST-induced acute stress effect. The data suggest that an enriched environment can in fact positively impact depressive behavior, likely via reducing the environmental/stress contribution to it's etiology, without influencing genetic susceptibility. Supported by the Davee Foundation.

Title: Effect of neuron-specific deletion of Rbfox1 on learning and cocaine-related behaviors in mice

Authors: *J. DRGONOVA[1], G. R. UHL[2];
[1]Dept Mol Neurobiol, Natl. Inst. Drug Abuse, NIH, Baltimore, MD; [2]NMVAHCS and BRINM, Albuquerque, NM

Abstract: Rbfox1 (A2BP1; Fox1) is a member of the Rbfox family of splicing regulators that displays high levels of expression in brain. Molecular genetic studies in humans associate variants in Rbfox1 with vulnerability to substance dependence as well as epilepsy, schizophrenia and intellectual disability/ autism. Genes whose primary transcripts are differentially spliced in brain and/or differentiated stem cells include many that have been implicated in addiction and in glutamatergic neurotransmission. Previous studies have shown that the brains of CNS-specific Rbfox1 knockout mice were hyperexcitable and that the homozygous knockout mice display epileptiform activities. Here, we expand the behavioral characterization of these mice, adding novel data for heterozygous Rbfox1 mice that might more accurately model common human level- of- expression variation. Rbfox1 knockout mice exhibit impaired learning/memory, altered sensitivity to cocaine reward as assessed by conditioned place preference test and baseline and cocaine-induced locomotor activities that are indistinguishable from those in wildtype littermates. These behavioral observations are consistent with contributions of variants in this gene to human phenotypes that include vulnerability to substance use disorders. Support: NIH IRP (NIDA).

Title: Relationship between altered vesicular monoamine function and complex behavior

Authors: *R. A. CLIBURN, K. LOHR, L. RAJAN, J. SCHROEDER, D. WEINSHENKER, G. MILLER;
Emory Univ., Atlanta, GA

Abstract: Vesicular monoamine transporter 2 (VMAT2) is a presynaptic transmembrane protein which sequesters dopamine, norepinephrine, and serotonin from the cytosol into the vesicular lumen to prepare neurotransmitters for release. Our laboratory utilizes transgenic mice across a continuum of vesicular function: VMAT2-LO, -WT, and -HI mice, which contain 5%, 100%, and 200% of WT levels of VMAT2, respectively. As VMAT2 gene dose increases, both basal concentration of dopamine and stimulated release of dopamine increases. We hypothesized that this increase in VMAT2 function mediates a range of monoamine-mediated complex behaviors in mice, including fear behavior and the appetitive response to psychostimulants. As previously reported, VMAT2-LO mice display an anxiety- and depressive-like phenotype, whereas VMAT2-HI mice show improved outcomes in these tests as evidenced by reduced immobility time in a forced swim test (21.7%) and fewer marbles buried in a marble burying assay (38.7%) compared to WT mice. Furthermore, VMAT2-LO mice exhibit a 34% increase in freezing response compared to VMAT2-WT or -HI mice in a test of contextual fear conditioning. Furthermore, VMAT2-HI mice display a reduced (50%) preference for a cocaine-paired context in a test of conditioned place preference at 10 mg/kg, but show no difference in cocaine-induced locomotion when compared to WT mice. Alternately, VMAT2-LO do not display an altered preference for cocaine at 10 mg/kg, but do display a marked increase in cocaine-induced locomotion. The ability of atered VMAT2 to influence response to psychostimulants, anxiety, depression, and fear response suggests that therapeutic approaches aimed at modifying VMAT2 function may be of benefit in these conditions.

Abstract: Dopaminergic projections arising from ventral tegmental area (VTA) play a key role on drug induced effects in the mesocorticolimbic system. Chronic cocaine administration produces an increased VTA dopamine (DA) cell excitability. VTA DA neurons express a large hyperpolarization activated cation current, known as Ih, that contributes to the electrophysiological properties of neurons in the CNS. We hypothesized that Ih -enhances VTA DA cell activity during the development of cocaine sensitization. Cocaine sensitization is the progressive escalation of psychomotor responses that results with repeated cocaine administration. We performed intra VTA microinfusions of Lamotrigine (LTG), an Ih current enhancer. Male Sprague-Dawley rats (250-300g) were anesthetized and stereotaxically implanted with bilateral 26-gauge cannulas in the VTA. Animals were divided as following: Vehicle/Saline, LTG/Saline, Vehicle/Cocaine, LTG/Cocaine (microinjections/ i.p. injections, respectively).Daily LTG microinjections (0.1ug bilateral) were administered for 7 days. Cocaine treated rats (15 mg/kg, i.p.) were injected 10-15 minutes after the LTG microinfusion. Locomotor activity was recorded for 1 hour every day. On day 8, rats received a first cocaine challenge in the absence of LTG. After a 7 days withdrawal period, a second cocaine challenge was performed. Total ambulatory and stereotype activities were analyzed using One-Way ANOVA followed by Newman-Keuls Test. LTG/Cocaine rats showed a significant increase in the acute response to cocaine ($p < 0.01$). Moreover, these animals developed sensitization two days before the control group. Their locomotor response to cocaine during days 1-3 was significantly higher ($p < 0.01$) compared to Vehicle/Cocaine rats. However, during cocaine challenge, when no LTG was administered the LTG/Cocaine group's locomotor activity was not significantly different from the Vehicle/Cocaine group. We postulate that LTG in the VTA, acting through the Ih current, enhances neural excitability caused by chronic cocaine administration. Taken together, our data suggest that an enhanced Ih current activity in the VTA may contribute to a greater susceptibility to cocaine neurobiological effects.

Title: Effects of PKMζ inhibitor (ZIP) on the initiation and expression of cocaine sensitization

Authors: ***A. VAQUER-ALICEA**[1], R. VÁZQUEZ-TORRES[2], B. SANTOS-VERA[2], C. MARÍA-RÍOS[4], A. MONTIEL-RAMOS[4], M. DEVARIE[3], M. VÉLEZ-HERNÁNDEZ[5], T. C. SACKTOR[6], C. A. JIMÉNEZ-RIVERA[2];

Abstract: Cocaine addiction induces long-lasting alterations in the mesocorticolimbic system; some of which may be mediated by the mechanisms of long-term potentiation (LTP). Persistent phosphorylation by protein kinase M zeta (PKMζ) mediates the maintenance of late-LTP (L-LTP). The myristoylated z-pseudosubstrate inhibitory peptide (ZIP) selectively inhibits atypical PKCs, including PKMζ, and reverses established L-LTP. Previous laboratory data showed that ZIP microinjection in the ventral tegmental area (VTA) (important for initiation) on day 5 of a cocaine behavioral sensitization protocol blocked initiation of sensitization but not expression. We hypothesized that uninterrupted neural signaling from the VTA to the nucleus accumbens (NAc) (important for expression) for 5 days before inhibiting PKMζ, triggered plastic changes in the NAc. In accordance with this hypothesis, ZIP microinjections into the NAc after 7 days of withdrawal blocked expression. These data indicate that VTA LTP plays a role in the initiation of sensitization and NAc LTP allows sensitization expression. To elucidate if VTA LTP is

essential for plasticity changes in the NAc to occur, we continuously interrupted VTA LTP formation and looked for changes in expression. For this, male Sprague-Dawley rats (250g) were stereotaxically implanted with bilateral cannulas into the VTA and were given daily ZIP microinjections for 5 days, 6 hours after cocaine i.p. injection followed by a 7 day withdrawal period and a cocaine challenge. Results showed a decrease in total and stereotypic locomotion on day 5, but not on challenge day. This suggests that PKMζ is important but not essential for the initiation phase and that NAc neuroadaptations can develop independently of VTA LTP. In order to see if these neuroadaptations in the NAcc can be naturally restored once interrupted, we inhibited PKMζ a week after a withdrawal period and allowed another 7 days of withdrawal. A cocaine challenge was given on day 20. We observed a persistent decrease in total and stereotypic locomotion by day 20, indicating NAc LTP disruptions during the maintenance phase of the cocaine sensitization protocol are long-lasting. Further studies regarding PKMζ's role in cocaine-induced LTP formation in the reward circuit, will shed some light into the pathological mechanisms that underlie cocaine addiction.

Title: A within-animal assessment of neural ensembles associated with novelty and cocaine

Authors: ***N. N. NAWARAWONG**[1,2], M. J. MUELBL[1,2], H. ZHU[3], Y. LIM[1,2], B. L. ROTH[3], C. M. OLSEN[1,2];
[1]Pharmacol. and Toxicology, [2]Neurosci. Res. Ctr., Med. Col. of Wisconsin, Milwaukee, WI; [3]Pharmacol., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Novelty seeking is a personality trait associated with an increased vulnerability for substance abuse. In rodents, elevated novelty seeking has been shown to be a predictor for elevated drug self-administration and compulsive use. While previous studies have shown that both novelty and drugs of abuse have actions within similar mesocorticolimbic regions, little is known as to whether the same neural ensembles are engaged by these two stimuli. In this project, we wanted to determine the activation patterns associated with novelty and cocaine. Using the TetTag mouse model (a dual transgenic reporter line that allows for long lasting temporally controlled tagging of active neurons), we compared neurons engaged by cocaine and novelty seeking. We investigated the infralimbic and prelimbic prefrontal cortex, the nucleus accumbens (NAc) core and shell, the ventral hippocampus, and the basolateral amygdala for overlap between neurons associated with cocaine and novelty seeking, and found significant overlap, especially in the NAc core. To test the functional significance of overlap between neural encoding of novelty and cocaine, we are using the TetDREADD mouse model; a variant of the TetTag mouse that yields activity-dependent expression of Gi/o coupled DREADD receptors (hM4Di) in a temporally controlled manner. TetDREADD mice were trained to self-administer cocaine and novelty (operant sensation seeking: OSS) in different contexts to test the ability of silencing neurons engaged during one of these behaviors to affect expression of the other behavior. The data suggest that increasing Gi/o signaling in neurons engaged during cocaine self-administration can reduce OSS. Ongoing studies are further parsing the functional overlap of neurons involved in cocaine and novelty seeking.

Abstract: In the past decade, novel methods using engineered receptors have enabled researchers to manipulate neuronal activity with increased spatial and temporal specificity. One widely used chemogenetic method in mice and rats is the DREADD (designer receptors exclusively activated by designer drugs) system in which a mutated muscarinic G-protein coupled receptor is activated by an otherwise inert synthetic ligand, clozapine-n-oxide (CNO). Recently, the Roth lab developed a novel inhibitory DREADD in which a mutated kappa opioid receptor (KORD) is activated by the pharmacologically inert drug salvinorin B (SalB; Vardy et al., 2015). They demonstrated the feasibility of using KORD to study brain circuits involved in motivated behavior in mice. Here we used behavioral, electrophysiological, and neuroanatomical methods to demonstrate the feasibility of using the novel KORD to study brain circuits involved in motivated behavior in rats. In Exp. 1, we show that SalB dose-dependently decreased spontaneous and cocaine-induced locomotor activity in rats expressing KORD in midbrain (ventral tegmental area/substantia nigra). In Exp. 2, we show that SalB completely inhibited tonic firing in KORD-expressing putative dopamine neurons in midbrain. In Exp. 3, we used a 'retro-DREADD' dual-virus approach to restrict expression of KORD in ventral subiculum neurons that project to nucleus accumbens shell. We show that KORD activation selectively decreased novel context-induced Fos expression in this projection. Our results indicate that the novel KORD is an excellent tool to selectively inactivate brain areas and neural circuits in rat studies of motivated behavior.

Title: Oxidative stress response exacerbates cocaine addiction after social defeat stress

Authors: *Y. N. OHNISHI[1], Y. KAWAHARA[2], Y. H. OHNISHI[2], M. KUROIWA[2], V. F. VIALOU[3], R. L. NEVE[4], E. J. NESTLER[5], A. NISHI[2];

Abstract: Generally, mental stress enhances irresistible impulse to addictive craving. However, the molecular mechanism is not fully understood. We reproduced this behavior in a mouse model, in which pre-exposure of mice to social defeat stress increased cocaine preference. Motivation for preference is well known to be controlled by dopamine neurotransmission in reward system network from the ventral tegmental area to nucleus accumbens. We therefore performed microdialysis to detect dopamine levels in the nucleus accumbens. Dopamine levels in the nucleus accumbens increased when mice were placed in cocaine-conditioned box, and the increase in dopamine levels was significantly enhanced after social defeat stress. As dopamine is known to be an inducer of oxidative stress, we measured the expression level of oxidative stress response proteins, and found that nuclear respiratory factor was significantly increased only when mice were treated with cocaine after social defeat stress. Furthermore, overexpression of dominant negative form of nuclear respiratory factor in nucleus accumbens suppressed cocaine preference after social defeat, as in the case of delta2deltaFosB overexpression (Ohnishi YN et al., 2015). Now we are trying to determine whether the increase in nuclear respiratory factor can be reduced by antioxidant-rich-foods.

Engin., Lausanne, Switzerland

Abstract: The main aim of our research is to understand the response of zebrafish larvae to psychoactive substances in order to evaluate the suitability of this system for prediction of the effects of such compounds in mammals. Here, we focus on the neurobehavioral effects and toxicokinetics of cocaine, a central nervous stimulant. The neurobehavioral effects of cocaine were assessed at 5 days post fertilization (5 dpf) by adding the drug to the fish water, followed by monitoring the locomotor activity. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) was used to study the uptake, biotransformation and elimination over time. Internal drug distribution was studied by matrix-assisted laser desorption ionization mass spectrometry imaging (MALDI-MSI) and also by LC-MS/MS quantification of cocaine in dissected body parts. Cocaine caused a significant reduction in the locomotory activity at the concentrations above 5 μM, while no significant effects were observed at lower concentrations. In mammals, cocaine is known to induce hyperactivity at low doses and hypoactivity at high doses, but in zebrafish larvae, only hypoactivity was observed. The reasons for the lack of hyperactive responses in zebrafish larvae are not known, but we hypothesized that it might be due to the differences in exposure routes used for fish and mammals. Hence we performed toxicokinetics and the distribution assessment. LC-MS/MS analysis confirmed the uptake and biotransformation of cocaine in zebrafish larvae and showed gradual elimination after transfer into clean water and effective concentrations were comparable to those causing similar effects in mammals. MALDI-MSI was used for the first time to study the distribution of cocaine in zebrafish larvae, revealing accumulation in the trunk (melanophores) and in the head region; more precisely, in the brain, but also, surprisingly, in the eyes. In dissected brain, eyes and trunk, cocaine was detected in all the measured tissues, with a highest concentration found in the eyes. In conclusion, this study provides new insights into toxicokinetics concurrently with the neurobehavioral effects of cocaine and is the first of its kind to demonstrate the possibility of drug distribution analysis by MALDI imaging in zebrafish larvae.

Title: The role of DNA methylation and demethylation in the expression of cocaine-induced behavioral sensitization

Authors: *K. ANIER[1], M. URB[1], T. MATSALU[1], K. KIPPER[1], K. HERODES[1], T. TIMMUSK[2], A. KALDA[1];
[1]Univ. of Tartu, Tartu, Estonia; [2]Tallinn Univ. of Technol., Tallinn, Estonia

Abstract: Repeated administration of psychostimulants (such as cocaine) induces an enhanced behavioral response to subsequent drug exposure, a phenomenon known as behavioral sensitization, which can be separated into two components - induction and expression. Induction of sensitization refers to the progressive increase in locomotor activity during the repeated drug treatments. Expression of sensitization is demonstrated following challenge with a low dose of psychostimulant after a drug-free period. Behavioral sensitization is remarkably persistent phenomenon. In rodents, it can persist from months to years after drug treatment is discontinued. Persistent behavioral sensitization indicates that drug-induced short- and long-term changes in gene expression may be involved. Accumulating data suggest that epigenetic mechanisms such as DNA methylation (catalyzed by DNA methyltransferases - DNMTs) contribute to drug-induced transcriptional and behavioral changes. Recently, it has been reported that ten-eleven translocation (TET) enzymes TET1-3, which add a hydroxyl group onto the methyl group of 5-methylcytosine (5-mC) to form 5-hydroxymethylcytosine (5-hmC) participate in DNA demethylation process and might play a role in cocaine action (Feng et al., 2015). Our aims of this study were: 1) to assess the effect of cocaine treatment on DNMT and TET family transcripts levels in the nucleus accumbens (NAc), cerebellum and peripheral blood of mice in the induction and expression phase of sensitization; 2) to determine whether or not treatment with DNMT inhibitor RG108 may affect the expression of cocaine-induced behavioral sensitization. Using qPCR, we found that cocaine treatment in the induction and expression of sensitization causes DNMT1 and DNMT3A overexpression and TET family transcripts (mainly TET1, TET3) downregulation in the NAc and cerebellum of mice and these changes are tightly correlated with changes in peripheral blood. ELISA-based DNMT and TET activity analysis showed that cocaine treatment in the expression phase of sensitization increased DNMT and

decreased TET hydroxylase activity levels in the NAc. Using LC-ESI-MS/MS assay, we measured global 5-mC and 5-hmC levels in the NAc and we found that cocaine treatment alters 5-mC and 5-hmC levels in the induction and expression phase of sensitization. Finally, we show that repeated bilateral into NAc treatment with RG108 affects the expression of cocaine-induced sensitization in mice. These data indicate that cocaine treatment alters the balance between methylation and demethylation processes in the NAc and may affect the development of behavioral sensitization.

Title: Glycogen synthase kinase 3 in the rat ventral hippocampus is necessary for the development of cocaine-induced behavioral sensitization

Authors: ***J. L. BARR**, E. M. UNTERWALD;
Temple Univ., Philadelphia, PA

Abstract: The ventral hippocampus is involved in drug-seeking behavior and psychostimulant-induced behavioral sensitization. We have previously demonstrated that rats exposed to repeated cocaine exhibit greater increases in both locomotor activity and dopamine efflux in the medial shell of the nucleus accumbens in response to NMDA stimulation of the ventral hippocampus. Furthermore, cocaine-sensitized rats exhibit a greater density of NR2B-containing NMDA receptors in the ventral hippocampus. Glycogen synthase kinase 3 (GSK3) is a significant mediator of many intracellular signaling pathways, including increases in NMDA receptor function and trafficking of NR2B-containing NMDA receptors to the cell surface. Therefore, the current study examined whether inhibition of GSK3 in the ventral hippocampus diminishes cocaine-induced locomotor activity and the development of locomotor sensitization. Male rats were bilaterally infused with vehicle or the selective GSK3 inhibitor SB216763 (1ng) into the ventral hippocampus, 20 min prior to cocaine (15 mg/kg, ip.) or saline (1ml/kg, ip.) once daily for five days. After a ten day abstinent period all rats were challenged with a cocaine injection in

the absence of microinfusions. Pretreatment with the selective GSK3 inhibitor SB216763 into the ventral hippocampus significantly reduced cocaine-induced activity on days 2-5. Further, pretreatment with SB216763 attenuated the development of sensitization to the locomotor-stimulating effects of cocaine. The role of GSK3 in the regulation of NMDA receptors in the ventral hippocampus of cocaine-sensitized rats is currently under investigation. Overall, the findings suggest that GSK3 activity within the ventral hippocampus is necessary for the development of sensitization following repeated cocaine exposure. NMDA receptors may represent an important target for cocaine-activated GSK3 in the ventral hippocampus.

Title: Behavioral sensitization following concurrent exposure to MDPV and cocaine in CF-1 mice

Authors: *M. D. BERQUIST, JR, L. E. BAKER;
Psychology, Western Michigan Univ., Kalamazoo, MI

Abstract: In the United States, reports indicate the specific “bath salt” constituent, 3,4 methylenedioxypyrovalerone (MDPV), is one of the most frequently encountered synthetic cathinones by law enforcement agencies. Recent reports indicate MDPV’s neurochemical actions on the dopamine transporter (DAT) are comparable to those of cocaine, although MDPV is considerably more potent. Moreover, preclinical behavioral assays of abuse liability indicate MDPV has a high risk for abuse. Behavioral sensitization to the hyperlocomotor effects of psychomotor stimulants is suggested to reflect changes in brain pathways associated with drug addiction and abuse. Although other synthetic cathinones (e.g., mephedrone) have been reported to induce behavioral sensitization following repeated dosing in rodents, MDPV has not yet been examined in this paradigm to our knowledge. Additionally, there is a scarcity of preclinical substance abuse research using female experimental subjects. The current study assessed the extent to which repeated exposure to mixtures of MDPV and cocaine (COC) produce augmented motor-stimulant responses in mice. Adult male (N=48) and female (N=48) CF-1 mice were

randomly assigned to receive intraperitoneal injections of saline, COC (5.0 mg/kg), MDPV (0.5, 1.0, or 5.0 mg/kg), or MDPV (0.5, 1.0, 5.0 mg/kg) + COC (5.0 mg/kg) daily for 7 days. After a 10 day washout period, all animals were dosed with 5.0 mg/kg COC. Activity was assessed for 30 min prior to injections and continuously monitored for 60 min after injections on days 1, 7, and 17. The development of behavioral sensitization was evident following repeated dosing in male mice treated with 1.0 mg/kg MDPV, 0.5 mg/kg MDPV + 5.0 mg/kg, or 5.0 mg/kg MDPV + 5.0 mg/kg COC. None of the above treatments induced sensitization in female mice. After the washout period, both male and female mice treated with 1.0 or 5.0 mg/kg MDPV, and those treated with MDPV+COC mixtures displayed cross-sensitization to the locomotor stimulant effects of 5.0 mg/kg COC. These findings suggest concurrent use of synthetic cathinones and cocaine may increase their risk of abuse. Additional studies evaluating sex differences in behavioral responses to the synthetic cathinones may be warranted.

Title: A role for nucleus accumbens somatostatin interneurons in cocaine induced plasticity

Authors: *E. A. RIBEIRO[1], B. JUAREZ[1], R. BAGOT[1], I. PURUSHOTHAMAN[1], B. LABONTE[1], E. CALIPARI[1], J. FENG[1], J. SCARPA[1], H. CATES[1], M. HESHMATI[1], A. KASARSKIS[1], S. RUSSO[1], L. SHEN[1], M.-H. HAN[1], J. KOO[2], E. NESTLER[1];
[1]Friedman Brain Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Korea Brain Res. Inst., Dengu, Korea, Republic of

Abstract: The nucleus accumbens (NAc) is a brain region that is involved in regulating behavioral responses to both natural and drug induced reward. While the NAc is mainly comprised of D1- or D2-receptor expressing medium spiny neurons (MSNs), there are several classes of GABAergic Interneurons in the area as well. MGE (medial ganglionic eminence)-

derived somatostatin (Sst) expressing interneurons account for 2-3% of the total neurons in the region and have previously been shown to be activated after cocaine administration. We show that after 7 days of I.P. cocaine Sst transcription is increased in the NAc up to 4 hours following the last injection. This supports our previously reported finding that 7 days of IP cocaine leads to a decrease in H3K27Me3 binding at the Sst promoter in NAc. We utilized optogenetics, viral mediated circuit tracing, along with stem cell transplantation of MGE interneuron precursors to study the role of NAc Sst interneuron populations in behavioral responses to cocaine. We found that NAc Sst interneurons are innervated by many of the same glutamatergic, dopaminergic, and serotonergic afferents as D1/D2 MSNs in the region and that these circuits undergo remodelling after chronic cocaine exposure. Using optogenetics *in vivo* to control the activity of NAc SSt interneurons, we show that stimulation of NAc Sst interneurons suppresses locomotor responses and conditioned place preference (CPP) to cocaine, whereas silencing the interneurons has similar but distinct effects, suggesting that the activity of NAc Sst-interneurons plays a critical role in regulating cocaine induced plasticity in the NAc. We next studied the effect of transplanted fetal MGE cells in cocaine action and found that MGE transplantation into NAc, which produces an increase in the number of Sst interneurons, reduced CPP scores, suggesting that transplanted Sst-interneurons are functionally equivalent to endogenous NAc Sst interneurons. Finally, we performed RNA-seq on FACS isolated NAc Sst interneurons after chronic cocaine administration *in vivo* and identified genome wide transcriptional changes induced by cocaine specifically in this cell type. By combining molecular and behavioral analyses of this specific cell type, we hope to contribute to the fields of addiction and stem cell research to ultimately gain a deeper understanding of the fundamental molecular, electrophysiological, and epigenetic mechanisms that regulate cocaine-induced neuroplasticity.

Title: Cocaine regulates monoubiquitination of histones H2A and H2B in nucleus accumbens

Authors: *J. RABKIN[1], D. M. WALKER[1], E. S. CALIPARI[1], O. ENGMANN[1], H. M. CATES[1], H. SUN[2], E. A. RIBEIRO[1], D. BUREK[1], R. NEVE[3], E. J. NESTLER[1]; [1]Dept. of Neurosci. and Friedman Brain Inst., New York, NY; [2]Columbia Univ. Med. Ctr., New York, NY; [3]McGovern Inst. for Brain Res. at MIT, Cambridge, MA

Abstract: Although the etiology of drug addiction is multi-factorial, mounting evidence suggests that drug-induced alterations in gene expression in the brain's reward circuitry contribute to the chronic, relapsing nature of the syndrome. Our group and others have shown that histone post-translational modifications represent one important mechanism by which chronic exposure to cocaine induces these changes. Histone ubiquitination, despite being known to exist for decades, is less well studied than other histone marks. The dominant form of ubiquitinated histones in the cell are monoubiquitinated H2A and H2B, and both have been shown to regulate transcription in yeast and cultured human cells. However, very little is known about the role of histone ubiquitination in brain, especially in disease models such as drug addiction. Here, we show that repeated cocaine administration in mice and cocaine self-administration in rats regulate levels of H2A and H2B monoubiquitin as well as levels of monoubiquitin ‘writer’ and ‘eraser’ enzymes in the nucleus accumbens, a key brain reward region. Quantitative ChIP is currently being performed to identify how these marks are distributed at genes known to be regulated by cocaine. We are additionally examining the effect of histone monoubiquitin on behavioral responses to cocaine by viral-mediated overexpression or knockdown of H2A ubiquitin ligases Ring1 and RNF2. To our knowledge, this is the first evidence for a role of histone ubiquitination in the pathophysiology of drug addiction and points to a new area of research with potential therapeutic benefits.

Title: Cocaine augments local synaptic translation in the nucleus accumbens through a small GTPase network

Authors: ***M. E. CAHILL**[1], R. C. BAGOT[1], D. WALKER[1], J. FENG[1], H. SUN[1], J. KOO[1], R. NEVE[2], A. GANCARZ[3], G. L. SCHROEDER[3], Z. WANG[3], D. M. DIETZ[3], E. J. NESTLER[1]; [1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Massachusetts Insititute of Technol., Cambridge, MA; [3]SUNY Buffalo, Buffalo, NY

Abstract: Dendritic spines are the sites of most excitatory synapses in the central nervous system, and withdrawal from drugs of abuse alters the density and morphology of dendritic spines on medium spiny neurons (MSNs) of the nucleus accumbens (NAc), a primary reward region. Members of the Rho subfamily of Ras-like small GTPases are critical regulators of spine morphogenesis in MSNs, and guanine nucleotide exchange factors (GEFs) directly activate small GTPases. Our studies indicate that early withdrawal from both investigator-administered and self-administered cocaine increases the synaptic expression of the Rap1 small GTPase in the NAc. Conversely, late withdrawal from cocaine decreases synaptic NAc Rap1 levels. To date, no downstream effectors of Rap1 in NAc MSNs have been identified, and here we characterize a novel role for Rap1 in stimulating the activity of an AKT/mammalian target of rapamycin (mTOR) local translation network within dendritic spines. Via viral-mediated gene transfer and pharmacological manipulations, we found that altered Rap1-AKT-mTOR signaling controls NAc spine morphogenesis with resulting time-dependent effects on cocaine-mediated behavioral reward. Using optogenetic methods we dissected the excitatory inputs to the NAc that regulate Rap1-AKT-mTOR signaling. These optogenetic studies revealed a specific role for prefrontal cortex (PFC) to NAc projections in increasing synaptic Rap1-AKT-mTOR activity, and we found that PFC terminal stimulation in the NAc increases behavioral reward through Rap1. Our recent work has identified specific proteins that are locally synthesized in NAc synaptosomal fractions through mTOR, and current studies are aimed at determining how these locally formed proteins regulate cocaine-mediated spine morphogenesis and behavioral reward. Title: Cocaine-induced enhancement of D1, and suppression of D2, medium spiny neuron activity in the nucleus accumbens is associated with cocaine seeking

Authors: *E. S. CALIPARI[1], R. C. BAGOT[2], I. PURUSHOTHAMAN[1], T. J. DAVIDSON[3], S. T. PIRPINIAS[1], K. GUISE[1], K. DEISSEROTH[4], E. J. NESTLER[1];

Abstract: Reward learning is robust and long-lasting, and cue/context presentation elicits seeking for the previously paired reward. This process is dysregulated in cocaine addiction, whereby potentiated cue/context-reward associations combined with an inability to extinguish previously learned drug associations are thought to drive relapse. Previous work has defined the role of dopaminergic neurotransmission in cue/contextual learning and outlined how these processes are altered in nucleus accumbens (NAc) following cocaine administration; however, dopamine has opposing actions at D1- versus D2-type medium spiny neurons (MSNs) in the NAc, making it critical to determine how cocaine produces lasting alterations to each of these neuronal subpopulations. Utilizing fiber photometry calcium imaging in freely moving animals, we dissected the cell-type specific mechanisms encoding cocaine reward as well as context-elicited cocaine seeking. We virally targeted the genetically encoded calcium indicator, GCaMP6f, in mice that express Cre-recombinase in D1 or D2 MSNs and recorded activity in NAc during acquisition, expression, and extinction of conditioned place preference. Subsequently, we determined how prior chronic exposure to cocaine altered these processes. Consistent with previous work, acute cocaine administration increased D1 MSN activity, while reducing D2 activity, suggesting that biasing towards D1 MSN output is a critical determinant in the ability to form context associations. Further, we found that D1 and D2 MSNs encode very different temporally specific information about associations. Enhanced D1 MSN activity immediately preceded entry into the drug-paired context, while D2 activity was suppressed only after entry into this context. Both D1 and D2 effects diminished across extinction of place preference. Chronic cocaine administration facilitated place preference and impaired extinction, effects which were positively correlated with D1 activity, suggesting that cocaine experience strengthens context/cue-reward associations via augmented D1 firing. Together, we demonstrate distinct temporal patterns of D1 and D2 MSN signaling in the NAc associated with cocaine reward learning, providing new insight into the circuit basis of drug-cue associations and drug

seeking. Supported by NIDA DA008227, the DARPA Neuro-FAST program, and the Gatsby Foundation

Title: Activation of estrogen receptors in the nucleus accumbens enhances the development of cocaine conditioned place preference in female mice

Authors: *R. SATTA, A. W. LASEK;
Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Clinical studies indicate that there are sex differences in behavioral responses to cocaine, with females being more sensitive than males. Findings from humans and animals suggest that estradiol might contribute to these differences. The aim of this study was to identify the specific estrogen receptor (ER) that modulates the rewarding properties of cocaine and to investigate the molecular mechanisms responsible for this effect. Ovariectomized female mice were treated with specific agonists to ERα or ERβ in the cocaine conditioned place preference (CPP) protocol. Mice underwent 6 conditioning sessions (3 with intraperitoneal injections of 5 mg/kg cocaine and 3 with saline). ER agonists were administered 1 hour before each conditioning session. We found that the ERβ agonist, diarylpropionitrile (DPN; 1 and 5mg/kg) significantly increased cocaine CPP compared to a vehicle-treated group. Activation of ERα by propylpyrazoletriol (PPT; 1mg/kg) also resulted in a slight increase in cocaine CPP, but this increase was not statistically significant. To complement these findings, we stereotaxically injected lentiviral vectors that express short hairpin RNAs (shRNAs) targeting ERα or ERβ in the nucleus accumbens of intact female mice. Mice injected with lentivirus expressing either ERα or ERβ shRNAs exhibited decreased cocaine CPP compared to mice injected with lentivirus expressing a control non-targeting shRNA. Together, our results suggest that activation of both ERα and ERβ might play a role in the enhancement of cocaine reward in females.

Title: A time and a region-specific role of astrocytic lactate in the formation and maintenance of positive affective memories associated with cocaine-associated cues

Authors: ***B. BOURY JAMOT**[1], A. CARRARD[2], J.-L. MARTIN[2], O. HALFON[4], P. J.MAGISTRETTI[5,6,3], B. BOUTREL[2,4];
[1]Ctr. (KAUST), Thuwal, Saudi Arabia; [6]Brain Mind Inst., Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

Abstract: Drug memories that associate contextual cues with the effects of drugs are known to shape persistent drug seeking behaviors. Since the transfer of glycogen-derived lactate from astrocytes to neurons is required for long-term memory (Suzuki et al., 2011), we explored the possibility that disrupting glycogenolysis in the basolateral amygdala (BLA) could impair the acquisition and maintenance of positive affective memories associated with cocaine-associated cues. We have observed that rats that received intra-BLA infusions of the inhibitor of glycogen phosphorylase, 1,4-dideoxy-1,4-imino-D-arabinitol (DAB 300 pmol/side) did not acquire a cocaine-induced conditioned place preference (CPP). Most importantly, a double DAB infusion (15 minutes prior and 5 hours after contextual re-exposure) in conditioned rats exhibiting a strong preference for the cocaine compartment abolished the cocaine attractiveness for up to two weeks. Finally, we demonstrated that drug memory was rescued by L-Lactate co-administration through a mechanism requiring the synaptic plasticity related transcription factor Zif268, and extracellular signal-regulated kinase (ERK) signalling pathway. We then targeted the prefrontal cortex (PFC) with a similar protocol, but rats continued to exhibit a strong preference for the cocaine compartment. However, recent evidence established that consolidation of drug reward memories depended on successive phases (Gholizadeh et al, 2013), with the BLA involved in the early phase and the PFC possibly involved in the late phase of memory consolidation. To

confirm this assumption in our model, rats were injected with DAB (480 pmol) into the PFC fifteen minutes and twelve hours after the contextual re-exposure. In contrast to rats injected with DAB 15 min/5h, those treated 15 min/12h exhibited a significantly reduced exploration of the cocaine compartment. Taken together, these results highlight a signaling role of astrocytic lactate in both acquisition and maintenance of cocaine-seeking behavior following a BLA - PFC temporal pathway.

Title: *In vivo* use of dopamine aptamers designed to cross the blood brain barrier in a preclinical mouse model of cocaine exposure

Deleted: *In vivo*

Authors: *K. VENTURA[1], M. HOLAHAN[1], E. MCCONNELL[2], M. DE ROSA[2];
[1]Neurosci., [2]Chem., Carleton Univ., Ottawa, ON, Canada

Abstract: Presently there are few effective treatments capable of reducing the reinforcing nature or craving associated with addictive drugs. It has been well established that cocaine acts by inhibiting the reuptake of dopamine (DA); ultimately, increasing the amount of DA in the synaptic cleft. This increase in DA concentration appears to be most important for the stimulating, reinforcing, and addictive properties of cocaine. Often times, cocaine self-administration is preceded by a craving response. Studies have suggested that craving is induced by DA accumulation following cocaine addiction. Craving is also believed to be a critical factor in contributing to relapse following abstinence. This supports the need to design novel treatments capable of reducing this craving response as a treatment program for addiction. To this end, we investigated the potential use of aptamers as a novel treatment option to quell the reinforcing nature of cocaine. Aptamers are short, single-stranded DNA, RNA, or peptide sequences that exhibit unique three-dimensional structures capable of binding to a specific molecular target. We synthesized an aptamer to cross the blood brain barrier designed to inhibit synaptic DA, thereby inhibiting post synaptic activation of DA receptors. First, we administered our aptamer

systemically in a chronic manner and found that repeated aptamer treatment did not induce any toxic effects. We then tested the efficacy of our aptamer in an acute model of cocaine exposure. Animals were pre-treated systemically with the aptamer at two different concentrations then given an intraperitoneal injection of either 1, 5, or 10 mg/kg of cocaine. Locomotor activity was measured for the 30 minutes immediately following the cocaine injections. Animals were then euthanized and tissue samples were collected. As was expected, we found that cocaine increased locomotor activity in a dose-dependent manner. Importantly we found that our aptamer was able to attenuate this drug-induced behaviour with no difference between the two aptamer concentrations. It is possible that no difference was observed at different aptamer concentrations due to potential aggregation of the aptamer within the liposome that may have limited the amount of the aptamer capable of crossing the blood brain barrier. To test this hypothesis we took tissue punches from multiple brain regions and peripheral organs and analysed via qPCR to quantify the amount of aptamer present in the tissue. In summary, our DA aptamers have been shown to cross the blood brain barrier and exhibit the ability to significantly decrease cocaine-induced hyperlocomotor activity.

Abstract: Glutamatergic neurons projecting from the prefrontal cortex to the ventral tegmental area (VTA) appear to activate VTA GABA neurons, thereby inhibiting dopamine release in the nucleus accumbens (NAc). Our previous studies have shown that acupuncture at Shenmen (HT7)

points reduced cocaine-primed reinstatement of cocaine-seeking behavior via activation of GABA neurons in the VTA. The present study was carried out to investigate the effects of HT7 acupuncture on prefronto-cortical modulation of VTA GABA neuron activity in acute cocaine-treated rats using electrophysiological methods and microdialysis. HT7 acupuncture inhibited decreases in glutamate and GABA release and GABA neuron firing rate in the VTA induced by a systemic cocaine challenge, which was reversed by GABA mixture microinjections into the infralimbic cortex, but not the prelimbic cortex. Acupuncture activated neurons in the infralimbic cortex and increased glutamate and GABA release and GABA neuron firing rate in the VTA. Similar to this result, activation of infralimbic projections by microinjection of PEPA, a positive allosteric modulator of AMPA receptors, enhanced glutamate and GABA release in the VTA. Our results suggest that glutamatergic neurons in the infralimbic cortex may mediate acupuncture's role in modulating VTA GABA neuron activities and suppressing the reinforcing effects of cocaine.

Title: Mediation of lateral habenula in acupuncture inhibition of cocaine-induced locomotor activity

Authors: *S. CHANG[1], D.-H. KIM[1], Y. RYU[2], Y. GWAK[1], Y. FAN[1], H. KIM[1], S. BANG[1], C. YANG[1], H. KIM[1];
[1]Daegu Haany Univ., Suseong-Gu Daegu, Korea, Republic of; [2]Korea Inst. of Oriental Med., Daejeon 305-811, South Korea, Korea, Republic of

Abstract: Our previous studies have shown that acupuncture at *Shenmen* (HT7) points suppresses addictive behaviors of abused drugs including cocaine, alcohol and morphine and the effects are mediated by A-fiber activation of ulnar nerve originating from superficial and deep tissue. It is known that lateral habenula (LHb), an epithalamic structure, is excited by peripheral sensory stimuli and its activation produces strong inhibition of midbrain dopamine neurons thereby leading to an inhibitory influence on positive reinforcement. To explore if lateral habenula mediates the inhibitory effects of acupuncture on addictive behaviors, we tested (1) the effects of acupuncture at HT7 on cocaine-induced locomotion after electrolytic lesions of LHb or its output tract, fasciculus retroflexus. (2) excitation of LHb neurons during acupuncture stimulation by using extracellular recordings and (3) c-Fos expression in VTA-projecting LHb neurons following acupuncture by immunohistochemistry and retrograde labeling of Fluorogold. Locomotor activity was measured using a video tracking system after an intraperitoneal injection of cocaine (15 mg/kg) in male Sprague-Dawley rats. Acupuncture was applied at bilateral HT7 points for 20 s using a mechanical acupuncture device immediately after systemic cocaine injection. HT7 acupuncture suppressed cocaine-induced locomotor activity, which was blocked by lesion of either Lateral habenula or fasciculus retroflexus. An increase in action potentials recorded from extracellular recordings and c-Fos expression in LHb was seen in HT7-treated rats. These results suggest mediation of lateral habenula in inhibitory effects of acupuncture on cocaine-induced locomotor activity.

Title: Molecular and behavioral contributions to cocaine action arising from SERT inhibition as studied in the SERT I172M mouse model

Authors: *L. D. SIMMLER[1], M. H. LEVIN[1], N. M. VASWANI[1], J. WANG[2], B. ZHANG[2,3], R. D. BLAKELY[1,4,3];
[1]Pharmacol., [2]Biomed. Informatics, [3]Silvio O. Conte Ctr. for Neurosci. Res., [4]Psychiatry, Vanderbilt Univ., Nashville, TN

Abstract: Cocaine abuse remains a world-wide health problem. The psychostimulant inhibits the dopamine- (DA), serotonin- (5-HT), and norepinephrine-reuptake transporters (DAT, SERT, and NET), inducing complex molecular and circuit level plasticities that remain an active area of investigation. We developed a mouse model with an I172M substitution in the SERT gene (Slc6a4) that significantly diminishes the sensitivity of the transporter to cocaine. In these mice cocaine (20 mg/kg) fails to elevate extracellular 5-HT *in vivo*. Here, we describe efforts to capitalize on the SERT M172 model to 1) identify specific brain regions with SERT-dependent activation after acute cocaine administration, 2) establish transcriptional networks linked to these areas of activation and 3) evaluate contributions of SERT antagonism to the behavioral actions of repeated cocaine injections. To determine brain regions where SERT antagonism may play a prominent role in cocaine action, we quantified c-Fos positive nuclei in male and female WT and SERT M172 mice after a single 20 mg/kg i.p. cocaine injection. In these studies, we found no genotype differences in c-Fos activation in the nucleus accumbens. In contrast, cocaine-induced increase in c-Fos staining was significantly higher in the prelimbic cortex (PrL) of SERT M172 mice compared to WT, suggesting the presence of a strong serotonergic suppression of neuronal activation in the PrL of WT animals. As with c-Fos studies, RNASeq-defined transcriptome profiles of the nucleus accumbens demonstrated few differences after cocaine injections comparing SERT M172 and WT animals. In contrast, in the PrL we found genotype-dependent activation of cell signaling networks, including those linked to DA and 5-HT pathways. Finally, with repeated cocaine administration (15 mg/kg, i.p.), we assessed the contributions of serotonergic signaling to locomotor sensitization and conditioned place preference (CPP). We found no genotype effects on baseline locomotor stimulation by cocaine, nor in the overall capacity for sensitization. However, when analyzed individually, we found a significant impact of the SERT M172 mutation on the sensitization ratio (challenge vs. first cocaine application) of male mice (WT, 1.8 ± 0.2 vs SERT M172, 5.3 ± 1.4; mean ± SEM, N=12-14), suggesting a male-specific role of 5-HT in attenuating cocaine-induced behavioral plasticity. In the CPP paradigm, both male and female WT and SERT M172 mice demonstrated equivalent preference for cocaine. Our ongoing studies with the SERT I172M model offer insights into possible 5-HT contributions to the adaptations that underlie stress-induced cocaine reinstatement.

Title: GIRK channels in VTA DA neurons regulate the sensitivity of the mesolimbic DA system to cocaine

Authors: *L. A. KOTECKI[1], N. M. MCCALL[2], N. C. VICTORIA[1], N. CARLBLOM[1], K. WICKMAN[1];
[1]Pharmacol., [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The ventral tegmental area (VTA) is a key anatomic substrate for reward, for both naturally reinforcing stimuli and drugs of abuse. The VTA is a heterogeneous nucleus consisting of dopamine (DA), GABA, and glutamate neurons. DA neurons are the most abundant neuron population in the VTA, and they mediate the increase in DA neurotransmission in the mesolimbic DA system triggered by *in vivo* exposure to drugs of abuse. As the loss of GIRK channel activity in projection targets of the VTA, such as the mPFC, are also known to show enhanced behavioral sensitization to cocaine, here we evaluated the impact of the loss of GIRK channels in VTA DA neurons on reward-related behaviors triggered by cocaine. Our preliminary data using a novel conditional mouse line where *Girk2* was ablated in DA neurons (DATCre:*Girk2*$^{flox/flox}$ mice) show that loss of GIRK2 blunts the $GABA_BR$-dependent inhibition of VTA DA neurons. In these studies we also show that GIRK2 ablation leads to loss of autoreceptor-dependent inhibition in VTA DA neurons. This correlates with enhanced locomotor responses to acute and repeated cocaine relative to control mice. Moreover, data from conditioned place preference and other reward-related assays in DATCre(+):*Girk2*$^{flox/flox}$ mice, along with regional and cell-type specific DREADD manipulations, suggest that GIRK channel activity in VTA DA neurons controls the sensitivity of the mesocorticolimbic system to cocaine.

Title: Ablation of the patch compartment reduces cocaine-induced stereotypy

Authors: *K. A. HORNER, M. LOGAN, R. C. MURRAY;
Div. Basic Med. Sci., Mercer Univ. Sch. Med., Macon, GA

Abstract: Repeated exposure to cocaine (COC) induces stereotypy, which is characterized as inflexible, repetitive behavior. Enhanced relative activation of the patch compartment of the striatum has been shown to positively correlate with the emergence of stereotypy following repeated COC treatment, suggesting that stereotypy may be related to preferential activation of this region. However, the specific contribution of the patch compartment to COC-induced stereotypy following repeated exposure is unknown. To elucidate the involvement of the patch compartment to the development of stereotypy in response to repeated COC exposure, we determined if destruction of this sub-region altered COC-induced behaviors. Animals were bilaterally infused in the striatum with the neurotoxin dermorphin-saporin (DERM-SAP; 17 ng/μl) to ablate the neurons of the patch compartment and allowed to recover for eight days. The animals were given daily injections of COC (25 mg/kg) or saline for one week, followed by a weeklong drug-free period. Animals were then given a challenge dose of COC, placed in activity chambers, observed for 2h and sacrificed. DERM-SAP pretreatment reduced the number of mu-labeled patches in the striatum. DERM-SAP pretreatment significantly reduced the intensity and spatial immobility of COC-induced stereotypy. In support of this observation, increased locomotor activity was seen in DERM-SAP pretreated, COC-treated animals. DERM-SAP pretreatment attenuated COC-induced c-Fos expression in the patch compartment, while enhancing COC-induced c-Fos expression in the matrix compartment. These data indicate that the patch compartment is necessary for repetitive behavior and suggests that alterations in activity in the patch vs matrix compartments may contribute to this phenomenon.

Title: Contribution of stress to the effects of a 5-HT1B receptor agonist on cocaine-induced locomotion before and after abstinence from repeated injections in C57BL/6 mice

Authors: *T. DER-GHAZARIAN[1], K. DAI[2], S. BRUNWASSER[2], R. GARCIA[2], K. STEFANKO[2], N. PENTKOWSKI[2], J. NEISEWANDER[2];
[1]Sch. of Life Sci., [2]Arizona State Univ., Tempe, AZ

Abstract: We previously showed that 5-HT1B receptors (5-HT1BRs) modulate cocaine abuse-related behavior in opposite directions depending on the addiction cycle phase (i.e., maintenance vs. abstinence) in rats. Recently we showed that C57BL/6 mice treated daily with either saline (1 mL/kg, IP) or cocaine (15 mg/kg, IP) for 21 days exhibited different responses to test day pretreatment with the 5-HT1BR agonist CP94253 (CP) depending on whether the agonist was given on the last day of the chronic treatment or 21 days later. Specifically, CP increased locomotion on the last chronic treatment day but decreased locomotion when given 21 days later, and surprisingly this effect occurred regardless of whether the mice had received chronic cocaine or chronic saline. In this study we assessed whether the flip in the agonist effect on locomotion in chronic saline-treated mice was due to injection stress and/or housing with chronic cocaine-treated mice. Drug-naïve mice arrived at the same age as mice from our previous study. One group received NO INJECTIONS and were handled twice per week during which their tails were colored for identification. Another group was treated similarly except that they received daily repeated SALINE INJECTIONS at the same time of day for 21 days similar to our previous study. On the last day of treatment, after a 1-h habituation period in test chambers, mice in both groups received either vehicle (1 mL/kg, IP) or CP (10 mg/kg, IP) and were returned to their home cage for 30 min. Next, mice were injected with saline or cocaine (5 mg/kg, IP) and placed immediately into test chambers for 1 h. The same test session was repeated after a 21-day period during which mice were handled twice per week to remark tails. Our results show that drug-naïve, No Injection mice, showed no change in locomotion in response to CP on either test day. However, chronic Saline Injection mice still exhibited a mild decrease in locomotion when pretreated with CP after a 21-day abstinence period. Literature suggests that chronic injections are a stressor in mice. We postulate that the decrease in locomotion in response to CP 21 days after ending chronic Saline Injections (present study) or chronic cocaine injections (previous

study) likely involves the same mechanisms as reflected by cross sensitization between chronic injection stress and cocaine. The CP-induced attenuation effects of chronic saline stress and chronic cocaine suggests that 5-HT1BR agonists may have therapeutic potential for treating cocaine dependence.

Title: Ambient GABA release is detrimental to neurons in the deafferented cochlear nucleus

Authors: ***B. J. CARROLL**, R. L. HYSON;
Florida State Univ., Tallahassee, FL

Abstract: To better understand the effects of deafness, this project examines how hearing loss disrupts the balance between excitatory and inhibitory inputs to permanently alter the auditory system. In the avian primary auditory nucleus, nucleus magnocellularis (NM), afferent deprivation resulting from deafness triggers neuronal death. While previous experiments assumed this death is due to the absence of excitatory input from the auditory nerve, we examined whether inhibitory feedback from the superior olivary nucleus might also be involved. Using an *in vitro* preparation, we pharmacologically altered activity at GABA receptors in NM, and assayed the treated neurons for a marker of neuronal health, antigenicity for the ribosomal antibody Y10B (Y10B-ir). Periodic application of exogenous GABA reduced Y10B-ir on the treated side of the brain slice, compared to untreated neurons on the opposite side of the same tissue section. This effect was blocked in the presence of GABA-A antagonist picrotoxin, and mimicked by periodic application of the GABA-A agonist muscimol. Additionally, whole cell voltage clamp recordings demonstrated that currents through GABA-A receptors dominate activity in deafferented NM neurons. To determine whether this ambient GABA-A activation also modulates Y10B-ir, we periodically applied the GABA-A antagonist gabazine which increased Y10B-ir on the treated side of the brain slice, compared to untreated neurons on the opposite side of the same tissue section. Our results suggest that, in the absence of excitatory input, ambient inhibition via ionotropic GABA receptors is detrimental to NM neurons. This finding implicates dysregulated superior olivary nucleus activity in deafness-induced plasticity.

Title: The ventral cochlear nucleus in humans

Authors: ***J. S. BAIZER**[1], S. WITELSON[2], K. WONG[1];
[1]Physiol. & Biophysics, Univ. at Buffalo, Buffalo, NY; [2]Psychiatry & Behavioural Neurosciences, McMaster Univ., Hamilton, ON, Canada

Abstract: Auditory information is carried from the cochlea to the brainstem via the eighth cranial nerve. Afferent fibers synapse in the dorsal (DCN) and ventral (VCN) cochlear nuclei (CN). In several species, the VCN is subdivided into the anterior (VCA) and posterior (VCP) nuclei. Several classes of neurons distinguished by anatomical and electrophysiological criteria have been described in different CN subdivisions. We have recently shown, in agreement with several older studies, that both the laminar and cellular organization of the DCN in the human is unique compared to that of other mammals. By contrast, the classic studies on human VCN, using Nissl and Golgi stains, suggest that the VCN in human is relatively similar to that in other mammals, although the division into VCA and VCP has been questioned. We have examined the organization of the human VCN using the cases from the Witelson Normal Brain Collection in which we previously studied the DCN. We used Nissl staining and immunohistochemistry with antibodies to several markers to see if the subdivisions and distinct cell populations described in animals could be distinguished in humans. In agreement with earlier studies we found individual variability in the configuration of the different components of the cochlear nuclei and major differences among humans, cats and rodents. We also found that immunoreactivity to three markers, nonphosphorylated neurofilament protein (NPNFP), the calcium-binding protein calretinin (CR) and a synthetic enzyme for nitric oxide, nitric oxide synthase (nNOS) labeled cells in the VCN. Both CR-ir and NPNFP-ir were seen in caudal VCN in neurons with round or oval somata. These may correspond to the octopus cells of the VCP described in other species. More rostrally, CR-ir, NPNFP-ir and nNOS-ir was seen in neurons with round somata; these neurons were embedded in a meshwork of stained processes, probably dendrites, running in all directions. These neurons may correspond to the bushy cells of the VCA. The results suggest that

the human VCN does include two subdivisions and that at least two major neuron types described in VCN of other animals are present in the human VCN.

Title: Quantification of auditory and non-auditory input to the dorsal cochlear nucleus

Authors: ***C. NEAL**[1], H. STAECKER[2], D. DURHAM[2];
[2]Otolaryngology, [1]Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Increasing evidence implicates the dorsal cochlear nucleus (DCN) in the induction of chronic tinnitus, which is the perception of sound with no corresponding external stimulus. Fusiform cells within the DCN integrate auditory and non-auditory input via a cerebellar-like circuit. Acoustic trauma results in reduced output from the cochlea to the dorsal cochlear nucleus due to damage and loss of the sensory hair cells (HC). This damage initiates neuroplastic changes within the DCN, which redistributes auditory and non-auditory inputs to the fusiform cell circuit. Differential distribution of the vesicular glutamate transporters 1 and 2 (VGut1/2) in the DCN allows for visualization of the auditory (VGlut1) and non-auditory input (VGlut2), respectively. We have previously quantified HC loss resulting from exposure to two 16 kHz sound damage paradigms (114 dB, 1 hour and 118 dB, 4 hour) in our rat model of tinnitus. The current study aims to quantify the distribution of auditory and non-auditory input in the DCN in control animals prior to evaluation in sound damaged animals. Rats were perfused using 4% paraformaldehyde and brains were harvested, embedded in 10% gelatin, and sectioned (40 um) on a vibratome. Sections were then processed for fluorescent immunohistochemistry using antisera to VGlut1 and VGlut2 and imaged at 20X using confocal microscopy. The Otsu method of automated local thresholding was applied. The area of our regions of interest was determined, and puncta number was calculated, using automated counting in ImageJ. Puncta density can be

plotted as a function of DCN layer (granule, fusiform, and deep) and/or frequency region (high, mid, and low). Initial quantification of puncta density in control animals suggests auditory input (VGlut1) is evenly distributed across the deep and fusiform cell layers of the DCN. The density of non-auditory input (VGlut2) across the fusiform cell and granule cell layers is greater than that of VGlut1. Additionally, these data show VGlut2 density peaking in the mid-frequency region, with reduced density in the low and high frequency regions.

Title: Postnatal refinement of conduction velocity of inputs to the medial nucleus of the trapezoid body is accompanied by changes in intrinsic cell characteristics

Authors: *J. L. SINCLAIR;
Div. of Neurobio., Ludwig Maximilians Univ. Munich, Munich, Germany

Abstract: The trapezoid body (TB) is a myelinated commissural pathway projecting from the ventral cochlear nuclei on one side of the brainstem to the superior olivary nuclei on the other. TB axons may be large (approx. 3µm diameter), with each fiber giving rise to a single giant calyx of Held synapse. In myelinated axons fiber diameter positively correlates to an increase in conduction velocity. However, conduction velocity also depends on neuron-glia interactions which are developmentally and activity-dependently regulated. Postsynaptic to the calyx of Held are the principal cells of the medial nucleus of the trapezoid body (MNTB) which are well known for their fast and temporally precise firing behavior, facilitated by a distinct set of voltage and ligand gated ion channels. Here we ask whether conduction velocity in the afferent fibers and intrinsic properties in MNTB neurons are co-regulated during development and whether there are species specific differences between mouse and gerbil in the maturation of this pathway. Both species are invaluable animal models for auditory neurophysiology because of the genetic tools available for mice and because of the overlapping range of low-frequency hearing between gerbils and humans. We performed *in vitro* patch-clamp recordings of the MNTB in mouse and gerbil. Examination of passive cell characteristics in mouse showed a decrease in

Deleted: in vitro

MNTB principal cell capacitance between P9 and P27 (P9: 35.9±6.8pF, n=16, P27: 30.0±7.7pF, n=29, p = 0.01, paired t test). The capacitance of MNTB neurons in mouse and gerbil was similar at P21 (m: 32.3±7.0pF, n=24, g: 30.4±14.7pF, n=30) and P27 (g: 31.9±20.1pF, n=19). Future analyses will characterize development of tonotopic gradients of pre- and post-synaptic specializations in these models. The conduction velocity of single TB fibers was measured far from the calyx of Held by whole-cell patch clamp recording from MNTB neurons while electrically stimulating the trapezoid body fibers in two locations. One stimulating electrode was placed near the midline and the other one further on the contralateral side. The distance between the two stimulating electrodes was divided by the difference in the latency of the postsynaptic responses evoked when stimulating with the different electrodes, in order to estimate a mean axonal conduction speed. Preliminary data suggest that conduction velocity increases post hearing onset in the mouse (P9: 3.9 ± 1.4m/s (n=8) P16: 6.1 ± 2.1 m/s (n=4), P27: 7.5 ± 6.3 m/s (n=3). In the gerbil, conduction speed is similar to mouse at P16 (P16: 6.1 ± 2.1m/s (n=7). Future experiments will examine earlier and later time points in both species.

Abstract: The calyx of Held nerve terminal, located in the auditory brainstem, is a powerful model system for studying neurotransmission and the development of neural circuitry. However, little is known about the ultrastructure of the calyx following the onset of hearing (P10-12). In order to understand the function of the calyx of Held, the detailed organization of synaptic machinery must be thoroughly characterized. To this end, we have employed serial block-face scanning electron microscopy (SBEM), three-dimensional reconstruction, and nanoscale identification of synaptic structures to produce the first complete reconstruction of a P30 mouse calyx of Held (CH) and its associated postsynaptic partner, the principal cell of the medial nucleus of the trapezoid body (MNTB). The MNTB cell was ovoid in shape, and measured approximately 24.96 µm in diameter, with a total surface area of 2011 μm^2. The apposition of the CH to this cell covered 430 µm, or 21.4% of the total somatic surface. This terminal contained 286 identified synapses, resulting in a synaptic density of 0.65 synapses/μm^2. The calyx had a maximum thickness of 4.6 µm. We also investigated morphological features of the calyceal axon. The axonal diameter was 1.97 µm and, interestingly, the myelinated axon transitioned nearly seamlessly into the calyceal body without a discernable heminode. In addition, a myelinated collateral branch extending from the calyx body was identified, and this collateral created a medium-sized terminal (27 μm^2) with 17 synapses (synaptic density of 0.62 synapses/μm^2) on the dendrite of a neighboring cell. These parameters were then applied to a biophysical model in the NEURON software to simulate the physiological characteristics of the mature calyx. Taken together, these findings provide a comprehensive morphological description of an adult mouse calyx, which can be used as a comparative endpoint for developmental studies and to explore functional elements of synaptic transmission.

Title: Source of monoaminergic and CART-ergic afferents to the elementary circuitry of the acoustic startle reflex

Authors: ***A. V. DA SILVA**[1,2], K. R. TORRES DA SILVA[1], N. O. BARIONI[1], S. A. RODRIGUES[1,3], C. R. PADOVANI[1], R. S. BEDUSCHI[1], M. S. FERREIRA[1], R. GOMEZ-NIETO[4,5], D. E. LÓPEZ[4,5], J. A. C. HORTA-JUNIOR[1];

Inst. of Castilla y León, Salamanca, Spain; [5]Inst. de Investigación Biomédica de Salamanca (IBSAL), Salamanca, Spain

Abstract: The acoustic startle reflex (ASR) is a rapid motor reaction elicited by a sudden intense acoustic stimulus. This is an acoustic-motor reflex of the brainstem conserved across mammal's species including man. Moreover the ASR is a defensive behavior against possible aggressive circumstances and act as an alert to unexpected events. The ASR evokes skeletal muscles responses as well as of autonomic nervous system with blood pressure increase and heart rate acceleration. In the rat, the elementary neural circuitry of ASR is mediated by organ of Corti ganglion cells, the cochlear root neurons (CRN), the pontine caudal reticular nucleus (PnC) and motoneurons of the spinal cord. The ASR can be modulated by habituation, sensitization, prepulse inhibition (PPI), and fear potentiation. These modulations are mediated by the influence of neuroactive substances upon the components of the neuronal circuitry of ASR. In this work we evaluated the origin of monoaminergic (serotonin and noradrenaline) and CART-ergic afferents to CRN and PnC and behavior test (startle and PPI) after neuronal lesion in this possible afferents. Adult Female Wistar rats (n=54) were submitted to injections of neuronal tracers (retrograde and anterograde), neurotoxic and identification of neuroactive substances in brain by immunohistochemistry techniques. All experimental protocols were made according to the Ethics Committee on Animal Use (protocol: 17/08). Our results demonstrated that noradrenergic area A5 (A5) is a source of noradrenergic and CART-ergic afferents to CRN and PnC, and the dorsal raphe nucleus (DR) is an origin of serotoninergic afferents to these regions. There are reciprocal connections between DR, A5 and PnC. Furthermore, after 14 and 21 days of lesion in A5, the percentage of PPI increased within the intervals of 100 and 150 milliseconds without modification of ASR. This data suggest that A5 have a direct action on the ASR elementary circuit evidenced by its connections and modulations of PPI. Moreover, A5 and DR connections bring new insights about modulation of ASR and PPI by noradrenaline, serotonin and CART.

Title: Long-term potentiation of glycinergic inhibition in the medial superior olive of Mongolian gerbils

Authors: B. D. WINTERS[1], *N. L. GOLDING[2];
[1]Neurosci., [2]Dept. of Neurosci., Univ. of Texas at Austin, Austin, TX

Abstract: Principal neurons of the medial superior olive (MSO) in the brainstem of mammals are a key component in the processing of binaural cues used for sound localization. They detect extremely minute timing differences between the arrivals of sounds at the 2 ears by acting as coincidence detectors. Glycinergic inhibitory inputs onto MSO neurons are coordinated in time with binaural excitation and are critical for shaping their responses. This inhibitory drive is dramatically refined after hearing onset; supernumerary inhibitory inputs are pruned and those that remain are well timed with binaural excitation and concentrated onto the soma. Despite the relevance of inhibition to the function of this important circuit, little is known about the cellular mechanisms that guide these experience-dependent refinements. To mimic coincident inhibitory input activation and suprathreshold binaural excitation in acute brain slices from Mongolian gerbils in the first week of hearing (P12-15) we combined short current injections that elicited action potentials (APs) and electrical stimulation of MSO afferents. Driving both at a physiologically relevant frequency of 200 Hz induced a robust long-term potentiation of inhibitory potentials (iLTP, 54 ±5% of baseline [BL] at 24-34 min. post induction) isolated by blocking α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors with NBQX or CNQX (15 μM). Neither the coefficient of variance (0.307 BL, 0.276 end) nor the paired pulse ratio (0.996 BL, 1.038 end) of the responses were altered by iLTP suggesting a postsynaptic mechanism. The use-dependent N-methyl D-aspartate receptor (NMDAR) antagonist MK-801 (30 μM) added to the bath blocked induction of iLTP (14 ±2% of BL) indicating that calcium influx through NMDARs is a critical mechanism underlying iLTP. Neither APs nor electrical

stimulation alone (-9 ±4% and 6 ±3% of BL respectively) were sufficient to induce iLTP. NMDAR-dependent synaptic plasticity that increases synaptic strength is well correlated with morphological changes and maintenance of connections. After hearing onset in the MSO, intracellular chloride has shifted such that inhibitory synapses no longer provide their own depolarization, yet the need for experience-dependent synaptic plasticity remains. Our data suggest a synaptic plasticity model for inhibition in MSO neurons in which glutamate, either co-released with glycine from inhibitory terminals or through spillover from adjacent excitatory inputs, binds to NMDARs and coincident AP firing relieves the Mg^{2+} block, triggering calcium influx and changes in inhibitory synaptic efficacy.

Title: Altered synaptic balance and impaired sound processing in auditory brainstem neurons of the fragile x mouse model

Authors: E. GARCIA-PINO[1], N. GESSELE[2], *U. KOCH[1];
[1]Biologie, Chemie Pharmazie, [2]FU Berlin, Berlin, Germany

Abstract: Individuals with fragile X syndrome (FXS) experience a myriad of symptoms including intellectual disability, language impairments and behavioural irregularities. Sensory processing abnormalities such as auditory hyperreactivity play a causal role in the progress of these symptoms. The auditory hyperreactivity can be studied in the mouse model of FXS (Fmr1 KO). These mice show abnormal acoustic startle response and increased audiogenic seizure susceptibility. However, the physiological mechanisms underlying this elevated sensitivity to acoustic stimuli in FXS remains poorly understood. Even less is known how the auditory pathophysiology progresses during development. Here, we addressed these questions by investigating the functional development of a primary sound localization circuit in the brain, the lateral superior olive (LSO), in the Fmr1 KO mice. To this end, whole-cell recordings from LSO neurons were performed on acute brainstem slices at various developmental stages. The stimulation of inputs from the ipsilateral cochlear nucleus revealed a drastic increase of

excitatory synaptic strength of Fmr1 KO mice at the end of the third postnatal week, which was partially due to an increment of inputs converging onto one single LSO neuron. At the same time, release probability determined by high frequency stimulation remained unchanged. Furthermore, the spontaneous excitatory postsynaptic events were elevated in frequency while the amplitude and time constants remained unaffected. In contrast, inhibitory synaptic inputs from the medial nucleus of the trapezoid body were unchanged. At the end of the third postnatal week, LSO neurons of Fmr1 KO mice also showed larger input resistance and longer action potential duration. Next, we investigated whether these changes in synaptic and membrane properties, indicating enhanced excitability of this circuit, affected the auditory processing abilities of LSO neurons. To address this, single-unit *in vivo* recordings were performed on anaesthetized adult animals. Ipsilateral stimulation with pure-tones of different frequencies revealed a significant broadening of frequency tuning in LSO neurons. Bilateral stimulation at various interaural level differences (ILDs) resulted in a shift of the ILD-function, consistent with the increased excitatory synaptic drive. Altogether, our data demonstrate that the enhancement of excitatory synaptic inputs in the LSO contributes to altered balance of excitation and inhibition in the auditory brainstem, and might play a fundamental role in the auditory hyperreactivity observed in FXS.

Title: Glycinergic circuitry in the Inferior Colliculus

Authors: ***A. B. LOPEZ**, S. RODRIGUEZ, S. LAVANIA, M. MIRANDA;
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: The inferior colliculus (IC) is considered a relay center for the integration of ascending information from various lower level auditory nuclei. Therefore a fine balance between excitation and inhibition is vital for auditory processing and perception. Unlike

glutamatergic, cholinergic and GABAergic inputs to the IC which are well described, the cytoarchtecture of glycinergic fibers still remains to be fully elucidated. Glycinergic neurons are defined by expression of glycine transporters 1 and/or 2, encoded by two different genes. In this study, we have used a transgenic mouse line expressing GFP under control of the GlyT2 promoter (kindly provided by Dr. H.U. Zeilhofer, University of Zurich) to trace specific glycinergic circuits within the IC. We carried out neuronal tracing with the retrograde tracer FlouroGold delivered in the colliculus combined with immunohistochemistry . Preliminary results identify cell bodies of glycinergic neurons in several areas of the brain stem, particularly the pons and midbrain. A detailed characterization of glycinergic inputs to the IC should expand our knowledge about the auditory inhibitory circuitry.

Title: Nitrergic signaling in the inferior colliculus

Authors: *A. W. STAFFORD[1], A. HARTMAN[2], J. HALL[2];
[1]Biochem. and cellular and molecular biology, [2]Univ. of Tennessee, Knoxville, TN

Abstract: Nitric Oxide (NO) is a gaseous molecule that functions as a retrograde messenger subserving long-term potentiation in the hippocampus where it plays a significant role in learning and memory. Activation of glutamate N-methyl-D-aspartate (NMDA) receptors stimulates NO production via the activity of nitric oxide synthase (NOS). NO is released and subsequently enhances the presynaptic release of glutamate. Staining for β nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) as well as immunohistochemical studies have revealed the presence of NOS-labeled neurons in a number of vertebrate brain structures including the inferior colliculus (IC), an important auditory processing center. These neurons presumably produce and release NO. However, the function of NO in auditory processing at the level of the IC is not known. Here we address this issue using NADPH-d histochemistry, NO microsensors, and single-unit recording combined with microiontophoresis to investigate the role of NO in the analysis of acoustic signals by neurons in the IC of the northern leopard frog, *Rana pipiens pipiens*. Five morphologically distinct classes of NOS-labeled neurons (multipolar, bipolar-fusiform, bipolar-round, triangular and piriform) were identified in the three subdivisions

of the frog's IC (n=8) known to be involved in auditory processing; namely, the laminar, principal and magnocellular nuclei. Utilizing a slice preparation of the frog's IC (n=4), bath application of glutamate (10-100 mM) elicited a concentration-dependent release of NO (69.4-273.1 nM). The increase in NO generation induced by glutamate was blocked by the glutamate receptor antagonist, AP5 (200 uM). *In vivo* iontophoretic application of L-NAME (a NOS inhibitor) was used to evaluate the effect of NO on the sound-evoked responses of neurons (n=18) in the IC. Responses to tone bursts were either phasic (n=8) or tonic (n=10). No change in discharge pattern, best frequency, threshold, or tuning curve of either phasic or tonic units was seen during L-NAME application. In contrast, tonic, but not phasic, units always showed a decrease in stimulus-evoked firing rate during L-NAME application. For 3 tonic units tested, an NMDA-induced increase in sound-evoked discharge rate was antagonized by the co-application of L-NAME. Our data suggest a role for NO in gain control in the IC that may influence the output of neural circuits engaged in the analysis of behaviorally relevant acoustic signals, such as speech.

Title: Differences in GABAergic cell types distinguish the rostral pole of the inferior colliculus and the medial and lateral intercollicular areas

Authors: ***N. L. FOSTER**[1,2], W. A. NOFTZ[1,2], B. R. SCHOFIELD[1,2];
[1]Anat. and Neurobio., Northeast Ohio Med. Univ., Rootstown, OH; [2]Kent State Univ., Kent, OH

Abstract: The inferior colliculus (IC) is classically divided into a central nucleus (ICc) and dorsal (ICd) and lateral (IClc) cortices. Morest and Oliver (1984, J Comp Neurol, 222:209) identified several more structures in the rostral IC. The rostral pole (ICrp) is distinguishable from ICc due to its non-laminar structure and distinct cell types. Intercollicular tegmentum surrounds the ICrp and can be further subdivided based on cell types. We examined the ICrp and the

intercollicular tegmentum medial or lateral to the ICrp (MI and LI, respectively) to see if these areas are distinguishable in guinea pigs. We assessed soma size as well as staining for glutamic acid decarboxylase (GAD, a marker of GABAergic cells), perineuronal nets (PNs), and dense axosomatic input from vesicular glutamate transporter 2 (VGLUT2) immunopositive terminals. We have shown previously that these markers distinguish the ICc, ICd, and IClc in guinea pig IC. Do they also differentiate the ICrp, MI, and LI? Transverse sections from 4 adult guinea pigs were stained for PNs using Wisteria floribunda agglutinin (WFA) labeled with a fluorescent tag. Tissue was also immunostained for GAD, VGLUT2, and neuronal nuclear protein (NeuN). Each marker was tagged with a different fluorophore to yield quadruple staining. With a Neurolucida system, NeuN staining was used to outline each soma in the top 4 µm of a section. Outlines were then coded based on expression of GAD and the presence of a PN or a perisomatic ring of VGLUT2 positive terminals (VGLUT2 ring). Mean soma profile area was largest in LI (158 µm2), followed by ICrp (138 µm2) and MI (125 µm2). ICrp and LI had similar proportions of GAD-immunopositive (GAD+) cells (29% and 27%, respectively) whereas MI had a lower proportion (14%). In each area mean soma size of GAD cells was larger than that of non-GAD cells. As in the three main IC subdivisions, four GAD cell types were distinguishable: GAD-only (lacking a PN and VGLUT2 ring), GAD-PN (surrounded by a PN but lacking a VGLUT2 ring), GAD-VGLUT2 ring (having a ring but lacking a PN), and GAD-PN-VGLUT2 ring (having both PN and ring). The 3 regions differed in their proportions of the four GAD cell types. LI contained the highest proportion of both GAD-PN and GAD-PN-VGLUT2 ring cells (16% and 28% of all GAD+ cells, respectively). MI contained the highest proportion of GAD-only cells (74% of all GAD+ cells). These results support a continued distinction between ICrp and the three main IC subdivisions, as well as between ICrp, MI, and LI. PNs and VGLUT2 rings have been emphasized in the ICc; the present results suggest that these structures also play a role in more rostral IC subdivisions.

Title: Neural circuit reorganization in the auditory midbrain of mice with behavioral evidence of tinnitus

Authors: ***J. J. STURM**[1], H. ROOS[1], T. NGUYEN[2], K. KANDLER[1];
[1]Otolaryngology, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [2]The Col. of New Jersey, Ewing, NJ

Abstract: Hearing loss leads to a myriad of cellular and synaptic changes in the central auditory system, some of which are thought to lead to the perception of phantom sounds (tinnitus). However, the synaptic circuit mechanisms contributing to tinnitus have remained poorly understood. To identify hearing-loss-induced reorganizations of synaptic circuits that correlate with tinnitus, we applied laser-scanning photostimulation (LSPS) with caged glutamate to map the organization and strength of intrinsic excitatory and inhibitory synaptic inputs onto glutamatergic and GABAergic neurons in the inferior colliculus (IC) of noise-traumatized mice. Tinnitus behavior was quantified using the acoustic startle gap detection method. One week after noise-exposure, about 50% of noise-exposed mice (19/37 animals) showed behavioral evidence of tinnitus, as evidenced by significant reductions in gap-mediated inhibition of the acoustic startle reflex. All noise-traumatized mice had similar hearing loss and exhibited substantial reorganization in IC circuits. Interestingly, however, only mice with tinnitus showed a profound shift in the balance of synaptic excitation and inhibition in both glutamatergic and GABAergic neurons. Our findings suggest that in the IC, noise trauma leads to a complex yet cell-type specific reorganization of excitatory and inhibitory local circuits, the nature of which correlates with the presence or absence of behavioral evidence of tinnitus.

Title: Projections from the auditory midbrain to the superior colliculus and the thalamus have separate origins

Authors: *J. G. MELLOTT, B. R. SCHOFIELD;
Anat. and Neurobio., NEOMED, Rootstown, OH

Abstract: The auditory midbrain, including the inferior colliculus (IC) and the nucleus of the brachium of the IC (NBIC), are critical contributors to the analysis of sound location. Spatial information is transmitted from the IC and NBIC to both the medial geniculate body (MG) of the thalamus and the superior colliculus (SC). The MG projects to auditory cortex and thus contributes to many aspects of auditory perception. The SC is tied to orienting movements, and may contribute as well to attention. An unanswered question is whether the spatial information sent to these targets from the IC and the NBIC arises from different populations of cells or arises (in whole or in part) as branching axonal projections from a single population of cells. Separate origins would allow for different information to be sent to each target (or for that information to be modulated independently). In contrast, branching axonal projections (i.e., collaterals) would suggest similar information is transmitted and modulation would likely affect both targets. We used double labeling with the fluorescent retrograde tracers to identify individual cells in the IC or the NBIC that send branching axonal projections to both the SC and MG in adult pigmented guinea pigs. We injected one tracer (red RetroBeads [RB] or FluoroGold; [FG]) into one MG and injected the other tracer into the homolateral SC in the same animal. Both targets received large deposits of tracer in order to maximize the number of labeled cells. After 5-7 days for axonal transport, we analyzed single and double labeled cells in the IC and NBIC ipsilateral to the injections. Injections into the MG covered much of the nucleus and labeled many cells in the IC and the NBIC. Injections into the SC labeled large populations of cells in the NBIC, the rostral pole of the IC (ICrp) and the lateral cortex of the IC (IClc). Despite the overlapping distributions in the NBIC, the ICrp and the IClc, few cells were double labeled. Preliminary quantitative analysis suggests double labeled cells (in ICrp, IClc and NBIC, combined) constituted 1.6% of the 5,361 MG-projecting cells and 5.2% of the 1,614 SC-projecting cells. We conclude that the spatial (or other) information transmitted to the SC or to the MG arise from separate populations of cells in the IC and NBIC. The existence of separate origins would allow the auditory midbrain to send different information to the MG and the SC, and also allow for these two pathways to be modulated independently (even if similar information is transmitted).

Title: Neurons projecting from the mouse lateral cortex of the inferior colliculus to the auditory thalamus are organized into distinct clusters correlating with glutamic acid decarboxylase-positive modules

Authors: *A. M. LESICKO, D. A. LLANO;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: While the inferior colliculus is classically viewed as an integration center for ascending auditory information, its lateral cortex likely performs a distinct function, as evidenced by its multimodal connectivity. In addition to auditory inputs, the lateral cortex receives information from a number of somatosensory and visual structures. Its major targets include the superior colliculus, paralaminar thalamic nuclei, and the central nucleus of the inferior colliculus. Previous retrograde and anterograde tract-tracing studies have indicated that both the input terminals and output cell bodies of the lateral cortex are distributed in discontinuous clusters. These clusters strongly resemble the patch-like neurochemical modules that have previously been described in the lateral cortex of the rat. In the present study, we sought to determine if the input and output clusters in the lateral cortex are spatially related to the underlying neurochemical modules in the mouse inferior colliculus. To label the outputs of the lateral cortex, injections of the retrograde tracer Fluorogold were placed into the paralaminar thalamic nuclei. Following a week survival period, animals were sacrificed and brains were processed for glutamic acid decarboxylase-67 immunohistochemistry. The cell bodies that project to the paralaminar thalamic nuclei were found to cluster within these GAD-positive modular zones. Combined with our previous data, these results reveal that the output cell bodies that project from the inferior colliculus to the paralaminar thalamic nuclei are coupled with the somatosensory input modules. The present study indicates that the lateral cortex exhibits connectional as well as neurochemical modularity, and that these two levels of organization are correlated.

Sch., Boston, MA

Abstract: Neurons in layers 5 and 6b of the auditory cortex (A1) form a massive projection system, innervating all levels of the central auditory pathway in addition to brain areas outside the classic central pathway, such as the striatum and amygdala. Little is known about how descending projections modify the representation of auditory signals in subcortical brain areas in real time. We directed our focus to the inferior colliculus (IC), an auditory midbrain structure that receives a large number of layer 5/6b cortical projections, and asked how activation of these projections might affect the ongoing processing of sound. To address this, we used an optogenetic approach to activate the corticocollicular pathway while recording unit activity from the IC of head-fixed awake mice. We interleaved trials in which a 250 ms broadband noise burst was either presented alone or in combination with photoactivation of A1 neurons expressing 'Chronos', an ultra-fast channelrhodopsin. Activating A1 with a pulse of light matched in duration to the sound had only weak effects on IC unit activity, with less than 20% of IC recording sites being significantly enhanced by cortical stimulation, and an average increase in sound-evoked firing of only 6%. To identify more effective modes of cortical stimulation, we used a real time closed loop spike feedback optimization algorithm (Chambers et al., 2014) that modified the voltage command signal to the laser in search of activation patterns that could either enhance or suppress sound-evoked activity in the IC. When the algorithm was tasked with finding a stimulation pattern to maximally enhance IC firing, the number of responsive sites more than doubled and the mean sound-evoked firing was increased by 42%. The algorithm was also able to learn to maximally suppress IC firing (rather than enhance) in a specific sub-region of the central nucleus, suggesting that the net effect of cortical output in this midbrain region is bi directional, producing either gain or attenuation depending on the temporal patterning of A1 stimulation. Having identified that corticocollicular activation patterns can lead to bi-directional modulation of IC firing rates, an important question becomes whether or not these enhancing or suppressive firing patterns arise naturally during purposeful behavior. To this end, our ongoing

work is focused on recording from genetically identified corticocollicular neurons while mice are engaged in active listening tasks.

Title: Making inhibition work for you: An electrophysiological study of chemical and photochemical stimulation of the thalamic reticular nucleus

Authors: ***B. SLATER**[1], D. LLANO[2];
[1]Neurosci., [2]Mol. and Integrative Physiol., Univ. of Illinois, Urbana, IL

Abstract: The thalamic reticular nucleus (TRN) has been implicated to play a major role in a variety of brain functions, including sleep, attention, and information processing. One of the major tools to tackle the function on various nuclei in the brain is electrophysiological recordings using various stimulation paradigms to probe the inputs and outputs of any given brain region. Electrical stimulation is one of the most common ways to stimulate neurons, however when studying brain structures that are small and/or have white matter tracts passing though, it becomes difficult or impossible to separate what structures are being stimulated. The TRN is a small structure which surrounds much of the thalamus and has many of the thalamic axons passing through it, chemical stimulation, especially focal application, avoids some of these difficulties. Here we present a variety of chemical and photochemical methods to stimulate the thalamic reticular nucleus, and how robust each of these methods are in producing either action potentials or somatic depolarization. To test this, we used a mouse brain slice with the auditory portion of the thalamic reticular nucleus. Single cell electrophysiological recordings were done using whole-cell patch clamp and stimulation was done using either pressurized application of glutamate or acetylcholine or using a laser to photostimulate a variety of caged glutamate and cholinergic compounds. We used a variety of stimulation frequencies and intensities to explore the most robust stimulation parameters. We find that chemical cholinergic stimulation is more

robust than glutamatergic stimulation in generating action potentials and that varying frequency and intensity of stimulation can produce a variety of TRN spike outputs.

Title: Synaptic contacts between auditory Golgi cells

Authors: ***D. B. YAEGER**[1], L. O. TRUSSELL[2];
[1]Physiol. and Pharmacol., [2]Oregon Hearing Res. Ctr., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: In the cerebellum and in cerebellum-like circuits, axons of individual Golgi cells diverge to inhibit hundreds of granule cells. Recent results in the cerebellum have shown that Golgi cells make chemical and electrical synapses onto each other that promote synchronous firing of Golgi cells and coordinated inhibition of granule cells. We tested whether such a circuit arrangement exists in the dorsal cochlear nucleus using acute mouse brain slices. Injection of current into one Golgi cell resulted in a voltage deflection in a simultaneously recorded Golgi cell in over 90% of dual recordings, with an average coupling constant of 0.10 +/- 0.01 (n = 57). Electrical coupling showed only weak voltage-dependent rectification and electrical coupling was absent in the Cx36 knock-out mouse, indicating that coupling was mediated by connexin 36. Spikes in prejunctional Golgi cells evoked currents (spikelets) in postjunctional Golgi cells that were insensitive to blockers of fast chemical inhibition, suggesting that Golgi cells make electrical, but not chemical, synapses onto each other. Spikelets recorded in voltage clamp were composed of a brief inward current and a prolonged outward current, the charge of which exceeded that of the inward current, suggesting that spikelets have a net inhibitory effect on postjunctional Golgi cells. Indeed, in current clamp recordings, spikes in prejunctional Golgi cells reduced the probability of postjunctional Golgi cell spiking in response to brief current injections for tens of ms after the prejunctional spike. Despite the absence of chemical synapses between Golgi cells, bath application of the K+ channel blocker 4-AP evoked GABAergic and

glycinergic IPSCs in Golgi cells. In 3 of 30 paired recordings, molecular layer interneurons (MLIs) made inhibitory synapses onto Golgi cells, and IPSCs in MLI-Golgi cell pairs were completely blocked by the GABA-A receptor antagonist SR 95331 (n = 2). Thus, our results suggest that Golgi cells provide spike-mediated inhibition to each other through electrical synapses and also receive GABAergic inhibition from MLIs.

Title: Mechanisms of auditory gain enhancement following acute noise trauma

Authors: *B. D. AUERBACH[1], K. E. RADZIWON[1], P. V. RODRIGUES[2], G.-D. CHEN[1], R. J. SALVI[1];
[1]Ctr. for Hearing and Deafness, SUNY At Buffalo, Buffalo, NY; [2]Dept. of Anesthesiology, Sch. of Med. and Publ. Hlth., Univ. of Wisconsin, Madison, WI

Abstract: Hearing loss often gives rise to debilitating auditory perceptual disorders like tinnitus- a phantom ringing or buzzing sensation - and hyperacusis- where moderate intensity sounds are perceived as intolerably loud or even painful. While tinnitus and hyperacusis are often triggered by cochlear damage, it is now widely believed that these conditions arise from pathological plasticity in the central auditory system. We and others have proposed that tinnitus and hyperacusis are the result of disrupted gain control in the central auditory system. Central auditory neurons can modulate their dynamic range based on the pattern and level of incoming sound, thereby allowing them to maintain a relatively stable range of activity and preserve neural coding efficiency. According to the central gain model, under pathological conditions such as acute noise trauma or long-term hearing loss, this gain modulation can result in the over-amplification of spontaneous neural activity and supra-threshold sounds, which may underlie tinnitus and hyperacusis. Indeed, human and animal studies indicate that despite the reduced cochlear output following sensorineural hearing loss, spontaneous and sound-evoked responses at higher auditory structures can be paradoxically increased. However, it is still unclear where this hyperactivity is initiated, how it propagates through the auditory system, and how it relates

to the spectral profile of hearing loss. To address these questions, we recorded auditory-evoked local field potentials (LFP) and multi-unit spike discharges from several auditory areas simultaneously and examined the effect of acute noise trauma that resulted in temporary threshold shifts of 10-20 decibels (dB SPL). While responses from the auditory midbrain and thalamus were generally decreased at all intensities, there was a robust enhancement of supra-threshold responses in the cortex. Current source density analysis demonstrated that this enhancement was primarily the result of enhanced intracortical processing. These results suggest that gain enhancement may not be passively transmitted from lower to higher levels of the auditory system, and in fact may originate within the cortex. This work not only has direct implications for our understanding of tinnitus and hyperacusis but is likely to provide insight more generally towards the mechanisms of experience-dependent plasticity and gain modulation in the auditory system.

Title: Nonlinear resonance and plasticity as a basis for musical consonance

Authors: *J. KIM, E. W. LARGE;
Psychology, Univ. of Connecticut, Storrs, CT

Abstract: The consonance and dissonance of musical intervals is one of the oldest concepts in music theory and has been a subject of scientific inquiry from antiquity. Currently, there are two main theories of the basis for musical consonance. A dominant view of the past century has been that dissonance arises from sensory roughness produced by the beating of nearby frequency components and that consonance merely indicates a lack of roughness. Another view with a long history at least from the time of Pythagoras is that consonance is based on a harmonic relationship between sounds, which can be expressed as a simple integer ratio. Recent investigations have shown that harmonicity is a stronger factor in the perception of consonance than is roughness, especially for musically trained listeners. Here we explain the relationship

between harmonicity and consonance in terms of nonlinear resonance arising in the network of oscillatory neural populations tuned to auditory frequencies. We use a network of generic oscillators as a model of nonlinear auditory processing and show that the dynamical interactions between neural oscillators tuned to different frequency ratios match empirical findings and music-theoretical accounts of the relative consonance of musical intervals. A mathematical analysis of nonlinear resonance in oscillator networks shows how the strength and stability of nonlinear resonance varies as a function of natural frequency ratio and other model parameters. We also introduce Hebbian plasticity to the network of nonlinear oscillators and discuss its implications for the relationship between musical experience and the role harmonicity plays in the perception of consonance.

Title: Neural mechanisms of temporal prediction in naturalistic auditory stimuli

Authors: *B. MANISCALCO[1], P. ABRY[3], T. HOLROYD[2], B. J. HE[1];
[1]Natl. Inst. of Neurolog. Disorders and Stroke, [2]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD;
[3]Physics Dept., CNRS, Lyon, France

Abstract: Many features in both natural stimuli and brain activity exhibit power-law scaling relationships between power and temporal or spatial frequency ($P \propto 1 / f^{\beta}$). In the temporal domain, such scaling relationships manifest as autocorrelations that can be exploited for the purpose of prediction. Yet, the literature on prediction and prediction error has predominantly focused on stimulus sequences with relatively simple patterns of local and global regularities. Here, we investigate whether human observers can extract statistical regularities from stimuli with more complex and ecologically valid patterns of autocorrelation and use this information for temporal prediction, and if so, what neural mechanisms underlie this process. We presented subjects with sequences of tones whose pitch fluctuated over time. Pitch autocorrelation was parametrically modulated across trials, and sequences were chosen so as to yield a range of

values for the expected value of the final tone pitch. Subjects judged the degree of pitch autocorrelation in each sequence and rated the probability of the final tone. Crucially, subjects' ratings of final tone probability tracked the expected value for final tone pitch, suggesting that subjects were able to extract the autocorrelation statistics in the sequence necessary for making valid predictions about upcoming tones. MEG data reveal that tone sequences elicited phase locking in an arrhythmic 1/f pattern in low frequencies (< 5 Hz). This component of the neural response also contributed to sequence prediction, as shown by its modulation by the expected value of final tone pitch. MEG sensors carrying this prediction signal exhibited topographical overlap with those whose activity tracked the tone pitch instantaneously or with history-dependence, suggesting a possible local computation of predicted pitch on the basis of the present and previous tone pitches. Distinct sensor clusters showed sensitivity to prediction error derived from sequence autocorrelation statistics vis-à-vis local changes in pitch, suggesting cortical separation of local and global prediction errors. Taken together, the results suggest that naturalistic stimuli with 1/f-type temporal fluctuations in stimulus properties modulate low-frequency arrhythmic brain activity, and that this arrhythmic brain activity mediates sequence prediction. This study also expands on previous studies on prediction and prediction error by employing stimuli whose statistical regularities are more complex and more representative of patterns found in natural stimuli.

Title: Brief restraint in mice alters stress levels, vocal behavior and the neural representation of sound in the basolateral amygdala

Authors: *J. M. GRIMSLEY[1], E. G. HAZLETT[1,2], N. VALLABH[1], S. SHETH[1], C. A. GRIMSLEY[1], M. LATSKO[3], A. JASNOW[3], J. J. WENSTRUP[1];
[1]Anat. and Neurobio., Northeast Ohio Med. Univ. (NEOMED), Rootstown, OH; [2]Sch. of Biomed. Sci., [3]Psychological Sci., Kent State Univ., Kent, OH

Abstract: Interpreting the meaning of a sound depends on contextual cues, including other sensory stimuli and the internal state of a listener. The basolateral amygdala contributes to the analysis of a sound's meaning by integrating information from several senses as well as internal state. The amygdala's analysis of internal state has the potential to modulate the primary auditory system via its direct and indirect projections to auditory cortex. We hypothesized that even brief restraint, such as normally occurs in auditory neurophysiological studies, will alter stress levels as well as responses to sounds in the BLA. This study assesses effects of restraint on neurophysiological responses in the BLA as well as behavioral, vocal, and hormonal measures of stress. Blood corticosterone levels were measured in 10 free-moving and 10 restrained (2 hour) CBA/CaJ mice. In other mice, we measured the effect of brief restraint using a light/dark box, a marble bury test, and recorded vocalizations. Test mice were restrained for 2 hours on 3 consecutive days; control mice were placed in the test chamber without restraint. To assess effects on the auditory responses in the BLA, we recorded 160 repetitions of noise-evoked local field potentials (LFPs) in 13 adult male mice. Auditory responses were recorded in two sets from free moving mice, followed immediately by two sets of recordings from the same animals during restraint. Signals were transmitted wirelessly from custom multi-electrode implants using a wireless headstage. Several measures of stress were significantly higher in mice after restraint: corticosterone levels ($F(19) = 10$, $p = 0.006$), time in dark ($p = 0.002$), and number of buried marbles ($t(15) = 3.809$, $p = 0.002$). The frequency and duration of emitted syllables differed dramatically for mice during restraint compared to mating encounters or isolation in a novel chamber ($p<0.001$). The magnitude of noise-evoked LFPs was typically greater during restraint (9/13 mice, $p < 0.001$). A one way ANOVA revealed a main effect of discriminatory information from comparisons of recording sets ($F(3,37)= 4.7$, $p = 0.007$); the free vs. restrained comparison had significantly higher levels of discriminatory information ($p<0.05$). The recording condition could be determined by computations on the single trial LFP for an average of 72% of trials. Restraint comparable to that commonly used in auditory neurophysiology caused consistent changes in the neural responses to sound and generated long-lasting stress in mice. This increased neural response may contribute to the increased auditory sensitivity and improved auditory signal detection that is caused by stress.

Title: Synaptic signature of optimal and suboptimal states for sensory signal detection

Authors: *M. J. MCGINLEY[1], S. V. DAVID[2], D. A. MCCORMICK[1];
[1]Neurobio., Yale Univ., New Haven, CT; [2]Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The cortical subthreshold membrane potential and synaptic dynamics underlying optimal sensory signal detection are not well known. Human and animal studies have reported that performance on signal detection tasks is highly state-dependent, exhibiting an inverted-U dependence on arousal and the activity of neuromodulatory pathways. This relationship, known as the Yerkes-Dodson curve, predicts that optimal performance occurs at intermediate levels of arousal (Yerkes and Dodson, 1908). But what are the synaptic and circuit mechanisms of this inverted-U dependence of optimal states for behavior and neural responses? To address this question, we recorded membrane potentials of auditory cortical neurons in mice trained on a challenging tone-in-noise detection task while assessing arousal with simultaneous pupillometry and hippocampal recordings. We find that the mouse's internal state fluctuates continuously and rapidly (in seconds or less), and arousal can be quantified simply as the diameter of the pupil. The pupil diameter closely tracks the rate of occurrence of hippocampal sharp waves. In addition, auditory cortical membrane potentials of layer 4 and 5 excitatory neurons exhibit: slowly fluctuating (1-10 Hz) rhythmic activity with low arousal; hyperpolarization and low variability at intermediate arousal; depolarization and variability with sustained hyper-arousal (with or without walking); and transient depolarization in synchrony with micro-arousal events. Optimal signal detection behavior and sound-evoked responses, at both sub-threshold and spiking levels, occurred at intermediate arousal when pre-decision membrane potentials were stably hyperpolarized. These results reveal a cortical physiological signature of the classically-observed inverted-U relationship between task performance and arousal, and that optimal detection exhibits enhanced sensory-evoked responses and reduced background synaptic activity. Furthermore, these results provide a framework with which to resolve apparent discrepancies between species and sensory systems in cortical membrane potential dynamics. Revealing the neural mechanisms by which the state of the brain and periphery is controlled on a moment-to-moment basis promises to clarify many interesting aspects of neural network function, including the neural basis of optimal performance, and may reveal a nervous system that is considerably more accurate and less variable than previously thought. Title: Long-lasting recalibration to auditory listening conditions

Authors: ***N. C. RABINOWITZ**[1,2], M. SCHEMITSCH[1], O. BRIMIJOIN[3], E. P. SIMONCELLI[1,2];
[1]Ctr. for Neural Sci., NYU, New York, NY; [2]Howard Hughes Med. Inst., New York, NY; [3]MRC Inst. of Hearing Res., Glasgow, United Kingdom

Abstract: Perception can be described as a process of inferring the properties of objects in the world from incoming sensory signals [Alhazen 1040, Helmholtz 1867, Kersten et al 2004]. This inverse process is particularly difficult as object properties are entangled with those of contextual "viewing conditions". For example, before emitted sounds reach the ears, they undergo spectro- and spatio-temporal filtering by the room and head. The details of these transformations depend on the complex geometry and physics of a given environment, and can change considerably with head position. Thus, in order to make inferences about source objects, the brain must separate an incoming signal into "source" and "listening condition" components. We hypothesized that the brain accomplishes this feat by factoring out systematic regularities that are learned from experience. To test this, we built a novel psychoacoustic chamber, wherein features of sound sources were systematically varied according to human subjects' head positions. When we coupled the carrier-frequency of a pure tone to subjects' head angle, they passively learn to compensate for this in perceptual judgments, without being aware of the perturbations. Curiously, this does not occur for other sound features such as modulation rate or depth [Rabinowitz et al, ARO 2014]. Based on these findings, we developed a model for perceptual recalibration based on known physiological properties of the peripheral auditory system, and used it to predict how listeners would be biased by altered environmental statistics. We hypothesized that spectral recalibration involves a rescaling of the gain of peripheral frequency channels to partially compensate for systematic discrepancies across head angles, and that these gain changes have a fundamental resolution limit imposed by the peripheral representation. From this model, we predicted that listeners would not only compensate for spectral discrepancies that

they had been exposed to, but that they would maladaptively "anti-compensate" at nearby frequencies which were not part of the exposure regime. Indeed, we find that this effect manifests precisely as predicted. Moreover, the spectral resolution of perceptual recalibration appears to be comparable to that of peripheral critical bands. The effects we report last for tens of minutes after the end of the exposure period. Control experiments in the closed-field rule out the possibility that they result from peripheral adaptation. Thus listeners' inferences about sound sources can be biased by systematic relationships experienced over extended time scales, but only through means allowed by physiology.

Title: Measurement of acoustic frequency discrimination thresholds in common marmosets (Callithrix jacchus)

Authors: *Y. GUO, M. S. OSMANSKI, X. SONG, X. WANG;
Johns Hopkins Univ., Baltimore, MD

Abstract: The common marmoset (*callithrix jacchus*), a New World non-human primate, has emerged as a promising animal model system in auditory neuroscience research. It is thus important to characterize the fundamental auditory perceptual abilities of this species, such as their capacity for frequency discrimination. We trained marmosets on a discrimination task using operant conditioning procedures and measured the minimum change in frequency (i.e., the frequency difference limen, or FDL) that marmosets could detect using pure tones at eight different frequencies. Stimuli spanned the entire hearing range of the marmoset from 220 Hz to 28.16 kHz with octave intervals. All stimuli were presented at a relatively constant sensation level. Sound level was also roved +/- 3dB to eliminate the possibility of using intensity fluctuation as a cue to perform the task. Our data show that (1) the absolute FDL increases as the testing frequency increases; (2) the relative FDL decreases from ~2.5 semitones (1 semitone equals ~6% of the testing frequency) until it reaches minimum value of ~0.5 semitones around 7kHz, then slightly increases as the testing frequency goes higher. The frequency range with lowest relative FDL overlaps with the most sensitive region in the marmoset audiogram, as well

as with the fundamental frequency range of their typical vocalizations. We also tested marmosets' pitch discrimination abilities using harmonic complex tones with fundamental frequencies of 110 Hz, 220 Hz, 440 Hz and 880 Hz. It is shown that as the fundamental frequency increases from low to high, the relative difference limen first decreases and then increases, with a highest value of ~1.4 semitones at 110 Hz and a lowest value of ~0.4 semitones at 440 Hz. These results reveal auditory perceptual capacities of the marmoset and help guide further studies of auditory behaviors of this species. This research is supported by an NIH Grant (DC003180).

Title: Musical interpretation in blind pediatric subjects. An MR study

Authors: *B. DE CELIS ALONSO[1], S. HIDALGO TOBÓN[2], P. DIES SUAREZ[2], C. GUERRERO ARENAS[4], E. CASTRO-SIERRA[3];
[1]BUAP (Benemérita Univ. Autónoma de Puebla), Puebla, Mexico; [3]Lab. de Psicoacústica y Fisiología Auditiva, [2]Hosp. Infantil, Federico Gómez, Mexico DF, Mexico; [4]Escuela Nacional de Musica, UNAM, Mexico DF, Mexico

Abstract: Introduction. The objective of this study was to assess the physiological differences in brain recruitment and connectivity when interpreting melodic and non-melodic music in control and blind pediatric populations. To this end, a BOLD-fMRI experiment was performed to quantify BOLD representations and connectivity. Methods. 26 pediatric subjects were recruited for this study. During the BOLD-fMRI study two stimuli were delivered to subjects: A melodic (M) and a non-melodic (N) music sequence. Eight contrasts were built: M for blind (B), N for B, M for Controls (C), and N for C. Also Blind M vs. N, Control M vs. N, Music B vs. C, Noise B vs. C. Finally, connectivity calculations were performed for these contrasts in which ROI to ROI correlations were calculated. Results & Discussion. In the BOLD study (Figure 1), cerebellum and fusiform regions played a big role in sound interpretation for both groups. Frontal lobe activations were strongly associated with music while temporal activations were found for all the sound stimuli. Regions of activation in the frontal and temporal lobes changed with the group and kind of stimuli applied. Blind volunteers had right hemisphere predominance contrasting

with the left prominence of controls. For the connectivity study (Figure 2) different networks were involved in the musical or the noise interpretation depending on the group studied. In contrast similar mechanisms existed between blind and controls when differentiating melodic from non-melodic stimuli.

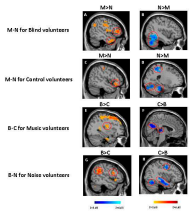

Figure 1. Some examples from BOLD results. Sagittal anatomical images are used to overlay BOLD activations on them. The contrast studied appears on the left column while the direction of contrast appears indicated by labels between figures (i.e. Second row is the Music vs. Noise contrast for control volunteers exclusively). C represents results where Music was more significant than Noise). Threshold values of 0.001(p<0.001 were used to build these images. A pseudo-colored bar with significance of results can be found under the panels. 1A shows activation in the inferior temporal and frontal lobes. Trends of activation also appear in the rolandic operculum and the supra-marginal gyrus. 1B shows activation in the left fusiform and also on cerebellum structures. 1C shows activation in the frontal inferior right cortex. 1D shows activation encircled in red figures in the cerebellum (region 4 and 6) as well as in the post-central region of cortex, all on the left hemisphere. 1E shows significant results in the insula (inside red circle) and also in the frontal cortex and the fusiform cortex. 1F shows results in the cuneus and the thalamus of right brain hemisphere. 1G when found representations in the superior temporal lobe as well as the frontal inferior operculum. 1H shows characteristic left cerebellum, fusiform and pre-central activations.

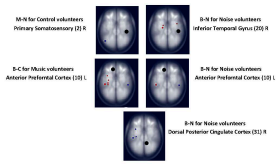

Figure 2. Examples of the connectivity Study. This figure presents connections which were significant (p<0.05 FDR corrected). The black points on top of coronal template images are the reference BA region mentioned in the text by each image. BA region and hemisphere are indicated in the text. Red color indicates correlations which were stronger for the first group than the second. (i.e. top left panel shows a blue correlation indicating stronger correlation for noise than music between these regions for control volunteers).

Title: Is there an effect of long-lasting exposure to industrial noise in the adult auditory system of rats

Authors: *B. GOURÉVITCH, F. OCCELLI, J.-M. EDELINE;
Dept. Cognition & Behavior, Inst. De Neurosci. Paris-Saclay (neuropsi), Orsay, France

Abstract: Over the last decades, an increasing number of people have been exposed on a daily basis to important levels of noise. Short term damages induced by traumatic noise (>105 dB

SPL) have been widely studied in the literature. Recent studies have shown that, even at a non-traumatic and legally authorized intensities (<85dB SPL), alterations of the auditory system occurred at the cortical (Noreña et al 2006) and peripheral levels in the absence of efferent feedback (Maison et al 2013). Only a few articles have tried to compare electrophysiology data and behavioral deficits after non-traumatic noise exposure after a 2-4 months exposure. Our whole project aims at evaluating the impact on the auditory system of adult rats after a long-lasting exposure (3-18month, starting at 2 months old) to a structured (industrial) non-traumatic noise (80dB SPL, 8h/day). Here, we assess on every single animal the consequences of such exposure on brainstem, behavioral and cortical response to noisy backgrounds and auditory contrasts. First, although auditory brainstem thresholds were affected by aging, they were not degraded by long-term exposure. Second, after very long-term exposure, exposed animals showed as good as or even better response features than control animals in the primary auditory cortex. If confirmed, these results might indicate that the type of noise (pure tone vs. dynamic noise) and/or the age at which animals started to be exposed are crucial factors that influence the impact of environmental noise.

Title: Flexible scripted software system for delivery and analysis of F0 perturbation experiments

Authors: ***B. ROGERS**[1], C. L. CHAN[2], A. B. NEW[1], C. R. LARSON[2], D. A. ROBIN[1]; [1]Res. Imaging Inst., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX; [2]Northwestern Univ., Evanston, IL

Abstract: The ability to control voice fundamental frequency (F0) is essential for successful and efficient speech production. Pitch perturbation techniques have often been used investigate the role of auditory feedback in F0 control. This set of four computer applications combines

experiment scripting, paradigm presentation with real-time audio feedback, browsing of results and speech analysis. Script Generator is a web based application used to build a pitch perturbation experiment. An experiment is a set of trials with a single vocalization per trial. Script Generator provides the user with a point and click interface with options to create a sequence of events presented during a trial. Each event has a set of attributes specifying cuing, timing, vocal perturbations, and recording. Cues can be audio clips, text, or images. The timing and the magnitude of each of these events can be specified as well as the number of repetitions. A number of different trial types can be combined in an experiment. The resulting script is a JavaScript Object Notation (json) file that is then fed into the PitchPresent program. In PitchPresent, participants vocalize in response to audio or visual cues. During vocalization participants receive audio feedback where the F0 may be intermittently shifted in pitch. Headphones are worn for the delivery of audio cues and for receiving audio feedback. Visual cues to the participants are displayed on a monitor. Vocalizations are captured and saved for further analysis. The presentation of cues and the audio processing is completely software based and requires no special hardware. PitchBrowse is used for review and export of the data collected in PitchPresent. It can display audio waveforms for each trial, play the audio, and show the timing of the events during individual trials. This data can be exported in json, text, or WAV files, and in a binary format suitable for Matlab. The Speech Analysis toolkit is a web based app that parses the json data exported from the PitchBrowse program and provides the experimenter with a set of individual, averaged and waterfall graphs of the pitch contours from collected data. The participant's response for each condition is automatically averaged and measured. All of the data are stored in a SQL database and each data set is attached to the participant's personal and demographic information (collected during the pre-experiment stage). The results are averaged both within-participant and across participants. The four applications were developed using free or open source software. The web based applications depend heavily on Javascript. PitchPresent and PitchBrowse are written in C++ for performance reasons.

Title: Effects of poor hearing acuity on gait during dual-task execution: data from cognitively healthy older adults

Authors: *C. RODRIGUEZ-ARANDA, M. MITTNER, K. WATERLOO, O. VASYLENKO, M. M. GORECKA;
Dept. of Psychology, Univ. of Tromsø, Tromsø, Norway

Abstract: Hearing acuity can become seriously compromised with advanced age. Troubles associated with impaired hearing include difficulties with communication, balance and mobility. In fact, reduced hearing acuity in the elderly is associated with slower walking speed and lower walking endurance. Also, hearing impairments interfere with the ability to filter out competing sound sources, which jeopardize selective attention. Clinical data suggest that a decline on hearing acuity may be a central cause of greater risk of falls in older adults who need to cope with daily situations demanding sustained attention during walking. However, to date there are no experimental data on this matter. **Aim.** We investigated whether older adults with poor hearing acuity are more prone to show gait disturbances than elderly with good hearing function when performing a dual-task during walking.**Method.** 29 elderly with reduced hearing acuity (M age =74.4 years) and 35 elderly with normal hearing (M age = 68.5 years) were the participants. All were right-handed and free of cognitive dysfunction. Cognitive assessment and pure tone audiometry were applied. Also, pure tone average (PTA) at thresholds 0.5, 1, 2, and 4 kHz was calculated. Best-ear PTA was used to classify groups into low (LHA) or normal hearing acuity (NHA). Participants were excluded if interaural asymmetry between ears >5dB or PTA threshold >45dB. The dichotic listening (DL) test was used as concomitant task to walking. The dual-task situation followed the 3 standard conditions of DL: Non-forced, Forced-Right and Forced-Left. Gait was evaluated over ground with the OptoGait system during dual-task performance and also during comfortable walking. Standard spatio-temporal measurements of gait were quantified. Mean (*M*), standard deviation (SD) and coefficient of variation (CV) were used for group comparisons. ***Statistics.*** Factorial analyses of variance with repeated measures were conducted. ***Results.*** At baseline, *M* for step, stride, speed and distance were significantly reduced in the LHA group while CV for speed and cadence were significantly higher. Across DL conditions, double support time significantly increased in the LHA group. Especially, the LHA group showed more gait disturbances during Forced-Left condition in which *M* for step length and CV for step width showed asymmetric perturbations on the right foot. ***Conclusions.*** Older adults with low hearing acuity show clear differences in spatio-temporal parameters during walking as compared to elderly with normal hearing. Moreover, LHA showed further alterations in gait stability during dual-task performance, which confirms that LHA elderly are at higher risk of falling.

Title: Task-specific electrophysiological differences between musical pitch and valence judgment

Authors: *F. FOO, J. HIROTA, R. MALZYNER, R. T. KNIGHT;
Univ. of California, Berkeley, CA

Abstract: The processing of successive pitch changes and simultaneous pitch combinations are important yet distinct percepts in music, respectively facilitating the perception of musical contour and driving emotional responses toward music. The neural correlates of each percept have been studied extensively in humans, but no study to date has investigated these percepts with the same stimuli to examine task-specific differences in the cognitive processes involved. We present a novel experimental design where changes in pitch (up/down) and valence (consonance/dissonance) are both present in the same stimulus sequence. Subjects (n=22) heard 2 piano chords in succession, and made either a pitch direction judgment (Pitch Task, PT) or a valence judgment (Valence Task, VT) while EEG and behavioral data were recorded. We observed that: 1) The target chord generated a larger N1 ERP amplitude ($p<0.05$) that was maximal over central regions than the cue chord in PT, but no significance was observed in VT. This supports the hypothesis that pitch direction judgment requires greater attention to the target chord, while valence judgment requires a similar amount of attention to both chords. 2) Consonant chords elicited a larger P2 ERP amplitude ($p<0.05$) over frontocentral regions than dissonant chords in VT, but no significance was observed in PT. Notably, spectral analyses revealed greater frontal alpha asymmetries and beta reductions for VT. This suggests that attention to valence enhances the contrast between ERP and spectral responses for consonant and dissonant chords. 3) The target chord evoked a smaller P3b component ($p<0.05$) over centroparietal regions in VT, which may reflect higher cognitive workload and reduced decision certainty. This is further supported by increased frontocentral theta activity in VT, longer mean reaction times (PT: 1068ms, VT: 1150ms) and a negative correlation between accuracy and reaction time for VT that is absent in PT (r2(PT): 0.007, r2(VT): 0.342). No difference was

found in mean accuracy for either task (PT: 90.2%, VT: 91.7%). 4) A larger negative ERP component 400-500ms after stimulus onset ($p<0.05$) was observed for dissonant chords over frontocentral regions in PT than in VT, but this component was not present for consonant chords in either task. This is in line with findings of a similar N4 component in response to unexpected words in language tasks, and suggests a heightened unexpected quality of dissonant chords when attention was directed away from its valence. In conclusion, attention to pitch or valence differentially modulates ERP and spectral components associated with early auditory and late cognitive processing of musical percepts.

Title: Dissociation between spiking activity and local field potentials in the auditory cortex during auditory decision-making

Authors: ***J. TSUNADA**[1], A. S. K. LIU[1], J. I. GOLD[2], Y. E. COHEN[1];
[1]Dept. of Otorhinolaryngology, [2]Dept. of Neurosci., Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Auditory decision-making requires the conversion of incoming auditory information into a categorical judgment. For a decision regarding the frequency content of an auditory stimulus, spiking neural activity in the middle-lateral belt region (ML) and the anterolateral belt region (AL) of the auditory cortex represents relevant frequency information, but only in AL does this activity directly and causally provide evidence for this decision. However, it is unknown the degree to which ML and AL activity reflects inputs from other brain regions or how it is shaped by local neural processing. To begin to address these questions, we recorded spiking activity, which provides the output signals from a given brain region, and local field potentials (LFPs), which reflect a combination of input, local, and output signals, from ML and

AL, while monkeys performed an auditory frequency-discrimination task. For this task, the monkeys reported whether a sequence of tone bursts contained more high-frequency tone bursts (>1.75 kHz) or low-frequency (<1.75 kHz) tone bursts. The monkeys could report their choice at any time during the presentation of tone bursts. We manipulated task difficulty by systematically changing the proportion of high-frequency and low-frequency tone bursts. The monkeys' choice accuracy and response times depended systematically on the proportion of high- and low-frequency tone bursts, with faster and more accurate responses for stronger stimuli (i.e., a relatively high proportion of either high-frequency or low-frequency tone bursts). We obtained 79 pairs of spiking activity and LFPs (ML: 35 pairs, AL: 44 pairs) from two monkeys performing the task. Both ML and AL spiking activity was modulated comparably by the frequency content of the tone bursts: spiking activity increased as the proportion of tone bursts with frequencies matching the neuron's best frequency increased. However, ML LFPs had stronger frequency-dependent modulations than those in AL. Furthermore, a modulation index indicated that ML spiking activity and LFPs had similar frequency selectivity; whereas AL LFPs were less selective than AL spiking activity. Consistent with this observation, the spike-field coherence was stronger in ML than in AL. Together, these results suggest that there is dissociation between spiking activity and LFPs in AL, but not in ML. Based on these findings, we discuss a hypothesis that ML relays sensory inputs to other brain regions, including possibly AL, and AL transforms sensory inputs to a systematically organized representation of sensory evidence used to form the decision.

Title: A synaptic and circuit logic for task engagement in auditory cortex

Authors: *K. KUCHIBHOTLA, J. V. GILL, R. C. FROEMKE;
Skirball Inst., NYU Sch. of Med., New York, NY

Abstract: Animals can change their behavior based on behavioral context. A pedestrian will move rapidly away from traffic if she hears a car honk while crossing a street - executing a learned sensorimotor response. The same honk heard by the same pedestrian will not elicit this response if she is seated on a nearby park bench. How do neural circuits enable such flexible interpretation of the same stimuli? Here we show that context-dependent behavioral flexibility controls neural ensembles in the auditory cortex, via cholinergic modulation and local inhibition. Mice were trained to perform a go/no-go operant task in response to pure tones in one context ("engaged", target tone is rewarded) and listen to the same pure tones but execute no behavioral response in another context ("passive"). When task "engaged", auditory cortical neurons exhibit broad suppression across a majority of neurons but selective activation of a specific sub-network. Neural responses shifted within a single trial after the context switched. Task performance was reduced by atropine suggesting a role for the nucleus basalis (NB), the primary source of cortical acetylcholine. Using axonal calcium imaging in behaving mice, we show that fibers and terminals projecting from NB to auditory cortex show increased activity in animals only after task learning and during task engagement when compared to passive exposure. Whole-cell voltage clamp recordings in behaving mice showed robust context-dependent changes in inhibitory drive and only modest changes in excitation. Cell-type specific calcium imaging showed that these changes were partially mediated by PV-positive interneurons. Thus, local synaptic inhibition gates long-range neuromodulation from the nucleus basalis to rapidly and reversibly alter auditory cortical output, temporarily decorrelating excitatory and inhibitory inputs, and improving behavioral flexibility. These mechanisms may help explain pathological states, such as post-traumatic stress disorder and addiction, in which flexibility is compromised and innocuous stimuli trigger maladaptive behaviors.

Title: Contribution of primary auditory cortex to auditory-streaming behavior

Authors: *K. L. CHRISTISON-LAGAY[1], Y. E. COHEN[2];
[1]Perelman Sch. of Med. At the Univ. of Pennsylvania, Philadelphia, PA; [2]Otorhinolaryngology, Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA

Abstract: A fundamental component of auditory perception is the grouping and segregation of auditory stimuli into distinct perceptual units—a process that is known as "auditory scene analysis". The auditory brain groups and segregates stimuli based on their spectral, temporal and spatial regularities (or differences). Once grouped, a single perceptual auditory unit is called an "auditory stream". One important psychophysical task that has illuminated many of the principles and mechanisms underlying a listener's ability to segregate and group acoustic stimuli is the "streaming" task, in which listeners report whether a sequence of tone bursts at two, alternating frequencies sounds like one "auditory stream" (i.e., "galloping" tones) or two auditory streams. The probability of a listener hearing one or two streams can be manipulated by changing certain parameters of the tone-burst sequences, including (1) the frequency separation between the tones, (2) the listening duration, and (3) the temporal overlap of the tones. Using this tone-burst sequence, we recently demonstrated directly, for the first time, that non-human primates segregate the auditory scene in a manner comparable to human listeners and, consequently, are a valid model of human stream-perception. Here, for the first time, we present findings from extracellular recordings from neurons in the primary auditory cortex (A1) while the animals performed this streaming task. We found that (1) A1 neurons are more broadly tuned during the streaming task than during a passive-listening condition and (2) the firing rate in response to the tone bursts habituates over time. We also find that (3) neural activity is modulated as a function of behavioral report. The degree of choice activity is comparable to that seen in other brain areas that contribute sensory evidence to the decision but do not code the decision itself. Further, unlike previous computational models, we find that choice behavior is not coded by neural habituation but, instead, can be explained by instantaneous firing rate. We discuss these finding in the context of the role of A1 and the hierarchical mechanisms of the ventral auditory pathway.

Title: In-ear-EEG indicates neural signatures of effortful auditory processing

Authors: *L. FIEDLER[1], T. LUNNER[2,3], A. BRANDMEYER[1], M. WÖSTMANN[1,4], C. GRAVERSEN[2], J. OBLESER[1,4];
[1]Auditory Cognition, Max Planck Institute, Cognitive & Brain Sci., Leipzig, Germany; [2]Eriksholm Res. Ctr., Snekkersten, Denmark; [3]Swedish Inst. for Disability Research, Linnaeus Ctr. HEAD, Linköping University,, Linköping, Sweden; [4]Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: Hearing aids (HA) amplify, compress and further process incoming acoustic signals and are fitted to individual hearing impairment. However, HA thus far are unable to completely restore hearing in challenging listening situations, likely because HA operate uncoupled from the listeners' neural and cognitive processes. We here present data in a new approach to gather neural control signals for steering the HA. As a basis we took signals measured in N = 3 participants using Electroencephalography (EEG) recordings from three electrodes placed in the external ear canal ("in-ear-EEG") alongside with conventional 64 electrodes scalp EEG. The objective of this project was to detect reliable neural signatures of auditory cognitive processing in the in-ear-signals. To this end, we tested two established auditory paradigms: First, a concurrent dichotic oddball paradigm (with 1.4- and 1.8-Hz driving stimulus frequencies) to evaluate the detectability of auditory evoked potentials (AEP) in the in-ear-EEG and second, a cocktail-party, multi-talker scenario to extract neural responses to ongoing speech signals. First, our results show significant P1- and N1-equivalent event related potential (ERP) deflections in the in-ear-EEG on the single subject level in all participants. Second, spectral analysis disclosed evoked components at the two driving frequencies of the oddball paradigm and their higher harmonics. Furthermore, we found a prominent peak in the alpha frequency band for each participant. Third, using cross-correlation techniques, the cocktail-party scenario revealed significant neural phase-locking of in-ear-EEG to the speech envelope. Lastly, validating our approach, there was a significant and spatially distributed correlation of time-domain in-ear-EEG with simultaneously acquired conventional scalp EEG. In sum, by using established challenging-listening paradigms and data analyses, our results prove the feasibility of in-ear-EEG and the availability of neural signatures related to auditory processing. These findings thus provide a promising basis for further research using more real-life listening paradigms and brain-computer-interface (BCI)-geared analyses.

Title: The role of parvalbumin-positive interneurons in auditory gap detection

Authors: *L. OSTERHAGEN, K. J. HILDEBRANDT;
Cluster of Excellence 'Hearing4All', Dept. of Neurosci., Univ. of Oldenburg, Oldenburg, Germany

Abstract: Age-related hearing deficits often include impairment of the processing of temporal fine structure, which may be due to deterioration of cortical processing. Age-related structural and functional changes of the auditory cortex have been found within the inhibitory interneuron (IIN) system: The levels of IIN- targeting neurotransmitters are decreased in older mammals. Besides, a decrease of parvalbumin-positive (PV+) IINs, one main group of IINs, had been shown. PV+ IIN in the auditory cortex have been proposed to play an important role for temporal sound processing. We hypothesize that impairments of processing temporal fine structure, which affect primarily older people/mammals, are related to decreased activity in PV+ IIN and that it is possible to enhance the detection of short gaps in noise by artificially activating those neurons. In order to test for the effect of altered PV+ activity, we choose to use optogenetic activation of PV+ cells and test for both physiological and perceptual consequences. We circumvent the interactions of timing of light and sensory stimulus by using stable step-function opsin (SSFO), which can be rendered continuously active and inactive with short pulses of light. By using SSFO, we were able to examine the effects of prolonged low-level and probably more physiologically accurate activation on both neural and behavioral gap detection thresholds. In a first step, we performed electrophysiological recordings in awake, passively listening mice with and without optical activation of PV+ cells. Neural gap detection thresholds for gaps in noise were significantly enhanced both in local field potentials and spiking responses. Units that displayed a significant change in gap detection thresholds also showed increased offset responses at the end of noise stimuli, possibly suggesting a role of cortical offset responses in gap detection. In a second step, we developed an acoustic gap detection task that is embedded in a Go/No-Go paradigm in order to test for perceptual consequences of PV+ manipulation. During the task, continuous noise is presented to the animal. When, a gap of varying length is inserted into the noise stream the mouse has to leave a platform in order to gain a reward. Mice reached

performance level > 80% within 20 training sessions. Behavioral gap detection matched neural detection thresholds (~ 3 ms). Currently, we are testing behavioral performance with, the activity of PV+ cells either manipulated through optical stimulation or left untouched. We expect detection performance to be increased in trials in which PV+ IINs are artificially activated by light stimulation as compared to trials without stimulation.

Title: How do anesthetics affect fMRI responses to auditory stimuli ?

Authors: *L. UHRIG[1,2,3], M. DUPONT[1], B. JARRAYA[1,2,4];
[1]INSERM, CEA Neurospin, Gif-sur-Yvette, France; [2]INSERM Unicog, Gif-sur-Yvette, France; [3]Necker-Enfants Malades Hospital, Descartes Univ., Paris, France; [4]Neuromodulation unit, Dept. of Neurosurgery, Foch Hospital, UVSQ, Univ. Paris-Saclay, Suresnes, France

Abstract: Functional magnetic resonance imaging (fMRI) can be performed either in awake or anesthetized monkeys. Conducting fMRI under anesthesia is a powerful mean of studying brain dynamics during consciousness manipulation [1]. However, for a rigorous interpretation of fMRI data, the anesthesia protocol should ideally use a single hypnotic drug, reproduce the same level of targeted anesthesia depth, maintain and carefully monitor physiological parameters that are key for the fMRI signal stability. Moreover, anesthetic agents can directly affect fMRI responses to sensory stimuli. We first established a protocol designed for non human primate studies that could address these challenges by using either propofol or ketamine as a single anesthetic agent, measuring electrical brain activity (EEG) during event-related fMRI study, and maintaining stable body temperature and end-tidal CO2 among other physiological parameters. Then, we evaluated the fMRI response to low and high frequency sounds in different arousal states (awake and anesthesia) in 2 Rhesus macaques for each state. In the awake study, monkeys were trained

to fixate. For the anesthesia study, we used two different anesthetic agents that act on different pharmacological receptors: either propofol (GABA-A agonist) with two levels of sedation (light or deep), or ketamine (NMDA antagonist). The level of sedation states was controlled using both an adapted clinical scale and EEG. Monkeys were scanned in a 3T MRI scanner (Siemens Trio) using MION contrast agent. MR compatible headphones were adapted to monkeys (MR Confon, Germany). Data were analyzed to determine the fMRI activations linked to high and low frequency sounds (SPM5, Matlab). We found reproducible activations of the macaque auditory cortex in the awake state, during propofol anesthesia and ketamine anesthesia. Activations to sounds within the auditory cortex decreased between the awake state and anesthesia, with a major decrease for low frequency sounds under ketamine anesthesia. The extent of activation also decreased most under ketamine anesthesia. This difference may be related to the fact that propofol and ketamine act differently on the neurovascular coupling, or to the fact that the two anesthetics, while keeping feedforward inputs, affects the feedback processes differently. These differences have to be taken in consideration when performing fMRI under general anesthesia.

Title: Differences in EEG activity between right and left handed on a sound localization task: an exploratory study

Authors: ***M. CASTRO GONZÁLEZ**[1], Y. DEL RÍO-PORTILLA[2];
[1]Univ. Nacional Autónoma De México, México, Mexico; [2]Lab. de Sueño, Univ. Nacional Autónoma de México, México, Mexico

Abstract: Differences in brain organization and brain processing between right and left handed have been described, nevertheless is continue to be an issue of fact. There is also known that sound processing is different for both hemispheres in relation to sound localization. The aim of

this study was to analyze brain response and brain processing during a sound localization task before and after eye movements. We used twenty stimuli (musical note A, 2s each). Stimuli were presented in a classical random block design, for each group (left handed and right handed). After each run, subjects (n=20 male) respond on a PC keyboard according to where they heard the stimuli (right or left side) and at the same time to gaze on the direction they heard the stimuli (right or left side). For eye movements recording, we placed electrodes according EOG. Results showed significant differences on brain activity between left and right handed according to sound localization. There is an increased on absolute power over widespread brain regions for both hemispheres especially on high frequencies, alpha2, beta1, beta2 and gamma higher on right handed. Left handed presented a decrease on absolute power on c4, t4, t5, t6, p4, o1, fz, pz involving high frequencies alpha2, beta1, beta2 and gamma. Inter correlation showed differences between beta1 and gamma higher for left handed. Behavioral data analysis showed higher response on right side comparing Pc keyboard answers for both right and left handed, nevertheless there is a major response to left side for eye movements especially for left handed. By the time we might say that brain processing during a sound localization task, is similar for right and left handed according to EEG results, so brain widespread response especially in high frequencies were corroborated. Moreover on behavioral analysis, it seems that on PC keyboard answers and eye movements response, there is a difference denoting that for eye movements, laterality plays an important role that might be related to orientation reflex, so eye movement response is faster and spontaneous in relation to PC keyboard answers where subjects need to be more attend to the task to give an answer. This project is partially financed by DGAPA project IN224414-2. María del Carmen Castro-González is granted by DGAPA project IN224414-2.

Title: Misophonia: reflecting on self-generated trigger sounds

Authors: ***M. EDELSTEIN**[1], D. BRANG[2], B. MONK[1], R. ROUW[3], V. S. RAMACHANDRAN[1];
[1]UC San Diego, La Jolla, CA; [2]Interdepartmental Neurosci. Program, Northwestern Univ., Evanston, IL; [3]Dept. of Brain and Cognition, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Misophonia, literally translated as the “hatred of sound,” is a newly characterized condition where inflicted individuals (misophonics) experience autonomic arousal and intense negative emotions to specific sounds. These “triggers” are typically repetitive sounds generated by another person, including chewing, breathing, tapping, lip smacking and pen clicking. The extreme aversion misophonics experience when exposed to these sounds is characterized by an intense fight-or-flight response which can include emotions of rage, anger, anxiety and panic, far beyond what is typically displayed by non-misophonic individuals. The reactions to these sounds can be so debilitating that many misophonics feel the need to habitually avoid commonplace situations or particular people (including family members), all which can significantly diminish quality of life. As only specific sounds evoke these negative responses, misophonia is distinguished from a general aversion or oversensitivity to sounds (such as hyperacusis). Additionally, misophonia severity appears to be modulated by contextual factors such as sound source, suggesting that there is a strong ‘top-down’ cognitive component to the condition. Anecdotally, many misophonics have reported that they are not bothered when they produce their own trigger sounds with some even employing mimicry as a coping strategy; further, trigger sounds produced by infants or animals were reported to be less aversive than sounds produced by adult humans. In order to empirically validate these anecdotal reports, we performed several assessments that explored whether the misophonic fight-or-flight response is modulated by context. Here we present preliminary behavioral (aversiveness ratings) and physiological testing (galvanic skin response) data gathered from these experiments. This preliminary data reveals that misophonics quickly habituate to self-generated sounds when watching themselves perform these actions in a mirror. Currently there is no standard treatment for misophonia; however, these findings provide important insight towards the development of therapies for attenuating the symptoms associated with the misophonic condition.

Title: Primacy of frequency over amplitude modulation rate in retrieval of auditory memory

Authors: *P. YIN, S. A. SHAMMA, J. B. FRITZ;
Univ. Maryland, College Park, MD

Abstract: In order to explore the representation of sound features in auditory memory and the role of dorsolateral frontal cortex (dlFC) in auditory long-term memory, we developed an auditory task that requires information retrieval from an auditory long-term memory (LTM) store. Two ferrets were each trained on two versions of a 3-zone classification task based upon the acoustic features of either: 1) tone frequency (TN-task), or 2) amplitude modulation rate with white noise carrier (AM-task). While tone frequency and AM rate form a continuous distribution, in the LTM tasks both TN and AM sounds were divided into three distinct zones (Low, Middle and High) with clear boundaries. The animals were trained with a positive reinforcement Go/No-Go paradigm, with one stimulus presented in each trial. They learned to approach a waterspout for reward (Go-response) when a sound from the Middle zone was presented, and to avoid a time-out by not licking the waterspout (No-Go response) after a sound from either the Low or High zone was presented. Animals were initially trained on the TN-task, and after reaching behavioral criterion, were then trained on the AM-task. After learning both tasks to criterion, acoustic probes (unrewarded) were presented during task performances. Four sets of probe testing were conducted, in which animals were engaged in: A) the TN-task with AM noise as probe sound, B) the AM-task with the TN as probe sound, C) the TN-task or D) the AM-task with a hybrid combination of AM and TN as probe sounds (i.e. AM modulated tones). The ferrets showed no influence of task-set on probe trial performance i.e. displayed similar discrimination behavioral response to sounds whether they were presented in a probe-free task, or if the same sounds were played as probes while the animals engaged in different task (testing-A,B). Our results show that animals were able to simultaneously activate both classification systems during a session with mixed stimuli. However, when the AM-TN combination (hybrid) probes were used, we found that the frequency feature dominated behavioral choice - no matter whether the animals were engaged in either the TN-task or AM-task (testing-C,D). These results suggest that the frequency feature has primacy over the AM feature during retrieval of the auditory LTM. We recorded from single units in the dlFC in the different task and test conditions in order to gain insight into the neural basis of these behavioral results and to explore how the frontal cortex encodes, represents, classifies and retrieves the associative meaning of different sensory stimuli during passive stimulus presentation and during performance of multiple tasks.

Title: Neural substrate for sound symbolism: Visual size judgment with combinations of voiced and voiceless plosives with a vowel “o” or “i”

Authors: ***S. ITAGAKI**[1], S. MURAI[2], K. I. KOBAYASI[2], J. AURACHER[3], H. RIQUIMAROUX[2];
[1]Doshisha Univ., Kyotanabe, Kyoto, Japan; [2]Grad. Sch. of Life and Med. Sci., Doshisha Univ., Kyoto, Japan; [3]Konan Univ., Kobe, Japan

Abstract: The sound symbolism is argued to help language acquisition and is possibly related to language evolution. In most of the previous psychology and linguistics researches, stimuli were presented visually with alphabets, and subjects directly answered the impression of the sound. This study had two goals, 1) verifying whether sound symbolism could be observed even when the sound stimulus was presented aurally, 2) establishing a behavioral paradigm applicable to functional magnetic resonance imaging (fMRI) research. In this experiment, we focused on sound symbolism in visual size. Subjects were all right-handed Japanese native speakers, and they were required to answer visual size difference between standard and target stimulus. Visual stimuli were a gray circle on black background LCD screen, and had 1 type of standard and 6 types of target. Target size was either smaller or bigger than the standard by ±5%, ±10%, or ±20%. Sound stimuli were /bobo/ and /pipi/, and were assumed to have impression of “bigger” and “smaller” respectively, according to previous researches. Congruent trials were defined as those where circle sizes were correlated with the impression of accompanying sounds, and incongruent trials were with opposite stimulus contingency. As a result, reaction times in incongruent condition were longer than congruent condition. Moreover, reaction time differences (= congruent versus incongruent) in 5 % size difference condition is smaller than 10% and 20% size difference condition. These results suggest that sound symbolism does occur even when the sound stimulus was presented aurally. We are currently investigating neural substrate of the sound symbolism in MRI using the same behavior paradigm. The reaction times in incongruent condition under MRI scan were longer than in congruent condition; and the difference of reaction time was longer as visual size difference got greater. In addition, analysis of MR signal showed a steady activation of auditory cortex during the presentation of standard stimulus. These data demonstrate that our paradigm is able to use for fMRI study. However, the blood flow in brain did not appear to differ between congruent condition and incongruent condition across subjects; MRI imaging results shows that the location and amount of activity is different by subjects, suggesting the neural substrate of the sound symbolism could vary between individuals. We will also discuss relationships between the brain differences and individual behavioral differences.

Title: A brain system for auditory working memory

Authors: ***S. KUMAR**[1], S. JOSEPH[2], P. GANDER[3], N. BARASCUD[4], A. HALPERN[5], T. D. GRIFFITHS[1];
[1]Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Inst. of Cognitive Neurosci., London, United Kingdom; [3]Human Brain Res. Laboratory, Dept. of Neurosurgery, The Univ. of Iowa, Iowa City, IA; [4]UCL Ear Inst., London, United Kingdom; [5]Dept. of Psychology, Bucknell Univ., Lewisburg, PA

Abstract: We examined the human brain system for auditory working memory: the process of holding sounds in mind over seconds. Neural activity was measured using fMRI data acquired at 3T. 16 human subjects listened to a pair of tones followed by a visual cue instructing them to remember one tone after which they were required to maintain that tone for 16s before they were required to compare the remembered tone with a test tone. During the maintenance period, when no sound is present, sustained activation in individual voxels was observed in belt homologues in auditory cortex (planum temporale and lateral part of Heschl's Gyrus, HG). Sustained activity was also observed in hippocampus and frontal regions including inferior frontal gyrus (IFG). Multivoxel pattern analysis (MVPA) showed that although activity in most voxels in HG was subthreshold, patterns of activity in it could distinguish which of the two tones subjects were maintaining in memory. Above chance classification of maintained tones from patterns of neural activity was also observed in the left IFG. Functional connectivity analysis using psycho-physiological interactions (PPI) demonstrated long-range connectivity between posterior auditory cortex and both hippocampus and inferior frontal gyrus during the maintenance period. Our data suggest a system for auditory working memory in which specific representations in the auditory cortex are kept active during the maintenance period by projections from the higher order areas in hippocampus and inferior frontal gyrus. This role of hippocampus in working

memory is in accord with the emerging idea that its mnemonic role is not confined to episodic memory.

Title: White matter microstructure correlates with sensorimotor synchronization

Authors: ***T. BLECHER**[1], I. TAL[1], M. BEN-SHACHAR[1,2];
[1]The Leslie and Gonda Multidisciplinary Brain Res. Ctr., [2]Dept. of English Literature and Linguistics, Bar Ilan Univ., Ramat Gan, Israel

Abstract: Sensorimotor synchronization to an external rhythm is a developed ability in humans, particularly evident in dancing and singing. Audio-motor synchronization likely relies on direct or indirect connections relaying information between the auditory and motor brain systems, but the exact pathways that mediate this ability have not been identified to date. The goal of this study is to examine the contribution of fronto-temporal and callosal connections to specific measures of sensorimotor synchronization. Twenty neurotypical adults were recruited for this study (age range 19-40, 9 males). Each participant underwent behavioral and MRI measurements at 3T. Rhythmic synchronization was evaluated via a finger tapping task, in which the participants were asked to tap along with an auditory metrically structured rhythm using their right hand. The meter of the auditory stimulus changed several times during each session and participants had to adjust their tapping pattern to it. For each participant, we quantified the negative asynchrony between the motor taps and the auditory stimuli, as well as the time it took to resynchronize with an altered meter. Using diffusion MRI and deterministic tractography we identified the bilateral arcuate fasciculus, the temporal and the frontal segments of the corpus callosum (CC). We found significant correlations between negative asynchrony and fractional anisotropy (FA) in the temporal-CC and in the left (but not right) arcuate fasciculus. In addition,

FA in the motor-CC correlated with the mean time to resynchronize with an altered meter. To our knowledge this is the first demonstration that diffusivity parameters of white matter tracts are selectively associated with specific audio-motor synchronization measures. We propose that left fronto-temporal fibers are involved in ongoing comparison between motor programs and auditory input, in order to optimize synchronicity between them. Resynchronizing with a new meter engages frontal callosal connections, perhaps involved in inhibiting the automatic tapping to the old meter and switching to a new perceived meter. Our findings offer a possible explanation for recent reports of impaired sensorimotor synchronization in children with developmental speech and language impairments. This association may stem from the reliance of sensorimotor synchronization on the same pathways involved in language skills such as phonological awareness.

Title: Object-based sound signal classification

Authors: *Y. LIM, J. CHOI;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Most sound recognition method often begins with the acoustic feature vectors that are obtained from the spectral amplitude of sound signal. Although several studies have shown the importance of the phase in speech coding and its benefit for improving the performance of the recognition system [1]-[4], spectral phase information has been neglected. Recently, we have proposed an object-based time-frequency representation in which the elementary units are adaptive contours that define the phase coherent areas in time-frequency plane [5]-[7]. From simple static signals to natural sounds such as birdsong, we have shown that this method can adaptively represent signals, such that individual components of a sound stream are represented in their own natural time-scales, or bandwidths. Here, we introduce a new method for sound

signal classification with the object-based acoustic feature vector that does not take account of spectral amplitude of signal. In the method, statistically significant contour objects from multiple analysis parameters are used to build an object-based acoustic feature vector, which represents the temporal transition of analysis parameters for the selected objects. We have applied the proposed method to represent the various kinds of sound in our natural environment such as human scream, dog, and so on. Since there is no amplitude information involved in the recognition process, we believe that this new forms of object-based acoustic feature vector could allow for the construction of a amplitude invariant recognition system. Finally, we speculate that neural auditory perception may involve a similar feature selection process by utilizing a parallel and redundant computations along the auditory pathway. [1] A. C. Title: An acoustic discrimination task can be used to monitor psychical stress and enhanced cognitive demands in hearing impaired people

Authors: C. GORF[1], R. HUONKER[1], E. EMMERICH[2], *F. RICHTER[2];
[1]Univ. Hosp. Jena, Biomagnetic Center, Germany; [2]Univ. Hosp. Jena, Jena, Germany

Abstract: Hearing impaired people complain of psychical stress that is enhanced by listening or by solving auditory recognition tasks. An increased level of psychical stress is assumed to

contribute to the extra-aural effects of noise, i.e. increased heart rate, hypertension or disturbances in the endocrine system. Here we wanted to establish a paradigm to test whether psycho-vegetative parameters and central processing of auditory signals are changed in hearing impaired people and whether these changes are aggravated if auditory signals are masked by noise. In two groups of young adults (one group normal hearing, 20 participants; one group with moderate hearing impairments above 20 dB SPL in the frequency range of 3-4 kHz, 16 participants) we recorded the magnetoencephalogram (MEG) and auditory evoked magnetic fields in order to analyze the distribution of the sources and to perform a wavelet analysis. We recorded the classical EEG, the electrocardiogram, arterial oxygen saturation and breathing frequency. As a marker for psychical stress we measured the concentration of cortisol in the saliva prior to and after the experiments. Auditory stimuli were tone pips with slightly modified frequencies presented at an intensity of 65 dB SPL. In a “one back task” the subjects had to decide, whether the next to last pip had a higher or lower frequency than the last pip, and correct responses were rewarded. In a second series the tone pips were overlaid by random noise and the same task was performed. In the hearing impaired group the detection level for higher versus lower tone pips was significantly worse, but error rates and reaction times were lower than in normal hearing people, thus indicating a higher alert level. The rates of missed answers were higher, and mean EEG-frequency at rest shifted to higher frequencies in the alpha range in the hearing impaired group. In this group the heart frequency was higher even at rest but did not further increase during the auditory task. In hearing impaired participants the content of cortisol in the saliva at rest was higher than in the control group and remained at still higher levels during the auditory task. We conclude that hearing impairment per se induces psychical stress at rest and in workaday life, and this stress enhances the cognitive demand during auditory tasks in profession and leisure activity. This higher mental load has to be considered in employment medical care particularly with regard to hearing impairment.

Title: Combined effects of frequency and location differences on auditory streaming

Authors: J. LEE[1], S. BENNUR[1], Y. I. FISHMAN[2], *Y. E. COHEN[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Albert Einstein Col. of Med., Bronx, NY; [3]Dept. Otorhinolaryngology-Head Neck Surgery, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: A fundamental aspect of hearing is the perceptual organization of time-varying acoustic inputs to form auditory objects corresponding to sound sources in the environment (i.e., “auditory scene analysis”). One process contributing to auditory scene analysis involves the integration or segregation of sequential sound inputs based on acoustic cues such as frequency; this is a phenomenon known as auditory streaming. Another process utilizes spatial cues to infer auditory objects based on their location. Whereas many studies have separately examined auditory streaming and sound localization, few studies have tested how these two processes interact in auditory scene analysis. Here, we examined this issue by conducting a series of psychophysics experiments in human subjects aimed at identifying the relationship between auditory-streaming cues, sound localization, and auditory scene analysis. Specifically, we presented sequences of alternating tone bursts that varied in frequency, location, and sound level. Subjects were asked to report when they heard a deviant louder tone burst. We varied task difficulty by changing either the frequency difference between the tones, the spatial separation between the tones, or both. To our knowledge, this is the first human psychophysical study to examine the interactive effects on auditory streaming of three fundamental acoustic cues used in auditory scene analysis: differences in frequency, azimuth, and intensity.

Title: Temporal dynamics of processing task-relevant and irrelevant sound feature changes

Authors: S. PUSCHMANN[1], R. J. HUSTER[2], *C. M. THIEL[1];
[1]Univ. of Oldenburg, Oldenburg, Germany; [2]Univ. of Oslo, Oslo, Norway

Abstract: Previous fMRI studies demonstrated change-related activations in human auditory cortex but also in frontal and parietal brain regions (Sabri et al., 2011). Due to its low temporal

resolution, fMRI can, however, not capture the temporal dynamics of the activation spread across the different brain regions. The interplay of auditory sensory regions with fronto-parietal brain regions during deviance processing has therefore not been investigated in detail. We aimed to solve this issue by concurrently measuring fMRI (3T, TR=1.5 s) and EEG (64-channel). We used an auditory stimulus categorization task, in which participants (N=24, right-handed, normal-hearing) had to sort successively presented complex tones (mean SOA = 1,500 ms) via button press into one of two stimulus classes, either depending on the fundamental frequency (F0 = 500/630 Hz) or the stimulus duration (150/300 ms). The categorization rule was randomly switched after variable delays of 12 to 48 seconds as indexed by a visual cue. Functional MRI responses were analyzed for task-relevant and irrelevant frequency changes. Change-related activity was found in secondary auditory cortex, but also in the superior parietal lobe, the temporo-parietal junction, the inferior and medial frontal gyrus, the frontal eye fields, and the insula. BOLD responses in the superior parietal lobe, the inferior frontal gyrus, and the insula were increased for irrelevant as compared to task-relevant changes, whereas no differences were observed in any of the other brain regions showing change-related responses. EEG source reconstruction (sLoreta) was used to extract the time course of neural activity from all brain regions showing change-related activity in fMRI. An analysis of source activation peak latencies revealed that activation spreads from auditory sensory areas and parietal brain regions to the insula and subsequently to inferior and medial frontal gyrus, before re-activating parietal regions and auditory cortex. Supporting the fMRI results, differing response amplitudes between behaviorally relevant and irrelevant changes were evident in the insula and, later, in the superior parietal lobe. Our data show a propagation of change-related activity from auditory sensory areas into parietal and then frontal brain areas of the dorsal and ventral attention network. This finding complements previous work on auditory attention switching showing similar spatio-temporal dynamics (Green et al., 2011). First relevance-related differences emerged at the level of the insula, supporting the view that this structure is involved in evaluating the behavioral relevance of sensory input (Menon & Uddin, 2010).

Engin., Johns Hopkins Univ., Baltimore, MD; [6]Dept. of Neurosurg., Chinese PLA Gen. Hosp., Beijing, China

Abstract: The discrimination and recognition of different categories of sounds are assumed to be processed by functionally specialized cortical areas. However, the specific locations of these areas and the neural mechanisms underlying sound discrimination and recognition are largely unknown. We used both electrocorticographic (ECoG) and functional magnetic resonance imaging (fMRI) techniques for brain activity recording. Five different categories of voice and non-voice complex sounds (including voiced speech, scrambled voiced speech, non-speech voice sounds, animal vocalizations and natural sounds) were used to investigate the roles of various cortical areas in processing sound categories. Our results revealed potential hierarchical organizations of sound category processing. Neural signals recorded from individual ECoG electrodes in five epilepsy patients showed different selectivity to distinct sound categories. After mapping the ECoG signals (60-140Hz) onto the average brain surface, we identified four responsive sites in the left hemisphere (anterior STG, middle STG, posterior STG and middle pre-central areas) and three responsive sites in the right hemisphere (anterior STG, middle STG, posterior STG) that exhibited sound category selectivity. Furthermore, using peak latency and Granger causal connectivity analysis (GCCA), we observed a progression of cortical activity corresponding to sound category from middle STG to anterior STG and from middle STG to posterior STG, respectively. More specifically, we found anterior STG of the left hemisphere only responded to Chinese voiced speech, which may indicate its involvement in the processing of lexical information. We also found the activation of middle pre-central areas in the left hemisphere, which may indicate the implicit transformation of acoustic representation to sensorimotor representation. These findings suggest a potential hierarchical processing of sound category in the human brain.

Title: Perceptual restoration of missing speech sounds in human auditory cortex

Authors: *M. K. LEONARD[1], M. J. SJERPS[3], M. O. BAUD[2], E. F. CHANG[1]; [1]Neurolog. Surgery, [2]Neurol., UCSF, San Francisco, CA; [3]Linguistics, UC Berkeley, Berkeley, CA

Abstract: Humans rarely hear speech under ideal listening conditions. Yet even in noisy environments, listeners can understand spoken input, and may even be unaware that segments of the signal are not physically audible. The phoneme restoration effect is a robust phenomenon in which the acoustic signal for a phoneme in a word or sentence is removed from the speech stream, and replaced by a non-speech signal like broadband noise. Rather than perceiving a gap in the speech signal, listeners report hearing the missing phoneme, and are typically unable to report which sound was replaced. This phenomenon is central to the debate over whether speech perception networks utilize feedback mechanisms to alter lower-level representations based on higher-order knowledge in real time. We recorded neural activity directly from the surface of the brain in human subjects implanted with multi-electrode arrays as part of their treatment for medically refractory epilepsy. Participants listened to words where one phoneme was replaced with broadband noise, and the original versions of those words. The missing phoneme could restore to only two sounds to create real English words (/fæ#tr/ restores to “factor” or “faster”), and listeners reported which word they heard on each trial. Despite hearing the same physical stimulus (/fæ#tr/), subjects reported different percepts on individual trials. Superior temporal gyrus electrodes showed responses to noise trials that matched listeners’ subjective perception. For example, when subjects reported hearing the word “factor”, the neural response to the noise closely matched the neural response to the plosive /k/ when subjects heard the original stimulus, /fæktr/. Across lateral temporal and frontal lobe electrodes, perception-matched responses to

noise stimuli occurred during the same time window that showed differential responses to the original phonemes (/k/ vs. /s/). Stimulus spectrogram reconstruction revealed that neural populations represented the spectrotemporal features of the perceived phoneme, indicating online warping of the acoustic representation. Finally, pre-stimulus fronto-temporal neural activity predicted subsequent perception, suggesting both bottom-up and top-down causal influences on subjective experience. Resilience to acoustic occlusion is a fundamental component of speech perception in natural conditions. These results demonstrate that missing acoustic content is not simply inferred from contextual cues, but is created in auditory cortex during ambiguous input. This provides direct evidence for interactive models of speech perception, in which lower-level representations are altered online.

Title: Sensorimotor representations in the language network during sentence repetition

Authors: ***K. MÜSCH**[1], T. A. VALIANTE[2], K. HIMBERGER[1], C. J. HONEY[1];
[1]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Div. of Fundamental Neurobio., Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: Motivation: Sensorimotor response patterns are observed in both left and right hemispheres during basic linguistic processes, such as phoneme perception and production (Cogan et al. 2014). Why are joint sensory and motor responses observed during perceptual and productive aspects of language? One fundamental aspect of real-life language is its temporally extended structure, and higher-order sensory and motor systems may support language comprehension by organizing and integrating sequential patterns of information over many seconds of time. To investigate the role these higher-order systems in the process of temporal integration, it is important to map the spatial distribution and functional signatures of sensory and motor response patterns during temporally extended, meaningful language perception and

production. Methods: We recorded electrocorticographic (ECoG) signals from the lateral surface of the human cerebral cortex, in seven patients with pharmacoresistant epilepsy. Participants performed a sentence repetition task: on each trial (i) two sentences were presented sequentially, (ii) participants silently rehearsed the second sentence, and (iii) finally they repeated the second sentence aloud. To estimate activity of neuronal populations beneath each electrode during task performance, we measured fluctuations of broadband power (70-200 Hz) in the voltage trace. Results: During the initial perception of the sentence, we observed bilateral responses both in sensory regions (the superior temporal gyrus) as well as the motor system (dorsal motor and premotor cortices). During the silent rehearsal phase, we observed that (i) the dorsal motor and premotor activations were augmented by recruitment of ventral motor sites; and (ii) the activity in the superior temporal gyrus was shifted posteriorly towards lexico-semantic regions. Finally, during repetition, activity was focused in bilateral dorsal motor and premotor cortex. Conclusions: These results suggest that the representation of temporally extended information in natural linguistic contexts is supported by higher-order sensorimotor circuits within dorsal and ventral precentral sites as well as by circuits in the posterior temporal cortex. Our findings complement prior observations of sensorimotor transformations supporting phoneme production and perception, and extend them to the context of temporally extended linguistic perception and production. Title: Temporal ensemble coding in sub-second sensory events: simultaneous EEG and fNIRS signatures

Authors: *L. CHEN[1,2], L. GUO[3], H. YILTIZ[1], M. BAO[3];
[1]Peking Univ., Beijing, China; [2]Key Lab. of Machine Perception (Ministry of Education), Peking Univ., Beijing, China; [3]Inst. of Acoustics, Chinese Acad. of Sci., Beijing, China

Abstract: For decades, investigations into the encoding of temporal precision have mainly focused on the paradigm of direct perceptual estimation with two paired sensory events. Modality temporal precision hypothesis states precisions of temporal processing differ across visual and auditory modalities, with the former higher and latter lower. The present study examined the ensemble coding towards a sequence of sensory events containing multiple sub-second inter-intervals. We implemented two experiments. In Experiment 1, after hearing a sequence of sound beeps (5 sounds, with mean inter-interval of 600 ms), participants made perceptual estimation with respect to whether the time interval between the last beep of the sequence and the target stimulus (beep or visual flash after the sequence) was shorter or longer than half, sharp or double 'mean' interval of the preceding inter-intervals of sound beeps. In Experiment 2, immediately after the preceding sound sequence, participants produced half, sharp or double 'mean' interval instead. The results have shown general over-estimation of the mean interval for multiple sensory events. Importantly, in both experiments, variances of estimated interval (hence the 'encoding') for the sharp mean intervals were larger than those in 'half' and 'double' conditions, although our brain embraces remarkable ability of temporal ensemble coding. Corresponding to the behavioral tasks, we recorded simultaneously EEG signals and brain activities by functional Near-Infrared-Spectroscopy (fNIRS). In prefrontal areas, when the target stimulus was auditory beep, the estimation of target interval elicited more negative going ERPs than the visual flash target did, indicating the encoding of auditory interval was more precise and but more task-demanding for processing. Moreover, the sharp-cycle sampling led to more negative contingent negative variation (CNV) components than the half-cycle and double-cycle samplings did, and the changes of concentration of deoxyhemoglobin (HbR) was largest in sharp-cycle sampling condition.Taken together, the results indicate that characteristics in temporal ensemble coding of sub-second sensory events could be captured by EEG and fNIRS signatures.

Title: Perceived timing of multisensory events during a fall

Authors: *M. BARNETT-COWAN, K. DUGGAN, J. LUPO;
Dept. of Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: About one-third of seniors fall each year, with hip fractures being the most common fall injury and about 20% of injury-related deaths among seniors can be traced back to a fall. The current clinical paradigm is to assess unisensory function (e.g., visual acuity), and correct unisensory impairment (e.g., corrective lenses), with the intent of preventing falls. However, it may be that the clustering of visual impairment with other sensory impairments and/or the way the central nervous system (CNS) integrates multisensory cues differently during aging is what puts adults in later life at a higher risk. The CNS receives information about the environment from all the senses. To safely interact with the environment, the CNS must quickly make sense of this converging multisensory information in order to form a reliable and accurate percept with which to guide decision-making and behaviour. As we age, however, natural changes occurring in the CNS affect the way the senses provide accurate and reliable information about the world in timely fashion. While it is well understood that the senses become less sharp as we age, how the CNS continues to integrate multisensory cues with unreliable sensory information available in later life is less clear. Older adults have trouble separating multisensory events in time, an observation that cannot be entirely accounted for by an age-related reduction in unisensory detection thresholds, potentially explaining why many sensory-related challenges experienced in later life (e.g., decision-making, communication, balance control) persist despite the use of corrective devices designed to address unisensory loss. For example, it is relatively unknown how conscious awareness of sensory processing changes during a fall. Common anecdotal reports of falling suggest that people often report distortions in their perception of time with little to no recollection of what occurred during the fall. Our work has previously shown that the perceived onset of self-motion is slow compared to the other external sensory events. Here I will review recent studies focused on the perceiving timing of multisensory events during a fall. The results show perceptual delays of fall onset and distorted duration estimation that further change with age. These results and future work will be discussed in the context of developing new falls prevention assessment techniques to help prevent falls in later life.

Title: Audiovisual integration in cochlear implant users

Authors: *I. BUTERA[1], R. A. STEVENSON[3], R. H. GIFFORD[2], M. T. WALLACE[1]; [1]Vanderbilt Brain Inst., [2]Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN; [3]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Cochlear implants (CIs) are highly successful neuroprosthetic devices that can enable remarkable proficiency in speech comprehension. However, most CI users still struggle to communicate in noisy environments. Audiovisual integration is known to play an important role in boosting speech intelligibility in noise, yet clinical evaluation of a user's proficiency with a CI is typically restricted to auditory-only measures. The purpose of this study is to assess audiovisual integration in children with CIs and relate this ability to other measures of auditory and visual perception and speech recognition. Participants included 15 CI users and 15 age-matched controls between 6 and 18 years old. Measures included an audiovisual speech-in-noise task, the McGurk Illusion, and psychophysical assessments of audiovisual temporal acuity using either a complex audiovisual stimulus (i.e. the recorded utterance of the syllable "ba") or a simple audiovisual stimulus (i.e. a flashed circle and 1kHz tone pip). By varying the stimulus onset asynchrony (SOA) between the respective auditory and visual components of these pairings and having subjects perform a simultaneity judgment, we are able to define a subjective "temporal binding window" of audiovisual integration. We hypothesized that temporal acuity and the fusion of auditory and visual speech tokens would differ between CI users and controls and generalize to measures of speech in noise intelligibility. Our data reveal four preliminary findings: (1) significant differences in the SOA at which perceived simultaneity peaked (i.e., the point of subjective simultaneity) for the simple audiovisual stimulus (62 ms for CI v. 22 ms for control; $p=0.02$), (2) no significant group differences in the width of the temporal binding window with either simple or complex audiovisual stimuli, (3) decreased reports of the fused, illusory token in the McGurk task for CI users (31% v. 75%; $p=0.01$), and (4) a strong correlation between the report of fused, illusory tokens in the McGurk task with the percentage of correctly identified phonemes in an audiovisual word recognition task presented at a 0dB signal-to-noise ratio ($r^2=0.64$, $p<0.01$). Taken together, these results suggest a greater visual bias

in perception at multiple levels of sensory processing in CI users and highlight practical benefits for enhancing audiovisual integration in realistic listening environments.

Title: Crossmodal interactions in the timing of a visual event: An EEG study

Authors: *H. KAFALIGONUL[1,2], U. KAYA[3];
[1]Natl. Magnetic Resonance Res. Ctr. (UMRAM), Bilkent Univ., Ankara, Turkey; [2]Interdisciplinary Neurosci. Program, Bilkent Univ., Ankara, Turkey; [3]Informatics Institute, METU, Ankara, Turkey

Abstract: The integration of information from different senses is central to our perception of the world including the fundamental attributes of space and time. Audiovisual interactions have been particularly well studied in this context and various illusions have demonstrated strong influences of audiovisual interactions on our final perception (Chen & Vroomen, 2013). An interesting phenomenon is temporal ventriloquism, in which sounds drive the perceived timing of visual events. Even though temporal ventriloquism has been well studied at the perceptual level, the neural processes underlying auditory influences on visual timing are still unknown. In the current study, we investigated the neural correlates of temporal ventriloquism by collecting behavioral and EEG data in tandem. During the experimental sessions, a brief visual bar (50 ms duration) was presented either on the right or the left of a central fixation point. The visual stimulus was accompanied by an auditory click (20 ms duration) with varying stimulus-onset asynchrony (-160 ms < SOA < 120 ms). The auditory click was introduced either before

(SOA<0) or after (SOA>0) the visual bar. Observers (n=12) were asked to report the location of the visual bar as soon as it was seen. As expected by temporal ventriloquism, the reaction times required to discriminate the location of visual stimulus were significantly modulated by auditory timing. Reaction times increased linearly as the SOA values were increased. In agreement with recent reports (e.g., McDonald et al., 2013), the auditory click elicited ERPs over early visual cortex (occipital electrodes). Moreover, interactions (mostly super-additive) between auditory and visual responses were observed and the magnitude of these interactions varied with SOA. Time-frequency analysis revealed that the audiovisual interactions led to an increase in 4-12 Hz (theta and alpha bands) power when the SOA value was between -80 and 80 ms. More importantly, for this range of SOA values, we also found that changes in the temporal dynamics of 4-12 Hz power that paralelled behavioral data: the latency was increased linearly as the SOA was increased. Together, our results, in combination with accumulating evidence (Naue et al., 2011; Romei et al., 2012), support an important role for low-frequency oscillations in crossmodal interactions at early stages of perceptual processing.

Title: Electrophysiological correlates of performance variability in multisensory detection

Authors: *A. THELEN[1], M. M. MURRAY[2,3], M. T. WALLACE[1];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Dept. of Clin. Neurosciences and Dept. of Radiology, The Lab. for Investigative Neurophysiol. (The LINE), Vaudois University Hospital center of Lausanne, Switzerland; [3]Ctr. for Biomed. Imaging (CIBM) of Lausanne and Geneva, Electroencephalography Brain Mapping Core, Lausanne, Switzerland

Abstract: Multisensory facilitation of neuronal and perceptual responses has been extensively demonstrated over the past decades. Generally, these studies report averaged responses derived

from a group of participants, which can conceal substantial between- and within-subject variability in the processing of audiovisual information. Little work has focused on better understanding the brain bases for trial-by-trial differences in audiovisual perception. In the current study, we investigated the neural correlates of trial-by-trial perceptual variation, within the context of a detection task. Participants were asked to detect visual targets (presented alone or in combination with a tone), and to indicate their location (i.e., central vs. peripheral visual field). Response accuracy and reaction times were collected for each trial. Concurrently, high-density EEG recordings were carried out, in order to identify differences in both response strength (i.e., global field power) and neural generator configuration (i.e., topography) of the electrophysiological signals. Analyses focused on identifying differences associated with trials exhibiting multisensory perceptual facilitation compared to identical trials where no perceptual enhancement occurred, as well as detailing how this is affected by target location and stimulus structure (i.e., auditory vs. audiovisual). Preliminary findings suggest that audiovisual interactions within the peripheral visual field are dependent on visual target contrast polarity (i.e., bright vs. dark), leading to differential gains in the efficacy of stimulus processing (quantified as smaller speed-accuracy tradeoffs). EEG data analyses aim at understanding the neural network changes involved in the early, perceptual processing stages of multisensory events that determine the trial-by-trial speed-accuracy tradeoff observed at the behavioral level.

Title: Audiovisual spatiotemporal binding windows in depth

Authors: ***J.-P. NOEL**, M. WALLACE;
Vanderbilt Univ., Nashville, TN

Abstract: The integration of information across different sensory modalities is known to be dependent on the statistical characteristics of the stimuli that are combined. Namely, the closer in space and in time unisensory (e.g., visual, auditory) stimuli are from one another, the more likely they are to be integrated or bound. Recent psychophysical work has focused on the characterization of audiovisual ‘temporal binding windows’ by asking subjects to judge the simultaneity of paired auditory and visual stimuli presented at different stimuli onset

asynchronies. In this manner, an estimate of the temporal interval over which subjects are highly likely to perceive these as synchronous can be derived. However, the manner in which spatial features drive multisensory binding - and more specifically the characterization of 'multisensory spatial binding windows' analogous to temporal binding windows - is less well understood. Most importantly, an understanding of how multisensory temporal and spatial binding windows interact with one another is missing. Such information is crucial if we are to fully understand how dynamic stimuli in our world are integrated. In the current project we set out to define: 1) temporal, 2) spatial, and 3) spatio-temporal multisensory binding windows in the same subjects by offsetting audio-visual stimuli in either time, space, or both, and asking subjects to judge either their simultaneity, co-localization, or the occurrence of a single event. In the spatial domain, stimulus location was varied in the dimensions of azimuth, elevation, and depth. In the temporal domain, stimuli were separated by asynchronies ranging from 250ms to 0ms. Results reveal that while spatial binding windows enlarge as stimuli are move farther away from subjects, the opposite pattern is exhibited by the temporal windows. These results illustrate that the spatial and temporal filters through which the perceptual world is created are strongly interconnected, and that stimulus depth, whose processing is likely to be strongly modulated by the constructs of peripersonal and extrapersonal space, plays an important role in shaping these filters.

Title: Discrimination of auditory and audio-visual time intervals_an event-related potential study on effects of task difficulty

Authors: *E. HASUO[1], E. GONTIER[3], T. MITSUDO[2], Y. NAKAJIMA[2], S. GRONDIN[3]; [1]Fac. of Med. Sci., [2]Kyushu Univ., Fukuoka, Japan; [3]Univ. Laval, Québec, QC, Canada

Abstract: Discriminating short and long time intervals is easy when the beginning and the end of the intervals are marked by signals of the same sensory modality (intra-modal), but becomes much more difficult when they are marked by signals of different modalities (inter-modal). The

present study examined the neural correlates of such difficulty levels using event-related potentials. Time intervals were marked either by two auditory signals (AA) or by an auditory and a visual signal (AV), and there were two levels of discrimination difficulty (easy and difficult). A negative component (contingent negative variation), which is reported to reflect time perception, appeared at fronto-central sites during the interval presentation. This component was larger for AA than for AV, and was not influenced by discrimination difficulty. A principal component analysis was performed on data from all electrodes sites and all conditions. The first principal component was distributed over a wide area from fronto-polar to central sites with differences between modalities and difficulty levels appearing after 250 ms from the beginning of the time interval. The third principal component was distributed at parieto-occipital sites, and differences between difficulties within the AA condition appeared at around 300-500 ms after the termination of the interval. The second principal component had opposite tendencies between the fronto-polar and the central sites, and showed surprisingly similar time courses in the component scores for all conditions until the end of the time interval. The first and the third principal component seemed to capture differences in brain activity patterns between sensory modalities and difficulty levels, whereas the second principal component seemed to capture a common activity pattern related to the temporal processing independent of the sensory modalities.

Title: Non-symmetric auditory-visual interactions at perceptual and cortical levels in mice

Authors: ***T. DENEUX**, A. KEMPF, B. BRICE;
CNRS UPR 3293, Gif-sur-Yvette, France

Abstract: Although auditory responses have been reported in mouse primary visual cortex (V1), their computational and perceptual role in a multisensory context remains elusive. In particular, it is unclear whether specific multimodal information is channeled through these responses. To address these questions, we recorded neuronal populations in V1 using 2-photon imaging in

awake, GCAMP6-transfected mice, during 2 sec drifting gratings and looming or receding visual and/or auditory stimuli. Among 3,500 recorded V1 neurons, 25% responded to sounds. In contrast we did not find visually-responding neurons in the primary auditory cortex. A large part of auditory responses in V1 were non-specific onset responses and combined linearly with the visual responses, although 7% of the neurons exhibited non-linear bimodal summation properties and appeared to signal specific combinations of bimodal stimuli. Interestingly, auditory population responses correlated strongly with the nonspecific onset visual responses. To assess the perceptual impact of this cross-modal activity, we trained mice to discriminate between looming and receding disks in a head-fixed Lick/No lick protocol, first without sounds. Mice tended to lick on the onset of both visual stimuli, as predicted by the poor specificity of V1 onset responses, and learned to adjust their licking during the more specific phase of V1 responses (about 500 ms after onset). Interestingly, the initial unspecific licking behavior was spontaneously generalized to previously untrained sounds, reflecting the similarity of auditory and visual onset responses in V1, as we demonstrate using a simple computational model of the task. Altogether our results show that specific information about the multimodal context is present in V1, but that the first order impact of auditory signals on mouse visual representation and on perception in a simple task is a boosting of stimulus onset saliency. We also highlight that multisensory integration exhibits complex, non-symmetrical, interactions where one modality can dominate on another.

Title: Investigating the influence of visual deprivation on multisensory processing in the superior colliculus

Authors: *L. KURELA[1], J. KRUEGER-FISTER[1], M. WALLACE[2];
[1]Vanderbilt Brain Inst., [2]Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN

Abstract: Combining information from different sensory modalities is a prerequisite for navigation of the external world. The superior colliculus (SC) is a central hub for multisensory processing. Over half of the neurons in the intermediate and deep layers of the cat SC receive convergent information from two or more sensory modalities, and many of them transform these

different inputs. Developmental studies have shown that multisensory SC neurons mature gradually during early postnatal life. This maturation is critically dependent upon sensory experience, and elimination of visual experience via dark-rearing results in the inability of SC cells to integrate their multisensory input. Restoration of visual experience in adulthood has relatively minimal effects on multisensory processing in these animals, with most neurons still lacking integrative capacity and suggesting the presence of a sensitive period for multisensory experience. If such is the case, then changes in sensory experience only during adulthood should have little effect on multisensory processing. To examine this, cats were reared under normal sensory conditions until adulthood (i.e. for approx. 6 months) and then transferred to a visually deprived environment for an additional 6 months (6+6). Extracellular recordings of local field potentials (LFP) and multi-unit activity (MUA) were conducted using a 24-multichannel U-probe from the SC of these 6+6 animals, and compared with recordings from normally-reared (NR) and completely dark-reared animals (DR). These experiments revealed that although multisensory integration remains in intermediate and deep layer neurons following adult visual deprivation, less of these multisensory neurons are present. When comparing the integrative capacities of the neurons from 6+6 animals with those of NR and DR animals, substantial differences were found, most notably in the response amplitudes and response latencies to unisensory (visual, auditory) and multisensory stimulus presentations at both the LFP and spiking levels. Additionally, current source density (CSD) analyses showed laminar differences in processing between the three groups. Collectively, these findings show that adult (multi)sensory experience remains an important factor in the preservation of normal unisensory and multisensory processing in SC neurons.

Title: Neural and behavioural signatures of the temporal integration window for auditory and facial-tactile stimulation

Authors: ***J. M. ZUMER**, T. P. WHITE, U. NOPPENEY;
Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Synchrony between sensory signals is a fundamental cue indicating whether they were caused by a common source. Previous studies indicated that integration may occur directly between auditory and somatosensory cortices via oscillatory phase resetting, rather than through higher integration regions. Tactile stimulation to the face is particularly alarming and requires a fast decision if harmful. We sought to determine the effect of temporal synchrony between auditory and tactile stimuli to the face on behavioural measures and neural signatures measured by EEG. We presented audio-tactile stimuli (both 200ms duration) to young, healthy adults (N=25; 3 excluded). The tactile signal was the tip of a fibre optic cable, driven by pressurised air, presented to the left cheek. Sounds were delivered via foam in-ear inserts with plastic tubing; the auditory target was given a left bias through inter-aural amplitude (IA) cues and presented on top of constant, balanced-IA background (MRI) noise. Ten trial types were presented randomised: tactile alone, auditory alone, null stimulation, and 7 multisensory asynchronies (+/-500ms, +/-70ms, +/-20ms, 0ms). On day 1, participants were asked to respond as quickly as possible when they sensed stimulation in either modality. On day 2, 64-channel EEG data was recorded as participants passively received the same stimulation. The redundant target effect was found in reaction times (RT): participants responded faster to (near) synchronous multisensory compared to unisensory or +/-500ms asynchronous multisensory signals. We compared 1) the sum of a multisensory condition plus null versus the sum of auditory and tactile alone conditions and 2) multisensory conditions to each other, shifted appropriately. We observed multisensory integration effects in both evoked response potentials (ERP) and theta-band phase-locking (similar approach as Senkowski et al., 2007; Exp Brain Res) predominantly for asynchronies +/-20ms and +/- 70ms, indicating that auditory and tactile signals are integrated only within a specific temporal window. These effects emerged earlier (100-250ms) over sensory regions and later (250-400ms) over posterior regions. Furthermore, correlations over participants of the RT redundancy effect with the contrast of multisensory to unisensory ERPs were also found, indicating a trait stable over days. Neural indices, and behavioural trait correlates, of a novel auditory/facial-tactile paradigm revealed relevant evoked and phase-locked effects dependent on the critical window for temporal integration. This passive paradigm is well suited to future studies (e.g. asleep, motor/cognitive impairments).

Title: Differential visual modulation of auditory activity in cat A1 between supra- and infragranular layers

Authors: *J. KRUEGER FISTER[1], L. R. KURELA[1], A. R. NIDIFFER[2], T. A. HACKETT[2], M. T. WALLACE[2];
[1]Neurosci., [2]Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN

Abstract: Objects and events in our world are frequently specified by more than one sensory modality. Specialized regions within the brain are tasked with actively integrating these multisensory cues in order to facilitate behavior and perception. Traditional association regions in cortex receive convergent inputs from different thalamic and cortical sources and have been intensively studied for their multisensory processing capabilities. However, recent findings implicate that sensory-specific (i.e., unisensory) cortices can also be modulated by information from a different sensory modality. For example, neuronal responses within regions of auditory cortex are influenced by visual and somatosensory stimulation at the level of both spiking and local field potentials (LFP). Here we sought to expand upon these observations by examining visual influences on auditory responses in the primary auditory cortex of the cat (n = 3), with an emphasis on laminar differences that may provide important insights into multisensory modulatory networks. A 16 or 24 channel multilaminar electrode was advanced into primary auditory cortex (A1) and multi-unit (MUA) as well as LFP activity was recorded to visual only, auditory only, and combined audiovisual stimulation while stimulus location varied across azimuth and elevation. Although visual only MUA was rarely encountered, visual LFPs were robust and had similar activity onsets across all layers. Auditory and audiovisual LFPs were also stimulus location dependent and varied between cortical layers. When measuring peak activity, visual LFPs were maximum in infragranular (IG) layers while auditory and audiovisual LFPs peaked in supragranular (SG) and granular (G) layers. Multisensory interactions across the laminae strongly dependent on the magnitude (area under the curve) of the visual influences and the location of the stimuli. When collapsing across all tested elevations, stimuli at central locations elicited reduced audiovisual LFPs when compared to auditory LFPs in the SG layers, while audiovisual LFPs exceeded auditory LFPs in IG layers. With peripheral azimuths, the opposite held true. Findings when collapsing across all azimuths are less clear but suggest a general trend of decreased audiovisual LFPs in SG and increased audiovisual LFPs in IG laminae when contrasted to auditory LFPs. These results indicate that although visual influences into auditory cortex are broad across all layers, they have differential modulatory effects in SG and IG layers dependent upon stimulus location, hinting at potentially distinct processing strategies between networks involving cortical or thalamic loops.

Title: Exploring the role of synchrony in auditory-visual integration in ferrets and humans

Authors: ***G. P. JONES**, S. M. TOWN, K. C. WOOD, H. ATILGAN, S. DUNN, J. K. BIZLEY;
UCL Ear Inst., Univ. Col. London, London, United Kingdom

Abstract: Animals and humans integrate sensory information over time, and combine this information across modalities in order to make accurate decisions in complex and noisy sensory environments. Multisensory integration occurs at multiple levels within the brain, including within early sensory cortices. However, little is known about the perceptual consequences of early sensory integration in the context of multisensory integration and decision-making. To address this question we adapted a previously published audio-visual decision making task (Raposo, et. al. 2012). This required that subjects (ferrets and humans) accumulate evidence over time in order to estimate the average rate of trains of short auditory and/or visual events. Events were 20 ms white noise bursts or flashes and formed trains lasting 1000 ms. Throughout the event train the instantaneous event rates were varied using fixed “short” and “long” gap lengths (610/120 ms for humans, 50/230 ms for ferrets), meaning the accuracy with which the overall event rate could be estimated increased over time (subjects were unable to respond before the end of the presentation period). Rate discrimination was assessed in both unisensory auditory and visual conditions as well as in synchronous and asynchronous multisensory conditions. In the asynchronous multisensory condition event distributions (for the same rate) were allowed to vary between modalities, and/or a variable offset was added the stimulus onset time between the two modalities. As previously reported for rats and humans, humans’ performance improved in by a similar extent in the multisensory conditions, and was not greatly affected by event distribution asynchrony. In addition relative offsets (-50 to 50 ms) to stimulus onset times did not reduce

performance, and reaction times were significantly faster in the multisensory conditions. Ferrets exhibited a similar pattern of behaviour, with improved discrimination in both multisensory conditions. Trained ferrets were implanted with chronic electrode arrays allowing recording from auditory cortex (AC) during task performance. Given the prevalence of auditory-visual interactions documented in AC of the anesthetised ferret (Bizley et al., 2007) it seems likely that auditory and visual signals might be integrated in early sensory cortex during behaviour. Analysis will focus on how synchronous and asynchronous visual signals influence the representation of auditory events in AC via both spiking and local field potential activity, and whether neural correlates of improved multisensory discrimination can be observed in AC.

Title: Cross-modal interactions rescue temporally suppressed saliency of visual stimuli: A computational model

Authors: *G. GILLARY[1,2,3], E. NIEBUR[1,2,3];
[2]Solomon H. Snyder Dept. of Neurosci., [3]Zanvyl Krieger Mind/Brain Inst., [1]The Johns Hopkins Univ., Baltimore, MD

Abstract: In current models, visual saliency is computed independently for each image frame. However, both physiological and psychophysical evidence shows that object representations admit a level of permanence thereby causing interactions across time. For instance, recent psychophysical data (van der Burg et al, J. Exp. Psych HPP 34:1053-65, 2008) demonstrate that visual saliency also has a coarse temporal representation. Search for a visual target that by itself is found efficiently is made inefficient when the target image frame is embedded in a series of frames with salient distractors. If, however, the target frame co-occurs with a salient short tone

(or a short tactile stimulus; van der Burg et al, Neurosci. Lett. 450:60-4, 2009), search for the target becomes efficient. We interpret these results by assuming that the salient stimuli in the frames surrounding the target frame suppress the saliency of the target. Extra-visual stimuli presented simultaneously with the target then increase its salience, making it pop-out from its surround and resulting in efficient search. Here we present a model showing that cross-modal modulation of neural activity in early sensory areas can provide the precise temporal and spatial interaction that is necessary to increase the salience of the target visual stimulus. We do this by filtering each event through two layers, one with a slow and the other with a fast time constant of decay. The saliency read-out occurs in the layer with the longer time constant. Choosing the latter as about 200 ms, compatible with the time course of proto-object representation in extra-striate cortex (O'Herron and von der Heydt, Neuron 5:801-9, 2009), generates interference between subsequent frames, thereby suppressing the target's inherent saliency. Cross-modal modulation of the short time constant layer, but not the long time constant layer, at the time of target onset rescues its salience. Our model makes two important contributions. First, it extends saliency models (e.g. Itti et al, IEEE-PAMI 11:1254-9, 1998) to include permanence of proto-objects. Second, it shows that interactions between salient auditory or tactile events and early visual areas can provide temporally precise modulation of temporally broad representations in later areas.

Title: Enhanced tactile perception in musicians

Authors: *S. P. LANDRY, S. PAGE, F. CHAMPOUX;
Univ. de Montréal, Montreal, QC, Canada

Abstract: PROBLEMATIC: The perception of our environment is based on the integration of proximal and distal, or respectively egocentric and allocentric, sensory information. From a

sensory point of view, long-term musical training, which is essentially an enriched multisensory training environment, has been suggested to alter anatomical sensory regions and enhance behavioural sensory abilities. It has also been suggested that long-term musical training could have effects on the integration of multisensory information. However, no study has investigated the effects of musical training on sensory frames of reference. The crossed arm temporal order judgement (TOJ) task has been suggested to measure the role of vision, an allocentric sensory information, on a tactile, an egocentric sensory information, response criterion. OBJECTIVE: The main objective of this study is to determine the effect of long-term musical training on the crossed arm TOJ task. We hypothesise that musicians will be more influenced by information from the egocentric frame of reference in the crossed arm TOJ condition than control group participants. METHODS: 28 participants (14 musicians, 14 controls), matched for age and sex, were recruited for the present study. A TOJ task was used in which a conflict is induced between allocentric and egocentric response criteria. The two groups' average proportion of correct responses (PCD) scores were compared using a t-test. RESULTS: The performed analysis revealed a significant difference between PCD scores between groups ($p = 0{,}016$). DISCUSSION: These results suggest that long-term musical training alters the influence of conflicting information from egocentric and allocentric sensory frames of reference. Musical training, which requires individuals to have an enhanced sense of spatial limb position, appear to place greater importance on limb position in relation to the self, thus enhancing the egocentric frame of reference. Moreover, these results suggest a previously unreported effect of musical training on sensory frames of reference that could be used to explain previously reported altered multisensory ability in musicians.

Abstract: Divided attention affects behavioural performance due to interference from multiple brain processes [Luck et al. (2000), Driver and Noesselt (2008)]. During perceptual stage, sensory-specific cortices can be modulated by events of other sensory processes. For example, tactile or auditory discriminative performance can be enhanced in the presence of visual stimuli [Lovelace et al. (2003), Cardini et al. (2011)]. Stimulation to one sensory modality may silence another, thus enhance modality-specific processing for the latter. Interference can occur at subcortical (e.g. thalamic, superior colliculus) or cortical multisensory convergence zones (e.g. superior temporal sulcus, VIP/LIP in parietal lobe). However, neural mechanisms underlying these phenomena are unclear; specifically the difference in intracranial neural dynamics at sensory cortices between single- and multi-sensory stimulation conditions has not been well studied. It has been shown that neural excitation and inhibition co-tune at evoked and adaptation conditions [Zheng et al. (2012)]. Do they remain balanced under divided attention? Does attention modulate inhibition or does it affect both excitation and inhibition? By applying forepaw or visual stimuli preceding whisker stimulation on anaesthetised rodent, we investigate modulations of neural excitation and inhibition by divided attention within tactile modalities and between tactile and visual modalities. By pharmacological manipulation of neural inhibition [Bruyns-Haylett et al. (2014)] and further applying compartmental local field potential (LFP) models [Luo et al. (2014)], we are able to isolate excitatory and inhibitory components at multiple intracranial depths, thus showing their amplitude and latency modulation as a function of attention manipulation. Title: Crossmodal perceptual adaptation implies neuronal convergence of auditory and tactile frequency signals

Authors: *L. CROMMETT, A. PÉREZ-BELLIDO, J. M. YAU;
Baylor Col. of Med., Houston, TX

Abstract: We perceive temporal frequency information by audition and touch. Because these modalities reciprocally influence each other in frequency perception, temporal frequency channels appear to be linked across audition and touch. Auditory and tactile perceptual channels may be tied explicitly if common neural populations support auditory and tactile frequency processing. Adaptation paradigms have been used previously to infer neural tuning properties in psychophysical experiments. In a series of psychophysical experiments, we employed a crossmodal frequency adaptation paradigm to test the hypothesis that a common frequency-tuned neural population processes auditory and tactile frequency signals. Participants (n = 20) each performed a tactile frequency discrimination task in 3 experiment sessions. Each session began with an auditory adaptation period (180s) during which the participant received prolonged auditory stimulation (adaptation conditions with bandpass noise stimuli centered at 200Hz or 400Hz) or silence (control condition). After initial adaptation, participants performed trials of a 2AFC tactile discrimination task in which they judged which of two vibrations presented sequentially to their finger was perceived as being higher in frequency. Vibration frequencies ranged from 100-300Hz. We used a generalized linear mixed effects model (GLMM) to test whether auditory adaptation modulated tactile discrimination performance and whether this modulation was frequency-specific. Crossmodal adaptation significantly improved tactile frequency sensitivity when the spectral composition of the noise adaptor overlapped the tactile test frequencies. We implemented a simple and biologically plausible model that represents tactile frequency information with likelihood functions computed from a population of sensory neurons. By allowing auditory adaptation to modify the model's sensory neuron response characteristics, our model reproduced the frequency-specific crossmodal aftereffects. These psychophysical and modeling results support the hypothesis that auditory and tactile signals converge on a common frequency-tuned neural population.

Title: Decoding modality-specific and modality-invariant temporal frequency representations in the human brain

Authors: A. PEREZ-BELLIDO[1], *K. A. BARNES[2], M. TOMMERDAHL[3], J. M. YAU[1]; [1]Neurosci., [2]One Baylor Plaza, Baylor Col. of Med., Houston, TX; [3]Univ. of North Carolina, Chapel Hill, NC

Abstract: We perceive temporal frequency information by audition and touch. Traditional models of sensory cortex function segregate auditory and somatosensory information in modality-specific cortical systems, but temporal frequency processing for audition and touch may not be so independent. Auditory and tactile temporal frequency perception is closely linked and spatially overlapping regions of sensory cortex respond to auditory and tactile stimulation. These results may reflect common auditory and tactile frequency representations that are supported by shared neural circuitry. In the present study we combined functional magnetic resonance imaging (fMRI) and multivariate pattern analysis (MVPA) to characterize auditory and tactile frequency representations. In an event-related fMRI experiment, participants received auditory and tactile stimulation (75, 130, 195, 270 and 355 Hz) in separate scans as they performed an attention-demanding frequency discrimination task. This design enabled us to quantify BOLD signal changes and spatial activation patterns to identical stimulus frequencies presented separately by audition and touch. We trained linear support vector machines to classify stimulus frequency in whole-brain searchlight and ROI-based analyses. We sought to identify modality-specific frequency representations by training and testing our frequency decoder on data acquired from only the auditory or tactile scans (within-modality classification). We sought to identify common frequency representations by training the decoder on data from one modality and testing classification on data from the other modality (across-modality classification). Preliminary analyses indicate robust stimulus frequency decoding performance for both within-modality classification and across-modality classification. These preliminary results reveal modality-specific and modality-invariant temporal frequency representations in the human brain.

Title: Multisensory temporal processing in the inferior colliculus

Authors: ***A. R. NIDIFFER**, R. RAMACHANDRAN, M. T. WALLACE;
Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN

Abstract: The presence of a cue in one sensory modality can enhance the detection of and the speed of reaction to cues in another modality. Furthermore, the magnitude of this behavioral enhancement has been shown to be dependent on both the intensity and the temporal relationship of the unisensory components of the multisensory stimulus complex. It is well established that these behavioral enhancements occur over a restricted range of stimulus onset asynchronies (SOAs), within the so-called “temporal window of multisensory integration.” Prior neurophysiological work has shown that multisensory enhancement in the superior colliculus is dependent on the temporal relationship between the component unisensory stimuli. Additionally, visual cues have been shown to modulate the responses of auditory signals in the inferior colliculus and even elicit responses when presented alone. Despite this growing evidence for multisensory processing in a traditional component of the ascending auditory pathway, numerous questions remain about the nature of the visual influences on auditory responses in the IC. One of these questions is whether similar temporal constraints exist for these audiovisual interactions in the IC as have been detailed for the SC. To begin to answer this question, monkeys were trained in a focused attention paradigm to report the detection of an auditory cue via lever release. Brief bursts of broadband white noise at varying intensity levels were presented alone and in the presence of an irrelevant, low-intensity visual stimulus at several different SOAs, and responses from IC neurons were recorded and related to behavioral performance. Behaviorally, monkeys showed speeded responses in the presence of the visual cue, but only for a restricted window of SOAs. Auditory neurometric thresholds were found to change in the presence of the visual stimulus, and were typically above concurrently measured psychometric thresholds. Furthermore, visual modulation of auditory responses was found to be dependent upon the

temporal relationship of the irrelevant visual cue in a manner concordant with that found for the SC. Collectively, these results illustrate the relationship between neurometric and psychometric performance for IC neurons and auditory detection, and show that the temporal relationship between the auditory and visual signals in the IC is an important factor in how these signals are integrated.

Title: Perceptual training enhances temporal acuity for audiovisual speech

Authors: *M. A. DE NIEAR[1], P. B. GUPTA[2], M. T. WALLACE[1];
[2]Chem. and Biomolecular Engin., [1]Vanderbilt Univ., Nashville, TN

Abstract: The synthesis of information from different sensory modalities, termed multisensory integration, has been shown to alter behavior and affect higher order cognitive processes. The integration of auditory and visual cues is a particularly important process for the comprehension of speech. The temporal relationship between the auditory and visual components of speech is critical for their proper integration and binding, and has been characterized by constructs such as the temporal binding window ([TBW] i.e., the time interval within which auditory and visual stimuli are highly likely to be integrated or bound). Recently, several studies have examined the plasticity of the TBW and have shown a significant narrowing, but have only focused on low-level multisensory stimuli (visual flashes and auditory beeps). The present study explored whether perceptual training was capable of altering temporal acuity for higher order multisensory stimuli - audiovisual phonemic speech - in typically developed adults. The TBW for phonemic speech and low-level multisensory stimuli (visual flashes and auditory beeps) was measured

using a simultaneity judgment (SJ) task prior to and following feedback training. Training constituted receiving trial-by-trial visual feedback in the form of a green check mark or red X while completing the SJ task during one hour of training on four consecutive days. To control for exposure to phonemic speech stimuli, an additional group of participants completed a passive exposure paradigm that required them to complete an oddball detection task while audiovisual stimuli were presented at identical SOAs for the groups receiving perceptual training. In agreement with previous findings, perceptual training enhanced temporal acuity for low-level stimuli as indexed by a narrowing of the TBW. Novel to this study, perceptual training also enhanced temporal acuity for audiovisual phonemic speech as indexed by a narrowing of the TBW while TBW narrowing was not observed for participants in the exposure group. Changes in temporal acuity observed following perceptual training were exclusive to either speech or low-level stimuli, suggesting that the perceptual training paradigm used by this study did not enhance general temporal acuity for multisensory processes. Future work will explore whether perceptual training for phonemic speech elicits generalized behavioral benefits for speech comprehension. Overall, the results suggest that perceptual training is capable of enhancing temporal acuity for audiovisual speech in adults.

Title: Connecting individual differences in sensory and cognitive function in healthy aging

Authors: ***S. H. BAUM**[1], R. A. STEVENSON[4], P. A. NEWHOUSE[2], M. T. WALLACE[3]; [1]Vanderbilt Brain Inst., [2]Psychiatry, [3]Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN; [4]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Traditional aging research has focused on changes in domains such as sensory function and cognitive performance, with performance declines noted on a number of tasks in both domains. However, little work has been done to link across these seemingly disparate domains. Given that incoming sensory information forms the building blocks for higher order cognitive processing, we hypothesized that individual differences in sensory function would be correlated with measures of cognitive processing. Healthy older adults (ages 45-70) completed a battery of sensory and cognitive tasks across two laboratory visits. The sensory task battery included measures of auditory temporal acuity (auditory Temporal Order Judgment [TOJ]), visual temporal acuity (visual TOJ), as well as a series of measures of audiovisual (AV) integration, including an AV TOJ with both flash/beep and speech stimuli, Simultaneity Judgment (SJ) with both flash/beep and speech stimuli, the sound induced flash illusion (SIFI), and the McGurk illusion. The cognitive task battery included Critical Flicker Fusion (CFF), Choice Reaction Time (CRT), the Connors Continuous Performance Task (CPT), and the Buschke Selective Reminding Task (SRT). We found significant correlations within (*e.g.* temporal acuity on the flash/beep SJ task with temporal acuity on the speech SJ task for both auditory leading: $r = 0.75$, $p = 0.03$ and visual leading asynchronies: $r = 0.88$, $p = 0.004$) and across (*e.g.* greater reaction time variability in the CPT with decreased susceptibility to the SIFI illusion, $r = -0.92$, $p = 0.02$) domains (Figure 1A). A hierarchical clustering analysis (Figure 1B) revealed both expected connections (*e.g.* clustering of the two AV illusions) but also interesting connections across domains (*e.g.* temporal acuity in the flash/beep TOJ task and relevant intrusions in the SRT). A rich characterization of both sensory and cognitive function may be able to create a unique profile for healthy older adults, which can be compared to clinical populations to determine what kinds of changes might be precursors to different aging pathologies.

Title: Speeded microstate transitions are associated with multisensory perceptual segregation

Authors: *D. M. SIMON, A. THELEN, M. T. WALLACE;
Vanderbilt Univ., Nashville, TN

Abstract: Multisensory integration is the process of combining information from multiple sensory modalities and has been shown to confer numerous behavioral and perceptual benefits. A primary determinant of multisensory interactions is the temporal relationship between paired sensory inputs, and the temporal binding window (TBW) is a probabilistic construct representing the interval of time in which there is a high likelihood of events occurring in close temporal proximity of being fused into a single perceptual event. The overall size of the TBW serves as a measure of multisensory temporal acuity, and large individual differences have been reported across studies. This indicates that the ability to segregate multisensory stimuli that are occurring in close temporal proximity into separate events is highly variable. Here we investigated the neural correlates of such perceptual segregation both within and between subjects using audiovisual stimuli and high density EEG recording. Whole brain topographic analysis revealed that differences in neural generator configuration during perceptual processing corresponded with both individual ability to segregate stimuli and perceptual outcomes. Individuals with narrow TBWs, and thus high ability to segregate stimuli with small temporal offsets into two events, had faster transitions to a sequentially second functional microstate. Within subject comparisons further indicated that faster transitions to a sequentially second functional microstate were associated with perceptual segregation for both auditory leading and visual leading stimuli. Further, overall duration of the second microstate was longer in individuals with superior temporal acuity and when stimuli were perceived as occurring separately. These results provide evidence that the latency of neural generator recruitment corresponds with perceptual outcomes during a multisensory temporal task.

Title: Multisensory processing within thalamocortical networks occurs by temporal coupling of neuronal firing and oscillatory activity

Authors: ***M. BIELER**, N. CICHON, K. SIEBEN, I. L. HANGANU-OPATZ; Developmental Neurophysiology, Inst. of Neuroanatomy, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Behavioral performance relies on optimal integration of information from different sensory modalities. Phase reset and power modulation of oscillatory activity have been identified as mechanisms underlying the integration of sensory inputs within interconnected primary somatosensory (S1) and visual (V1) cortices. However, the contribution of individual neuronal firing in these areas to multisensory interactions remains largely unknown. Moreover, the fast timing of these interactions suggests that already subcortical areas on the sensory tract, such as thalamic nuclei, might converge inputs from different sensory modalities. Here we assess the impact of uni- (light flash or whisker deflection) and bimodal stimulation (i.e. simultaneous light flash and whisker deflection) on neuronal firing and oscillatory activity within thalamocortical networks by performing simultaneous extracellular recordings from S1 and V1 as well as the corresponding thalamic nuclei, ventral posteromedial nucleus (VPM) and lateral geniculate nucleus (LGN), in juvenile rats *in vivo*. The identity of spiking neurons was assessed by feature-based clustering analysis. After bimodal stimulation the firing of pyramidal neurons in S1 significantly decreased when compared to unimodal stimulation. While both uni- and bimodal stimuli phase-locked the firing of pyramidal neurons in S1 and V1 to the corresponding gamma activity, the coupling between the firing in one primary cortex and theta-alpha activity in the other primary cortex was strengthened only after bimodal stimulation. Moreover, the preferred phase of firing for S1 neurons switched from the trough of network oscillations in V1 after unimodal stimulation to the peak of V1 network oscillations when bimodal stimuli were applied. Bimodal stimulation strongly modulated the neuronal firing of thalamic nuclei VPM and LGN. In line with their position on the sensory tract, the firing to bimodal stimulation in both thalamic nuclei occurred at a shorter latency when compared to S1 or V1. In contrast to the primary sensory cortices, thalamic firing was enhanced by bimodal stimuli. Taken together, temporal coupling of individual neuronal firing and oscillating population activity provides the framework for cross-modal processing within thalamocortical networks.

Title: fMRI adaptation reveals population tuning for tactile and auditory stimulus frequency in human cortex

Authors: K. A. BARNES[1], M. TOMMERDAHL[2], *J. M. YAU[1];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: We perceive temporal frequency information by audition and touch. Traditional models of sensory cortex function segregate auditory and somatosensory information in modality-specific cortical systems, but temporal frequency processing for audition and touch may not be so independent. Auditory and tactile temporal frequency perception is closely linked and spatially overlapping regions of sensory cortex respond to auditory and tactile stimulation. These results may reflect interactions between distinct neural populations that independently represent auditory and tactile frequency information. Alternatively, a subpopulation of frequency-tuned neurons could represent both auditory and tactile information. Here, we used fMRI adaptation to characterize population neural tuning for auditory and tactile temporal frequency in human cortex. This method exploits the tendency for sensory neural responses to be attenuated following repeated stimulation to infer voxel-level population tuning preferences. In an event-related fMRI experiment, participants received auditory and tactile stimulation as they performed a frequency discrimination task. Each trial comprised a series of 3 stimuli (adaptor stimuli; always matching in frequency) followed by a single (probe) stimulus. Adaptor and probe stimuli could be auditory or tactile. Stimulus frequency could be 100Hz or 300Hz. To test for frequency tuning, we compared BOLD responses from trials in which the frequencies of the adaptor and probe stimuli matched (SAME) with responses from trials in which the frequencies differed (DIFF): smaller responses for SAME trials likely reflect frequency-specific neural adaptation. From analysis of trials in which adaptor and probe modalities matched (auditory-auditory or tactile-tactile trials), we sought to identify voxels exhibiting modality-specific frequency tuning. From analysis of trials in which adaptor and probe modalities differed

(auditory-tactile or tactile-auditory trials), we sought to identify voxels exhibiting modality-invariant frequency tuning. Notably, crossmodal BOLD adaptation reveals convergence of auditory and tactile frequency signals on a common neural population. Preliminary results reveal the existence of modality-specific and modality-invariant frequency tuning mechanisms.

Title: Phase selectivity of simple and complex cells in visual cortex

Authors: ***C. PONS**[1], M. JANSEN[1], X. LI[1], Y. BERESHPOLOVA[2], H. SWADLOW[2,1], J. ALONSO[1,2];
[1]Biol. Sci., State Univ. of New York, New York, NY; [2]Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Neurons in primary visual cortex (area V1) are classified into simple and complex cells based on their linearity of spatial summation (Hubel and Wiesel, 1962; Movshon et al., 1978). It is commonly assumed that simple cells are more phase selective than complex cells. However, the relationship between linearity of spatial summation and phase selectivity has not been systematically measured. In order to address this question, we measured the linearity of spatial summation and phase selectivity of 189 V1 single neurons (90 simple, 99 complex) recorded in two awake rhesus monkeys. Linearity of spatial summation was measured with drifting gratings as the response amplitude at the frequency of the grating (F1) divided by the mean firing rate (F0). Phase selectivity was measured as the phase bandwidth from responses to static gratings (10 different phases, each presented for 500 msec and separated by 500 msec blanks). The phase bandwidth (PB) was measured at half-maximum response directly from the raw data (PBr) or from a von Mises fit (PBf, $R^2 > 0.7$). Our results demonstrate that linearity of spatial summation is correlated with phase selectivity in the entire cell population (PBr: $r = -0.62$, $p < 0.0001$, $n = 189$; PBf: $r = -0.51$, $p < 0.0001$, $n = 131$) and in simple cells (PBr: $r = -0.47$, $p < 0.0001$, $n = 90$; PBf: $r = -0.46$, $p < 0.0001$, $n = 78$) but not in complex cells (PBr: $r = -0.18$, $p = 0.075$, $n = 99$; PBf: $r = -0.04$, $p = 0.765$, $n = 53$). Correlation values were slightly

stronger when measured from responses evoked when the grating was turned on than when it was turned off (e.g. PBr: r = -0.62 versus -0.55 for entire cell population and r = -0.47 versus -0.31 for simple cells). As expected, the mean phase bandwidth was significantly larger for complex cells (0.74 ± 0.27 cycles for F1/F0 < 0.8) than simple cells (0.43 ± 0.27 cycles for F1/F0 > 1.2, $p < 0.00001$, Wilcoxon test). However, the range of phase bandwidths was surprisingly broad in both (PBr: 0.18-1 versus 0.27-1 cycles, PBf: 0.16-1 versus 0.17-1 cycles), even if we selected only cells at the borders of the F1/F0 distribution (F1/F0 > 1.5 versus F1/F0 < 0.5, PBr: 0.18-1 versus 0.27-1, PBf: 0.17-0.70 versus 0.27-1). The distribution of phase bandwidth for the largest F1/F0 values (simple cells) was best described by a Gaussian function (e.g. PBr for F1/F0 > 1.5, $R^2 = 0.84$, n = 31; PBf for F1/F0 > 1.2, $R^2 = 0.91$, n = 62) and the distribution for the lowest F1/F0 values (complex cells) was best described by an exponential function (e.g. PBr for F1/F0 < 0.5, $R^2 = 0.98$, n = 29; PBf for F1/F0 < 0.2, $R^2 = 0.66$, n = 45). These results indicate that, although complex cells show less phase selectivity than simple cells, both simple cells and complex cells are robustly tuned for spatial phase.

Title: Changes in the balance of ON and OFF cortical responses with the spatial-frequency content of the visual scene

Authors: ***M. JANSEN**[1], X. LI[2], R. LASHGARI[2,4], J. KREMKOW[2], Y. BERESHPOLOVA[5], H. SWADLOW[5], Q. ZAIDI[3], J.-M. ALONSO[2];

Abstract: We have previously demonstrated that low spatial frequencies generate stronger OFF than ON responses in cat visual cortex and that this OFF-dominance is reduced as the spatial frequency increases (Kremkow 2014). Here, we demonstrate that the spatial-frequency dependency of cortical OFF dominance is also present in the visual cortex of awake behaving primates and we investigate its possible neuronal mechanisms. We recorded from 235 single neurons from the primary visual cortex of two awake macaques using a chronically implanted, ultrathin, multi-electrode array (Swadlow 2005; Chen et al., 2008). We mapped the receptive fields by spike-trigger-averaging gratings (Ringach et al. 1997) that were presented in a rapid sequence (80 Hz) with 88 different orientations, 41 spatial frequencies and 4 phases. The gratings had four different sizes that were scaled so that a decrease in size by 2, 4 and 8 times resulted in an increase in spatial frequency content by the same factor. Measurements of preferred spatial phase with flashed gratings optimized for the cell's stimulus preferences (orientation, spatial frequency and size) revealed a slight bias towards OFF-dominated phases (65% in 110 comparisons between even phases measured within ± 1/8 of a phase cycle). This OFF-dominance became very pronounced when we mapped receptive fields with low spatial frequencies (79% of 235 neurons) and was only reduced to 50% when we increased the spatial frequency content of the stimuli by reducing the grating size to 1/8th. The ratio between the number of ON and OFF dominated receptive fields mapped with flashed gratings was strongly correlated with grating size (R2=0.99, n=4 sizes), a correlation that could be explained by two possible mechanisms: changes in ON/OFF balance within the receptive field of each neuron or changes in the relative number of ON and OFF dominated neurons driven with flashed gratings. To distinguish between these mechanisms, we measured changes the balance of ON and OFF responses across stimulus conditions for each cell and found that the changes were modest but significant (reducing grating size by half changed ON/OFF balance from 0.67 to 0.87, p=0.005, paired t-test). Moreover, increasing the spatial frequency of a drifting grating caused an average shift in phase (-0.12 ± 0.07) that was ~0.1 cycles greater than the average shift expected from changes in response latency (e.g. -0.02 ± 0.02 for contrast and 0.04 ± 0.02 for size). We conclude that the spatial-frequency dependency of cortical OFF dominance is generated by both changes in the relative numbers of ON and OFF-dominated neurons and small changes in the ON/OFF response balance within each single neuron.

Title: Classification of GABAergic interneurons in turtle visual cortex

Authors: ***C. M. MUELLER**, J. FOURNIER, G. LAURENT;
Max-Planck-Institute For Brain Res., Frankfurt am Main, Germany

Abstract: Information processing in sensory cortices relies on balanced interactions between and within populations of excitatory and inhibitory neurons. In turtle, the primary cortical recipient of geniculate afferents, the three-layered dorsal cortex, is in a position analogous to that of primary visual cortex (V1) in mammals. In the present study we defined the outlines and extent of turtle (Trachemys scripta) visual cortex by transneuronal tracing from the eye, and estimated the fraction of inhibitory neurons by staining for GABA and the pan-neuronal marker NeuN. Finally, using immunostaining for a variety of known markers of mammalian GABAergic neuronal subtypes, we examined the degree of heterogeneity among interneurons. Transneuronal tracing using intra-ocular injection of wheat germ agglutinin conjugated to horseradish peroxidase (WGA-HRP) revealed cortical labeling restricted to superficial layer I of the contralateral cortex. Labeling extended from the rhinal fissure to the cortical midline in the rostral third of the telencephalon. The neuronal marker NeuN labeled an average of about 26.000 neurons per mm^2 of visuo-recipient cortical area, of which only 1.700 cells/mm^2 (~7%) was immunoreactive to GABA - a fraction smaller than in mammalian V1. Double-immunostaining with antibodies directed against GABA and individual markers co-expressed with GABA in mammalian cortex revealed four antigens present in a substantial fraction of $GABA^+$ neurons: NPY (16%), somatostatin (18%), calbindin (28%), and the ionotropic 5HT-receptor (5HT3aR, 31%). All four antigens were mainly found in the lower half of the cortical thickness (layers II, III, and lower layer I). Additional antigens (e.g. calretinin and nitric oxide synthase) were found in minor fractions (<1%) of cortical GABAergic cells. Immunopositivity to parvalbumin and choline acetyl transferase was entirely absent in turtle visual cortex, despite reliable staining in subcortical tissue. Double staining revealed a full overlap of NPY with somatostatin expression. Triple-labeling with antisera against somatostatin, calbindin, and 5HT3aR revealed widespread co-expression of two or all three of these markers in individual neurons. About half (53%) of the interneuron population expressed no co-marker. GABAergic neuron heterogeneity in turtle visual cortex, assessed by immunochemical co-markers, thus appears to be less than in mammalian cortex. Parallel experiments are now testing the possible co-segregation of interneurons into physiological, connectional, and functional subtypes.

Title: Estimating synaptic density using 3D FIB/SEM and 3D confocal microscopy of LGN afferents in monkey V1

Authors: ***V. GARCIA-MARIN**, M. J. HAWKEN;
Ctr. For Neural Science. New York Universty, New York, NY

Abstract: The main thalamocortical (TC) recipient layers in primate primary visual cortex (V1) are the two sublayers of 4C, 4Cα and 4Cβ, with additional input to layer 6, layer 4A, patches in layer 2/3 and layer 1. A number of studies have focused on estimating the number of synapses made by terminals of TC afferents from the Lateral Geniculate Nucleus (LGN) in layer 4C using a range of different techniques, such as: tracing studies, degeneration techniques, or immunohistochemistry. These studies have provided a wide range of estimates of the TC contribution to layer 4C, from 1.3% to 32% depending on species, sublayer, and microzones, with a median of around 8%. Recently in a 2D transmission electron microscopic (TEM) study using an antibody against the Vesicular Glutamate Transporter 2 (VGluT2) to label the LGN TC afferents we found that in layer 4Cβ, VGlut2 accounted for around 16% of the total synapses, while the density in layer 4Cα was 8% of the total synapses. However, recent studies using 3D EM reconstructions indicate the total number of synapses have been underestimated in 2D EM studies. We confirmed these findings using 3D Focussed Ion Beam/Scanning Electron Microscopy (FIB/SEM), showing that quantification in 2D TEM was an underestimation of the total number of synapses by a factor of 2 - 2.5. Therefore although some of the previous studies have provided a relatively reliable estimation of the proportion the TC population contributes to the total synaptic population, they have not accurately estimated the total number synapses or the subset that are TC. To obtain estimates of synapse density in relatively large regions of cortex we

used confocal fluorescent microscopy and 3D reconstruction to estimate the number and volume of VGluT2-ir terminals in layer 4Cβ and in conjunction with estimates of the number of postsynaptic densities (PSD's) per terminal from 3D EM reconstructions we estimated the total number of TC synapses. We found a close match between the numbers of terminals estimated from EM and those using 3D reconstruction of confocal images. Using these methods allows for systematic studies of the populations of identified synaptic terminal populations across different layers, in different regions and between animals. In addition, obtaining accurate estimates of the total number of synaptic populations is fundamental to establishing the realistic models of brain circuits.

Title: Spontaneously c-Fos-positive neurons are spatial clustered in mouse primary visual cortex

Authors: *K. MAKINO[1], K. FUNAYAMA[2], Y. IKEGAYA[2,3];
[2]Grad. Sch. of Pharmaceut. Sci., [1]The Univ. of Tokyo, Tokyo, Japan; [3]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Osaka, Japan

Abstract: The networks of cortical neurons are spontaneously active. The firing rate of the neurons under spontaneous activity exhibits a heterogeneous distribution, ranging from very low activity levels to very high activity levels. Highly active neurons constitute a small population of cortical neurons and are sparsely distributed among the majority of low active neurons. However, little is known about the spatial arrangement of these highly active cells in the cerebral cortical microcircuitry. To elucidate their special distribution, we used c-Fos to label them. c-Fos is one of the immediately early genes that are widely used as a marker for neuronal activity. Most previous studies have observed c-Fos expression after exposing animals to external stimuli. However, some neurons spontaneously express c-Fos even under home-cage conditions. Recently, these "defaultly" c-Fos expressing neurons have been shown to comprise specific

groups of neurons in the neocortex (Yassin et al., Neuron, 2010; Jouhanneau et al., Neuron, 2014). In this study, we observed strong c-Fos expression sparsely throughout the primary visual cortex under home-cage conditions. To evaluate the spatial distribution of c-Fos expression, we introduced energy-like and entropy-like parameters. These analyses did not require arbitrary thresholds on the c-Fos positivity. Instead we utilized the c-Fos intensity as an analogue signal, without separating them into c-Fos positive or negative neurons. Using geometric energy analysis, we found that strongly c-Fos expressing neurons were spatially clustered in each cortical layer except for layer 1. Using geometric entropy analysis, we were able to determine the mean size of these clusters. The cluster size measured approximately 100 μm in diameter and was significantly smaller in layer 2/3 than in layers 5 and 6.

Title: Advancing a biomarker of reduced GABAergic action in the autistic brain

Authors: ***C. E. ROBERTSON**[1], A. MYNICK[2], S. RAJA[2], E.-M. RATAI[3], N. KANWISHER[2]; [1]Harvard Society of Fellows, Cambridge, MA; [2]2McGovern Inst. for Brain Research, MIT, Cambridge, MA; [3]3Martinos Imaging Center, MGH, Charlestown, MA

Abstract: Intro: The primary inhibitory neurotransmitter in visual cortex, GABA, has been linked to autism etiology in animal studies as well as genetic and post-mortem work in humans. Specifically, GABAergic action is posited to be reduced in the autistic brain, producing an overabundance of excitatory neurotransmission. Yet, perturbations in GABAergic signaling have never been experimentally associated with behavioral symptoms in people with autism. We recently demonstrated a striking autistic deficit in binocular rivalry (Robertson et al., 2013), a visual behavior that is governed by excitatory/inhibitory dynamics in the brain. Here, we tested whether the dynamics of binocular rivalry are correlated with levels of excitatory (glutamate) and inhibitory (GABA) neurotransmitters measured *in vivo*. Methods: In 41 participants (21 ASD, age and IQ matched to 20 TDs), we measured binocular rivalry dynamics, the concentration of excitatory (Glutamate) and inhibitory (GABA) neurotransmitters in the primary

Deleted: in vivo

visual (test) and primary motor (control) areas of each individual's brain using Magnetic Resonance Spectroscopy (MRS), and autistic symptom severity (ADOS). Behavioral Results: We replicate our original finding of atypical rivalry dynamics in ASD. Individuals with ASD demonstrate slower rivalry dynamics than controls ($p < 0.001$), with a reduced proportion of fully suppressed percepts ($p < 0.01$). These findings strongly predicted autistic symptoms ($rho = -0.69$, $p < 0.003$). Imaging Results: As predicted from models of binocular rivalry, the average concentration of GABA and Glutamate predicted binocular rivalry dynamics across both groups, predicting the proportion of perceptual suppression ($rho = 0.390$, $p < 0.014$). Critically, these neurotransmitters exerted differential impact on binocular rivalry dynamics in ASD and Controls: GABA in V1 strongly predicted the dynamics of binocular rivalry in Controls ($rho = -0.61$, $p < 0.009$), but demonstrated no impact on rivalry dynamics in the ASD group ($rho = 0$, $p = 1$). Conversely, Glutamate predicted rivalry dynamics in both individuals with ($rho = 0.64$, $p < 0.005$) and without ASD ($rho = 0.38$, $p < 0.1$), as well as autistic symptomatology ($rho = -0.51$, $p < 0.026$). These results were specific to V1: GABA concentration in M1 did not predict rivalry dynamics ($p > 0.19$). Conclusions: Here, we demonstrate a robust disturbance in a fundamental visual phenomenon in individuals with ASD, which strongly predicts GABA concentration. These data validate computational models of binocular rivalry, and mark the first experimental demonstration of a link between a robust autistic symptom and a prominent theory of autistic neural circuitry.

Title: Probing excitatory/inhibitory dynamics in awake visual cortex

Authors: *I.-C. LIN, M. OKUN, M. CARANDINI, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Cortical activity arises from the interplay of recurrently connected excitatory (E) and inhibitory (I) neurons. While theoretical models of E-I interactions have existed for many years (e.g., Wilson and Cowan, 1972), quantitative experimental analysis of E-I dynamics has become possible only recently, thanks to developments in population recording and optogenetics. To study and manipulate E-I dynamics in a quantitative manner, we combined electrophysiological recording using multisite silicon probes with optogenetic stimulation of pyramidal and parvalbumin-expressing (Pvalb) neurons in primary visual cortex (V1) of quietly awake mice. To separately stimulate excitatory and inhibitory populations we used multi-wavelength optogenetics. We crossed the Thy18 mouse line (which expresses ChR2 in a subpopulation of excitatory neurons) with a Pvalb-Cre driver line, and we expressed the red-shifted opsin C1V1 in Pvalb neurons by injecting a conditional virus. Brief blue (445 nm) and green (561 nm) laser pulses were delivered to stimulate the excitatory and Pvalb populations. We summarized the network activity at each moment by two population rates, representing the total firing rates of all recorded wide-spiking (presumed to be mainly excitatory) and narrow-spiking (putative Pvalb) neurons. We derived these population rates directly from the recorded data via a novel analysis technique that did not require spike sorting: for each spike, we used locality-sensitive hashing to estimate a smooth waveform whose width could then be measured accurately. A single blue-light pulse caused an initial brief activation in the excitatory population, which in turn excited the putative Pvalb population, followed by prolonged suppression of both populations. Responsiveness to a second pulse was suppressed to various degrees depending on the interpulse interval. Similarly, a single green-light pulse reliably increased the population activity of putative Pvalb neurons, followed by a less noticeable quiet period. We are currently developing a dynamical system model to predict single-trial responses as a function of spontaneous activity preceding the stimulation. These initial results indicate that in V1 of quietly awake mice, repeated delivery of single laser pulses or pairs of pulses at controlled intervals is effective in probing the dynamics of the network. It may thus be possible to predict the dynamics of excitatory and Pvalb neuronal populations quantitatively on a trial-by-trial basis.

Title: Thalamocortical input to putative fast-spike interneurons in layer 4 of rabbit visual cortex

Authors: *X. HEI[1], Y. BERESHPOLOVA[1], C. R. STOEZEL[1], J.-M. ALONSO[2], H. A. SWADLOW[1];
[1]Psychology Dept., Univ. of Connecticut, Storrs, CT; [2]Dept. of Biol. Sci., State Univ. of New York, New York, NY

Abstract: In somatosensory barrel cortex of the rabbit, putative fast-spike inhibitory interneurons in layer 4 (suspected inhibitory interneurons, SINs) receive strong and highly convergent/divergent inputs from neurons in the topographically aligned ventrobasal thalamic barreloid (Swadlow, 1995; Swadlow and Gusev, 2002). We have recently shown that SINs in layer 4 of rabbit visual cortex receive strong input from the retinotopically aligned region of the lateral geniculate nucleus (LGN, Zhuang et al., 2013). However, the rules governing thalamocortical connectivity onto layer 4 SINs in the visual cortex are not known. Here, we simultaneously recorded, in awake rabbits, spontaneous spike trains of concentric neurons in the LGN and SINs in the retinotopically aligned region of layer 4. Cross correlation analyses show that, like SINs in S1, most layer 4 SINs in V1 exhibit sharp peaks in the cross correlograms (indicative of monosynaptic connectivity) at appropriate intervals following the thalamic spikes when LGN and SIN receptive fields are very well aligned. Our preliminary data indicates that the connection probability/strength does not depend on matching either (a) the sign of the preferred contrast of the LGN cell and the layer 4 SIN (on-center or off-center in the LGN, on-dominated vs. off-dominated in the SINs), or (b) the Sustained/Transient response classification of the two cells. Thus, our results suggest that SINs of V1, like those of S1, receive a highly divergent/convergent input from multiple thalamic cell types in the topographically aligned region of their associated specific thalamic nucleus.

Title: Acetylcholine drives cortical microcircuit and modulates temporal dynamics in V1

Authors: *H. SUGIHARA[1], N. CHEN[1,2,3], M. SUR[1];
[1]The Picower Inst., MIT, Cambridge, MA; [2]Singapore Bioimaging Consortium, Biomed. Sci. Institutes, Agency for Science, Technol. and Res., Helios, Singapore; [3]McGovern Institute, MIT, Cambridge, MA

Abstract: Acetylcholine (ACh) modulates cortical functions including information processing and plasticity. To understand the physiological basis of these functions, it is critical to identify the cortical circuit elements involved. We have previously shown that cholinergic activation of astrocytes and their facilitatory influences on pyramidal neurons (PYR) are crucial to induce plasticity (Chen N, Sugihara H et al., PNAS 2012). In this work, we aim to dissect the neural circuit involved in cholinergic modulation of sensory processing. Specifically, we focus on the temporal dynamics of cortical activity: decorrelation of neuronal responses and desynchronization of local field potential (LFP) using L2/3 mouse primary visual cortex (V1) as a model. Recent studies suggest that inhibitory neurons are important for mediating temporal changes in neural activity. Candidate neurons include regular-spiking inhibitory neurons: somatostatin-expressing (SOM), vasoactive intestinal peptide-expressing (VIP) and layer 1 (L1) neurons. We recorded the cholinergic responses of these inhibitory neuronal subtypes in slice preparations. ACh induced concentration-specific responses in these neurons: SOM neurons were activated by a range of ACh concentrations while VIP/L1 neurons were activated only at high concentration. We further show that this is likely due to the active shaping of inhibitory neuronal responses through defined inhibitory connections between them: SOM neurons inhibit VIP/L1 neurons and this counters the ACh-induced facilitatory responses in the VIP/L1 neurons. In addition, we show that ACh-activated SOM (but not VIP/L1) induced inhibitory currents in parvalbumin-expressing (PV) and PYR neurons. This suggests the presence of an ACh-activated neural circuit comprising direct SOM-PYR and indirect SOM-PV-PYR connections. We next tested the causal relationship between this SOM-driven circuit and decorrelation/desynchronization through hyperpolarizing Arch-expressing SOM neurons *in vivo*. Indeed, hyperpolarization of SOM neurons blocked the cholinergic-mediated desynchronization/decorrelation. Hyperpolarization of VIP neurons did not affect the LFP

Deleted: in vivo

desynchronization. Finally, we stimulated SOM neurons directly by expressing ChR2 in these neurons. Photostimulation of SOM neurons, in the absence of cholinergic stimulation, induced LFP desynchronization. This suggests that direct activation of SOM-driven circuit is sufficient to change temporal dynamics of V1. Collectively, these findings reveal the powerful role of SOM neurons in dynamically shaping the temporal pattern of cholinergic-mediated responses.

Title: What does cytochrome oxidase histochemistry truly represent in the visual cortex?

Authors: *T. TAKAHATA[1,2];
[1]Interdisciplinary Inst. for Neurosci. and Technol., Zhejiang Univ., Zhejiang, China; [2]Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Since late 1970's, cytochrome oxidase (CO) histochemistry has been widely used for histological analysis to reveal cytoarchitecture of mammalian brains. Particularly in the primate visual cortex, CO staining is useful to identify layers, sublayers and other functional compartments, including CO blobs/patches in the primary visual cortex (V1) and thick/thin stripes in the secondary visual cortex (V2), in otherwise obviously uniform structure. It has been suggested that the enzymatic activity of CO reflects metabolic activity in mitochondria, especially because CO staining intensity drops in the ocular dominance columns (ODCs) for the deprived eye after eye occlusion or removal. Thus, CO staining pattern has been supposed to show map of neuronal activity. Here, I pose a question to this view. First, in any cortical area of any mammalian species, CO staining pattern is fairly similar to the staining of immunohistochemistry for vesicular glutamate transporter 2 (VGLUT2), which has already been confirmed to visualize thalamo-cortical axon terminals. In fact, I have observed that VGLUT2-immunoreactivity (ir) also dramatically decreases in ODCs of V1 after monocular deprivation in the same manner as CO staining, although VGLUT2-ir does not represent neuronal activity of cortical neurons. Second, CO staining pattern does not match to the expression patterns of immediate-early genes, c-Fos, Zif268 and Arc, which have also been suggested to visualize

activity of neurons. Third, CO activity is rarely seen in cell bodies but seen in fibers in the cortex. Therefore, we suggest a possibility that CO staining pattern indeed shows difference in metabolic activity between thalamo-cortical fibers and cortical neurons in the cortex, or strong metabolic activity of distal dendrite of cortical neurons that directly receive inputs from thalamus. In either case, CO staining may show connectivity, but not activity in the cortex. If this is true, the paradigm change will urge us to review the interpretation of CO blobs in V1 and CO stripes in V2: They may represent distribution of thalamo-cortical connectivity, not portions with strong activity of cortical neurons. In addition, interpretation of studies with CO staining for development, cross-species comparison and any disease/transgenic models should be reconsidered.

Title: A developmental model of salt-and-pepper type orientation map in visual cortex

Authors: *C. LEE, J. JANG, S.-B. PAIK;
KAIST, Daejeon, Korea, Republic of

Abstract: Orientation map in mammalian visual cortex is one of the most studied functional architectures in brain. It has been observed that higher mammals have well-organized quasi-periodic orientation maps, and recently a model study showed that a moiré interference pattern between ON and OFF retinal ganglion cell (RGC) mosaics can seed a consistent spatial periodicity in the maps (Paik & Ringach, 2011). On the other hand, in rodents visual cortex, smooth and periodic map structures are not found, but what is observed is “salt-and-pepper” type structure where preferred orientations of neurons are scattered randomly (Ohki et al., 2005). Despite extensive studies, developmental mechanism of this structure has not been completely understood yet. Here in our model study, we show that the salt-and-pepper type maps can be seeded by a conditional statistical feedforward wiring between the RGC mosaics structure and primary visual cortex (V1). In the developmental model of ON and OFF RGC mosaics, we

assumed local repulsive interactions between the same and the different types of RGCs. To find the wiring rule between retina and V1 that can induce a salt-and-pepper map, we tried two statistical wiring models: (1) sparse wiring model where a small set of RGCs in local sampling area is selected to be wired with the probability of connection as a function of the distance from the V1 cell, and (2) complete wiring model where a V1 cell is connected to every RGC in sampling area with weighted connection strength. In both models, we simulated the wiring with various sampling ranges and examined the orientation selectivity of each V1 cell and the spatial organization of them. We observed that salt-and-pepper map is developed in sparse wiring model with a long sampling range, while a smooth map is achieved as the wiring becomes less sparse, close to complete wiring and the sampling area becomes smaller. Our result suggests that the salt-and-pepper organization of rodents orientation map can be seeded by specific feedforward wiring rule between RGC mosics and V1. References 1. Title: Control of cortical tuning by VIP+ interneurons

Authors: ***I. AYZENSHTAT**, M. M. KARNANI, J. JACKSON, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Neuronal tuning defined by the level of selectivity to a specific stimulus is one of the hallmarks of cortical computation. Understanding the role of GABAergic interneurons in shaping cortical tuning is rapidly increasing with the ability to specifically manipulate them. Here we show that a class of interneurons that express vasoactive intestinal polypeptide (VIP) shapes the orientation tuning of neurons in mouse primary visual cortex. By combining two-photon imaging with bidirectional optogenetic and chemogenetic manipulation we found that VIP+ cells control the network selectivity to different stimuli. The effect indicates a dual action of VIP+ cells on the network, controlling the specific and non-specific responses, thus contributing to maintaining the variance, or signal-to-noise, across stimuli. These results reveal an important role of inhibition in cortical computations and strongly suggest that orientation selectivity does not merely arise from the projection of excitatory afferents into the cortex but rather is an emergent computation that is dynamically modulated via specific forms of intracortical inhibition.

Title: Polyploidy shapes the cellular and areal diversity of cortical layer 5

Authors: ***M. BRECHT**[1], J. SIGL-GLOECKNER[2];
[1]Humboldt University/ BCCN Berlin, Berlin, Germany; [2]BCCN Berlin, Berlin, Germany

Abstract: Principal cell diversity is a central, yet unresolved issue in the neurobiology of the cerebral cortex. We address this issue in rat cortex by analyzing soma / nucleus size on the one hand, and assessing DNA content and nuclear organization by DAPI-(DNA)-fluorescence on the other hand. In layer 4 of sensory cortices we find that neural somata and nuclei are of small and relatively homogeneous size. Nuclei of neural and non-neural layer 4 cells identified by NeuN-immunofluorescence had the same integrated DAPI-fluorescence. We also counted the number of chromocenters, bright spots of heterochromatic DNA fluorescence, the number of which often correlates with chromosome number. Layer 4 neurons and non-neural cells both showed a

similar number of ~19 chromocenters. These observations are consistent with a diploidy of layer 4 neurons. In layer 5 neurons, however, we observed much larger neurons and a remarkable size diversity of somata and nuclei. In primary visual cortex the integrated DAPI-fluorescence of layer 5 neurons was variable and showed multiple peaks. When normalized to non-neural cells, the largest peak in the integrated layer 5 neuron fluorescence distribution was found at 1.45fold the average non-neural cell fluorescence. A smaller peak was found at 1.05fold the fluorescence of non-neural cells. Chromocenter counts of visual cortex layer 5 neurons showed a wide distribution with a major peak at 26 to 27 chromocenters and a second smaller peak at 20 chromocenters. The variation in both DNA-fluorescence and chromocenter number, the distribution of multiple peaks at close to half-integer values is suggestive of polyploidy. Specifically, it may suggest that a majority of visual cortex layer 5 neurons is triploid and that another smaller fraction is diploid. Furthermore, in an even smaller ($\leq$ 10%) fraction of layer 5 neurons with very large somata we observed fluorescence values and chromocenter counts suggestive of tetraploidy. There are clear areal size differences within cortical layer 5 and visual cortical neurons are on average smaller than neurons in auditory or somatosensory cortices. Auditory cortex layer 5 neurons showed significantly higher normalized DAPI-fluorescence and chromocenter counts than visual cortex neurons. Our auditory cortex layer 5 data are compatible with presence of a large fraction of tetraploid neurons and also suggest the presence of pentaploid neurons. Our evidence supports and extends earlier conclusions from flow-cytometry and spectroscopy, which also indicated the presence of tetraploid layer 5 neurons. We suggest that patterns of polyploidy shape the laminar and areal cell diversity of the cerebral cortex.

Title: The 50-ms window of opportunity in V1 microcircuits

Authors: ***V. BHARMAURIA**[1], L. BACHATENE[1], S. CATTAN[1], N. CHANAURIA[1], J. ROUAT[2], S. MOLOTCHNIKOFF[1];
[1]Dept. Sci. Biologiques, Univ. De Montreal, Montreal, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Neuronal subnetworks are critical in encoding sensory information reaching the brain; however, the knowledge of the properties of these feature-encoding networks is still sparse. Here we show through simultaneous recordings of neurons in the primary visual cortex of anesthetized cats that a cell-assembly frames a salient functional network (revealed by the cross-correlograms) in relation to a particular stimulus. The dynamics of this network-selectivity is characterized by change of functional connections from one orientation to another, wherein some connections remain stable, others disappear with the changing stimulus and new ones appear too. The peak-probabilities in the cross-correlograms (that are an indication of weight of connections) also change as the orientation changes. The connected neurons within these networks cross-interact synergistically (an increase of ~50% of the firing rate) with each other in a characteristic 50-ms window (in relation to the spike of a reference neuron) that we call the temporal window of opportunity. Moreover, we found that there is an augmented gamma activity (30-80 Hz) for about 50 ms between the functionally connected neurons than the unconnected neurons in these circuits as a consequence of higher coherence in the gamma band between the connected neurons. Lastly, the higher gamma oscillations (60-80 Hz) are exclusively linked to the fast-spiking neurons. These results led us to postulate that in primary sensory areas information is processed within 50 ms after a salient functional network is formed within a cell-assembly. Furthermore this particular network exhibits stimulus selectivity.

Title: Gain modulation by serotonin in the macaque primary visual cortex

Authors: ***L. HRUBA**[1], T. OTT[2], A. NIEDER[2], P. POURRIAHI[1], H. NIENBORG[1]; [1]Univ. Tuebingen, Ctr. For Integrative Neurosci. (AG Nienborg), Tuebingen, Germany; [2]Univ. of Tuebingen, Inst. of Neurobio., Tuebingen, Germany

Abstract: The serotoninergic neuromodulatory system plays an important physiological role and has been implicated in a number of pathological conditions. However, despite anatomical evidence for substantial serotoninergic projections to the primary visual cortex (V1) and high expression of serotonin receptors in this brain area, little is known about how serotonin modulates visual processing in V1. Here, we used extracellular recordings in macaque V1 to examine the effect of serotonin on visual tuning properties. A macaque monkey was required to perform a standard fixation task (fixation for 2 sec within a 1 degree fixation window) while we presented sinusoidal grating stimuli inside the receptive field of single units in V1. We measured the effects of serotonin on tuning properties (binocular and monocular in each eye) for drifting gratings of varying orientation, spatial frequency, contrast and size. We recorded single units responses in V1 area while iontophoretically applying serotonin hydrochloride (10mM; pH=3.5; n=44 single units) or 0.9 % NaCl (pH=3.5; n=10 single units) as a control. The range of ejection currents was between 2 to 50nA (median: 10nA) for iontophoresis with serotonin and 10 to 50nA (median: 20nA) for the control iontophoresis using NaCl. We found that serotonin mainly decreased visual responses to a given stimulus while typically no changes were found after NaCl application. Across the neuronal population the changes induced by serotonin were mainly explained by a decrease in neuronal response gain, rather than additive changes. On average the gain was reduced to 72% of the gain without serotonin application, significantly different ($p<0.005$) from the results for iontophoretic NaCl application, while we found no significant additive change across the population. The sizes of the effects for the dominant and non-dominant eye were highly correlated ($r = 0.68$; $p<0.0001$ for multiplicative changes and $r = 0.66$; $p<0.0001$ for additive changes). In summary, our data showed that across a variety of stimulus dimensions serotonin predominantly decreased visual responses in macaque V1 by multiplicative, not additive changes.

Abstract: The extent and topographic organization of visual areas located anterior to V2 in macaques remains a matter of some contention. One of the most controversial aspects is the layout of areas on the dorsomedial aspect of the occipital lobe, in the depths of the lunate and parietooccipital sulci, and annectant gyrus. According to the most commonly accepted interpretation, this region includes dorsal area V3 (V3d), laterally, and another area (referred to as either V6 or PO, according to different definitions), medially. Surprisingly, no electrophysiological study to date has included a comprehensive exploration of this region. Thus, the nature of the topographic transition that marks the putative border between V3d and V6/ PO has remained unresolved. We explored the dorsomedial cortex in 3 macaques in acute recording sessions under sufentanil/ N2O anaesthesia. The brains were sectioned in the parasagittal plane, allowing the precise reconstruction of >1,000 recording sites relative to myeloarchitectural boundaries. The data were reconstructed in bi-dimensional maps using the software CARET. Rostral to the anterior border of V2 (marked by a representation of the horizontal meridian), we found a representation of the lower quadrant, which had a continuous representation of the inferior vertical meridian at its rostral border. This region formed a smooth eccentricity gradient, from central (laterally, in the annectant gyrus) to far peripheral (>50°, in the parietooccipital sulcus). There was no topographic transition at or near the border between putative areas V3d and V6/ PO. Rather, the lower quadrant representations that are usually interpreted as belonging to these areas merged into each other, forming a single map. Moreover, near the midline this map

continued into a representation of the upper peripheral visual field. Receptive fields in the upper central visual field were found near the lateral limit of our recording area, in the annectant gyrus, near the putative V3 border, but additional experiments will be needed to clarify the visual topography in this region. Our findings show similarities with evidence obtained in New World marmoset monkeys, and point towards a reinterpretation of the visuotopic organization of the cortex lying rostral to macaque V2.

Title: Evaluating the correspondence between category-selective and retinotopic organization of the lateral human occipitotemporal cortex

Authors: *E. H. SILSON[1], I. I. A. GROEN[1], D. J. KRAVITZ[2], C. I. BAKER[1];
[1]Lab-Brain & Cog, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. of Psychology, The George Washington Univ., Washington, DC

Abstract: The organization of lateral human occipitotemporal cortex (OTC) has been characterized according to two main principles: functional specialization (category-selectivity) and maps of the visual field (retinotopy). Recently, converging evidence from functional imaging and neurostimulation studies highlights that these organizing principles are not mutually exclusive, and indeed can be present in the same location. Here, we combined detailed mapping of both population receptive fields and category-selectivity to examine this spatial relationship within lateral occipitotemporal cortex across a large number of subjects (n=16). We focus in particular on a region of OTC defined as scene-selective (scenes > objects or faces), often referred to as the Transverse Occipital Sulcus (TOS). TOS covers a large swath of cortex, and we have previously shown that it has an overall bias for the contralateral lower visual field. To compare category-selectivity and retinotopy, we first delineated visual field maps (V1-V3d, V3A, V3B, LO1, LO2 & V7) on the lateral surface based on their representations of the visual field in all 32 hemispheres. Second, we calculated the proportion of spatial overlap between TOS

and these maps. Across both hemispheres, TOS exhibited maximal overlap with visual field maps V3B and LO2 - a pattern that increased when the threshold for category-selectivity was increased. There was a vanishingly small overlap with early visual areas V1-V3d and more modest overlap with V3A, LO1 and V7. Third, we assessed the frequency with which the peak of scene-selectivity fell within the boundaries of these maps. Across all hemispheres, the peak of scene-selectivity was located within the boundaries of either V3B or LO2 to a higher frequency than the other field maps or non-retinotopic cortex. The fact that TOS overlaps predominately V3B and LO2 is intriguing. Our measurements of visual field coverage within these maps indicate that whereas V3B represents the entire contralateral hemifield, LO2 represents predominantly the contralateral lower quadrant. The differing representations within V3B and LO2 may reflect differential sensitivity to particular visual features present within scenes. More generally, the combined lower field representations within LO2 and V3B likely account for our previous measurement of an overall contralateral lower field bias in TOS. Evaluating the relationship between category-selectivity and retinotopy is crucially important for neurostimulation studies of category-selectivity, which invariably target a single focal location. Overall, there appears no simple relationship between TOS and a single map of the visual field.

Title: Mapping spatial patterns of whole brain MRI using simultaneously recorded single neurons

Authors: *D. C. GODLOVE, B. E. RUSS, S. PARK, C. S. MPAMAUGO, F. Q. YE, D. B. T. MCMAHON, D. A. LEOPOLD;
Section on Cognitive Neurophysiol. and Imaging Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Neurons interact with each other and integrate information over many spatial scales. At large-scales, functional magnetic resonance imaging (fMRI) during rest reveals correlational maps thought to reflect specialized brain networks. At finer scales, hundreds of thousands of

adjacent neurons within each voxel of gray matter fire action potentials asynchronously. Linking these scales, the timing of a spike is often determined by specific afferent input to a neuron from another brain region. Here we report functional interactions between individual neurons and fMRI signal fluctuations recorded simultaneously throughout the brain. We recorded spontaneous spiking activity of single units in the anterior fundus face patch of the superior temporal sulcus (STS) of awake monkeys during whole-brain fMRI. A chronically implanted microwire bundle allowed for concurrent recordings from many neurons including sequential recordings from the same neurons isolated across multiple weeks. Functional maps were computed based on correlations between the spike trains of each cell and fluctuations in hemodynamic signals throughout the brain. These revealed discrete areas of robust correlation with changes in spike rate accounting for up to one third of the fMRI signal variance in some voxels. Maps from single neurons were reproducible within recording sessions and across recording sessions spanning several weeks, although the magnitude and borders of these maps varied with shifts in arousal (eyes open vs. eyes closed). Across the population, neurons measured from within an estimated radius of ~500 μm (much smaller than one voxel) gave rise to a striking diversity of maps. The majority of neurons showed correlations with fMRI signal within the STS; these were widespread for some cells and highly localized for others. Individual cells likewise varied in the extent to which their activity was correlated with fMRI signal in occipital visual cortex. Some neurons also showed correlations with hemodynamic signals in distinct areas such as the frontal and cingulate cortices. These results reveal a rich diversity of neural activity from adjacent neurons within a single voxel and give new insight into the functional interactions of individual cells with other brain regions.

Title: Dissecting the wiring diagram and function of cortico-cortical feedback from LM to V1 in mice

Authors: ***S. SHEN**, X. JIANG, J. REIMER, A. TOLIAS;
Neurosci., Baylor Col. of Med., HOUSTON, TX

Abstract: The mammalian visual system is composed of hierarchically organized cortical areas, which are reciprocally connected with feed-forward and feedback projections. Compared to feed-forward pathways, much less is known about the connectivity and function of feedback pathways. In mice, we found that the lateral medial area (LM) sends extensive feedback projections to the retinotopically corresponding area in primary visual cortex (V1). To characterize the wiring diagram of these feedback projections, we expressed channelrhodopsin2 (ChR2) in LM pyramidal cells, and performed multiple simultaneous whole-cell recordings of pyramidal cells, parvalbumin (PV), somatostatin (SST), and vasoactive intestinal peptide (VIP) expressing cells in L2/3, L4 and L5 of V1, while photostimulating feedback axon terminals. Although all these cell types exhibited monosynaptic excitatory responses to feedback activation, the amplitudes of their responses varied greatly depending on the cell types and layers. We found that among all the cell types, L2/3 PV and L2/3 SST had the largest response amplitude of EPSC and EPSP, 2-4 times as large as those of L2/3 pyramidal cells recorded in the same slice. To further reveal the net effect of feedback excitation to V1 pyramidal cells, we drove V1 pyramidal cells to fire by either injecting depolarizing currents in *in vitro* slice recordings, or presenting grating stimuli to the animal in *in vivo* whole-cell recordings, and on top of those, photostimulated the feedback projections. We found that both *in vitro* and *in vivo*, optogenetic excitation of feedback elicited a short depolarization followed by a long hyperpolarization of V1 pyramidal cells, creating a narrow temporal window of excitation that allows pyramidal cells to fire in a precise time. Our results suggest that feedback projections from LM to V1 help precisely time the firing of V1 pyramidal cells, thus potentially modulating their temporal coding.

Title: Cortex based alignment improves the intersubject alignment of cytoarchitectonic regions in the human ventral stream

Authors: *M. ROSENKE[1], K. S. WEINER[2], M. FROST[3], M. BARNETT[2], K. ZILLES[4,5], K. AMUNTS[4,6], R. GOEBEL[3,7], K. GRILL-SPECTOR[2,8];
[1]Brain Innovation BV, Maastricht, Netherlands; [2]Dept. of Psychology, Stanford Univ., Stanford, CA; [3]Fac. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands; [4]Inst. for Neurosci. and Med. (INM-1), and JARA Brain, Res. Ctr. Jülich, Jülich, Germany; [5]Dept. for Psychiatry, Psychotherapy and Psychosomatics, Univ. Hosp. Aachen, RWTH Aachen, Aachen, Germany; [6]C. and O. Vogt Inst. for Brain Research, Heinrich Heine Univ. Düsseldorf, Düsseldorf, Germany; [7]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [8]Stanford Neurosci. Inst., Stanford, CA

Abstract: Over the last 15 years, the Jülich group has developed observer independent methods to delineate cytoarchitectonic regions in the human brain (Amunts et al. 2000). These methods have identified 8 cytoarchitectonic regions in the human ventral stream. An initial four regions span the occipital lobe, ascending from hOc1 to hOc4v. An additional four regions continue to the temporal lobe and tile the fusiform gyrus (FG) ascending from FG1 to FG4 (Caspers et al. 2013; Weiner et al. 2014; Lorenz et al. 2015). While there is general consensus that hOc1 corresponds to striate cortex and is anatomically consistent across subjects (Fischl et al. 2008), there is little agreement that such a correspondence between cytoarchitectonic regions (cROIs) and cortical folding patterns persists in higher-order regions. We hypothesized that if such a correspondence exists, cortex based alignment (CBA) of cROIs will yield better registration across subjects than the standard volume based alignment to the MNI template. To test this hypothesis, we created cortical surface reconstruction of 10 postmortem brains in which these 8 cROIs were identified. We then used BrainVoyager to compare the registration of cROIs across subjects using three methods: (1) volume-based alignment to the MNI template, (2) CBA to the Freesurfer average brain (based on 39 independent brains, CBAfs), and (3) CBA to the average postmortem brain using the MFS as an additional constraint (CBApm+MFS). Our results show that both CBAfs and CBApm+MFS significantly improve the across subject correspondence of extrastriate cROIs compared to volume based alignment ($F(2,14) = 153.9$, $p < .001$, mean proportion overlap of cROIs: volume-based: 0.19±0.03, CBAfs: 0.29±0.04, CBApm+MFS: 0.30±0.04). Compared to CBAfs, CBApm+MFS does not additionally improve the overlap of cROIs across subjects ($t(15) = 1.7$, $p = .1$), even for FG1-FG4 ($t(7) = 1.2$, $p = .25$, CBAfs: 0.31±0.06, CBApm+MFS: 0.32±0.05). However, compared to CBAfs, CBApm+MFS significantly reduces intersubject variability in the location of the FG1/FG2 boundary as well as the FG3/FG4 boundary ($t(127) = 3.2$, $p = .002$, mean pairwise distance: CBAfs: 3.09±2.33 mm, CBApm+MFS: 2.46±1.69mm). Overall, these results suggest that CBA of cytoarchitectonic regions enables more accurate atlases of the cytoarchitectonic segregation of the ventral stream by preserving the location of cROIs relative to cortical folding patterns, and by improving between-subject alignment. Furthermore, adding the MFS as an additional constraint significantly improves the between-subject convergence of cytoarchitectonic boundaries between FG1 and FG2, as well as FG3 and FG4.

Title: GCaMP6 fluorescence-based retinotopic mapping reveals medial areas and complementaryrepresentations in the mouse visual cortex

Authors: ***J. ZHUANG**[1], D. WILLIAMS[2], M. VALLEY[1], M. GARRETT[1], J. WATERS[1]; [1]Neural Coding Dept., [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: The mouse visual cortex includes multiple distinct functional areas, each with its own representation of visual space. Here we locate 3 previously unidentified visual areas in retinotopic maps from awake mice, generated by widefield imaging of GCaMP6 fluorescence. A 50 ms visual stimulus evoked changes in GCaMP6 fluorescence that could be >2 orders of magnitude larger and 5 times faster than changes in tissue autofluorescence. The large signal and fast kinetics of widefield GCaMP6 imaging enabled rapid mapping: 15 minutes of imaging was sufficient to identify most known visual areas. More prolonged imaging and increased averaging revealed retinotopic organization that extended into retrosplenial and primary somatosensory cortices and included two medial areas (MMA and MMP) and one anterior area (RLL), the latter entirely within barrel cortex. The four positive field sign areas bordering V1 (LM, RL, PM, P) exhibit complementary coverage, comparable to V1, with modest duplication of the central hemifield. The remaining areas each represented smaller regions of visual space, mostly near the center of the hemifield. Our results extend our understanding of the organization of mouse visual cortex to include up to 15 retinotopically distinct areas, some with complementary representations of visual space.

Title: 3D interactive anatomical connectivity atlas of the claustrum in the macaque monkey

Authors: *K. S. SALEEM[1], D. GLEN[2], Z. SAAD[2], M. MISHKIN[1], J. L. PRICE[3]; [1]Lab. Neuropsychology (LN), [2]Scientific and Statistical Computing Core, Natl. Inst. of Mental Hlth. (NIMH/NIH), Bethesda, MD; [3]Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Until recently, researchers have relied largely on printed articles and atlases for connectivity information and anatomical references. While useful, this traditional format can be difficult to combine with imaging studies where the interconnections of numerous areas need to be understood simultaneously. Here we present a new software interface to show the extrinsic connections of the claustrum with different cortical areas in the macaque monkey using anatomical tracing methods. Restricted injections of retrograde and bidirectional tracers were made in subregions of the prefrontal (orbital, medial, lateral), temporal (superior, inferior, medial), inferior parietal, cingulate and retrosplenial cortices. The distribution of retrogradely labeled cells in the claustrum that project to these cortical areas was plotted in the histology sections using a microscope digitizer system. The main findings are: The labeled cells were found throughout most of the rostrocaudal extent of the claustrum after orbital, medial, and lateral prefrontal injections (e.g, areas 13m/l, 10mr, and 9d/46d/45a, respectively). A similar distribution of labeling was observed after restricted tracer injections into the caudal inferior parietal (area 7a), posterior cingulate (areas 23b and v23b), and the rostral belt and parabelt regions of the auditory cortex (RTL/RPB) in the superior temporal gyrus. In contrast, cell labeling was restricted mainly to the mid-portion of the claustrum after the inferior temporal lobe (areas TEad, TEav, and STSv) injections, or to both the mid- and rostral-portion of the claustrum after the rostral superior temporal gyrus (STGr) injections. Injections into the medial temporal cortex revealed a much stronger projection from claustrum to parahippocampal cortex (areas TF/TH) than to perirhinal cortex (areas 35/36). The dorso-ventral distribution of labeling varied between different injection cases but was restricted mainly to the ventral two-thirds of the

claustrum. These anatomical data are also implemented in software interface AFNI (Analysis of Functional NeuroImages; Cox 1996) and SUMA (Surface Mapper; Saad and Reynolds 2012) allowing the users to navigate the connectional data interactively in 3D, and integrate the information directly with their imaging results in volumetric and surface modes. The connectional data are in register with the Saleem and Logothetis MRI anatomical template atlas, and corresponding segmentation and cortical surfaces (Reveley et al, in preparation). Users can also display the cortico-cortical connections of individual cortical areas within this software interface (Saleem et al, OHBM 2015, Abstr 5109).

Title: Comparing fMRI maps derived from seed voxels, local field potential, and spiking activity during rest

Authors: ***C. S. MPAMAUGO**, D. C. GODLOVE, B. E. RUSS, S. PARK, F. Q. YE, D. B. T. MCMAHON, D. A. LEOPOLD;
Section on Cognitive Neurophysiol. and Imaging Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Functional magnetic resonance imaging (fMRI) of spontaneous brain activity reveals spatial patterns of synchronization thought to reflect interactions among regions making up distinct functional networks. One way to study these interactions is to measure the temporal correlations of the whole brain with a localized seed voxel or fMRI region of interest. Within a single voxel, however, there is a rich diversity of neural signals showing many patterns of activity. Here we investigate how fMRI maps vary when they are derived from different types of neural signals measured simultaneously from within a voxel using a seed-based approach. We recorded spontaneous local field potential (LFP), multiunit activity (MUA), and single unit responses from MR-compatible microwire bundles located within a voxel in the macaque superior temporal sulcus. These neural signals were recorded simultaneously with regional

cerebral blood volume changes during whole-brain fMRI acquisition. We obtained functional maps by correlating the time courses of either LFP power or spiking activity with hemodynamic signal fluctuations in each voxel. We then compared these maps to those obtained using an fMRI-based seed voxel located at the electrode tip. Functional activity maps obtained from the LFP power depended upon frequency content, and resembled results obtained previously from other brain areas (Schölvinck et al, (2010) PNAS). Maps derived from the gamma and theta LFP ranges showed a broad positive correlation throughout the cerebral cortex and generally resembled fMRI seed maps from voxels near the electrode tip. By contrast, maps obtained from the beta range recorded from the same electrodes showed more localized correlations that were more variable across sessions. Functional maps derived from spiking activity differed among neurons. MUA maps obtained from some channels were similarly broad, whereas others were more spatially restricted in their functional correlations. Maps based on isolated single units were generally more localized and dissimilar to one another than those derived from either MUA or LFP signals. Thus, the various types of spontaneous neural signals that can be measured and tracked within a single voxel at a given cortical position give rise to diverse but reliable whole-brain correlational maps using this method. We will address how particular signal-specific maps may provide insight into different components of resting-state brain activity.

Title: Calcium-binding proteins immunoreactivity in macaque V2 indicates differential population expression across cortical regions

Authors: ***J. J. COPPOLA**, A. A. DISNEY;
Vanderbilt Univ., Nashville, TN

Abstract: Inhibitory interneurons of the primate cortex comprise heterogenous populations, with considerable structural and functional diversity. Traditionally, these populations were classified based on their morphologies. More recently, immunocytochemical and genetic markers have

become a prevalent alternative for classification, with well-documented qualitative and quantitative data. In the present study, we use immunocytochemical markers to quantify the distribution and overlap of three neuronal classes in visual area V2. Expression of the calcium-binding proteins calbindin (CB), calretinin (CR) and parvalbumin (PV) by inhibitory interneurons has been found to define almost entirely non-overlapping classes of cells that, together, are believed to account for approximately 95% of the inhibitory neurons in the primary visual cortex (V1) of the macaque. Similarly, these proteins have been shown to represent distinct populations of neurons in the monkey prefrontal cortex (PFC). In the present study, triple immunofluorescence labeling was used to identify neurons expressing CB, CR, and PV in V2 of three macaques. Laminar distribution and degree of co-labeling for each population were quantified. 1146 calcium-binding protein-immunoreactive neurons were counted in a total area of approximately 7.587mm^2. Our results indicate that these calcium-binding proteins represent non-overlapping populations in macaque V2; no neurons were found to be triple labeled, or to be dual labeled for CR/CB. Less than 1% of all cells were dual labeled for CB/PV (0.785%), and less than 1% were dual labeled for CR/PV (0.175%). Overall, we found PV-immunoreactive neurons to account for 52% of the calcium-binding protein-immunoreactive population, with CB-immunoreactive neurons accounting for 25%, and CR-immunoreactive neurons accounting for 23% of the same population. Previously in macaque V1, a significant majority of inhibitory neurons was found to be PV-immunoreactive. In the macaque PFC, however, these proportions shift such that CR-immunoreactive neurons are the largest population. Our data indicate that the expression of these three populations of calcium-binding protein-immunoreactive neurons in V2 is distinct from that found in V1 and in PFC, and support the use of CB, CR, and PV as immunocytochemical markers for non-overlapping neuronal classes.

Title: Effects of TBS on visual cortex excitability depend on intensity as well as on coil geometry

Authors: S. BRÜCKNER, *T. KAMMER;
Univ. of Ulm, Ulm, Germany

Abstract: Transcranial magnetic theta burst stimulation (TBS) is an efficient method to modulate excitability of the human motor cortex, but it is still not clear whether the scheme, i.e. inhibitory effects by continuous TBS (cTBS) and excitatory effects by intermittent TBS (iTBS) can be transferred to other cortical regions. In 4 independent experiments we investigated the effect on the excitability of the visual cortex, using the individual phosphene threshold (PT) as dependent variable. In experiment 1 (n=20) and 2 (n=20), we applied either cTBS or iTBS with 100% PT intensity using a figure-of-eight-coil, respectively. In experiment 3 (n=15) and 4 (n=15), cTBS was applied with 80% PT intensity using either a figure-of-eight-coil (exp.3) or a round coil (exp.4). PT was measured before and 2min after TBS. Applying TBS with 100% of individual PT intensity on visual cortex we observed a significant modulation of PT with neither cTBS nor iTBS. However, cTBS decreased PTs numerically. As Franca et al. (2006) showed an inhibitory effect of cTBS on phosphene thresholds using 80% PT intensity and a round coil, we aimed to vary cTBS intensity and coil type. In experiment 3, we therefore applied 80% PT intensity with the figure-of-eight-coil used in experiments 1 and 2. A paired t-test showed decreased PTs following cTBS (t=2,4; p= 0.031), indicating a facilitatory effect. Using the round coil in experiment 4, no such effect was found (t=0.91, p=0.38). ITBS applied to the visual system seems not to modulate excitability. Our negative results using 100% of PT are in line with the non-finding of Franca et al. (2006) using 80% PT intensity. For cTBS, subthreshold intensities (80% PT) seem to be most effective in modulation of PT. An increase in intensity (100% PT) does not increase the modulatory effect, suggesting a non-linear system behavior. Surprisingly, in our data cTBS effects on visual cortex depend on coil geometry. Applying cTBS with 80% PT intensity using a figure-of-eight-coil had a facilitatory effect, whereas the effect using a round coil pointed in the opposite direction. This tendency to inhibition is in line with the effects reported by Franca et al. (2006). Thus cTBS effects in the visual system might depend on the focality of the applied electromagnetic field varied by the different coil geometries. The observed facilitatory effects applying cTBS with the figure-of-eight coil is in contrast to the canonical description in the motor system (Huang et al. 2005). Although we and others observed significant mean group effects in some protocols of TBS, with other protocols no effects were obtained. This points to the fact that TBS effects might act in different directions across individuals.

Title: Functional MRI mapping based on responses of face-selective neurons during free viewing of natural videos

Authors: *S. PARK[1], B. E. RUSS[1], D. B. T. MCMAHON[2], D. C. GODLOVE[1], D. A. LEOPOLD[1];
[1]SCNI, Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD; [2]Lab. of Sensorimotor Research, NEI, NIH, Bethesda, MD

Abstract: Neurons with similar response preferences are found clustered throughout macaque ventral visual pathway, with fMRI-identified patches showing largely homogeneous categorical responses to stimuli. Recently we reported that, while single neurons in the anterior fundus (AF) face patch responded consistently to multiple viewings of a natural video, their response time courses were often only weakly correlated across nearby neurons (< 500 μm) (McMahon et al., 2015). Here, we asked whether this diversity could be investigated by harnessing the spatial coverage of fMRI to map aspects of the functional information carried by individual neurons at the level of the whole brain. We therefore developed an approach that applied a combination of fMRI and single unit recordings to create a whole-brain fMRI readout based on individual neural responses. Subjects freely viewed a number of 5-minute movies replete with macaque and human social interaction (Russ et al., 2015). In some sessions, single unit responses were collected from the AF face patch, in others fMRI responses were recorded over the whole brain, and in some sessions the two measurements were conducted simultaneously. Each video stimulus served as a common currency for driving brain activity, which thus allowed us to assess the relationship between single unit and fMRI responses. Whole-brain functional maps were computed for each neuron as a matrix of correlation coefficients, with each voxel's value being the correlation between its fMRI time course the AF neuron's activity. This approach revealed that neurons located within a few hundred microns produced maps consisting of distinct, and often very different, combinations of visual areas. In general, individual AF neurons produced maps that featured positive or negative correlations with known face patches along with other subregions of the superior temporal sulcus. Many neurons, however, also showed positive or negative correlations with other areas, including the retinotopic visual cortex and prefrontal regions. As a population measure, we produced maps based on time courses of a set of principal components, or "eigenneurons," derived from the AF single unit responses. Results of this analysis revealed distinct spatial patterns of shared responses within the AF population. Finally, mapping the gamma power fluctuations of the AF local field potential revealed positive correlations in many of the specific regions measured from single units. This approach provides

a new means to investigate the diverse signals embedded within a local population of neurons by revealing the whole-brain functional pattern correlated with individual neurons.

Title: Macromolecular tissue properties of human high-level visual cortex develop with age and may shape cortical function

Authors: *J. GOMEZ[1], M. BARNETT[1], V. NATU[1], A. MEZER[2], K. GRILL-SPECTOR[1]; [1]Stanford Univ., Stanford, CA; [2]Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Computations performed by a given cortical region are constrained by its underlying cytoarchitecture and likely sculpted through development. Novel quantitative magnetic resonance imaging (qMRI) methods (Mezer 2013) have enabled unbiased *in vivo* measurements of macromolecular tissue properties, revealing development of macromolecular tissue volume and relaxivity in human white matter (Yeatman 2014). In parallel, other research has illustrated functional development in human ventral temporal cortex (VTC, Golarai 2007). However, it is unknown if there are concurrent changes in gray matter tissue and if they are related to the development of function. Here, we investigated how cortical tissue properties measured via qMRI develop with age from childhood (n=23, 5-12 years) to adulthood (n=20, 22-25 years) and how this measure of gray matter relates to functional selectivity. To measure cortical development consistently across subjects, we focus on anatomical ROIs of lateral and medial VTC. All subjects completed a multi-flip qMRI scan (protocol of Mezer 2013). We quantify in each subject both macromolecular tissue volume fraction (MTV) and spin-lattice relaxation rate (T1) per voxel. To test the relation between the development of anatomical properties to functional properties, each subject also underwent an fMRI localizer experiment to identify face-

Deleted: in vivo

selective regions on the lateral fusiform gyrus (pFus- and mFus-faces) and medial place-selective regions on the collateral sulcus (CoS-places/PPA). In both lateral and medial anatomical partitions of VTC, we observe a developmental shift in the voxelwise distribution of T1 and MTV values in gray matter. T1 values decrease from childhood to adulthood (mean decrease of 4.8%; KS-test Ps<10-50) and MTV values increase from childhood to adulthood (mean increase of 7.2%; KS-test Ps<10-50). Interestingly, in adults and children, the distributions of T1 values in pFus/mFus-faces differ from Cos-places (Ps< 10-14), suggesting that different functional regions have different gray matter properties. Additionally, this relationship varies across development. From childhood to adulthood, we observe a fivefold increase in the separability (d') of voxelwise T1 distributions between pFus/mFus-faces and CoS-places. Our findings suggest a novel structure-function relationship in human VTC, where anatomical development of the local tissue may contribute to shaping its cortical function.

Title: V1 population activity can drive development of highly diverse receptive fields in extrastriate cortex

Authors: *B. W. MEL[1], R. JAIN[2];
[1]Biomed. Engin., [2]Neurosci. Grad. Program, USC, Los Angeles, CA

Abstract: The mechanisms underlying the development of area V1 have been extensively studied both experimentally and with computer models. V1 is unusual among visual cortical areas, however, in that the majority of V1 cells respond well to the same basic shape -- an elongated edge or grating-like feature with varying preferences for orientation, spatial frequency, and other parameters. Reflecting this homogeneity, the core of most V1 models consists of a set of Gabor filters with varying orientation and scale parameters densely tiling the visual field. In contrast, mid-level visual areas such as V2 and V4 contain neurons selective for a multitude of diverse shape and/or texture features (Anzai, Peng, & Essen, 2007; Gallant, Braun, & Van Essen, 1993; Movshon & Simoncelli 2015; Pasupathy & Connor, 1999, 2001), but little is known as to what drives the development of such diverse RF properties in these areas. Given that V1 is a

major source of input to mid-level visual areas, we hypothesized that natural images that strongly activate local populations of V1 cells could provide the rich input statistics needed to drive the diversification process in extrastriate areas. To explore this, we collected natural image patches that strongly activated neighborhoods of cells in a V1 model, while varying (1) the size of the V1 neighborhood over which responses were pooled, and (2) the diversity of RF profiles within the V1 neighborhood, reflecting recent evidence that V1 profiles themselves have significant natural shape variation (e.g. Cossell et al. 2015). These image patches were then used to drive an unsupervised learning process in a model extrastriate area (hereafter EA), and the resulting RF structures were analyzed. We found that increasing the size of the V1 pooling neighborhood increased RF diversity in EA, but promoted the formation of RFs sensitive to repeating textures (i.e. "stuff" -- See Movshon and Simoncelli, 2015). In contrast, increasing the diversity of V1 RF profiles, to include curved Gabor-like profiles in addition to the conventional straight ones, led to an explosion of RF types more attuned to object boundary and junction structures (i.e. "things"). These finding provide a novel account for the formation of different types of RF diversity in mid-level visual cortex.

Title: Visual cortex in birds? Anatomical and physiological evidence favors a cortical organization for the intrinsic neural circuitry of the avian visual pallium

Authors: M. FERNANDEZ[1], P. AHUMADA[1], C. NORAMBUENA[1], *J.-C. LETELIER[2], G. MARIN[1,3], J. MPODOZIS[1];
[1]Univ. de Chile, Santiago, Chile; [2]Univ. of Chile, Santiago, Chile; [3]Univ. Finis Terrae, Santiago, Chile

Abstract: The mammalian cortex has two prominent features: lamination of characteristic neuronal types (including primary sensory neurons), and radially arranged projections between cortical layers, forming anatomical and physiological columnar modules. In contrast, the avian sensory pallium has long been considered as a necklace of sequentially related nuclei, lacking of

cortical features such as a columnar organization or recurrent interactions between their components. These seeming differences have been questioned by several recent studies addressing the organization of the neural circuits embodied in the sensory areas of the avian pallium. Recent studies from our Laboratory have shown that the visual sensory pallium is composed of three differentiated, layers: internal (Entopallium, E, thalamo-recipient), intermediate (intermediate nidopallium, NI, efferent) and external (ventral mesopallium, MV, associative), highly interconnected between them by a system of dorso-ventrally oriented, discrete and homotopic columnar bundles of axons. The detailed morphology of the cells and processes composing the columns, as well as the physiological operation of them, has not been investigated in detail. We have addressed these issues practicing intracellular cell fillings in chick brain slices, and current source density analysis (CSD) in anesthetized pigeons. Our results confirm that the neuronal axonal processes connecting these three layers are mostly dorso-ventrally oriented. Characteristic "column-forming" cell types of each layer were identified, including cells in the E and NI projecting to the basal ganglia. CSD maps elicited by the electric stimulation of discrete E loci show a layered/sequential arrangement of synaptic activation, with characteristic sinks in each layer. Finally, local electric E stimulation elicited at the MV spike activity restricted to the columnarly homotopic locus. Previous studies have reported that the E and the NI-MV share molecular identity with cortical layer 4 and layer 2/3 respectively. Taken togheter, these results strongly support a cortical-like organization for the avian visual pallium.

Title: Mapping the visual system devoid of visual stimuli

Authors: ***A. MENDELSOHN**[1], S. GABAY[2];
[1]Dept. of Neurobio., [2]Dept. of Psychology, Univ. of Haifa, Haifa, Israel

Abstract: The visual cortex represents incoming information according to distinct organization principles, one of which is eccentricity, whereby the object's distance from the center of gaze is represented along the posterior-to-anterior axis in V1. The ventral stream, known for its role in visual categorization and object recognition, obeys a related organization principle, such that

large entities are represented in medial portions, and smaller objects are represented more laterally. Despite the apparent link between the organizational principles in V1 and along the ventral stream, a direct link between these organization systems is lacking. Here we examined resting-state fMRI data using a novel functional connectivity technique that capitalizes on mapping brain areas according to functional correlations with distinct structural properties. Anatomical datasets of 31 participants from the NKI-Rockland Data program were segmented, and V1 voxels were delineated for each participant. Pearson correlations were then computed between fMRI time-courses of each cortical voxel and each and every voxel in V1. Finally, each cortical voxel was color-coded according to the y-coordinate (anterior-to-posterior) in V1 that had the maximal correlation with that particular voxel. Using this technique, a lateral-to-medial gradient was detected in ventral temporal cortex, whereby lateral-to-medial ventral temporal cortex was maximally correlated with posterior-to-anterior V1. In agreement with recent findings in the lateral surface of temporal cortex in response to objects with varying representational sizes, we detected a similar pattern, showing that ventro-lateral vs. dorso-lateral temporal lobes were maximally correlated with posterior vs. anterior V1, respectively. These results indicate that the retinotopic principle of visual eccentricity is detected in ventral and lateral temporal cortex, and importantly - in the absence of visual stimuli, revealing an anatomical infrastructure for the representation and categorization of visual information.

Title: Distinct balance of excitatory and inhibitory drive within feedforward and feedback pathways in mouse visual cortex

Authors: *R. D'SOUZA[1], Q. WANG[2], A. M. MEIER[1], A. BURKHALTER[1];
[1]Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Cortical areas communicate with each other via axonal projections that terminate in distinct laminar patterns that depend on whether the projections are feedforward (FF) or feedback (FB). Mouse visual cortex is composed of at least ten distinct areas that are interconnected by FF and FB pathways. To study the “interareal” communication between visual areas, we first determined the hierarchical positions of three such areas - V1, LM, and PM. We examined the laminar projection patterns of axons originating from each of these three areas to each of the other nine. FF axons originating in V1 tended to selectively target layers (L) 2-4 while avoiding L1, while FB projections to V1 preferentially terminated in L1. We therefore used the ratio of the optical density of projecting axons in L2-4 to that in L1, as a measure for quantifying the hierarchical level of each area. V1 had the highest L2-4:L1 projection ratio (and therefore the lowest position in the hierarchy), followed by LM, with PM holding the highest hierarchical position among these three areas. We next examined the cellular and synaptic properties of FF and FB pathways. The primary neuronal targets of interareal connections in the visual cortex are the pyramidal (Pyr) cells and the parvalbumin (PV)-expressing, GABAergic interneurons. Activated PV cells inhibit local Pyr cells; PV cells therefore provide feedforward inhibition (FFI) between visual areas. The strength of FFI within a circuit can determine the selectivity of signal transmission by restricting the time window for the integration of excitatory inputs. Therefore, to understand how visual signals are routed through the cortical hierarchy, we measured the strength of monosynaptic interareal inputs to Pyr and PV cells in FF and FB pathways. To do this we employed subcellular Channelrhodopsin (ChR2)-assisted circuit mapping in acute slices from 30-45 days old PV-Cre X Ai9 mice, in which PV cells express the fluorescent protein tdTomato. Excitation of ChR2-expressing axon terminals was achieved by a blue laser delivered in a grid pattern across all layers, and EPSCs were measured from neighboring Pyr and PV cells. Our results indicate that the interareal excitation of PV cells, relative to that of Pyr cells, is stronger in the FF than in the FB pathway, and stronger in L2/3 than in L5. This suggests more potent FFI in FF than in FB pathways in L2/3, with an overall lower level of FFI in L5. Further, synaptic inputs in L1 were stronger in FB than in FF pathways. We propose that FF circuits in L2/3 are selective for synchronous inputs, while FB projections more broadly connect to Pyr cells thus efficiently regulating their responses to FF input in a context-dependent manner.

Title: State-dependent processing in the brain

Authors: ***A. MARREIROS**, N. LOGOTHETIS, O. ESCHENKO;
Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany

Abstract: The level of norepinephrine (NE) in the brain modulates a variety of cognitive processes such as attention, perception, learning and memory. Stimulation of the Locus Coeruleus (LC), the major source of NE in the forebrain, can change spontaneous and task-related neuronal discharge in a large number of LC projection-targets. Few advances have been done on the study of the effects of phasic NE release on the responsiveness of mPFC cortical areas. In order to have a more complete understanding of the widespread projections of LC we need a multimodal approach. Here, we investigate the effects of LC discharge on ongoing and sensory-evoked cortical activity, by combining LC direct electrical stimulation (LC-DES) with multisite extracellular recordings and whole-brain fMRI in rats under anesthesia. The combination of these methods allows the acquirement of a richer dataset which carries unique insight into the mechanism of large scale NE modulation. The aim of this project is to combine multi-site extracellular recordings, DES and functional MRI techniques in an attempt to define brain “states” and their conditional probabilities with respect to the LC activity level and salient external events. The activity of the noradrenergic system is expected to strongly contribute to the modulation of the cortical state [Neuron 69:1061-1068, 2011]. The cortical recordings, from mPFC, are used to determine the network state prior to sensory stimulation and the neurophysiological responses to sensory stimuli with or without LC stimulation. In order to characterize the different cortical states induced by the anesthesia level and classify its maps accordingly, we computed a cortical synchronization index (SI) proxy [J Neurosci 29: 10600-10612, 2009] using the baseline preceding stimulation. We obtained representations for the distributions of a lower (a) and a higher (b) synchronization index during the same foot-shock (FS) condition. Subsequently, we looked at the cortical state-dependent effect of the FS

stimulation, which shows the Z-score of the BOLD time course difference between the SI distributions. Furthermore, fMRI maps for LC-DES have shown to produce an interesting dichotomy between BOLD responses of cortical and subcortical structures (belonging to metencephalon, mesencephalon and diencephalon cortices). Namely, they show the fraction of positively and negatively activated ROIs for the same LC-DES condition averaged over 10 sessions. This study suggests that it is possible to map the whole brain noradrenergic system by characterizing the FS or LC-DES stimuli responses and contextualize it according to the endogenous cortical synchronization state.

Title: Brain-wide mapping of functional neuron groups in larval zebrafish

Authors: ***X. CHEN**[1], Y. MU[2], Y. HU[1], J. WITTENBACH[2], J. FREEMAN[2], F. ENGERT[1], M. B. AHRENS[2];
[1]Harvard Univ., Cambridge, MA; [2]Janelia Res. Campus, Ashburn, VA

Abstract: Simultaneous whole-brain functional imaging should in principle provide a comprehensive understanding of the functional organization of the brain. With recent advances in light-sheet calcium imaging for behaving larval zebrafish (Vladimirov et al., 2014), we are able to record the ~100,000 neurons of the entire brain simultaneously at single-neuron resolution. However, the sheer quantity of neurons in whole-brain data makes extracting such an understanding a daunting task. An important first step is breaking up the neurons into functionally related clusters. These clusters then form manageable units for understanding and modeling the brain. Here we employ a unique combination of regression and clustering

algorithms that classify neurons into functional clusters (~100 clusters per animal). This algorithm identifies several known anatomical regions as well as many others exhibiting previously uncharacterized activity patterns. Using the imaging system developed in Vladimirov et al., 2014, we recorded the activity of practically all neurons simultaneously (at 2 brain-volumes per second), while presenting various visual stimuli (light gradients, moving visual scenes, etc.) and recording fictive swimming behavior. The average activity traces of individual neurons were automatically extracted for the vast majority of neurons in the brain. To obtain brain-wide clustering of neurons based on functional activity, we first had to address two closely related challenges intrinsic to this dataset: (i) the number of clusters is large and unknown; (ii) a large fraction of neurons lack well-defined membership to any cluster. We combined and customized a number of methods to suit this type of data, including both regression and temporal kernel fitting, and developed an automated iterative algorithm to cluster neurons based on the similarity of their activity profiles. Many of the extracted clusters are spatially localized, laterally symmetric and consistent across fish, even though no information of anatomical locations of the cells is used during the clustering. Many of these clusters correspond well to known anatomical regions (e.g. the Raphe nuclei) and other genetically defined cell populations. The collection of these functional clusters ranges from highly sensory-correlated to highly motor-correlated, although many clusters are not directly correlated to either and would have been hard to identify without simultaneous recording of whole-brain activity. This comprehensive collection of clusters allows us to explore large-scale features of brain activity, and provides a basis for further analysis such as inferring functional connectivity.

Title: Modulation of the pupil light reflex by frontal eye field microstimulation

Authors: *B. A. EBITZ[1], T. MOORE[2];
[2]Neurobio., [1]Stanford Univ., Stanford, CA

Abstract: The primate prefrontal cortex is involved in the flexible control of behavior in response to cognitive processes such as attention. However, the circuit-level mechanisms that underlie this control are unclear. In simpler nervous systems, higher-order control systems sometimes regulate the action of lower-order stimulus-response circuits. However, it remains unclear whether the primate prefrontal cortex can regulate lower-order stimulus-responses. In order to address this question, we asked whether activity in the prefrontal cortex is sufficient to modulate a canonical reflexive stimulus-response: the pupil light reflex. The pupil light reflex (PLR) is a transient pupil constriction elicited by luminance increments that depends on a well-characterized brainstem circuit. Critically, the magnitude of the pupil light response is not entirely determined by the evoking stimulus. Instead, emerging evidence indicates that attention and oculomotor processes modulate the PLR. However, the neurobiological origin of these modulations is unknown. One possible source is the frontal eye fields, a prefrontal area with an established role in attention and gaze control. Therefore, in two monkeys, we measured the effect of low-current microstimulation of the FEF on the PLR. In each experiment, we first evoked saccadic eye movements with microstimulation (100 ms train duration, 10-150 μA, biphasic pulses, 0.2 ms pulse duration, 250-333 Hz). This allowed us to identify the retinotipic location represented by a particular FEF site ("stimulated location") and its saccadic threshold (< 50 μA). Next, we lowered the current below the saccadic threshold (10-25 μA) and paired FEF stimulation with either flashed visual-probe stimuli that elicited the PLR or with sham stimuli that did not elicit a PLR. Critically, the probe stimuli were either placed within the stimulated location, or outside of it. We found that subthreshold FEF microstimulation (> 25 FEF sites) did not affect pupil size in the absence of probe stimuli. However, FEF stimulation increased the gain of the PLR. It enhanced the pupil response to light probes flashed in the stimulated location and suppressed the PLR outside of it. Thus, the FEF may contribute to the descending modulations of this brainstem reflex.

Title: Comparison of BOLD activity induced by microstimulation of pulvinar and LIP in a behaving monkey

Authors: *L. GIBSON[1], M. WILKE[2,1], I. KAGAN[1];
[1]Deutsches Primatenzentrum, Goettingen, Germany; [2]Cognitive Neurol., Univ. Med. Sch., Goettingen, Germany

Abstract: The thalamic pulvinar and the lateral intraparietal area (LIP) share strong reciprocal anatomical connections and are part of an extensive network of frontoparietal and temporal cortical and subcortical regions, involved in spatial attention and visuomotor planning of eye movements. Our goal was to map the effective connectivity of dorsal pulvinar (dPulv) and LIP and identify their shared circuitry and respective contribution to saccade planning activity. To this end, we applied unilateral electrical microstimulation in the dPulv and LIP in combination with event-related BOLD fMRI in a monkey performing a fixation and a memory-guided saccade task to left or right hemifield targets. Electrical microstimulation (biphasic pulses, 100-250 µA, 200 ms trains at 300 Hz, 1 train per s) was delivered during the 10 s memory period in saccade trials or during the corresponding epoch in fixation trials, interleaved with trials without stimulation. Microstimulation in both dPulv and LIP similarly enhanced task-related activity in frontal areas (e.g. medial FEF, area 46, caudate), in multiple regions along the dorsal bank and fundus of superior temporal sulcus ("sts": TPO, PGa, FST), and extrastriate cortex. In addition, dPulv stimulation led to activation in lateral FEF, areas 45, 44, PMd, insula and amygdala, while LIP stimulation activated medial parietal area PG. Despite extensive activation along the intraparietal sulcus evoked by LIP stimulation (LIP, VIP, LOP), more posterior LIP sites led to different activity patterns in frontal cortex (area 8B, 46v, but not FEF) and visual areas (PO, V3A) but not in sts. LIP microstimulation induced strong activity in the homologous part of the opposite LIP while for pulvinar stimulation no such homologous activation was found. Nevertheless, both dPulv and LIP stimulation induced activity in several cortical areas in the opposite hemisphere, implying transmission via polysynaptic connections. Most regions did not show a task-dependent stimulation effect: stimulation enhanced task-related activity to a similar extent. Task-dependent stimulation effects (i.e. stronger enhancement during planning of contraversive saccades) were more evident after LIP stimulation, especially in the opposite hemisphere. In conclusion, we identified overlapping and distinct patterns of thalamocortical and corticocortical connectivity of key visuospatial areas, highlighting the dorsal bank and fundus of sts as a prominent shared node. The fact that unilateral dPulv and LIP stimulation exerted major effects on saccade planning activity in both hemispheres may also constrain interpretations of behavioral effects of microstimulation.

Title: Effector-specific cortical mechanisms for memory-guided reaches and saccades: progression from target memory through motor planning and execution

Authors: ***D. C. CAPPADOCIA**[1], S. MONACO[2], Y. CHEN[1], J. CRAWFORD[1];
[1]Ctr. for Vision Res., York Univ., North York, ON, Canada; [2]Ctr. for Mind/Brain Sci., Univ. of Trento, Trento, Italy

Abstract: The human brain areas involved in reach and saccade planning have been studied extensively, but the effector-specific cortical mechanisms underlying target representation, motor planning, and motor execution have not been clearly differentiated. In this study, we used an event-related fMRI design that temporally separated the major stages of memory-guided reaching and saccades into three distinct phases: visual target representation, motor planning, and motor execution. In each trial, subjects (N=12) fixated at midline and were briefly shown a target located between 4-7 degrees to the left or right of the midline. After a delay of 8 seconds (the effector-independent target representation phase), subjects were instructed with an auditory cue to perform a reach or a saccade. This was followed by a second delay of 8 seconds (the effector-specific motor planning phase). Finally, an auditory ‘go signal’ prompted subjects to perform the instructed movement by reaching-to-touch a touchscreen with their right hand or performing a saccade (the effector-specific motor execution phase). In a control condition, subjects indicated the colour of the initial target. Our analysis to date (N=5) has focused on effector specificity in the motor planning and execution phases, i.e., cortical areas that show a preference for either reach or saccade tasks. This preliminary analysis indicates that during motor planning, bilateral dorsomedial parietal, M1, S1, and dorsal premotor areas show a preference for reach planning over saccades. During motor execution, the same areas contributed to a preference for reaches, while bilateral parietal areas (dorsolateral posterior parietal cortex and angular gyrus) and the right inferior frontal gyrus showed a preference for saccades. These preliminary results indicate

that a cortical preference for reaches emerges during movement planning, whereas planning for saccades only emerges during motor execution.

Title: Reduction of cortical activity during task learning reflects representation efficiency in the motor cortices

Authors: ***G. SPIGLER**[1], R. TIMMERS[2], S. WILSON[2];
[1]Dept. of Psychology, [2]The Univ. of Sheffield, Sheffield, United Kingdom

Abstract: In the present work we propose a biologically plausible framework for action learning in the motor cortex in the context of sensori-motor tasks. We then validate it against data on Repetition Suppression, that is the observed phenomenon of reduction in cortical activity after task learning and sensory priming. Within this framework, we assume that the reduced activity is due to learning of a specialized, efficient representation of motor patterns that are useful for the individual in the context of the task. We hypothesize that prior to training on a complex motor task, a large set of neurons is recruited in order to produce the desired novel actions, which is reflected in a widespread activation. After learning, however, a smaller specialized pool of neurons is sufficient to produce the desired task-specific actions, resulting in a lower overall activity. For the scope of our project, music is especially well suited as it is possible to measure how the brain is affected during musical training on naïve subjects that have no prior experience in music, and thus lack any neural representation of the actions involved. Finally, we investigate the role of our model in the context of embodied cognition, preparing future work on a humanoid robot platform.

Title: Prosthetic limb usage relates to increased visuo-motor functional coupling and enhanced visual processing of prosthetic limbs in hand-selective cortical regions

Authors: F. M. Z. VAN DEN HEILIGENBERG[1], T. ORLOV[2], S. MACDONALD[3], E. P. DUFF[1], D. HENDERSON SLATER[4], H. JOHANSEN-BERG[1], J. C. CULHAM[3], *T. R. MAKIN[1];

Abstract: Regions in the lateral occipitotemporal cortex (LOTC) selectively respond to images of hands and arms. The functional role of these regions in supporting motor control is unknown. Arm amputation introduces a change in individuals' ability to interact with their environment and in brain organisation. Using a prosthetic limb to compensate for hand loss strongly depends on both motor control and visual information, especially considering the lack of somatosensory inputs. Here we studied how prosthesis usage affects connectivity and activity in visual and motor hand-selective areas in 32 individuals with acquired or congenital upper limb loss. To study changes in coupling between the visual and the motor systems, we analysed resting-state functional connectivity. We placed a seed region in the territory of the missing hand in primary sensorimotor cortex (deprived cortex). We predicted that prosthesis usage in daily life should result in increased coupling between visual and motor hand-selective regions. We found a significant positive correlation between prosthesis usage and functional connectivity between the deprived cortex and visual hand-selective voxels in LOTC. We suggest that the increased connectivity between visual and motor hand-selective regions might result from coordination between these two regions during prosthesis usage. We predicted that usage-based changes in connectivity may also affect the way hand-selective visual regions respond when participants view their own and others' prostheses. We found a positive correlation between prosthesis usage and activation levels in the same LOTC region that showed experience-dependent connectivity changes. Moreover, the statistical relationship between prosthesis usage and prosthesis representation in LOTC was mediated by increased functional coupling, as assessed during rest. Our findings suggest that prosthetic limb usage can shape how high-level visual cortex interacts

with sensorimotor cortex to represent visual information. These results suggest that LOTC connectivity and function is influenced by visuomotor control. Visual hand-selective regions may therefore play a role in supporting action execution. Furthermore, these findings provide insight into the mechanisms underlying the mechanisms of successful prosthesis usage, which may aid in developing neurorehabilitation strategies.

Title: Functional modulation of corticospinal excitability in motor mirror neurons after observational skill learning

Authors: *M. VESIA, R. PELLICCIARI, R. F. CASH, R. ISAYAMA, R. CHEN;
Univ. of Toronto, Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: Background: Action observation of skill learning can lead to plastic changes at the motor system level. However, it remains unclear whether observing repetitive actions, in the absence of skill learning, modulates excitability of the human primary motor cortex (M1). We hypothesized that observing skilled motor learning not only improves behavioural performance in the untrained right-hand, but also enhances excitability of the motor representation for the action. By contrast, we hypothesized that observation of simple repetitive movements, in the absence of skill learning, produces no plastic changes in M1. Methods: Eight right-handed subjects were studied. We used transcranial magnetic stimulation (TMS) to probe cortical spinal excitability (CSE) adaptations associated with observing a video depicting another person: (1) learning a sequence-specific serial reaction-time task (SRTT) with the right hand; (2) performing a repetitive, right-hand movement on a random-sequence SRTT; and (3) learning a sequence-specific SRTT with no action (i.e., viewed inactive right-hand). Before and immediately after

each experimental condition, we measured behavioural performance (speed and accuracy of untrained right-hand) and CSE in motor mirror neurons with TMS. These include resting motor threshold (RMT) and motor evoked potential (MEP) amplitudes bilaterally. Results: We found learning by action observation (condition 1) not only decreased reaction time in the SRTT task in the untrained right-hand, but also increased M1 excitability in the left hemisphere. These changes were selective for learning by observation, as they did not occur after observing performance of the random sequence (condition 2). We also found that, although learning by observation modulates offline-resting CSE in M1, there were differences in the pattern of motor cortical plasticity when learning a repeating sequence structure with versus without motor action. Goal-based learning (condition 3) increased offline-resting CSE in M1 bilaterally, whereas learning by action observation (condition 1) was lateralized to the internal model of the body that maps the motor commands necessary to produce the overt movement. Conclusion: We conclude that the acquisition of a novel motor skill is a prerequisite factor in driving neurophysiologic changes in motor mirror neurons after action observation. We also show that the motor-memory formation is modulated by visual feedback of the action, suggesting a strong link between sense of agency and action outcome.

Title: Encoding action affordances during passive observation of graspable objects

Authors: *S. SIMON[1,2], R. GILRON[1,2], R. MUKAMEL[1,2];
[1]Sagol Sch. for Neurosci., [2]Sch. of Psychological Sci., Tel Aviv Univ., Tel Aviv, Israel

Abstract: In our daily life we constantly interact with various objects in the environment. Ethological perspectives view this interactive behavior as a result of an online selection process from different potential motor actions that can be made towards objects within reach. At the neural level, such potential actions can be simultaneously represented by different populations of visuo-motor cells. Canonical neurons, a subset of motor cells that are found in various regions of the motor system, respond during passive observation of graspable objects without an interacting agent. These neurons have the functional properties to support the representation of possible motor plans that are afforded by adjacent objects (e.g. action affordances). However, whether these neurons differentially encode specific action affordances triggered by different objects is not known. To address this issue we recorded whole-brain fMRI on nine healthy right handed subjects. The subjects passively viewed images of a mug with a handle positioned to the right or the left (i.e. affording a left or right hand grip orientation respectively). We performed whole brain searchlight Multi-Voxel-Pattern-Analysis (MVPA) to compare the spatial patterns of activity across multiple voxels differentiating the orientation of observed mug. Passive observation of mugs with identical grip orientation but different colors served as a control to the analysis. We found that spatial activity patterns in the left dorsal pre-motor cortex, left thalamus and bilateral primary visual cortices were selective to mug grip orientation with classification accuracy of 65% ($q<0.01$, FDR corrected). Importantly, these regions could not decode the color of the mug above chance level suggesting that low-level visual cues are not the source of this differentiation. Our results support the notion that passive observation of graspable objects, elicits a neural representation of specific action affordances that are encoded differently within motor and visual regions.

Title: Seeing another speak actives Spt and neighboring parietal area PFm

Authors: *D. CORBO, G. ORBAN;
Univ. of Parma, Parma, Italy

Abstract: Several regions of posterior parietal cortex are specifically activated by observing classes of actions (eg locomotion, manipulation, skin-displacing actions) performed by others and they are supposedly involved in the sensorimotor transformations for planning those actions. For technical reasons, it is often impossible to compare action observation with action execution. To establish such a match 22 human volunteers were presented video-clips showing an actor, viewed from the side, performing one of four action classes, each with four exemplars: mouth communication actions (speak, sing, shout and whistle) directed to a conspecific (communicative actions), mouth actions directed towards fruits (oral actions), hand actions directed towards objects (manipulative actions), both mouth and hand actions directed towards fruits (mouth & hand actions). Two different types of control stimuli were used: static images taken from the action videos, and 'dynamic scrambled' stimuli derived by temporally scrambling a noise pattern animated with the motion extracted from the original action video. In a different session the same volunteers mentally rehearsed "jabberwocky" sentences to localize area Spt in left parietal cortex, described by Hickok and collegues (JCNS 2003). A Spt ROI was defined in individual subjects in three steps. First the contrast rehearse vs rest (at $p<0.001$ as a threshold) was computed for each subject. Second, we looked for the local maxima nearest to the left Spt site according the coordinate of Hickok (-50, -48, 28). Finally, we built a 27 voxel ROI around the individual maxima. An ANOVA investigating the effects on the Spt activation of the factor type of action reached significance ($p<0.01$). Particularly the Spt activation was stronger for communicative action observation than any other. In addition in a whole brain analysis we defined the specific statistical maps for each action class, using inclusive and exclusive masking procedures. The specific map for oral communication observation included a parietal site located in left PFm, in addition to left BA45, and bilateral STS sites. The specific maps for manipulative, oral, mouth and hand actions included as expected phAIP. These results confirm that the same PPC regions are activated by both execution and the observation and suggest additional parietal regions specifically involved in the observation of a given action class. Title: Neural mechanisms of body language: Does body language share common neural mechanisms with vocal language?

Authors: *Y. SATO, A. MATSUO, S. MORIOKA;
health science, Kio Univ., Kitakatsuragi-Gun, Japan

Abstract: [Purpose]Humans communicate with each other not only using verbal language but also body language. Prior studies reveal that Broca's area is involved in verbal expression; however, the neural mechanisms of body language are unclear. Several cognitive psychology studies assume that verbal and body language have a common underlying mechanism prior to expression. A method to analyze effective connectivity in the brain has recently been established. We applied this method to discriminate between the neural mechanisms of body language and verbal language.[Methods]Eight subjects participated in this experiment. Electroencephalogram (EEG) data were recorded from 64 channels using the BioSemi Active Two system and a sampling frequency of 512 Hz. The processing was done using an EEGLAB tool box and SIFT. Subjects were seated in front of a computer screen and shown pictures that implied "big" or "small" (e.g., big bear or small butterfly). After seeing every picture, subjects were instructed to indicate their judgment using verbal language (Experiment 1) or hand gestures (Experiment 2). In the control condition, subjects were instructed to do nothing during seeing same pictures. EEG data were sampled during these tasks.[Results & Discussion]Although subjects saw the same pictures in both verbal language and hand gesture tasks, different effective connectivity (EC) was induced during the cognitive process prior to the expression. The network hub was located at the tempoloparietal junction in the former condition and at the fusiform gyrus in the later. In addition, we found difference of pass in EC after 150 msec of stimulus onset. These results indicated that behavioral tasks influenced the neural process of cognition and changed EC.

Title: Investigating interhemispheric transmission with tRNS

Authors: ***J. R. MCINTOSH**[1,2], C. MEHRING[1];
[1]Bernstein Ctr. Freiburg & Fac. of Biol., Freiburg Univ., Freiburg, Germany; [2]Bioengineering, Imperial Col. London, London, United Kingdom

Abstract: The Poffenberger paradigm (Poffenberger, 1912) demonstrated that when healthy subjects are asked to react to a stimulus with the same hand as the side of the visual hemifield in which it appears (uncrossed condition), their response times are faster than when their reaction must occur on the opposite side (crossed condition). This finding has been interpreted as being caused by information having to transfer via the corpus callosum in the crossed condition, consequently increasing reaction times. Here, we attempt to interact with this effect using transcranial random noise stimulation (tRNS). Our paradigm was based on a modification of the Poffenberger paradigm. Subjects sat in front of a monitor while fixating a cross placed in its centre. At brief randomised intervals in the range 1.8 - 3.2s, subjects are displayed a coloured target in either their left or their right visual field. The subject's task is to respond as quickly to the target colour as possible, pressing a key with their left hand for one colour, and with their right hand for the other, while ignoring the physical location of the target. Simultaneously, 40s tRNS blocks are interleaved with 40s sham blocks and applied via sponge electrodes positioned at FT7 and FT8 on the EEG 10-20 system. Response times to the appearance of the visual target were recorded and analysed. During the sham condition, as in the standard Poffenberger paradigm we find cross condition response times to be significantly slower than in the uncrossed condition. Our results are also consistent with a facilitation of communication between the two hemispheres in the crossed condition being caused by stimulation. More specifically however, a decrease in response time is apparent in the left-visual field to right hand condition, and not in the opposite, right-visual field to left hand condition. Via a meta-analysis of experiments utilising the Poffenberger task, Marzi et al. (1991) have shown that there is an asymmetry in response time between the two crossed conditions, with the left-visual field to right hand condition producing quicker responses. Consequently, a potential explanation for our results may be that via stochastic facilitation, tRNS enhances this inherent asymmetry. Poffenberger, A T. (1912). Reaction time to retinal stimulation with special reference to the time lost in conduction through nervous centers. Archives of Psychology, 23, 1-73. Marzi, C. A, Bisiacchi, P., & Nicoletti, R. Title: Chronic inflammation causes reduced peripheral drive in primary afferents in both young and aged mice

Authors: ***A. WEYER**[1], C. L. O'HARA[2], C. STUCKY[2];
[1]Cell Biol., [2]Cell Biology, Neurobiology, and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: It has long been known that peripheral inflammation causes enhanced pain sensitivity at the behavioral level and increased action potential generation in nociceptive primary afferents in rodent models. However, few studies have examined the effects of chronic inflammation (> 4 weeks) on pain behaviors in these animals, and fewer still have explored whether increased peripheral drive still contributes to pain sensation at this time point. Additionally, despite the significant pain epidemic in elderly human populations throughout the world, little basic science research has elucidated whether different pain mechanisms occur in aged animals as compared to young animals. Therefore, we sought to determine the contribution of primary afferent neurons in generating pain behaviors during both the acute and chronic phases of inflammation in both young and aged animals. We found that both young (2 months) and old (> 18 months) mice exhibited reduced paw withdrawal thresholds in response to mechanical stimuli following both acute (2 days) and chronic (8 weeks) Complete Freud's Adjuvant-mediated inflammation. Interestingly, however, young mice exhibited more behavioral sensitization to mechanical stimuli than their aged counterparts throughout the entire inflammatory process. Although young and old mice exhibited differences in their behavioral responses to acute and chronic inflammation, their primary afferents innervating the inflamed region responded with similar action potential firing rates in response to a series of increasing mechanical forces. This indicates that the difference in behavioral mechanical sensitivity following chronic inflammation is likely due to differences in central mechanisms in young and aged animals, and is unlikely to be due to differences in peripheral drive. As has been shown previously, action potential firing rates to mechanical stimuli were elevated following acute inflammation (2 days) in both young and aged animals as compared to controls. Surprisingly, however, we found that action potential firing rates from C fiber nociceptors in inflamed animals were significantly reduced as compared to controls at 8 weeks in both young and aged animals. This suggests a novel plastic change in peripheral sensory afferents that dampens their responses in order to limit pain transmission to

the central nervous system after chronic (8 weeks) inflammatory injury. Collectively, these results argue that acute inflammatory insult causes peripheral sensitization in C fiber nociceptors to generate pain sensation, but that pain behavior due to chronic inflammation is largely a central phenomenon in both young and aged animals.

Title: Mechanisms of complement C5a-induced mechanical sensitization in mouse: The roles of macrophages, cytokines and TRPV1

Authors: ***C. WARWICK**[1], L. P. SHUTOV[1], Y. M. USACHEV[1], D. J. CLARK[2], X. SHI[2]; [1]Pharmacol., Univ. of Iowa, Iowa City, IA; [2]Dept. of Anesthesia, VA Palo Alto Healthcare Syst. and Stanford Univ., Palo Alto, CA

Abstract: The complement system is a principal component of innate immunity. It consists of more than 30 proteins that are rapidly recruited through a cascade of enzymatic reactions to contribute to host defenses through diverse mechanisms. In spite of growing evidence implicating the complement system in the development of pain hypersensitivity, the underlying mechanisms are not understood. We found that injection of 500 ng C5a into a mouse hind paw produced strong mechanical sensitization that lasted for at least 3 hrs, and fully recovered to pre-injection levels within 24 hrs. Interestingly, this hyperalgesia produced by C5a was blocked by the TRPV1 antagonist AMG9810 and was strongly reduced in TRPV1 KO mice suggesting a possible role for neurogenic inflammation. Examination of inflammatory mediators in the skin induced by intraplantar C5a injection showed an increase in the levels of numerous cytokines including CCL2. C5a-induced mechanical sensitization was reduced in CCL2 KO mice. Immunohistochemical examination of plantar skin sections revealed that C5aR was expressed primarily in resident skin macrophages. Ca2+ imaging in cultured mouse primary macrophages demonstrated that C5a induced a large elevation in intracellular Ca2+ concentration ([Ca2+]i) in these cells. C5a-induced [Ca2+]i responses were blocked by the Gβγ inhibitor gallein and phospholipase C inhibitor U73122. We also found that drug-induced macrophage depletion in

transgenic MAFIA (macrophage Fas-induced apoptosis) mice reduced C5a-induced mechanical sensitization. We propose that the complement fragment C5a triggers macrophage-to-neuron signaling that involves CCL2 and TRPV1, which ultimately leads to mechanical sensitization.

Title: Modulation of nociceptive synaptic transmission by PAR2 receptors at spinal cord level in a model of peripheral inflammation

Authors: ***P. MRÓZKOVÁ**, J. PALECEK;
Inst. of Physiol. Acad. of Sci., Prague, Czech Republic

Abstract: Modulation of synaptic transmission in the spinal cord dorsal horn plays a key role in the development of pathological pain states and chronic pain diseases. Protease-activated receptors (PARs) are a family of four G-protein-coupled receptors (PAR1-4) activated by proteases. The role of PAR2 receptors in pain perception is well established in the peripheral tissues. However, the role of PAR2 receptors on the central branches of DRG neurons in the spinal cord is not fully understood. The present study aimed to study the role of PAR2 receptors in nociceptive processing and modulation of synaptic transmission in the superficial dorsal horn (DH) neurons in a model of carageenan induced peripheral inflammation. Whole-cell patch clamp recordings of miniature - mEPSCs and spontaneous - sEPSCs were made from superficial

DH neurons in acute spinal cord slices prepared from Wistar rats 21 days old, in the presence of strychnine (5uM) and bicuculline (10uM), at -70mV holding potential. TTX (0.5uM) application was used for mEPSC detection. Peripheral inflammation was induced by application of 3% mixture of carrageenan and kaolin into the paw 24h before the experiment. Application of PAR2 agonist SLIGKV-NH2 (PAR2 AP, 100μM) in slices from naive animals induced inhibition of miniature excitatory post-synaptic current frequency from the control level (60,0±4,3; % n=20; p<0,001), while under the inflammatory conditions it induced increase of mEPSC frequency (121,3±9.3%; n=17; p<0,01). This effect of the PAR2 agonist application was significantly different between the naive and inflammatory groups (p<0,001). PAR2 AP application induced spontaneous EPSC frequency increased in both the naive (122,9±6,0; n=18; p<0,01) and inflammatory conditions (137,8±15.1%; n=15; p<0,01). Inactive peptide VKGILS-NH2 (100uM) application did not evoke any change in the mEPSCs and sEPSC frequencies. Each neuron was tested for the presence of capsaicin (0.2 uM) evoked response in the end of the experiment. Out of the 70 neurons tested in this study 86% of them increased frequency of EPSC after the capsaicin application. Our results suggest that presynaptic PAR2 receptors may play an important role in modulation of nociceptive synaptic transmission in the spinal cord dorsal horn particularly under conditions of peripheral inflammation. Further experiments are needed to fully evaluate the role of spinal cord PAR2 receptors in pain modulation.

Abstract: Carbonic anhydrase-8 (CA8) is an allosteric inhibitor of inositol trisphosphate receptor-1 (ITPR1), which regulates neuronal intracellular calcium release. Calcium dysregulation is causally linked with chronic pain. Previously, we reported that the mouse ortholog Car8 was also involved in pain regulation. Here we investigate whether overexpression of human CA8 (hCA8) using sciatic nerve injection of AAV8-hCA8 virus with a C-termal V5 tag induces analgesia and inhibits hyperalgesia in a murine inflammatory pain model. Our pain behavior data show that overexpression of hCA8 in waddle mice, a naturally occurring Car8 null-mutant mouse (MT), completely reversed mechanical and thermal hyperalgesia. Our immunohistochemistry and western blot data show that overexpression of hCA8 protein inhibited forskolin-induced ITPR1 phosphorylation (pITPR1) *in vitro*; and in lumbar DRG of MT mice after sciatic nerve gene transfer of AAV8-hCA8 viral particles. Eighty-three percent of V5-positive DRG cells were small to medium-sized neurons (<700 μm^2), suggesting AAV8-hCA8 primarily infected nociceptive neurons. Double Immunofluorescence shows V5-positive cells co-localized with calcitonin gene-related peptide, substance P and Isolectin B4 in lumbar DRG. Horizontal sections of the lumbar spinal cord show V5-immunoreactive afferent fibers mainly within the superficial lamina I and II of the dorsal horn (DH), and colocalized with the neuronal marker, Tuj1. Many of these V5-positive afferents were highly branched and longitudinally located. V5-positive structures were also observed in DRG satellite cells and sciatic nerves (SN) Schwann cells. In addition, we showed hCA8 overexpression *in vitro* significantly inhibited ATP-induced cytoplasmic free calcium release. Finally, we demonstrate that hCA8 overexpression produces analgesia and anti-hyperalgesia in carrageenan sub-acute inflammatory pain models. Our data show that overexpression hCA8 in the DH, DRG and SN may regulate chronic pain through mouse peptidergic and non-peptidergic neurons, as well as glial cells. These findings suggest that hCA8 can be potentially used to treat chronic inflammatory pain through regulating the activity of ITPR1 and free intracellular calcium levels in critical nociceptive pathways.

Title: Phosphatidylinositol 3-kinase and phospholipase C mediate Epac-induced sensitization of rat sensory neurons

Authors: ***B. SHARIATI**[1], G. D. NICOL[2,3], M. R. VASKO[2,3,4];
[1]Dept. of Pharmacol. and Toxicology, Indianapolis, IN; [2]Dept. of Pharmacol. and Toxicology, [3]Stark Neurosciences Res. Inst., [4]Dept. of Anesthesia, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: We have previously demonstrated that activation of exchange proteins directly activated by cAMP (Epacs) sensitizes rat sensory neurons in a Ras-dependent manner. Because Ras has a number of downstream effectors, the question remains as to which signaling pathway(s) mediate the Epac-induced increase in sensitivity of sensory neurons. To examine this question, we studied whether selective inhibitors of phosphatidylinositol 3-kinase (PI3K), phospholipase C (PLC), or extracellular signal-regulated kinase (ERK) could alter the ability of the Epac agonist 8CPT-AM to augment action potential (AP) firing or capsaicin-evoked release of immunoreactive calcitonin gene-related peptide (iCGRP) from adult rat sensory neurons grown in culture. Pretreating sensory neuronal cultures for 30 min with 3 μM of the PI3K inhibitor, LY294002, blocked the ability of 8CPT-AM to increase APs generated by a ramp of current. This inhibitor also attenuated the ability of 8CPT-AM to augment capsaicin-evoked iCGRP release. In the presence of the inactive analog, LY303511, 8CPT-AM increased release with an EC50 of 2.7 μM, whereas in the presence of the PI3K inhibitor, LY294002, the EC50 for the Epac agonist was 7.9 μM. Pretreating sensory neurons with a selective inhibitor of PI3K gamma also blocked Epac-induced sensitization as measured by an increase in APs and an augmentation of capsaicin-evoked release of iCGRP, whereas, the selective PI3K alpha or PI3K beta inhibitors were ineffective. Exposing neuronal cultures for 30 min to 3 μM of the PLC inhibitor, U73122, did not alter the ability of 3 μM 8CPT-AM to enhance AP firing, but shifted the EC50 of 8CPT-AM to augment capsaicin-evoked release of iCGRP from 2.7 μM (in cells treated with 3 μM of the inactive analogue, U73343) to 3.5 μM in the presence of the PLC inhibitor. Pretreating neurons for 30 min with 3 μM of the mitogen-activated protein kinase kinase (MEK) inhibitor, U0126, did not alter the ability of the Epac agonist to increase ramp-evoked AP firing and did not affect the Epac-induced augmentation of iCGRP release. The EC50 of 8CPT-AM to augment capsaicin-evoked release was 2.5 μM in cultures pretreated with U0126, which was not statistically different from an EC50 value of 3.2 μM in untreated cultures. This concentration of U0126 blocked the ability of the Epac agonist to enhance ERK phosphorylation, demonstrating that it was sufficient to block MEK activity. These results

demonstrate that the gamma isoform of PI3K is a critical downstream effector of Epac-mediated sensitization of sensory neurons as measured by two endpoints. In contrast, blocking PLC likely alters the ability of Epac to enhance exocytosis independent of AP firing.

Title: Expression of NIPSNAP1, a neuropeptide nocistatin-interacting protein, following inflammatory pain

Authors: ***E. OKUDA-ASHITAKA**[1], K. OKAMOTO[1], M. OHASHI[1], K. OHNO[1], T. MINAMI[2], S. ITO[3];
[1]Osaka Inst. of Technol., Osaka, Japan; [2]Osaka Med. Col., Takatsuki, Japan; [3]Kansai Med. Univ., Hirakata, Japan

Abstract: The exclusive expression of 4-Nitrophenylphosphatase domain and non-neuronal SNAP25-like protein homolog (NIPSNAP) 1 is observed in the neurons. The levels of NIPSNAP1 protein and mRNA are changed by several neuronal diseases, including seizures, prepulse inhibition, and phenylketonuria. We previously reported that NIPSNAP1 interacts with the neuropeptide nocistatin (NST), and it is implicated in the inhibition of tactile pain allodynia induced by NST. NST also inhibits some inflammatory pain responses induced by peripheral injection of formalin and carrageenan. In the present study, we examined the gene expression of NIPSNAP1 in inflammatory pain model to determine the role of NIPSNAP1 to inflammatory pain. NIPSNAP1 mRNA was expressed in small- and medium-sized neurons of the dorsal root ganglion (DRG) and motor neurons of the spinal cord but not in a peripheral tissue paw. In the formalin test, nociceptive behavioral response increased in phase II, particularly during the later stage (26-50 min) in NIPSNAP1-deficient mice, and phosphorylation of extracellular signal-related kinase was enhanced at 5 and 30 min in the spinal dorsal horn of the deficient mice, suggesting that NIPSNAP1 deficiency induced the aggravation of inflammatory pain through central sensitization elicited by the formalin test. NIPSNAP1 mRNA level increased from 5 min to 60 min after formalin injection in DRG and reached 1.7-fold increase at 60 min. Moreover,

oral administration of aspirin completely inhibited nociceptive responses induced by formalin in NIPSNAP1-deficient and wild-type mice. Prostaglandin E_2 stimulated NIPSNAP1 mRNA expression via the cAMP-protein kinase A signaling pathway in primary DRG cells. The increased NIPSNAP1 mRNA expression is likely involved in the attenuation of inflammatory pain. In contrast, NIPSNAP1 mRNA levels in DRG were decreased by approximately 40% during 24-48 h after carrageenan injection. The prolonged inflammatory pain induced by carrageenan and complete Freund's adjuvant was exacerbated in NIPSNAP1-deficient mice, suggesting that the decreased NIPSNAP1 expression is involved in the exacerbation of prolonged inflammatory pain These results suggest that changes in NIPSNAP1 expression may contribute to the pathogenesis of inflammatory pain.

Title: DNA hydroxymethylation by Tet1 and Tet3 regulates chronic inflammatory pain

Authors: *Z. PAN[1], Z. XUE[2], L. HAO[2], Q. TANG[2], M. ZHANG[2], X. YANG[2], Y. LI[2], J.-L. CAO[2];
[1]Xuzhou Med. Univ., Jiangsu, China; [2]Xuzhou Med. Univ., Xuzhou, China

Abstract: The ten-eleven-translocation (Tet) family of methylcytosine dioxygenases converts methylcytosine (5mC) to 5-hydroxymethylcytosine (5-hmC), which plays an important role in regulation of gene transcription. 5hmC and Tet proteins are enriched in mammal central nervous

system. However, their functional regulatory role in chronic pain remains elusive. Here, we found a marked increase of 5hmC content and of Tet1 and Tet3 expression in spinal neurons in complete Freund's adjuvant (CFA)-induced chronic inflammatory pain mice. Knockdown of spinal Tet1 or Tet3 prevented and reversed thermal hyperalgesia and mechanical allodynia, and spinal neuronal sensitization induced by CFA. The genome-wide analysis revealed that the promoter region of Stat3, containing multiple CpG dinucleotides, is hyperdemethylated underlying chronic inflammatory pain status. Knockdown of spinal Tet1 or Tet3 reduced the increase of 5hmC in Stat3 promoter and Stat3 expression induced by CFA. In contrast, overexpression of Tet1 or Tet3 in naïve mice induced pain-responsive behaviors, which was accompanied with the increase in 5hmC content of Stat3 promoter and in Stat3 expression level. Together, these demonstrate a novel epigenetic mechanism of chronic pain that DNA hydroxymethylation by Tet1 and Tet3 regulates chronic inflammatory pain by targeting Stat3 in spinal cord.

Title: Toluene pronociceptive effect is increased after repeated exposures but is reduced by metamizol in the rat formalin test

Authors: ***L. F. ORTEGA-VARELA**[1], E. ALFARO-PEDRAZA[2], C. CERVANTES-DURÁN[3], M. Y. GAUTHEREAU-TORRES[3];
[1]UMSNH, Lic. En Salud Publica, Morelia, Mexico; [2]UMSNH, Facultad de Químico Farmacobiología, Morelia, Michoacan, Mexico; [3]UMSNH, Facultad de Ciencias Médicas y Biológicas "Dr. Ignacio Chávez", Morelia, Michoacan, Mexico

Abstract: Toluene can be found in products like thinner, paints and adhesives. Toluene misuse is an important public health problem in Mexico, mainly among street children and teenagers. This solvent shares actions with CNS depressants and several mechanisms have been proposed for its effect. *In vitro* studies demonstrate that toluene inhibits NMDA receptors and, since NMDA receptors have been implicated in pain, it was initially proposed that this solvent could have involved in neural processes like modulation of pain transmission. However, *in vivo* studies indicate that toluene produces pronociceptive effects in acute pain models in mice, by mechanisms other than blockade of glutamatergic system activity and it is unclear which neurotransmitter systems could have been participating in pronociception induced by toluene. In order to find out the participation of toluene on nociception in rats after acute or subacute exposure, we used metamizol (a wide-used non-steroidal anti-inflammatory drug with several mechanisms of action). Female Wistar rats (200-300 g) were placed in a static exposure chamber and exposed to toluene (6000 ppm) or air (control group) during 30 minutes (acute exposure) or 30 minutes twice a day during 7 days (subacute exposure). Other groups of rats received metamizol (600 mg/kg, p.o.) and then were exposed to toluene or air as described above. After acute or subacute exposure, rats were injected with 50 µl of 1% formalin in the dorsal surface of the right hind paw. This substance causes a typical flinching pain related behavior, the decrease in the number of flinches reflected as reduction of the area under curve (AUC) is considered as antinociception. We observed that toluene produced a significant increase in AUC compared with rats only exposed to air, both in acute and subacute exposure (568.5 ± 31.4 in toluene group vs. 445.4 ± 7.8 in control group [acute exposure] and 666.7 ± 14.2 in toluene group vs. 468.8 ± 7.5 in control group [subacute exposure]), indicating a pronociceptive effect, that was more pronounced after repeated exposure. On the other hand, metamizol showed an antinociceptive effect (AUC = 244.2 ± 7.9 [acute exposure] and 258.8 ± 5.8 [subacute exposure]) that can counteract toluene pronociceptive effect (AUC = 307.5 ± 6.8 [acute exposure] and 305.8 ± 6.7 [subacute exposure]). These results suggest that toluene repeated exposure increases its pronociceptive effect in rat formalin test; in contrast, metamizol may affect pronociception induced by toluene. This effect could be mediated through common molecular targets between toluene and metamizol.

Title: Antinociceptive properties of selective melatonin MT2 receptor partial agonists

Authors: *G. GOBBI[1], M. LOPEZ-CANUL[1,2], S. COMAI[1], S. DOMINGUEZ-LOPEZ[1], V. GRANADOS-SOTO[3];
[1]McGill Univ., Montreal, QC, Canada; [2]Inst. of Neuroethology,University Veracruzana, Xalapa, Mexico; [3]Neurobio. of Pain Laboratory, Dept. of Pharmacobiology,CINVESTAV, sede sur México D.F, Mexico

Abstract: Background: Melatonin (MLT) is a neurohormone acting through MT1 and MT2 receptors that has been involved in the regulation of acute and chronic pain likely through its activation of MT2 receptors. We have recently demonstrated that selective MT2 receptor partial agonists have antiallodynic properties in animal models of neuropathic pain by modulating ON/OFF cells of the descending antinociceptive system. Here, we further examined the antinociceptive/antinflammatory properties of the selective MT2 receptor partial agonists UCM765 and UCM924 in two animal models of acute/inflammatory pain: the hot plate and the formalin tests. Methods: UCM765 and UCM924 (5-40 mg/kg) were injected subcutaneously in male Wistar rats 30 min prior to the hot plate or the formalin tests. The effects of UCM765 and UCM924 were compared to those of melatonin (150 mg/kg), acetaminophen (200 mg/kg) and ketorolac (3 mg/kg). In order to confirm that the effects of UCM765 and UCM924 were MT2 receptor-mediated, they were blocked by the selective MT2 receptor antagonist 4-Phenyl-2-propionamidotetralin (4P-PDOT; 10 mg/kg) injected 10 min prior the MT2 partial agonists. Results and discussion: UCM765 and UCM924 dose-dependently increased the temperature of the first hindpaw lick in the hot plate test (two-way repeated measure ANOVA: $F_{3,20} = 23.57$, $P < 0.001$ and $F_{3,20} = 54.93$, $P < 0.001$, respectively), and decreased the total time spent licking the injected hind paw in the formalin test ($F_{4,24} = 11.32$, $P < 0.001$ and $F_{4,25} = 7.94$, $P < 0.001$, respectively). Antinociceptive effects of UCM765 and UCM924 were maximal at the dose of 20 mg/kg. At this dose, the effects of UCM765 and UCM924 were similar to those produced by 200 mg/kg acetaminophen in the hot plate test, and by 3 mg/kg ketorolac and 150 mg/kg MLT in the formalin test. Only in the hot plate test, MLT (150 mg/kg) effects were greater than those of 20 mg/kg UCM765 ($P=0.002$) and UCM924 ($P=0.002$). However, UCM765 and UCM924 were collectively more pharmacologically potent than MLT since their dose necessary to reach an antinociceptive effect was 7.5-fold times lower than that of MLT. Notably, antinociceptive effects of the two MT2 partial agonists were blocked by the pretreatment with 4P-PDOT in both paradigms. These results demonstrate the analgesic properties of MT2 partial agonists in

acute/inflammatory pain models and confirm that the activation of MT2 receptor rather than of both MT1 and MT2 receptors is a novel target for analgesic drug development.

Title: The role of activated peripheral kappa opioid receptors on the alleviation of arthritis pain

Authors: *S. O. MOON[1], H. HAN, male[2], E.-H. PARK, male[2], H. SUH, female[2];
[1]Col. of Med., Seoul, Korea, Republic of; [2]korea university, seoul, Korea, Republic of

Abstract: For the treatment of pain, chronic and systemic opioid application can be used because of its strong analgesic effect but extensive activation of opioid receptors beyond the target can cause unwanted complications e.g. dysphoria, pruritis, respiratory depression and constipation. So the selective activation of peripheral opioid receptors of involved tissue can be considered as the better strategy to reduce pain without unwanted complications and to increase the effectiveness of analgesia by opioid. This study was done to clarify the effect of peripheral kappa opioid receptor activation on arthritic pain for the purpose of the possible use of peripheral opioid receptor to treat the arthritic pain, We investigated whether the activation of peripheral kappa opioid receptors (kORs) could reduce the nociceptive behavior and the response of sensitized primary mechanosensitive afferents (MSA) after carrageenan-induced arthritis in *Sprague-Dawley* rat. In order to activate peripheral kORs, we administered U50488 (selective agonist of kOR) into the knee joint. We evaluated the nociceptive behavior by using dynamic weight bearing test which can measure the decreased weight load on affected side during freely walking, and recorded MSA activity in knee joint using extracellular single nerve recording technique before and after the injection of U50488. Four hours after the induction of arthritis, the activation of peripheral kORs by U50488 (0.1nM, 10nM and 1μM) significantly recovered the decreased weight load onto the inflamed knee joint during freely walking compared to saline treatment. Consistent with these behavioral results, we also found that the intra-articular injection of U50488 (10nM and 1μM) significantly decreased the response of MSA activities to stimuli by von Frey filaments (6 and 26g) during 10 - 60 min after U50488 injection compared to saline treatment. However, in the absence of inflamed knee joint, the application of 1μM U50488 had

no effect on MSA activities. These results implicate that the activation of peripheral kOR in the knee joint can contribute to reducing the nociceptive behavior by decreasing the activity of MSA in inflamed knee joint.

Title: Role of trace metal-generated oxidative stress in Toll-like receptor 4 signaling (TLR-4) in synovial fibroblasts

Authors: ***A. A. ALSOUSI**, O. J. IGWE;
Div. of Pharmacol. and Toxicology, Sch. of Pharm., Univ. of Missouri, Kansas City, MO

Abstract: Rheumatoid arthritis (RA) is a common chronic autoimmune systemic disease that affects the joints, especially in women. It is characterized by synovial inflammation, leading to tissue and bone destruction. It is proposed that RA is caused by a cross-talk between T and B lymphocytes, macrophages and synovial fibroblasts within the synovium. However, the importance of tissue reaction to immune stimulation, and not to the immune system itself, in causing the damage in RA, is considered a major cause of tissue damage. Reactive oxygen species (ROS) can interact with and modify cellular macromolecules, resulting in structural and/or functional changes in protein expression. High-mobility group box 1(HMGB1), is a nuclear protein that can bind to TLR 4, and it is recognized as a representative damage activated molecular pattern (DAMP) molecule. HMGB1 is passively released from necrotic or stressed cells and is actively secreted by inflammatory cells, mediating the response to inflammation. We have recently demonstrated that oxidative stress can activate the TLR4 MyD88/NFκB-coupled pathway, causing release of both pro-inflammatory and anti-inflammatory cytokines. The exact molecular mechanism of these events is not clear. We will determine the role of ROS/TLR4-coupled activation as a regulator of biochemical crosstalk in synoviocytes. We used three trace metals, potassium peroxychromate (PPC), cuprous chloride (CuCl), and ferrous chloride $FeCl_2$, as an exogenous pro-oxidants and ROS generating systems to examine interactions between ROS and TLR4. Intracellular ROS (iROS) was quantified using immunofluorescence and flow

cytometry. We used TLR4- signaling inhibitor CLI-095 and antioxidants to block ROS/TLR4-coupled interactions. HMGB1 release was measured upon pro-oxidants activation by western blot and ELISA. The trace metal ions (Cr^{+5}, Cu^{+} and Fe^{2+}) increased iROS accumulation in a time-dependent manner. Generation of iROS was significantly decreased when Ebselen and EUK-134 free radical scavengers were applied. Pro-oxidants sensitized synoviocytes to increase the expression of TLR4. TLR4- signaling inhibitor CLI-095 abolished the increase in iROS. Pro-oxidants increased HMGB1 release from the nucleus to the cytoplasm. Our data show that trace metals as sources of iROS can generate oxidative stress. The oxidant-induced TLR4 activation can cause HMGB1 release, which may mediate proinflammatory actions and contribute to the pathogenesis of RA.

Gen. "Dr. Manuel Gea González", Mexico, DF, Mexico; [7]Inst. of Neurobio., Kosice, Slovakia

Abstract: Chronic pain is characterized by a loss of pre- and post-synaptic inhibition and the occurrence of allodynia and hyperalgesia. After inflammation or nerve injury, GABAergic inputs

are less inhibitory or even excitatory due to the disruption of the neuronal transmembrane chloride gradient by changes in the expression of Na+-K+-2Cl- co-transporter 1 (NKCC1) and/or K+-Cl- co-transporter 2 (KCC2). It has been recently proposed that alpha 5-subunit containing GABAA receptors (apha 5-GABAA receptors) that mediate tonic inhibition might be involved in pain. The purpose of this study was to investigate the contribution of alpha 5-GABAA receptors in the loss of GABAergic inhibition and in formalin-induced long-lasting hypersensitivity. Formalin injection produced long-lasting secondary allodynia and hyperalgesia in both paws and impaired the rate-dependent depression of the Hofmann reflex (RDD) 6 days after injection. The peripheral and intrathecal pre-treatment or post-treatment with the alpha 5-GABAA receptor antagonist, L-655,708 (30-300 μM) prevented and reversed these long-lasting behaviors. Formalin injection increased alpha 5-GABAA receptors mRNA and protein expression in the spinal cord and dorsal root ganglia (DRG) at 3 days. alpha5-GABAA receptors were localized at the dorsal spinal cord, DRG and peripheral nerve fibers co-labeling with specific dorsal horn neurons and non-peptidergic fibers. Intrathecal administration of L-655,708 (300 μM) prevented and reversed the impairment of RDD. These results suggest that alpha 5-GABAA receptors play an important role in the loss of GABAergic inhibition and contribute to formalin-induced long-lasting secondary allodynia and hyperalgesia. Title: Participation of the potassium channels (K+) on the antinociceptive effect of peripheral administration of docosahexaenoico acid (DHA)

Authors: ***A. Y. LANDA**[1,2], A. E. CHÁVEZ PÍÑA[2];
[1]Lab. de Farmacología de la sección de estudios de Posgrado del IPN, Escuela Nacional De Medicina Y Homeopatía, Delegación Gustavo A. Madero, Mexico; [2]Farmacology, Natl. Polytechnic Inst. (IPN), Delegación Gustavo A. Madero, Mexico

Abstract: Introduction: The adverse effects caused by the use of analgesics limit their use. Nociceptors, which are the first cells involved in pain, depends on the ion channels expressed in cells. Docosahexaenoico acid (DHA) is an omega-3 fatty acid, having an important role over pain regulation, through a generation of antinociceptive effect (analgesic effect); however, its mechanism is still not well-defined. Moreover, there is evidence of analgesic drugs (nonsteroidal anti-inflammatory NSAIDs and opioids), that produce its antinociceptive effect through the regulation of a numerous potassium channels (K+). For that reason, the purpose or this study was to demonstrate that the antinociceptive effect of local administration of DHA is generated by the activation of K+ channels. Material and methods: female Wistar rats were administrated DHA (100 - 1778 µg/paw), 75 minutes before the formalin (1%); and percentage of antinociception was determined. In the same way, the antinociceptive mechanism of DHA was evaluated using specific potassium channels blockers for K ATP (glibenclamide and tolbutamide), Kv (4-aminopyridine and tetraethylammonium), KCa-cl (iberiotoxin and caribdotoxin), KCa-cc (apamin and dequalinium) inhibition. Results: DHA administration generated antinociceptive effect in a dose dependent fashion. The best antinociceptive effect was achieved with 1000 µg /paw (70.05 ± 3.70 %) of DHA. The antinociceptive effect of DHA was reverted with the administration of the blockers of K ATP, KCa-cl and KCa-cl channels; but not with Kv. Conclusions: DHA generates antinociceptive effect at peripheral level through the activation of potassium ATP-dependent, calcium large and small conductance K+ channels in the formalin test in the rat.

Title: SHANK3 regulates pain via possible peripheral and presynaptic mechanisms: Implication in pain dysregulation in autism

Authors: ***Q. HAN**[1], Y. KIM[1], X. WANG[2], W. CHANG[1], Y. ZHANG[1], T. BERTA[1], F. TANG[1], Y.-H. JIANG[2,3], R.-R. JI[1,3];
[1]Dept. of Anesthesiol., [2]Dept. of Pediatrics, [3]Dept. of Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Individuals with autism spectrum disorders (ASDs) usually experience a wide range of sensory dysfunction related to touch, smell, taste, and pain. The self-injurious behaviors such as head banging, scratching, bruising, and biting in ASD patients could be explained as pain insensitivity. SHANK3 is a postsynaptic scaffold protein and has been implicated in ASDs. SHANK3 maps to the critical region of chromosome 22q13.3. Patients with 22q13 deletion syndrome (also known as Phelan-McDermid syndrome with deletion of entire SHANK3 gene) demonstrated high incidence (77%) of pain insensitivity. However, it is unclear if SHANK3 is expressed in primary sensory neurons in the peripheral nervous system and plays a role in regulating pain sensitivity. Using *in situ* hybridization and immunostaining, we found the expression of Shank3 mRNA and SHANK3 in primary sensory neurons of dorsal root ganglion (DRG) in mice. We also observed SHANK3 immunoreactivity (IR) in primary afferent terminals in the superficial spinal cord dorsal horn. SHANK3-IR in the spinal cord dorsal horn was markedly reduced after ablation of TRPV1-expressing primary afferents with resiniferatoxin (RTX), indicating that SHANK3 in DRG neurons can be transported to axonal terminals in the spinal dorsal horn and modulates nociceptive transmission via a presynaptic mechanism. We also test pain behaviors in newly generated full-length Shank3-/- mice with deletion of exons 4 to 22 (Δe4-22-/-, referred as Shank3-/- mice). Shank3-/- mice displayed normal baseline pain. However, acute inflammatory pain in the formalin test and chronic inflammatory pain in the CFA model were markedly attenuated in Shank3-/- mice. Furthermore, knockdown of SHANK3 expression in DRG neurons with selective Shank3 siRNA, through peri-sciatic nerve injection, also reduced the formalin-induced inflammatory pain. Finally, SHANK3-IR was also found in human DRG neurons and nerve axons in the dorsal root. Our findings suggest that SHANK3 is required for the development of inflammatory pain via possible peripheral and presynaptic mechanism. Our results have also offered a mechanistic insight into pain deficits in autism patients.

Title: Local sympathetic denervation reduces pain behaviors and inflammation in the CFA model

Authors: S. CHEN, W. XIE, A. LI, J. A. STRONG, *J.-M. ZHANG;
Dept Anesthesiol, Univ. Cincinnati Coll Med., Cincinnati, OH

Abstract: Local sympathetic blockade is one treatment for some forms of chronic pain, and has recently been used as a pre-emptive analgesic for surgical pain. However, preclinical studies primarily use global sympathectomy or systemic blockade, or examine effects of sympathetic transmitters on immune cells and neurons *in vitro*. Both pro- and anti-inflammatory effects of the sympathetic nervous system have been reported in previous studies. In the study, we examined the effects of a very localized sympathectomy on the rat model of peripheral inflammation induced by injecting the hindpaw with Complete Freund's Adjuvant (CFA). Localized sympathectomy was achieved by cutting the grey rami to the L4 and L5 sensory ganglia on one side. Anatomical studies indicate this should cause sympathetic denervation of the paw region but not of primary immune organs. Control animals received sham surgery. These surgeries had no effect on baseline pain behaviors. One to 2 weeks later, CFA (25 µL of 1 mg/ml of mycobacterium tuberculosis in paraffin oil diluted with 25 µL of buffered salt solution) was injected s.c. into the ipsilateral paw. The injection led to mechanical hypersensitivity and swelling of the hind paw that persisted up to 14 days (longest time examined). Mechanical pain behaviors (von Frey test, mechanical allodynia test) were reduced by prior local sympathectomy, at some points to as low as 30% of the values in sham operated animals, while paw swelling was reduced by 50 to 60%. Immunohistochemical examination of the paw tissue verified that sympathetic fibers were still absent 14 days after the CFA injection, and did not undergo compensatory sprouting from adjacent non-denervated regions. Density of CGRP-positive fibers was modestly reduced by the local sympathectomy. The results suggest that the sympathetic nerves have a relatively large, local, pro-inflammatory effect in this model.

Title: Anti-cancer and analgesic effects of resolvin D-series in head and neck cancer

Authors: ***Y. YE**[1], J. CURTIN[2], D. BERNABE[4], B. SCHMIDT[3];
[1]Bluestone Ctr. for Clin. Res., [2]Col. of Dent., [3]Bluestone Ctr. for Clin. Research, Col. of Dent., New York Univ., New York, NY; [4]Araçatuba Dent. Sch., Univ. Estadual Paulista, Araçatuba, Brazil

Abstract: Head and neck cancer patients have poor survival and experience excruciating pain. Cancer progression and pain result from shared pathways that involve chronic inflammation. Resolvin D-series are endogenous lipid mediators derived from omega-3 fatty-acid that exhibit potent anti-inflammatory actions. Based on this known mechanism we hypothesized that resolvin D-series (resolvin D1 and resolvin D2) can inhibit cancer growth and pain in head and neck cancer. We examined the effect of resolvin D1 and resolvin D2 on proliferation of a head and neck cancer cell (HSC-3) using a real-time cell analyzer (RTCA). To study the effect of resolvin D-series *in vivo* we produced a mouse oral cancer model by inoculating HSC-3 into the right hind paw of mice. We measured tumor size and nociceptive behaviors weekly for four weeks. Tumor size was measured using a plethysmometer. Mechanical sensitivity was tested with an electronic von Frey device and thermal sensitivity was measured using Hargreaves' test. We found that both resolvin D1 and D2 reduced HSC-3 proliferation in a dose-dependent manner *in vitro*. 100ng Resolvin D1 treatment significantly increased paw withdrawal latency to thermal stimulation in cancer mice. 200ng resolvin D2 treatment significantly increased mechanical thresholds in cancer mice at week four compared to PBS treated cancer mice. Paw size was smaller in both resolvin D1 and resolvin D2 treated cancer mice, compared to PBS treated cancer mice. Our finding suggests resolvin D-series alleviate cancer pain and simultaneous reduces tumor burden. Ongoing studies are examining the specific immune cells and pro-inflammatory cytokines that resolvin D-series act on to exert its dual actions on both tumor progression and cancer pain.

Title: Characterization of the immune cell infiltrate in oral squamous carcinoma-induced cancer pain

Authors: ***N. SCHEFF**, B. L. SCHMIDT;
New York Univ., New York, NY

Abstract: Oral cancer patients report severe mechanically-induced pain. Opioids, despite their side effects and minimal efficacy, remain the primary therapeutic approach. Oral cancer pain is hypothesized to be due to tumor proliferation, perineural invasion, secretion of pro-nociceptive mediators and infiltration of the immune cells into the cancer microenvironment. Of those possible mechanisms immune infiltration into the cancer microenvironment is the least studied as non-steroidal anti-inflammatory drugs have minimal and unpredictable analgesic benefit. However, recent evidence shows that cytokines and chemokines produced by cancers can attract pro-inflammatory immune cells into tumors stimulating a proliferating microenvironment. We hypothesize that pro-nociceptive mediators secreted by human oral squamous cell carcinoma which include ET-1, NGF, ATP and proteases, not only sensitize and activate primary afferent neurons but also attract immune cells to the cancer microenvironment and cause pain. To simultaneously study the immune cell chemoattractant and pain-producing effects of cancer-secreted mediators, we injected oral squamous cell carcinoma (SCC) supernatant into the tongues of mice. Supernatant injection alone avoids the impact of tumor growth and perineural involvement. Immune cells from the tongue were typed and sorted with flow cytometry and pain behavior was measured with an objective operant assay (i.e., Dolognawmeter). Oral SCC supernatant exposure produced a roughly 60% increase in infiltration of total immune cells. Within this infiltrate, macrophages (CD11b+) population increased ~30% and T helper cell (CD3+ CD4+) population increased ~40%. Furthermore, a pro-inflammatory IL-17 producing CD4+ phenotype (Th17) was more prominent in tongues injected with oral SCC supernatant. This phenotype has been shown to induce production of pro-nociceptive cytokines, IL-6 and IL-8, as well as pro-angiogenic mediators and growth factors. Mice also displayed decreased orofacial function indicative of pain. We conclude that oral cancer pain is accompanied by an immune cell infiltrate which is triggered by cancer secreted products alone without tumor

growth. Future studies will analyze the immune cell infiltrate accompanying oral carcinogenesis in a mouse oral cancer model that recapitulates the human condition.

Title: Investigating the role of microglia and P2X7 receptors in monosodium iodoacetate induced joint pain

Authors: ***M. J. MOUSSEAU**[1], A. PILAPIL[2], N. BURMA[2], J. MATYAS[3], T. TRANG[2]; [1]Neurosci., [2]Physiol. and Pharmacol., [3]Univ. of Calgary, Calgary, AB, Canada

Abstract: Chronic joint pain is the cardinal symptom of all forms of arthritis, and is the underlying cause of disability in individuals afflicted by this disease. Although joint pathology is an underlying factor, some patients with severe joint pathology report little to no pain, while others with minor joint pathology experience debilitating and unremitting pain. This discordance between pain severity and peripheral pathology of the arthritic joint suggests the extent of joint damage is not necessarily a direct predictor of ensuing chronic pain. This study focused on the central mechanisms involved in modulating chronic osteoarthritis (OA) pain signaling. Emerging evidence suggests that altered pain processing within the spinal cord is a key determinant of joint pain. Here, we examined the involvement of spinal microglia and ATP-gated P2X7 receptors (P2X7R) in chronic OA pain. To induce OA pain, rats received intra-articular injection of monosodium iodoacetate (MIA), which resulted in a reduction in both mechanical and thermal nociceptive thresholds. The onset of mechanical allodynia and thermal hyperalgesia occurred as early as day 3 post-MIA injection, with allodynia persisting to least day 28. On day 7 post-MIA, we detected an increase in expression of microglial markers, Iba-1 and CD11b, in the ipsilateral

spinal dorsal horn. We assessed the OA joint pathology in rats 7 days post-MIA injection using the modified Mankin and OARSI scoring systems and found that MIA is sufficient to induce OA pathology. Given that P2X7Rs are involved in the pathophysiology of bone and cartilage disease, and are a locus through which microglia contribute to chronic pain, we asked whether P2X7Rs are causally involved in the development and expression of MIA-induced joint pain. We found that a 7-day intrathecal osmotic pump administration of the selective P2X7R antagonist A740003 attenuated the development of mechanical allodynia and thermal hyperalgesia in MIA-injected rats. In addition, we showed that an acute injection of A740003 in animals with established MIA-induced arthritis pain transiently reversed both the mechanical and thermal hypersensitivity. Collectively, our results demonstrate that spinal P2X7Rs are causally involved in the development and ongoing expression of arthritis pain.

Title: Potentiation of phase II formalin responses in zinc transporter-3 knockout mice

Authors: *C. Y. FAN[1], B. B. MCALLISTER[2], R. H. DYCK[2], T. TRANG[1];
[1]Neurosci., [2]Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Zinc is abundant in the central nervous system (CNS), and its activity is implicated in neuropathic and inflammatory pain. Expression of zinc is high in synaptic vesicles, the localization of which is tightly regulated by the vesicular zinc transporter, ZnT-3. Vesicular zinc release into the synaptic cleft regulates pain transmission via inhibition of post-synaptic N-methyl-D-aspartate receptors. In this study, we found that ZnT-3 is also expressed in microglia, which are resident immune cells in the CNS. Under physiological conditions, microglia are in a surveillance state, with a small cell body and long processes that actively survey the

environment. In the presence of damage and/or infection, microglia adopt a more activated state with a larger cell body, shorter processes, and an increase in the expression of cell surface markers alpha M integrin (cd11b) and ionized calcium-binding adapter molecule 1 (iba1). Aberrant microglia activation has been implicated in the development of neuropathic and inflammatory pain. Previous studies have shown the microglia activation can be triggered by extracellular zinc. In the present study, we asked whether ZnT-3 is critically involved in the sequelae of inflammatory pain. To test this, we examined the behavioural response of ZnT-3 knockout mice to a single intraplantar injection of formalin, which evoked a biphasic nociceptive response characterized by licking and shaking of the injected paw. We found that phase 1 of the formalin response (attributed to c-fibre activation) was comparable in ZnT-3 knockout and wild-type mice. In contrast, phase 2 nociceptive behaviours (associated with central sensitization) were significantly greater in the ZnT-3 knockout mice. We also determined that the deletion of ZnT-3 was associated with lower expression of the microglial and astrocytic markers, ionized calcium-binding adapter molecule 1 (iba1) and glial fibrillary acidic protein (GFAP), respectively. Collectively, our findings suggest that zinc transport mediated by ZnT-3 plays a critical role in the central sensitization associated with phase 2 of the formalin response.

Title: Mechanical allodynia following disc herniation requires intraneural macrophage infiltration and can be blocked by systemic selenium delivery or attenuation of bdnf activity

Authors: *Y. TU[1], M. SHAMJI[3], M. SALTER[2];
[2]Neurosciences & Mental Hlth., [1]The Hosp. For Sick Children, Toronto, ON, Canada;
[3]Neurosurg., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Objective: Disc-herniation induced radiculopathy arises from both mechanical compression and biochemical inflammation of apposed neural elements. This study demonstrated the need for intraneural macrophage migration after placement heterotopic disc tissue to generate the painful neuropathy phenotype. **Methods:** C57BL/6 mice underwent a

surgical procedure with mid-thigh exposure of the sciatic nerve. Control animals underwent exposure only (n=12) and experimental animals underwent placement of littermate tail nucleus pulposus (n=12). Animals were evaluated throughout one week for mechanical allodynia by Von Frey testing, thermal hyperalgesia by heat withdrawal latency, cold allodynia by acetone testing, and gait stability by RotaRod testing. At sacrifice, immunohistochemistry was performed to identify perineural and intraneural macrophage and lymphocyte presence. Necessity of an inflammatory response was tested by attenuating systemic inflammation with intraperitoneal selenium delivery. Necessity of BDNF-dependent macrophage activity was tested using a tamoxifen-induced CreER BDNF knockout system. **Results:** Mice exposed to heterotopic NP stimulation demonstrated substantial mechanical allodynia, cold allodynia, and gait instability compared to controls. Intraneural macrophage infiltration was observed in this group, alongside associated autoreactive lymphocytes at the disc-nerve interface. Systemic selenium administration blocked this behavioral phenotype in the acute inflammatory phase. Knocking out inflammatory cell BDNF activity in the CreER animals eliminated macrophage migration and the painful phenotype. **Conclusion:** Non-compressive disc herniation leads to altered behavior in this animal disease model, with demonstrated need for intraneural macrophage migration. Strategies to decrease perineural inflammation or maintain integrity of the blood nerve barrier may be effective in treating painful disc-herniation radiculopathy. Understanding the pathophysiology of disc-herniation radiculopathy carries implications on effective non-surgical and intraoperative management of a highly prevalent condition. This may also help define the transition from acute inflammatory pain to chronic neuropathic pain

Title: Cytokines of the IL-6/gp130 family increase the cAMP-ERK crosstalk in sensory neurons

Authors: ***A. GARZA CARBAJAL**, S. BROSIG, A. THIEL, T. HUCHO;
Experimentelle Anästhesiologie und Schmerzforschung, Uniklinik Köln (aör), Köln, Germany

Abstract: Sensory neurons in inflamed or damaged tissues are exposed to a multiplicity of extracellular factors. Beyond their direct effects on neurons, if these factors may also influence each other by modifying their intracellular signaling kinetics, is mostly unknown. Such mutual modulation may increase and/or prolong the signaling. Accordingly, such modulation would act as context detector and integrator for simultaneous or sequential stimuli. Sustained ERK activation in DRG neurons correlates with increased pain sensitivity. Additionally, increased or prolonged ERK activity downstream of cAMP production has been linked to pathological pain. Which factors and conditions govern this plasticity is mostly unknown. We now found that cytokines from the IL-6 family are able modify the cAMP-ERK crosstalk in DRG neurons. Exposure to some members of this family increases the amplitude of cAMP induced ERK activity without modifying cAMP production or PKA activation. Cytokine effects on cAMP-ERK crosstalk are time and dose-dependent, require protein translation and were resistant to the wash out of the cytokine. The increment in the cAMP-ERK crosstalk was observed despite at which level the cAMP pathway was stimulated. Our results identify a cellular mechanism governing this plastic connectivity of the cAMP-ERK crosstalk. Such mechanism has potential relevance for the processes of nociceptor sensitization and neuronal regeneration.

Title: F-actin links Epac-PKC signaling to sensitization of purinergic P2X3 receptors after inflammation

Authors: ***Y. GU**, C. WANG, G. LI, Y. CHEN, L.-Y. M. HUANG;
Univ. Texas Med. Br., Galveston, TX

Abstract: Sensitization of purinergic P2X3 receptors in dorsal root ganglion (DRG) neurons contributes to the production of the exaggerated nociceptive responses following inflammatory injury. Prostaglandin E2 (PGE2) produced in response to tissue injury has been found to

potentiate P2X3R-mediated responses in DRG neurons in both normal and complete Freund's adjuvant (CFA)-induced inflamed rats. In a previous study, we provided evidence that PGE2 potentiation of P2X3R responses depends only on PKA signaling in control neurons, but depends on both PKA and PKCε signaling in inflamed neurons. The activation of PKCε signaling, a result of PGE2-elicited activation of the cAMP-dependent guanine nucleotide exchange proteins (Epacs), gives rise to a much larger PGE2-induced enhancement after inflammation. It is not known, however, how the Epac-PKC signaling modulates P2X3R-mediated responses. Here we show that disruption of F-actin polymerization by either cytochalasin D (CD) or latrunculin A (LaA) blocks PGE2 enhancement of P2X3R-mediated ATP currents and inhibits alpha, beta_ATP-evoked nocifensive behaviors only under inflammatory conditions. The Epac activator, CPT, greatly increases the expression of F-actin. The increase is much reduced in the presence of PKC antagonists. Thus, Epac-PKC signaling modulates F-actin expression in DRGs. Furthermore, CPT also increases the membrane expression of P2X3Rs in DRG neurons and LaA greatly diminishes the CPT effect. These results suggest that F-actin is a critical link in the Epac-PKC signaling to bring about the sensitization P2X3Rs and the exaggerated pain responses following inflammation. Title: Preferred recycling pathway by internalized PGE2 EP4 receptor following agonist stimulation in cultured dorsal root ganglion neurons contributes to nociceptor sensitization

Authors: ***W. MA**[1], B. ST-JACQUES[2];
[1]Psychiatry, McGill Univ., Verdun, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., McGill Univ., Montreal, QC, Canada

Abstract: Chronic pain is an unmet clinical need which severely deteriorates the quality of life of individuals and imposes heavy financial burden on the society. It is generally believed that chronic pain results from sensitization of peripheral and central neurons along pain transmission pathway. Sensitization of nociceptive dorsal root ganglion (DRG) neurons (nociceptors) is a

prerequisite for transition from acute to chronic pain. Prostaglandin E2 (PGE2), a pain mediator over-produced in inflamed tissue, is known to sensitize nociceptors through its four EP receptors (EP1-4) expressed in DRG neurons. We recently showed that PGE2 or EP4 agonist stimulates EP4 externalization and this event was not only suppressed by the inhibitor of anterograde export, but also by the recycling inhibitor. These data suggest that EP4 recycling also contributes to agonist-enhanced EP4 surface abundance. In the current study, we tested this hypothesis by using antibody-feeding-based internalization and recycling assays as well as FITC-PGE2 binding assay. We observed that selective EP4 agonist 1-OH-PGE1 or CAY10850 time- and concentration-dependently increased EP4 internalization in cultured DRG neuron. Internalized EP4 receptors were predominantly localized in the early endosomes and recycling endosomes, but rarely in the lysosomes 1h after internalization, suggesting that internalized EP4 prefers to undergo the recycling pathway to return to cell surface than the degradation pathway to be degraded. These observations were also confirmed by FITC-PGE2 binding assay. We further revealed that 1-OH-PGE1 or CAY10850 time- and concentration-dependently increased EP4 recycling. Furthermore, double exposures to 1-OH-PGE1 significantly increased the levels of CGRP released from cultured DRG neurons compared to a single exposure or vehicle exposure. This event was blocked by the recycling inhibitor monencin pre-treated with the 1st EP4 agonist. Our data suggest that EP4 recycling contributes to agonist-induced cell surface trafficking and receptor sensitization. Facilitating EP4 externalization and recycling is a novel mechanism underlying PGE2-induced nociceptor sensitization.

Title: Targeted overexpression of Tumor Necrosis Factor-alpha increased Cyclin-dependent kinase 5 activity and the subsequent calcium influx in trigeminal ganglia neurons

Authors: ***E. UTRERAS PURATICH**[1], P. ROZAS[1], P. LAZCANO[1], R. PIÑA[2], A. CHO[3], A. TERSE[3], R. MADRID[2], C. GONZALEZ-BILLAULT[1], A. B. KULKARNI[3];

Abstract: We reported earlier that TNF-alpha, a proinflammatory cytokine implicated in many inflammatory disorders that cause orofacial pain, increases kinase activity of Cdk5, a key kinase involved in brain development and function, and pain signaling. To investigate a potential mechanism underlying inflammation in trigeminal ganglia (TG), we engineered a transgenic mouse model (TNFglo) that could conditionally overexpresses TNF-alpha upon genomic recombination by Cre recombinase. TNFglo mice were bred with Nav1.8-Cre mice that express the Cre recombinase predominantly in the sensory neurons. TNFglo; Nav1.8-Cre (cTg TNF) mice appeared normal without any gross phenotype. However, these mice displayed significant increase in TNF-alpha levels causing activation of NF-kappaB signaling pathway in TG. Additionally, increased IL-6 and MCP-1 levels along with intense immunostaining for Iba1 and GFAP indicated activation of microglia and astrocytes in TG. Most importantly, cTg TNF mice displayed increased p35 protein level and Cdk5 kinase activity in TG, and this increase was associated with elevated phospho-T407-TRPV1 and Ca+2 influx. Interestingly, this effect was reversed by roscovitine, a specific inhibitor of Cdk5, suggesting that TNF-alpha overexpression caused sensitization of TRPV1 channel, which is partially mediated by Cdk5. In summary, cTg TNF mouse model would be valuable in defining new approaches to investigate orofacial pain mechanism involving TNF-alpha mediated pain signaling.

Title: The role of neuronal Fc-gamma receptor I in antigen-specific pain

Authors: H. JIANG, X. SHEN, Z. CHEN, F. LIU, T. WANG, B. YUAN, Y. XIE, *C. MA; Inst. of Basic Med. Sciences, CAMS&PUMC, Beijing, China

Abstract: Antigen-specific immune disorders are often accompanied by pain but the underlying mechanisms are not fully understood. In previous studies we found that Fc-gamma-Receptors (including FcγRI, IIb and III) were expressed in dorsal root ganglion (DRG) neurons in rats and can be specifically activated by IgG immune complex (IgG-IC). Intradermal injection of IgG-IC to the rat hindpaw induced both mechanical and thermal hyperalgesia. This effect can be reduced by a high concentration of nonspecific IgG but not by mast cell stabilizer or histamine receptor blocker, indicating a role of FcγRI in pain transmission. Calcium imaging revealed that IgG-IC induced intracellular calcium increase in small-diameter, but not in the medium- or large-diameter dissociated DRG neurons. Electrophysiology recordings, both *in vitro* and *in vivo*, demonstrated that IgG-IC induced hyperexcitability and action potential discharges only in a subpopulation of C-nociceptive DRG neurons. The high-affinity activating IgG-Fc receptor FcγRI (CD64) were found upregulated in the relevant DRGs in a rat model of antigen-induced arthritis, with an increased incidence of spontaneous activities and enhanced responses to IgG-IC in nociceptive DRG neurons *in vivo*. These results suggest that nociceptive neuronal FcγRI may contribute to painful conditions induced by IgG-IC in antigen-specific immune disorders.

Title: The cellular and molecular identity of "silent" nociceptors

Authors: ***S. G. LECHNER**, A. ARCOURT, V. PRATO;
Heidelberg Univ., Heidelberg, Germany

Abstract: In addition to mechano-nociceptors and polymodal nociceptors, C-fibres and A-delta-fibers also comprise a significant proportion of fibers that are insensitive to mechanical stimuli under normal conditions, but become sensitized to such stimuli during inflammation. These so-called “silent” nociceptors have been found in many species, including mice, and were shown to innervate the viscera, deep somatic tissues and the skin. Here we show that silent nociceptors are characterized by the expression of the alpha-3 subunit of the nicotinic acetylcholine receptor (Chrna3) and that they can be “un-silenced” by NGF induced upregulation of mechanically-gated ion channels. Chrna3+ neurons account for app. 8% of all DRG neurons, they express the NGF receptor trkA, but do not express NF200 or bind the non-peptidergic neuron marker Isolectin B4. Moreover, Chrna3+ neurons are enriched in thoracic and sacral DRGs and are only present in small numbers in cervical and lumbar DRGs. Consistent with this, Chrna3+ afferents are present in large numbers in the viscera and in deep somatic tissues but are rather rare in the skin, which was reminiscent of the previously described distribution of mechanically-insensitive silent nociceptors. Patch-clamp recordings from cultured DRG neurons further showed that Chrna3+ neurons fire action potentials that exhibit a nociceptor-specific hump on the falling phase and that they are indeed insensitive to mechanical stimuli. However, following treatment with NGF, which is known to “un-silence” silent nociceptors *in vivo*, all Chrna3+ neurons acquired mechanosensitivity. The NGF-induced acquisition of mechanosensitivity is mediated by the MAP-Kinase pathway and requires gene transcription. Taken together, our results suggest that Chrna3+ neurons represent a functionally unique subpopulation of peptidergic c-fiber nociceptors that shares many features with silent nociceptors. To directly test this hypothesis, we analyzed the functional properties of Chrna3+ afferents in the intact skin using single unit teased fiber recordings from a skin-nerve preparation. To allow the unequivocal identification of Chrna3+ afferents in these experiments, we generated mice in which Channelrhodopsin-2 (ChR2) expression is confined to Chrna3+ afferents. Consistent with the results from our immunocytochemical studies and patch clamp recordings, transdermal illumination with blue light only evoked action potentials in slowly conducting unmyelinated c-fibers that were insensitive to mechanical stimulation of the skin, demonstrating that Chrna3+ neurons are indeed mechanically insensitive silent nociceptors.

Title: Elucidating the role of anti-inflammatory cytokine interleukin-10 in peripheral neuropathic pain

Authors: *A. G. VANDERWALL[1,2], S. NOOR[1], N. W. HARRIS[1], J. J. SANCHEZ[1], M. S. SUN[1], R. A. WHITEHEAD[1,2], X. O. YANG[3], E. D. MILLIGAN[1,2];
[1]Neurosciences, [2]Anesthesiol. and Critical Care, [3]Mol. Genet. and Microbiology, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Current treatments for neuropathic pain primarily target neurons, and are often ineffective for patients. Spinal glia have been implicated in neuropathic pain such as mechanical allodynia (pathological sensitivity to light touch). Glial pro-inflammatory cytokines are both necessary and sufficient for the development of chronic neuropathic pain demonstrated in a variety of animal models. Interleukin-10 (IL-10) is a powerful endogenous anti-inflammatory cytokine. Intrathecal (i.t., peri-spinal) viral vectors encoding IL-10 transiently suppress peripheral neuropathic pain for several weeks. Surprisingly, i.t. application of non-viral IL-10 transgene dramatically improves the duration of pain suppression, lasting 90+ days. Despite numerous reports demonstrating prolonged non-viral spinal IL-10-efficacy in pain suppression, the underlying mechanisms remain poorly understood. Furthermore, given endogenous IL-10 can impact transgene uptake and also the development and progression of neuropathic pain itself, we first investigated whether IL-10 deficiency alters the initiation and maintenance of allodynia caused by chronic constriction injury (CCI) of the sciatic nerve. Subsequent to characterizing the behavioral phenotype in IL-10 knockout (KO) mice following CCI, we then sought to determine whether i.t. IL-10 could alter the magnitude and duration of allodynia. In behaviorally verified mice, we aimed to quantify the spinal IL-10 protein expression timecourse in specific cell types using IL-10 knockout (KO) mice under chronic neuropathic conditions. Baseline (BL) hindpaw response thresholds to light touch stimuli (von Frey fiber test) of adult male IL-10 KO or C57BL/6 wild type (WT) mice were assessed prior to CCI or sham surgery. Thresholds were reassessed 1, 3, 5, 7, and 8 days post-surgery, then every 4-5 days until allodynia resolved. IL-10 KO mice exhibit exaggerated allodynia within 24-hours post-surgery compared to WT mice, but with comparable levels at subsequent timepoints, with allodynia resolved by Day 42. While

currently ongoing, pilot data demonstrates that a single i.t. co-injection (10.5µL total) of non-viral plasmid DNA encoding the IL-10 transgene (3µg) with the adjuvant D-mannose (25µg) on day 5 post-surgery produced reversal from allodynia to BL levels within 2 days in both IL-10 KO and WT mice. Ongoing studies continue to monitor hindpaw thresholds every 3-4 days until Day 42 post-injection. Future studies aim to identify IL-10 transgene expression in discrete spinal, spleen & lymph node cell populations. Other phenotypic markers of immune-cell activation will be analyzed using FLOW cytometric and ELISA techniques.

Title: MicroRNA-219 in ventral tegmental area regulates pain by targeting CC2D1A

Authors: ***S. ZHANG**, X.-N. YANG, T. ZANG, Z.-Q. PAN, H. LIU, Y.-Q. LI, H. ZHANG, J.-L. CAO;
Jiangsu Province Key Lab. of Anesthesiol., Xuzhou Med. Col., Jiangsu, China

Abstract: Chronic pain is still a basic science and clinical challenge. Unraveling of the neurobiological mechanisms involved in chronic pain will offer novel targets for the development of therapeutic strategies. Recent studies have showed that maladaptation of ventral tegmental area (VTA) dopaminergic neurons is implicated in pain modulation. A growing body of evidence has also demonstrated that epigenetic mechanisms participated in maladaptation of VTA dopaminergic neurons in the different pathological status like depression and drug addiction. Here, we demonstrated that microRNA-219 (miR-219) in the VTA regulates pain by targeting CC2D1A. We found that the expression level of miR-219 in VTA decreased after

intraplantar injection of CFA. Over-expression of miR-219 attenuated CFA-induced thermal hypersensitivity; while, down-regulation of miR-219 dramatically decreased the paw withdraw latency. Double staining showed that the GFP-tag of miR-219 was colocalized with glial fibrillary acidic protein (GFAP), but not with TH-positive DA neurons. Intra-VTA injection of fluorocitrate partially reversed the miR-219 down-regulation-induced thermal hyperalgesia. Down-regulation of miR-219 also increased the levels of proinflammatory cytokines in VTA and induced dopaminergic neurons activation. MiR-219 could directly regulate the expression of CC2D1A *in vivo* and *in vitro*. Genetic disruption of CC2D1A/NF-κB pathway by siRNA could reverse the miR-219 down-regulation-induced thermal hyperalgesia, increased levels of proinflammatory cytokines and dopaminergic neurons activation. Furthermore, inhibition of VTA DA neurons by microinjection of baclofen into VTA reversed the miR-219 down-regulation induced pain hyperalgesia. Collectively, our results support an integral role for VTA miR-219 in pain modulation by targeting CC2D1A and might therefore provide a novel target for pain therapy.

Title: Protein and transcript levels for Gα proteins in the rostral ventromedial medulla and dorsal horn of the spinal cord of rats with peripheral inflammatory injury

Authors: ***A.-S. WATTIEZ**, C. M. SANDE, R. Y. WALDER, D. L. HAMMOND; Anesthesia Res., Univ. of Iowa, Iowa City, IA

Abstract: Inflammation leads to persistent changes in the pharmacology and physiology of rostral ventromedial medulla (RVM) neurons, inducing a time-dependent increase in the potency of Mu-opioid receptor (MOPr) agonists. The mechanism responsible for this enhancement has not yet been fully discerned. We hypothesize that under conditions of peripheral inflammatory

pain the subcellular pathways to which the MOPr couples may change. Possibilities include a decrement in $G\alpha_i$ or $G\alpha_o$ proteins, or an increase in coupling to $G\alpha_s$ or $G\alpha_z$ proteins. This hypothesis led us to investigate the protein and transcript levels of the different Gα proteins subtypes in the RVM and the spinal cord - first relay of the pain pathway that can be modulated by neurons projecting from the RVM - of animals with or without persistent inflammatory pain. These experiments determined the protein and transcript levels of $G\alpha_i$, $G\alpha_o$, $G\alpha_s$, $G\alpha_q$, and $G\alpha_z$ in the RVM and dorsal horn of the spinal cord of rats following ipl injection of complete Freund's adjuvant (CFA) or saline in the hind paw. Four days or two weeks after ipl injection, tissue punches were obtained from the RVM and the ipsilateral dorsal horn of the spinal cord. Transcript levels were determined by RT-qPCR experiments and were normalized to levels of β-actin transcripts in the same sample. The amounts of Gα protein in the different conditions were assessed by Western blot experiments, and normalized to total protein staining in the same sample. Transcript levels for Gα protein subtypes were similar in between tissue and time points. $G\alpha_s$ transcripts were the most abundant, followed by $G\alpha_o$ and $G\alpha_{i2}$. $G\alpha_{i1}$ was half as abundant as $G\alpha_{i2}$, and the 2 least abundant transcripts were $G\alpha_q$ and $G\alpha_z$. Surprisingly, the inflammation induced by ipl injection of CFA did not change Gα transcript levels for any of the subtypes in either the RVM or the dorsal horn. The finding that levels of $G\alpha_s$ transcript were higher than $G\alpha_i$ or $G\alpha_o$ subunits in the RVM and the spinal cord was unexpected, and merits further study. At the protein level, preliminary Western blot data suggest that ipl injection of CFA decreases the amount of $G\alpha_o$ and $G\alpha_i$ protein in the dorsal horn both 4 days and 2 weeks after the injection. Experiments are underway to determine how persistent inflammatory nociception affects the abundance of the other Gα protein subtypes both in the dorsal horn and the RVM. . These results provide suggestive evidence that persistent inflammatory injury may fundamentally change the Gα protein landscape in the RVM and the dorsal horn of the spinal cord, two major sites of pain transmission and modulation.

Title: High fat diet increases pain behaviors in a rat model of low back pain

Authors: ***J. A. STRONG**[1], W. XIE[1], M. PRINT[1], Y. M. ULRICH-LAI[2], J.-M. ZHANG[1]; [1]Dept Anesthesiol, [2]Dept Psych and Behavioral Neuro, Univ. Cincinnati, Cincinnati, OH

Abstract: Obesity is assoicated with a chronic low-grade inflammation and activation of components of the sympathetic nervous system. Human studies indicate that some chronic pain conditions are more prevalent in obese patients. These conditions include low back pain, and evidence suggests this is not simply explained by the muscles being subjected to increased weight bearing. We used our established model of low back pain to investigate interactions between high fat diets and pain. In this model, longlasting mechanical pain behaviors are induced by locally inflaming the L5 dorsal root ganglion with the immune stimulator zymosan in CFA (LID model). Young adult male rats were ad libitum-fed either high fat diet (HFD; 40 % of calories from fat, primarily butter fat) or conventional low fat chow. Blood samples were obtained every 2 weeks for measurement of plasma adipokines and inflammatory cytokines. HFD had no effect on baseline mechanical sensitivity. The LID model was implemented after 6 weeks on the diet and the diet was continued for the rest of the experiment. The amount of zymosan injected was reduced to 1/10 of the amount usually used for this model, with the result that animals on normal chow displayed no increased mechanical pain sensitivity. However, animals on HFD showed marked mechanical hypersensitivity (von Frey test) and mechanical allodynia (responses to light strokes), similar to that previously seen at the higher dose of zymosan in rats on conventional low fat chow diets. Cold responding (acetone test) was also elevated by HFD on some days. Similar behavioral results were obtained in male and female rats. The marked effects of HFD on pain behaviors in this model should facilitate investigation of mechanisms for interactions between dietary fat and pain.

Title: Attenuation of opioid analgesia in T-cell deficient mice

Authors: ***S. F. ROSEN**, I. WALTERS, S. SOTOCINAL, J. S. MOGIL;
Psychology, McGill Univ., Montreal, QC, Canada

Abstract: It is now known that neurons are not the only cell type involved in pain processing, which involves Schwann cells, satellite cells, and cells of the immune system, such as microglia, macrophages, and T-cells. Many pain researchers have adopted the use of T-cell deficient mice in their experimental methods to elucidate the role of T-cells in neuropathic pain (Fitzgerald et al., 2009; Zuo et al., 2013), and T cells have been shown to release endogenous opioids (Dietrich et al., 2011). While it is well known that opioids have varying effects on the immune system, very little attention has been given to how the immune system may affect opioid regulation. We now have evidence that T-cell deficient mice (CD-1 nude and Rag1 null mutant) exhibit pronounced deficiencies in morphine analgesia, measured using the tail withdrawal or formalin test. We also observe a sex difference in morphine analgesia in the nude mice, which appears to be dose dependent; female nude mice need a much higher dose of morphine to exhibit analgesia than male nude mice. Furthermore, T-cell deficient mice do not exhibit stress-induced analgesia after restraint. These results suggest that T-cells play a role in opioid-mediated analgesia, in a sex dependent manner. Current experiments are investigating the mechanism behind this phenomenon.

Title: AAV-mediated human arginine decarboxylase (hADC) overexpression modulates opioid tolerance and reinstatement of opioid self-administration

Authors: *C. PETERSON[1], C. C. CHURCHILL[2], S. A. SCHNELL[3], M. RIEDL[3], K. F. KITTO[2], J. WEINHOLD[2], L. VOLCHANOVA[2], G. L. WILCOX[2], C. A. FAIRBANKS[4]; [1]Pharmaceutics, [3]Neurosci., [4]Exptl. and Clin. Pharmacol., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Agmatine, decarboxylated L-arginine, has been shown to reduce opioid analgesic tolerance and opioid-induced drug addiction. Agmatine inhibits NMDA receptor dependent-behavior and spinal long term potentiation; the mechanism by which agmatine reduces pathological neuroadaptation likely involves that system. Since agmatine is endogenous, it may be possible to increase local agmatine levels by overexpression of its enzyme (arginine decarboxylase, ADC). We have developed an adeno-associated viral vector (AAV) to express human ADC in peripheral neurons and the CNS. We then compared development of intrathecal endomorphin-2 induced analgesic tolerance in subjects treated with vector (AAV-hADC) or saline. We also evaluated the impact of AAV9-hADC delivered to the nucleus accumbens in a model of opioid reinstatement. **Methods:** *Endo-2 tolerance*. Mice were pre-treated with either AAV5-hADC or saline. Endo-2 tolerance was induced acutely with a 10 nmol intrathecal injection of Endo-2 or saline. Cumulative dose-response curves to Endo-2 were constructed in each of the groups (Saline-Saline, Saline-Endo-2, AAV5-hADC-saline, AAV5-hADC-Endo-2.) The impact of immunoneutralization of putative endogenously produced agmatine was assessed through the intrathecal pre-treatment of anti-agmatine IgG versus normal IgG. After testing, spinal cords were tested via HPLC analysis for agmatine content. *Oxycodone Reinstatment*. Mice were trained to lever press for oral oxycodone. Following abstinence, mice were injected with either AAV9-hADC or saline bilaterally in the nucleus accumbens. Reinstatement to oral oxycodone was assessed at 3 weeks post-injection. **Results:** A rightward shift in the Endo-2 dose-response curve was observed in control subjects. However, in subjects pre-treated with AAV5-hADC, the ED_{50} values were equivalent between the Endo-2 and saline groups, showing lack of tolerance. In AAV5-hADC subjects pre-treated with anti-Ag IgG (but not normal IgG) Endo-2 tolerance developed, suggesting the importance of endogenous agmatine. Spinal levels of agmatine were elevated in the AAV5-hADC-treated subjects versus controls. Also, subjects treated with AAV9-hADC demonstrated a trend toward reduced reinstatement to oxycodone relative to those treated with saline. **Conclusion:** We interpret the observed inhibition of endomorphin-2 analgesic tolerance in the AAV5-hADC treatment, which was reversed by the pre-treatment of the anti-agmatine IgG, as attributable to agmatine produced from the overexpression of hADC. This is supported by the elevation in agmatine spinal cord levels in the hADC-treated subjects.

Title: CaMKIIα controls the biogenesis of let-7 microRNAs in opioid tolerance

Authors: *Y. HE, Z. J. WANG;
Biopharmaceutical Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Emerging evidence suggests that microRNAs (miRNAs) - mediated cellular adaptations are critical for drug addiction. We previously reported that let-7 family miRNAs contribute to the development of opioid tolerance by targeting the μ opioid receptor. Chronic morphine treatment induced a marked increase of let-7 expression, which functionally correlated with the development of opioid tolerance. The aim of this study was to understand the mechanisms how let-7 is regulated by opioids. We first determined the transcription status of let-7 and found that the expression of primary let-7 (pri-let-7) remained unchanged in SH-SY5Y cells that were treated with morphine (1 μM, for 48 h). In agreement with the *in vitro* observation, chronic morphine tolerance (one 75 mg morphine pellet/mouse, *s.c.*) did not alter the level of pri-let-7 in mouse brain front cortex region. These findings suggested that the robust elevation of let-7 occurred at the post-transcriptional level. In the presence of KN93, inhibitor of Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII), chronic morphine treatment failed to generate let-7 up-regulation in SH-SY5Y cells. We further determined whether inactivation of CaMKIIα by T286A point mutation would affect let-7 expression and opioid tolerance. Indeed, antinociceptive tolerance was absent in $CaMKII\alpha^{T286A}$ mutant mice. Meanwhile, the level of let-7 in $CaMKII\alpha^{T286A}$ mutant mice was much lower than that in wild-type mice, and was resistant to chronic morphine stimulation. Taken together, these data suggested that the activity of CaMKIIα was essential for the biogenesis of let-7 in opioid tolerance.

Title: Study of neuropeptides involved in opioid induced hyperalgesia through liquid chromatography mass spectrometry

Authors: ***N. YANG**[1], S. RUBAKHIN[1], E. ROMANOVA[1], J. SWEEDLER[1], A. PRADHAN[2]; [1]Univ. of Illinois At Urbana Champaign, Urbana, IL; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Opioid induced hyperalgesia (OIH) refers to a paradoxical nociceptive sensitization state caused by exposure to opioids which are used for the treatment of chronic pain. Although the precise molecular mechanism of OIH has not been fully characterized, changes in neuropeptides within the pain pathway are hypothesized to lead in OIH. The role of specific neuropeptides (eg. dynorphin) have been suggested, but there has not been a comprehensive peptidomics study of nervous system regions involved in OIH. To better understand the role of neuropeptides in OIH, we characterized the endogenous peptides in several critical brain regions involved in OIH using a rodent model. OIH was established by injecting escalating doss of morphine twice daily for 4 days. Four different defined regions in the OIH biological circuits were isolated from rats, including the periaqueductal grey, nucleus accumbens, rostroventral medulla and dorsal horn of the spinal cord. Peptides were extracted from tissues and analyzed by nanoLC coupled to a high resolution Q-TOF mass spectrometer. PEAKS software was employed to perform database searches for peptide identification. Initially 43 neuropeptides derived from 11 prohormones have been identified. Opioid peptides play important roles in pain by interacting with opioid receptors. 12 opioid peptides were identified and pro-enkephalin derived peptides were detected in all the regions investigated. Other pain-related peptides were also detected, including substance P, short neuropeptide K and somatostatin (77-87) and pituitary adenylate cyclase-activating polypeptide (111-128). We also observed cerebellin in spinal cord which affects synapse plasticity, and may regulate the neural adaptations result in OIH. In addition, CGRP (19-37) was detected in the dorsal horn. This truncated CGRP has an arginine at the preceding position, which suggests it may not be a degradation product but a peptide enzymatically processed at the monobasic basic site. This work has laid the groundwork for exploring the role of neuropeptides in OIH. In the future, a comparative peptide quantitation study will be conducted between OIH and control groups to discover signaling peptides whose expressions are significantly influenced by OIH. Physiological experiments on the molecular level will help discover their functions and lead to a better understanding of the mechanism of this prevalent disease.

Title: Delta opioid receptor functional competence is inhibited by lipoxygenase metabolites in the carrageenan model of inflammatory pain

Authors: L. C. SULLIVAN[1], *W. P. CLARKE[2], K. A. BERG[1];
[1]Pharmacol., [2]Univ. Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: The function of delta opioid receptors (DOR) expressed by peripheral pain-sensing neurons (nociceptors) is regulated by both cyclooxygenase- (COX) and lipoxygenase (LOX)-dependent arachidonic acid (AA) metabolites. Unlike opioid receptors expressed in other areas (e.g. CNS) or in heterologous receptor systems, opioid receptors expressed by nociceptors are functionally inactive with respect to producing antinociception or inhibition of adenylyl cyclase activity. However, following brief exposure to inflammatory mediators such as bradykinin (BK) or AA, opioid receptors become responsive to opioid agonists (functionally competent) due to the actions of a COX-dependent metabolite of AA. Moreover, in response to metabolism of AA by LOX, DOR returns to an unresponsive state that is refractory to re-induction of functional competence (Sullivan et al., 2015, J Pharmacol Exp Ther 353(1):44-51). Here we show that DOR functional competence can also be induced *in vivo* by brief exposure to carrageenan. Carrageenan produces a state of inflammation that involves a variety of inflammatory mediators, including BK and AA. Intraplantar (i.pl.) injection of carrageenan (500 µg) produced thermal allodynia that lasted for at least 24 h. When tested 15 min after carrageenan, injection of the DOR agonist, DPDPE (20 µg, i.pl.) blocked carrageenan-induced thermal allodynia, indicating that DOR was functionally competent. When tested 3 h or 24 h after carrageenan, DPDPE did not inhibit thermal allodynia indicating that DOR had become unresponsive. However, following injection (i.pl.) of the 12- and 15-LOX inhibitors, Luteolin (3 ug) and Baicalein (3 ug), responsiveness to DPDPE (DOR functional competence) at the 3 h and 24 h time points was restored. These data indicate that opioid receptor system functional competence induced in response to local inflammation produced by carrageenan is transient. However, similar to our

Deleted: in vivo

findings with AA-mediated induction of DOR functional competence, the duration of functional competence can be increased by inhibition of LOX, suggesting that a LOX-dependent AA metabolite produces an unresponsive state of DOR. Results of this study further underscore the extraordinary regulation of the function of opioid receptors expressed by peripheral sensory neurons. Peripherally-restricted opioids may be very effective at treating pain due to inflammation.

Title: 6' -Guanidinonaltrindole (6'-GNTI) targets DOR-KOR heteromers in peripheral sensory neurons

Authors: ***B. A. MCGUIRE**, W. P. CLARKE, K. A. BERG;
UT Hlth. Sci. Ctr., San Antonio, TX

Abstract: Originally developed as a KOR agonist, 6'-GNTI has been shown to have agonist activity at KOR for Gi-protein-mediated signaling in brain and HEK cells and affinity (but no efficacy) for DOR. However, in peripheral nociceptors, we have found that 6'-GNTI agonist activity for Gi-mediated responses requires expression of both KOR and DOR. In primary cultures of peripheral sensory neurons, 6'-GNTI inhibited adenylyl cyclase activity by 65%. However, following siRNA knockdown of DOR, 6'-GNTI had no effect on adenylyl cyclase activity but antagonized the response to the KOR agonist, U50488. Similarly, when KOR expression was reduced with siRNA treatment, 6'-GNTI had no effect on adenylyl cyclase activity, but antagonized the response to the DOR agonist, DPDPE. Thus, 6'-GNTI has affinity, but not efficacy (i.e. acts as an antagonist) when either DOR or KOR expression is reduced.

Importantly, these data suggest that 6'-GNTI efficacy requires activation of DOR-KOR heteromers in peripheral nociceptors. Because we have demonstrated that allosteric interactions between protomers of DOR-KOR heteromers can regulate DOR and KOR agonist potency and efficacy in peripheral nociceptors, (Berg et al., 2012, Mol Pharmacol 81:264-272; and Jacobs et al this meeting), we next tested the hypothesis that 6'-GNTI occupancy of the DOR protomer of DOR-KOR heteromers allosterically enhances its own efficacy at KOR. In peripheral sensory neuron cultures, we measured 6'-GNTI-mediated responses in the presence of several different selective DOR antagonists. Both inhibition of adenylyl cyclase activity as well as antinociception in response to 6'-GNTI were reduced in the presence of the DOR antagonists naltrindole (2nM, 100x Ki) or 7-Benzlidenealtrexone (1nM, 100x Ki). By contrast, naltriben (NTB, 1nM, 100x Ki), fully substituted for 6'-GNTI occupancy of DOR. The concentration response curves of 6'-GNTI for inhibition of adenylyl cyclase activity were superimposable in the absence (DOR occupancy by 6'-GNTI) and presence of NTB (DOR occupancy by NTB). Similarly, in a behavioral model of thermal allodynia, 6'-GNTI produced the same robust antinociceptive response in the presence or absence of NTB. These data are consistent with the hypothesis that 6'-GNTI occupancy of DOR augments its own efficacy at KOR through allosteric interactions between DOR and KOR within the DOR-KOR heteromer.

Title: Prolonged functional competence of delta opioid-kappa opioid receptor (DOR-KOR) heteromers in the rat carrageenan model of inflammatory pain

Authors: M. M. PANDO, B. A. JACOBS, L. C. SULLIVAN, R. J. JAMSHIDI, P. M. LOCOCO, T. A. CHAVERA, W. P. CLARKE, *K. A. BERG;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Opioid receptor systems expressed by peripheral pain-sensing neurons (nociceptors) are under dual regulatory control by cyclooxygenase (COX) and lipoxygenase (LOX) dependent arachidonic acid (AA) metabolites. For example, delta opioid receptors (DOR) are functionally inactive under basal conditions, but become responsive (i.e., functionally competent) following exposure to inflammatory mediators (e.g., carrageenan, bradykinin (BK) or AA) that produce COX-dependent AA metabolites. Following induction of functional competence by AA, DOR reverts to a basal non-responsive state that is refractory to re-induction of functional competence. This refractory, non-responsive state can be blocked by inhibiting LOX thereby allowing DOR functional competence to be re-induced (Sullivan et al., 2015, J Pharmacol Exp Ther 353: 44-51). Recently we reported that, in peripheral nociceptors, DOR forms heteromers with kappa opioid receptors (KOR) that produce robust antinociceptive responses following exposure to BK (Berg et al., 2012, Mol Pharmacol 54:94-104). Here we sought to explore DOR-KOR heteromer responsiveness in the carrageenan model of inflammatory pain. We examined the actions of the DOR agonist, DPDPE, the KOR agonist, U50488 and the DOR-KOR heteromer agonist, 6'-GNTI, to inhibit carrageenan induced thermal allodynia in the rat. When tested 15 min after intraplantar (i.pl) injection of carrageenan (500 ug), all agonists were effective at reducing carrageenan-induced thermal allodynia. When tested either at 3h or 24h post-injection of carrageenan, neither DPDPE nor U50488 reduced the thermal allodynia. However, responsiveness (i.e. functional competence) was restored by inhibition of LOX. Interestingly and by contrast, 6'-GNTI remained capable of inhibiting carrageenan-induced thermal allodynia for up to 24h (longest period tested) post-injection. These data suggest that DOR-KOR heteromers are differentially regulated by LOX metabolites. Further, in striking contrast to DOR and KOR, DOR-KOR heteromers appear to remain functionally competent for a prolonged period of time under inflammatory conditions, suggesting that they may be suitable targets for development of peripherally-restricted pain medications.

Title: Epigenetic regulation of spinal cord gene expression contributes to enhanced postoperative pain and analgesic tolerance after continuous opioid exposure

Authors: *P. SAHBAIE[1,2], D.-Y. LIANG[1,2], X.-Y. SHI[1,2], Y. SUN[1,2], J. CLARK[1,2];
[1]Dept. of Anesthesia, Stanford Univ., Palo Alto, CA; [2]VA Palo Alto HCS, Palo Alto, CA

Abstract: Opioid induced hyperalgesia (OIH), as well as, analgesic tolerance are unfavorable consequences of extended opioid use. Both typically resolve within days after cessation of morphine treatment. Post-surgical pain is prolonged if mice are previously exposed to opioids. We have shown earlier that among several implicated gene targets, expression levels of Bdnf (Brain-derived neurotrophic factor) and Pdyn (Prodynorphin) were closely related to OIH. The present study was carried out to investigate the epigenetic regulatory changes of Bdnf and Pdyn in supporting the enhanced incisional pain hypersensitivity after opioid exposure. The study went on to characterize morphine analgesic tolerance at several timepoints following surgery in groups exposed to morphine earlier. Mice were treated with ascending doses of morphine for 4 days and subsequently received hind paw incisions. Mechanical withdrawal thresholds were significantly decreased in the morphine plus incision group compared to morphine or incision alone groups. Analgesic tolerance to morphine was increased on days 3 and 6 after surgery in the morphine plus incision group compared to respective controls. Experssion of Bdnf and Pdyn were increased on day 1 but only Pdyn levels were elevated on day 3 after surgery. ChIP (Chromatin immuoprecipation) assays demonstrated that promoter regions of Pdyn and Bdnf were more strongly associated with aceH3K9 (Acetylated histone H3 Lysine9) after morphine plus incision treatment than morphine or incision alone groups. The selective TrkB (tropomyosin-receptor-kinase) antagonist ANA-12 reduced hyperalgesia when given spinally one or three days after surgery. Intrathecal treatment with the selective kappa opioid receptor antagonist nor-BNI had similar effects on pain sensitivity. The administration of ANA-12 or nor-BNI attenuated morphine analgesic tolerance on day 1, but only nor-BNI was effective on day 3 after surgery in opioid exposed group. The co-administration of histone acetyltransferase inhibitor anacardic acid daily with morphine resulted in reversal of OIH and further treatment attenuated enhanced hyperalgesia in the morphine plus incision group compared to controls. The present study shows histone modification of spinal genes contributes to enhanced postoperative pain and analgesic tolerance after continuous opioid exposure. Treatments blocking the differential expression of BDNF and dynorphin by inhibiting histone acetylation would have a potential in reducing postoperative pain, OIH and tolerance.

Title: An allosteric modulator of the mu-opioid receptor promotes opioid-mediated antinociception

Authors: ***T. M. HILLHOUSE**[1], J. E. HALLAHAN[1], K. E. LIVINGSTON[1], C. MEURICE[2], M.-H. LI[3], S. L. INGRAM[3], J. R. TRAYNOR[1];
[1]Pharmacol., Univ. of Michigan, Ann Arbor, MI; [2]Pharmacol., Univ. of Pennsylvania, Philadelphia, PA; [3]Neurolog. Surgery, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Positive allosteric modulators (PAMs) of the mu-opioid receptor, such as BMS-986122, are compounds that bind to a site on the receptor that is distinct from the orthosteric site for endogenous opioid peptides and traditional opioid analgesics and enhance the activity of orthosteric agonists. Such mu-opioid receptor PAMs (mu-PAMs) could act as stand-alone analgesics and/or enhance the action of traditional opioid agonists and thereby reduce the level of opioid drug required to afford pain relief. In cells expressing the mu-receptor BMS-986122 is silent, i.e. it does not activate signaling downstream of the mu-opioid receptor. However, in membranes from both cloned cells expressing mu-opioid receptors and mouse brain membranes BMS-986122 enhances the binding affinity and potency and/or efficacy of a wide range of mu-opioid receptor orthosteric agonists, including endogenous opioid peptides, in a probe-dependent manner. The most robust increase in affinity and potency is seen with R(-)-methadone. Here we provide proof of principle that mu-PAMs can be effective *in vivo* by determining antinociceptive activity in the mouse using the hot-plate assay. In addition, opioid modulation of GABA synaptic transmission was monitored in periaqueductal gray (PAG) neurons. BMS-986122 given intracerebroventricularly (i.c.v.) caused a substantial increase in the antinociceptive activity of R(-)-methadone given i.c.v. or systemically and a moderate increase in the antinociceptive activity of systemic morphine. At higher doses BMS-986122 alone (i.c.v.) afforded a short-lived antinociception that was completely prevented by pretreatment of the mice with naloxone or the selective mu-antagonist beta-FNA. Furthermore, BMS-986122 promoted swim-stress induced antinociception that was blocked by pretreatment with naloxone. In slices of the PAG, BMS-986122 enhanced the ability of Met-enkephalin to inhibit presynaptic GABA release. These studies demonstrate that mu-PAMs enhance the activity of the mu-opioid receptor *in vivo* and so

Title: BK channel in microglia as a promising molecular target for the treatment of opioid-induced hyperalgesia

Authors: *Y. HAYASHI, H. NAKANISHI;
Fac of Dent. Sci. Kyushu Univ., Fukuoka, Japan

Abstract: BK channels are the intracellular Ca2+ and voltage gated potassium channel. They are widely distributed throughout the nervous system to control neuronal excitability and neurotransmitter release. They are also expressed in electrically non-excitable cells such as cancer cells and immune cells, whereas little is known about their functions. Recently, we have found that large outward currents mediated by BK channels in the spinal microglia contribute to the initiation of neuropathic pain. In the present study, we have examined a possible involvement of microglial BK channels in opioid-induced hyperalgesia, because some evidence suggests the involvement of microglia in this event. Repeated morphine administration gradually enhanced pain sensitivity. At the same time, repeated morphine administration activated BK channels in microglia, but not in neuron, by generation of arachidonic acid and its metabolites through μ receptors. Morphine-induced hyperalgesia was significantly suppressed by BK channel inhibitor. The development of hyperalgesia was accelerated by intrathecal administration of morphine-primed wild-type, but not BK channel-deficient, microglia. Furthermore, the activation of BK channels promoted P2X4 receptor trafficking to the cell surface of microglia. These results indicate that BK channels in the spinal microglia also play an important role in the development

of opioid-induced hyperalgesia. Therefore, the BK channel is a potential molecular target for the treatment of both neuropathic pain and opioid-induced hyperalgesia.

Title: Examination of classical and non-classical opioid receptor binding of neuroimmune targeted agents using radioligands

Authors: ***M. R. HUTCHINSON**[1,2], J. THOMAS[1], K. C. RICE[3], D. KYLE[4], A. A. SOMOGYI[1];
[1]Univ. Adelaide, Adelaide, Australia; [2]ARC Ctr. of Excellence for Nanoscale BioPhotonics, Adelaide, Australia; [3]Inst. on Drug Abuse and Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [4]Purdue Pharma, Cranbury, NJ

Abstract: Recent advances in opioid research has shown that opioid agonists cause significant reactivity in immunocompetent cells of the brain and spinal cord which is hypothesised to be key in mediating some unwanted side effects such as analgesic tolerance, hyperalgesia and reward processes. Pharmacologically inhibiting the immune reactivity, genetically removing TLR4, or (+)opioid antagonists significantly increases opioid analgesia and diminishes these unwanted pharmacodynamic responses. Here we present an independent replication of these opioid tolerance and hyperalgesia results in TLR null mutant animals. Additionally, this study set out to examine a range of key drugs that target this immune reactivity and to determine if they have any direct action at opioid receptors. Secondly, we assessed if TLR4 could modify [3H](-)naloxone binding kinetics. And thirdly, we assessed if a (+)opioid isomer binding site could be detected. Saturation binding studies were performed with increasing concentrations of [3H](-)naloxone, [3H]diprenorphine, and [3H](+)naloxone. Binding reactions were performed using HEK-μOR membrane, mouse brain membranes, mouse brain homogenate, or HEK-μOR, HEK-κ-OR, HEK-δ-OR, HEK-TLR4/MD-2 or RAW264.7 homogenates. Animal tissues were also sourced from wild type and TLR4 null mutant Balb/c mice. Our data demonstrated that of a range of examined neuroimmune active agents that only amitriptyline and WZ811 (CXCR4 antagonist) have direct

binding at the mu receptor but with no agonist activity. Brains from null mutant TLR4 animals displayed a small but significant increase in [3H]diprenorphine μOR binding affinity (lower Kd) and in the total number of binding sites (Bmax). No specific binding site for [3H](+)naloxone and minimal specificity was observed for [3H](-)naloxone in the nanoM to low microM concentration range in any of the models tested. Autoradiographic imaging will also be presented. Ongoing exploration of the characterisation of the specific binding site of (+)-naloxone will be discussed, along with unpacking of the disconnect between *in vivo* behavioural data and *in vitro* results.

Title: Nitric Oxide implicated in the reduced inhibitory response of the distal colon in mice lacking TLR2/4 receptors

Authors: ***V. STAIKOPOULOS**[1], E. A. H. BECKETT[2], X. Z. ZHANG[3], S. HENG[3], M. R. HUTCHINSON[2];
[1]Physiol., Univ. of Adelaide, Adelaide University, Australia; [2]Physiol., [3]Chem., Univ. of Adelaide, Adelaide, Australia

Abstract: Evidence suggests that the undesirable central side effects of opioid medications involve the activation of Toll-like receptors (TLRs) rather than the classical (mu, kappa, delta) opioid receptors. In addition to their expression within the CNS, TLRs are expressed within various cell types of the gastrointestinal (GI) tract, yet their functional role in this location remains unclear. The involvement of TLRs in opioid-induced inhibition of GI motility was investigated *in vivo* and *in vitro* using wildtype Balb/c and genetically TLR2/4 deficient male mice (TLR2/4-/-). *In vivo*, morphine-induced retardation of GI transit was significantly diminished in TLR2/4-/- mice by 57%. In organ bath experiments, a 10-fold higher concentration

Deleted: in vivo

Deleted: in vitro

Deleted: In vivo

of morphine was required to abolish migrating motor contractions (MMCs) at the distal end of TLR2/4-/- colon (1uM) compared to the corresponding region of wildtype animals (0.1uM). Additionally, morphine potentiated the amplitude of EFS-evoked relaxations of Balb/c distal colon segments (6.2 ± 1.0 mN pre-morphine to 10.0 ± 1.0 mN in morphine, 10Hz EFS) but a similar potentiation of relaxation response was not seen in TLR2/4-/- (4.18 ± 0.9 mN elicited by 10Hz EFS pre morphine and 2.67 ± 0.8 mN post-morphine). It has been suggested that attenuated TLR signalling *in utero* compromises the development of nitrergic nerves innervating the distal bowel. Our immunohistochemical analysis of distal colon segments of adult wildtype and TLR2/4-/- failed to reveal a significant difference in either the number of Hu-positive nerve cell bodies per ganglia nor the proportion of nNOS-positive cell bodies to the total number of Hu-positive cell bodies. However, decreased intensity of nNOS immunofluorescent labelling within intramuscular terminals was observed. Relaxations elicited by 10uM concentrations of the exogenous nitric oxide donor, sodium nitroprusside (SNP) were attenuated in TLR2/4-/- distal colon segments (relaxation to SNP (10 uM) 3.5mN in Balb/c and 1.7mN in TLR2/4-/-) suggesting a reduction in the post-junctional sensitivity to nitric oxide accompanies loss of TLR2/4 signalling. Through the joint efforts of the ARC Centre of Excellence for Nanoscale Biophonotics and Institute for Photonics and Advanced Sensing, we are currently working towards the development of a photo-switchable sensor that will allow us to measure nitric oxide release in real time within gastrointestinal specimens. We are hopeful that the development of such a tool will assist with quantifying and localizing release of NO for this and other biological research applications.

Title: Expression of an alternative delta-opioid receptor transcript in the mouse spinal cord

Authors: ***M. H. PILTONEN**, A.-J. CHABOT-DORÉ, M. PARISIEN, L. S. STONE, L. DIATCHENKO;
The Alan Edwards Ctr. for Res. on Pain, McGill Univ., Montreal, QC, Canada

Abstract: The delta-opioid receptor (DOR) is an opioid receptor whose endogenous ligands are enkephalins. Structurally, it has 7-transmembrane (7TM) domains, making it part of the G protein -coupled receptor family. Studies have linked DOR to pain perception, regulation of mood and neuroprotection. Although only one gene transcript is known to code for DOR in human and mouse, pharmacological characterization has led to classification of two receptor types: delta1 and delta2. The apparent simplicity of the DOR transcripts is surprising in the face of another closely related receptor, the mu-opioid receptor (MOR). MOR displays a diversity of transcripts; some encode for N-terminally truncated 6-transmembrane (6TM) domain receptors, while others are translated into single-TM domain chaperones, all in addition to the major 7TM isoform. Also, the human kappa-opioid receptor has a reported alternative transcript that is predicted to code for a 6TM receptor. Recently, we discovered an alternative transcript of the human DOR encoding for a 6TM receptor, which directed us to look at the mouse gene as well. While searching databases, we found an alternative DOR transcript for mouse in the NCBI library, annotated as a predicted transcript variant X1. Unfortunately, we found no literature regarding this transcript. Structurally, X1 consists of a fragment of exon 1, an additional exon A between exons 1-2, followed by exon 3. Exon A introduces a premature stop codon in respect to the canonical start site, but also incorporates a downstream second translational start site. Transmembrane domain prediction tool showed that it would yield a truncated 6TM receptor with an N-terminal peptide tail. From the spinal cord of a wild-type mouse, we were able to PCR amplify and sequence a long fragment of the X1, spanning from exon A to the last coding exon 3. Interestingly, the same fragment was found also in the DOR knockout mouse with a deletion of exon 1 (B6.129P2-Oprd1tm1Dgen). Our finding was supported by another experiment, in which we combined rapid amplification of 5’ ends PCR with deep sequencing of long transcripts derived from the mouse spinal cord. The same X1 transcript appeared in the sequence alignment. Taken together, our results provide a possible explanation for the existence of delta1 and delta2 receptor subtypes. It will be essential to study if the signaling of the 6TM DOR differs from that of the classic 7TM DOR, and to identify specific roles of these receptor types in normal physiology and disease pathophysiology. This will help to evaluate the potential of the receptors as a therapeutic drug targets, as there are no DOR-selective drugs available for clinical use yet.

Title: Awakening the delta opioid receptor in peripheral sensory neurons

Authors: ***A. P. DOYLE**[1], N. A. JESKE[2,3,4];
[1]Dept. of Pharmacol., [2]Oral & Maxillofacial Surgery, [3]Pharmacol., [4]Physiol., UTHSCSA, San Antonio, TX

Abstract: Peripherally acting opioids are desirable for producing analgesia while eliminating debilitating central side effects. However, peripheral opioid efficacy is reduced in the absence of tissue inflammation, such that the delta opioid receptor (δ-, DOR) is less responsive to agonist activation. Bradykinin (BK), a potent inflammatory mediator, has been shown to enhance receptor responsiveness and increase peripheral opioid efficacy in a protein kinase C (PKC)-dependent manner. Therefore, constitutively desensitized DOR becomes "primed" for activation following inflammation. A gap in knowledge exists concerning the mechanism regulating constitutive DOR analgesic incompetence and represents an important opportunity to identify new pharmaceutical targets to enhance opioid efficacy. Here we report that G protein-coupled receptor kinase 2 (GRK2) naively associates with DOR in sensory neurons. Conversely, BK pretreatment reduces this interaction. Moreover, siRNA-mediated knockdown of GRK2 in dorsal root ganglion (DRG) nociceptors resulted in a significant increase in functional DOR competence, independent of BK. Overexpression of GRK2 or a kinase inactive mutant blocked BK-induced DOR competence, and suggests that kinase activity is not necessary for GRK2 modulation of DOR. Given its role in DOR signaling, a change in GRK2 targeting in peripheral sensory neurons may enhance DOR competence. Raf-1 kinase inhibitory protein (RKIP) is an important signaling modifier. Following BK treatment, PKC promotes phosphorylation of RKIP and RKIP sequestration of GRK2 in primary sensory neurons. To determine the role of GRK2 sequestration by RKIP in functional DOR competence, DRG were nucleofected with RKIP or a phospho-deficient mutant. Overexpression of RKIP enhanced DOR activity compared to the mutant, and was further enhanced by pretreatment with BK. Conversely, RKIP siRNA treatment suppressed DOR activity. Thus, one mechanism responsible for functional DOR priming by BK is RKIP sequestration of GRK2. To further elucidate the role of GRK2 in DOR competence *in vivo*, we decreased GRK2 expression using targeted intrathecal antisense oligodeoxynucleotide (AS-ODN). GRK2 AS-ODN administration enhanced DPDPE inhibition of intraplantar PGE2-induced thermal allodynia relative to mismatch controls. Interestingly, the onset of DPDPE-induced analgesia occurred more quickly during GRK2 knockdown when pretreated with BK. Collectively, the results from these studies demonstrate that reducing chronic GRK2 association with DOR can significantly enhance DOR competence and improve analgesic efficacy. Title: Implication of COPB1 in intracellular retention of the delta opioid receptor

Authors: ***L. GENDRON**, E. ST-LOUIS, J.-L. PARENT;
Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: As opposed to most G protein-coupled receptors, the delta opioid receptor (DOP receptor) is poorly addressed at the plasma membrane. Indeed, it has been proposed that, under normal conditions, only a small proportion of DOP receptors can escape the endoplasmic reticulum (ER) and reach the plasma membrane. We and others have shown previously that the plasma membrane density of DOP receptors in neurons as well as the analgesic effects of delta agonists can however be increased by morphine and inflammation. Most recently, we have described an important role for cdk5 in mediating these effects. In this study, we sought to better described the molecular mechanisms involved in the regulation of DOP receptor trafficking. We have identified and investigated the role of 4 putative COPB1 binding motifs located in the intracellular loops (ICL) of the DOP receptor. In particular, one COPB1 binding motif was found within the consensus cdk5 phosphorylation motif in the ICL2 of the DOP receptor. In transfected HEK cells, the colocalization of DOP receptors with COPB1 was confirmed by confocal microscopy. When co-expressed in the same cells, we also found that COPB1-myc co-immunoprecipitated with Flag-DOP receptor. Using GST pull-down assays, we confirmed that COPB1 is able to interact with DOP receptor's ICL2 and ICL3 via the COPB1 binding motifs and that the mutation of these motifs interferes with the ability of COPB1 to associate with DOP receptors. Most interestingly, replacing T161 (the ICL2 amino acid residue phosphorylated by cdk5) by a negatively charged residue (i.e. pohosphomimetic) decreased the ability of COPB1 to

bind the ICL2 of the DOP receptor. Because COPB1 is known to be involved in the retrograde transport from the Golgi to the ER, we also studied the impact of mutations altering the COPB1 binding motifs on the surface expression of Flag-DOP receptors in HEK cells using an ELISA assay and found that one of the mutants had higher cell surface expression. Together, our results suggest that COPB1 is involved in the intracellular retention of DOP receptors. We now propose that cdk5 regulates the trafficking of DOP receptor by promoting the phosphorylation of T161, which in turn interferes with the association of COPB1, helping the receptor to escape the ER and reach the plasma membrane.

Title: The delta opioid receptor agonist SNC80 preferentially recruits beta-arrestin 1 to promote analgesic tolerance

Authors: *A. VICENTE-SANCHEZ[1], A. F. TIPTON[1], H. AKBARI[1], L. SEGURA[1], M. L. SMITH[2], A. A. PRADHAN[1];
[1]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [2]Semel Inst. for Neuropsychiatry and Human Behavior, Univ. of California, Los Angeles, CA

Abstract: Ligand directed signaling via the delta opioid receptor (DOR) has important implications given the potential therapeutic uses of delta agonists in the treatment of chronic pain and emotional disorders. We had previously shown that repeated injection of the high-internalizing delta agonist (+)-4-[(αR)-α-((2S,5R)-4-allyl-2,5-dimethyl-1-piperazinyl)-3-methoxybenzyl]-N,N-diethylbenzamide (SNC80), produced acute behavioral desensitization while the low-internalizing delta agonist N,N-diethyl-4-(phenyl-piperidin-4-ylidenemethyl)-benzamide (ARM390) did not. Since beta-arrestins are well known to regulate G protein-coupled receptors signaling and trafficking, we therefore investigated the behavioral significance of

ligand-specific interactions between beta-arrestin 1 and the DOR. Mice lacking beta-arrestin 1 showed enhanced and longer lasting pain-relieving effects of SNC80, and decreased acute tolerance following repeat exposure to the agonist. In contrast, ARM390 produced similar analgesic effects and no acute tolerance in both wildtype and knockout animals. Following chronic treatment, the absence of beta-arrestin 1 attenuated the extent of tolerance to SNC80, but not to ARM390. Furthermore, chronic treatment with SNC80 abolished delta agonist-induced GTPgammaS binding in wildtype brain membranes, whereas DOR-G protein coupling remained intact in beta-arrestin 1 knockout mice. Overall, these results indicate that delta opioid receptor agonists interact with beta-arrestins in a ligand-biased manner, and that the high-internalizing agonist SNC80 preferentially recruits beta-arrestin 1.

Title: Intracellular signaling pathway underlying Cannabinoid Receptor-2 activation-induced β-endorphin production in HaCaT cells

Authors: ***F. GAO**[1], L.-H. ZHANG[1], R. ZHOU[2], H.-L. PAN[3], M. LI[1];
[1]Dept. of Neurobio., Sch. of Basic Medicine, Tongji Med. Col., Hubei, China; [2]Dept. of Physics, Huazhong Univ. of Sci. and Technol., Wuhan, China; [3]Dept. of Anesthesiol. and Perioperative Med., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Activation of peripheral cannabinoid receptor-2 (CB2) by its selective agonist AM1241 results in the production of β-endorphin in keratinocytes cells, which then acts on primary afferent neurons to inhibit nociception. However, the intracellular signaling pathway underlying CB2 receptor activation-induced β-endorphin production, including the expression of its precursor POMC and release of β-endorphin is still unknown. The CB2 receptor is generally thought to couple to Gi/o to inhibit cAMP production, which cannot explain the stimulatory

effects of CB2 receptor activation. Using protein-protein docking, we found a novel interaction between CB2 receptor and Gαs and confirmed it with co-immunoprecipitation. However, GNAS shRNA targeting Gαs didn't inhibit CB2 receptor activation-induced β-endorphin production and AM1241 significantly attenuated the forskolin-stimulated cAMP accumulation. The Gi/o inhibitor pertussis toxin or the Gβγ inhibitor Gallein blocked CB2 receptor-induced β-endorphin production. Also, the ERK/MAPK kinase inhibitor PD98059, but not the PLC inhibitor U73122, abolished CB2 receptor activation-induced increases in β-endorphin production in cultured human keratinocytes cells. The elevation in intracellular Ca^{2+} occurred in parallel with CB2R activation-induced β-endorphin release. By using BAPTA-AM and thapsigargin to inhibit intracellular Ca^{2+}, we demonstrated that CB2 receptor activation-induced β-endorphin release was calcium dependent. Using a rat model of inflammatory pain, we showed that the MAPK kinase inhibitor PD98059 abolished the peripheral effect of the CB2 receptor agonist on nociception. We thus present a novel mechanism of CB2 receptor activation-induced β-endorphin release through Gi/o-Gβγ-MAPK-Ca^{2+} signaling pathway. Our data also suggest that stimulation of MAPK contributes to the peripheral analgesic effect of CB2 receptor agonists.

Modulation of G protein-coupled receptor trafficking and activity by receptor-interacting proteins from the Natural Sciences and Engineering Research Council of Canada (NSERC)

Title: Knockdown of the secretory protein secretogranin III results in a loss of NTS2 receptor-mediated spinal analgesia

Authors: ***M. ROUX**[1], M. LEMIRE[1], J. LAINÉ[1], J.-M. LONGPRÉ[1], A. M. JACOBI[2], S. D. ROSE[2], M. A. BEHLKE[2], P. SARRET[1];

[2]Integrated DNA technologies, Coralville, IA

Abstract: Export of neo-synthesized G protein-coupled receptors (GPCRs) from intracellular compartments to the cell surface represents a crucial checkpoint in controlling the level of functional receptors available at the plasma membrane and the magnitude of the cellular response elicited by a ligand. Although cell-surface export of GPCRs is commonly considered to implicate the constitutive unregulated secretory pathway, there is now growing evidence indicating that their post-Golgi trafficking to the cell surface is dynamically regulated by molecular accessory escort proteins and may also rely on the non-canonical regulated secretory pathway via their packaging into large dense-core vesicles. However, the molecular mechanisms underlying GPCR transport to the plasma membrane remain poorly defined. Among GPCRs, we previously demonstrated that activation of the neurotensin receptor 2 (NTS2) produces strong analgesia in different animal pain models. Despite its therapeutic potential, previous studies have shown that NTS2 is poorly expressed on the plasma membrane under basal conditions, but rather stored within the Golgi intracellular sorting compartment. In order to characterize the underlying mechanisms promoting the cell surface recruitment of NTS2, we first screened for interaction partners using a yeast two-hybrid system. This assay identified secretogranin III (SgIII), involved in the formation of regulated secretory vesicles as a NTS2-binding partner. The molecular association between SgIII and NTS2 was further supported by co-immunoprecipitation and GST pull-down assays, as well as by subcellular co-localization studies. As part of this project, we wished to further dissect the role of SgIII in NTS2 receptor function. To this aim, 27-mer Dicer-substrate siRNAs (DsiRNA) used to knockdown SgIII were evaluated in the acute tail-flick nociceptive test, in which intrathecal injection of the NTS2-selective agonist, JMV-431 induces a dose-dependent antinociceptive response. Rats, pre-treated 48h and 24h prior behavioral experiments with DsiRNA targeting SgIII, exhibited a 70% decrease of the JMV-431-induced analgesia. This result seems specific to NTS2 since the injection of SgIII DsiRNA did not affect the antinociceptive effects of morphine or deltorphin II, acting respectively on μ opioid (constitutive secretory pathway) and δ opioid (regulated secretory pathway) receptors. In conclusion, these results demonstrate that the sorting of NTS2 through its interaction with SgIII along the regulated secretory pathway drives NTS2-mediated spinal analgesia.

Title: Effect of eugenol in histamine-induced itch and hapten-induced atopic dermatitis

Authors: *S. LEE[1], P. CHO[1], J. LIM[1], S. OH[2], S. JUNG[1];
[1]Physiol. of Dept. Dept. Med. of Col. Hanyang Univ., Seoul, Korea, Republic of; [2]Natl. Res. Lab. for Pain, Dent. Res. Inst. and Dept. of Physiol. Sch. of Dentistry, Seoul Natl. University, Seoul, Korea, Republic of, Seoul, Korea, Republic of

Abstract: Eugenol is extensively used in dentistry because of local analgesic reagent via inhibition of voltage-gated sodium channel (VGSC) and became known as has properties such as antioxidant and anti-inflammation. Also, eugenol has analgesic effect that mechanical allodynia by peripheral nerve injury were relieved by inhibiting of HCN channels. In the present study, we have examined effect of eugenol in histamine-induced itch and hapten-induced atopic dermatitis. Histamine-induced itch were reduced by eugenol cream as dose dependent manner. Also, eugenol and eugenol isoform (methyl eugenol, isoeugenol) has inhibited histamine-induced itch. Next, we have examined function of eugenol using patch clamp. Eugenol has inhibited capsaicin-induced current at TRPV1-transfected HEK 293 cell. Next, we investigated that eugenol cream assists skin recovery in atopic dermatitis. When we applied eugenol cream for 1 week, improved tissue status and reduced cytokines (IL-4, IL-13) in tissue. Finally, we have tested effect of eugenol as behavioral test in atopic dermatitis model. Eugenol cream has inhibited itch response in hapten-induced atopic dermatitis. Taken together, these results revealed that eugenol is novel therapeutic agent in hapten-induced atopic dermatitis and histamine-induced itch.

Abstract: Although powerful, pharmacological antineoplastic therapies has led to increased survival for millions of cancer patients, chemotherapeutic agents such as cisplatin produce a number of serious side effects, including peripheral neuropathy. Chemotherapy-induced peripheral neuropathy (CIPN) causes sensory disturbances in the extremities including numbness, paresthesia, and pain, and is the primary dose-limiting side effect that reduces efficacy of treatment and ultimately affects survival. Analgesics typically used to treat neuropathic pain appear to be relatively ineffective in alleviating pain from CIPN as well as display their own display dose-limiting adverse effects, such as those associated with opiates. Given the requisite need for superior pharmacological agents in its treatment, we investigated the antihyperalgesic effects of a novel bivalent ligand, MCC22, in a murine model of cisplatin chemotherapy-induced neuropathic pain. MCC22 contains both mu agonist and CCR5 antagonist pharmacophores linked through a 22 atom spacer. Given the existence of opioid receptor heteromers in cultured cells and possibly *in vivo*, MCC22 may be a potent alternative for the treatment of neuropathic pain without attendant side effects. Adult male C3H/HeJ mice were tested for mechanical paw withdrawal responses on 2 consecutive days prior to treatment by determining the frequency of withdrawal evoked by a calibrated von Frey monofilament with a bending force of 3.9 mN applied to the plantar surface of the hind paws. Mice were then given 1 mg/kg of cisplatin intraperitoneal (i.p.) daily for 7 consecutive days and on day 14 post-injection, mechanical hyperalgesia was assessed. Compounds were administered intrathecally (i.t.) and i.p. weekly to determine peak time effects and ED50/80. Compared to the anti-hyperalgesic effectiveness of the standard opioid agonist morphine, we evaluated the effects of MCC22 both i.t. and i.p. and found MCC22 given i.t. (ED50: 0.0004 pmol/mouse (0.0002-0.0009 95% CI) to be significantly more potent than i.t. morphine (ED50: 27.44 pmol/mouse (16.57-45.43 95% CI) with a peak time of 20 minutes. MCC22 exhibited no tolerance and increased in potency over 115 days. It was also found to be significantly more potent when given i.p.(ED50: 3.07 pmol/mouse (2.45-3.84 95% CI) compared to morphine (ED50: 14.28 pmol/mouse (12.70-16.07

Deleted: in vivo

95% CI) with a peak time of 30 minutes and again did not exhibit tolerance. Morphine both i.t. and i.p. showed significant tolerance. MCC22 potently attenuates hyperalgesia in a cisplatin model of neuropathy and may offer a viable treatment for patients who suffer from CIPN pain without concomittment side effects.

Title: β-arrestin-2-biased apelin receptor agonists as novel potent analgesics

Authors: ***É. BESSERER-OFFROY**, M. LAFRANCE, M. OUIRZANE, A. MURZA, J.-M. LONGPRÉ, É. MARSAULT, R. LEDUC, P. SARRET;
Dept. of pharmacology-physiology, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Apelin is the endogenous ligand of the class A G-protein coupled receptor APJ. We and others have recently demonstrated that spinal or supraspinal delivery of apelin-13 exerts potent analgesic effects in both acute and tonic pain paradigms. Accordingly, APJ is highly expressed in brain regions involved in the regulation of pain transmission and modulation, notably the dorsal root ganglia as well as the periaqueductal grey and rostroventral medulla. The present study was aimed to decode by which signaling pathways the apelin peptide exerts its antinociceptive activity. For this purpose, we synthesized a series of apelin-13 analogs exhibiting unnatural amino acids in position 12 and 13. Pro^{12} and Phe^{13} were respectively substituted by aminoisobutyric acid (Aib) and by the aromatic residues 1-Naphtylalanine (Nal) or 2-Nal. The antinociceptive activities of these newly synthesized compounds were evaluated in the experimental model of formalin-induced tonic pain in Sprague-Dawley rats. We also determined, *in vitro*, their ability to trigger different signaling pathways such as engagement of G-proteins $G\alpha i_1$, recruitment of β-arrestins 1 and 2, and inhibition of cAMP production, following binding to APJ. We then quantified bias using the Black and Leff operational model by calculating the

Deleted: *in vitro*

transduction ratio for each pathway in order to identify potential biased APJ agonists. Our results revealed that all the tested compounds were less active than apelin-13 to inhibit forskolin-induced cAMP production with EC_{50} 10- to 20-fold higher than the native peptide. However, only three analogs were 2- to 8-fold more potent than apelin-13 to recruit β-arrestin 2. Interestingly, these compounds were also the ones to reverse the spontaneous pain behaviors elicited by intraplantar formalin. These analogs present a unique and conserved biased signaling profile towards β-arrestin 2 recruitment over inhibition of cAMP production with significant bias factors ranging from 35- to 83-fold. Taken together, our results demonstrate that incorporation of unnatural amino acids at the C-terminal end of the apelin peptide impacts on the APJ receptor signaling signature and that β-arrestin 2 biased APJ agonists elicit potent analgesia. These results also emphasize the involvement of the apelinergic system in central modulation of pain and represent valuable information for future development of analgesics targeting the APJ receptor.

Title: Site-selective modifications of the neurotensin hexapeptide fragment lead to the generation of highly active and metabolically stable NT(8-13) analogs

Authors: ***M. VIVANCOS**[1], E. BESSERER-OFFROY[1], R. BROUILLETTE[1], A. RENÉ[2], R. FANELLI[2], M. LAFRANCE[1], P. TÉTREAULT[1], J. COLERETTE-TREMBLAY[1], J.-M. LONGPRÉ[1], J. MARTINEZ[2], F. CAVELIER[2], P. SARRET[1];

Abstract: The field of peptide-based therapeutics and diagnostics is experiencing renewed interest during the last decade, when compared to small molecule therapies. However, despite their excellent safety, tolerability and efficacy profiles, naturally occurring peptides are often not directly suitable for use as future therapeutics because they have intrinsic weaknesses, including poor physicochemical stability, and a short circulating plasma half-life. In the present study, we

developed several strategies to increase the chemical stability and reduce the enzymatic degradation of the endogenous neurotensin hexapeptide fragment (NT(8-13)). To this aim, we synthesized a series of NT(8-13) analogs harboring site-specifically modified unnatural amino acids and reduced amide bonds. Pro^{10} and Leu^{13} were respectively substituted by silaproline (Sip) and (trimethylsilyl)alanine (TMSAla) unnatural amino acid residues and a reduced amide bond was incorporated between the Lys^{8}-Lys^{9} amino acid pair. Our results revealed that these new NT(8-13) analogs bind with high affinity to both NTS1 and NTS2 receptors and exhibited improved plasma stability, with half-life exceeding 1 hour. We also determined, *in vitro*, their ability to trigger different signaling pathways linked to NTS1 activation. To this end, we used a BRET-based biosensor assay to monitor béta–arrestins ρεχρυιτment and G-protein engagement. A few of these compounds were found to be more effective in promoting béta–arrestin and G-protein activation than the native NT peptide. We also demonstrated that these newly synthetized analogs were highly potent in reversing carbachol-induced ileal smooth muscle contractions in isolated organ bath. In *in vivo* assays, some of these NT(8-13) derivatives were shown to exert pronounced and sustained hypotensive and/or hypothermic actions. We finally tested their ability to reduce the pain sensations in the acute thermal tail-flick test and in the formalin-induced tonic pain model. Our results revealed that all the tested compounds were more potent than NT(8-13) to produce analgesic responses in the tail-flick assay and to abolish the formalin-evoked spontaneous nociceptive behaviors. Altogether, these results demonstrated that the chemically modified NT(8-13) analogs exhibit improved therapeutic profiles and may represent a promising avenue to regulate the physiological functions of the neurotensinergic system.

Title: Botulinum neurotoxin derivatives as pain specific inhibitors

Authors: ***R. RAMACHANDRAN**[1], S. PELLETT[2], W. H. TEPP[2], C. L. PIER[2], E. A. JOHNSON[2], T. L. YAKSH[1];
[1]Dept of Anesthesiol., UCSD, San Diego, CA; [2]Univ. of Wisconsin, Madison, Madison, WI

Abstract: Background: Botulinum neurotoxins (BoNTs), which consist of a heavy chain (HC) responsible for uptake and a light chain (LC) responsible for catalytic activity, when given intrathecally (IT), produce long term alterations in pain initiated by inflammation and nerve injury in animal models. The HC uptake mechanisms confer no cellular specificity. BoNTs can enter and block neurotransmission in any neuron. The use of IT BoNTs for pain treatment is therefore beset with serious side effects such as muscle paralysis and the potential for a heightened pain state due to a block of inhibitory neurons. For this study, we developed a recombinant BoNT LC- coupled to substance P (SP) that specifically targets sensory neurons involved in pain processing by enhancing clinical efficacy and safety. Therefore our aim was to test the efficacy of a recombinant SP-LC in *in vitro* using cell culture and in *in vivo*, using the intraplantar formalin model of facilitated processing. **Methods:** The truncated BoNT-A1 LC was chemically linked to SP-cys. Following exposure to cultured primary rat spinal cord (RSC) and dorsal root ganglion (DRG) cells as well as NK1 receptor expressing cell line (NG108-15), cleavage of SNAP-25 (SNARE protein) was analyzed. The effect of IT SP-LC was tested using mice with the formalin evoked flinching model. **Results:** Exposure of NG108-15 for 24 or 48 h resulted in uptake of SP-LC and cleavage of the SNARE protein SNAP-25 inside the cells in a concentration -dependent fashion. Mice injected IT (percutaneously) with SP-LC resulted in a significant reduction in Phase II but not Phase I flinching as compared to mice injected with saline, indicating an inhibition in central activation. Measurement of tactile allodynia by von Frey hairs 5, 6, and 7 days post formalin test revealed a prominent tactile allodynia in vehicle mice, but this was reduced in mice injected with SP-LC. **Conclusion:** These data suggests that SP-LC can enter NK1 receptor bearing cells and is catalytically active inside these cells as indicated by SNAP-25 cleavage in sensory neurons and thereby reduces central activation after induction of pain in mice. This indicates that BoNT can be tailored to selectively target the cells of interest and can be a promising approach towards the development of pain therapy. (NIH: 1R21AI113580-01)

Title: The granulocytes-derived chemokine bv8/pk2 is involved in g-csf induced pain

Authors: *L. NEGRI, Prof, R. LATTANZI;
Univ. La Sapienza, Rome, Italy

Abstract: Granulocyte-colony stimulating factor (G-CSF) is commonly employed to reduce the risk of chemotherapy-induced neutropenia in cancer patients, however pain is relevant side effect. G-CSF is the major inducer of the chemokine Bv8/PK2 in inflammatory granulocytes[1]. Bv8/PK2, through GPCR, PKR1 and PKR2, produces pro-algesic and pro-inflammatory effects[2, 3]. Receptors and signaling mediators of G-CSF are functionally expressed on DRG neurons[4]. **Aim**: To verify, in mice, whether thermal hyperalgesia induced by intraplantar (i.pl.) administration of G-CSF is mediated by Bv8/PK2 system. **Methods**: We evaluated thermal hyperalgesia (TH, plantar-test), induced by i.pl. increasing doses of G-CSF, in WT, PKR1-KO and PKR2-KO mice and the ability of a PKR_1-antagonist (PC1) and of a TRPV1 antagonist (NF1-56 HCl) to abrogate G-CSF-induced thermal hyperalgesia. Number of circulating granulocytes (Burker-chambre), PK2-mRNA (RT-PCR) and granulocyte-recruitment (myeloperoxidase-assay) in G-CSF or saline injected paw were assessed 4 h after injection. **Results**: In WT and in PKR_2-KO mice G-CSF (300ng) induced TH for 8h, whereas PKR1-KO mice were significantly less sensitive (>1 mcg vs 300ng). PC1 (50 ng) antagonized G-CSF-induced TH in WT and in PKR2-KO mice, whereas it was inefficacious (up to 500ng) in PKR1-KO mice. The TRPV1 antagonist, NF1-56-HCl (50ng), antagonized TH in all three genotypes. **Conclusions**: Our results underlay positive cooperation of PKR1 in G-CSF-induced hyperalgesia. Because PKR1 cooperates with TRPV1[2] we suppose a crosstalk between G-CSFR and PKR1 via TRPV1 sensitization. 1) Shojaei et al., (2007). *Nature,*450:825-831. 2) Negri et al., (2007). *LifeSciences,*81:1103-1116. 3) Giannini et al., (2009). *PNAS*,106:14646-14651.

Title: CYP-derived lipids in Chemotherapy-induced neuropathic pain

Authors: M. SISIGNANO[1], C. ANGIONI[1], C.-K. PARK[2], S. ZINN[1], S. HOHMANN[1], *A. SCHMIDTKO[3], C. J. WOOLF[4], R.-R. JI[2], K. SCHOLICH[1], G. GEISSLINGER[1];

Abstract: Chemotherapy-induced peripheral neuropathic pain (CIPNP) is a severe dose-limiting side effect of widely used cytostatics, such as taxanes, platinum derivates and vinca-alcaloids. The mechanisms of CIPNP are poorly understood but seem to involve increased activity of ligand gated ion-channels, such as TRP channels in sensory neurons. Several endogenous TRP-channel modulators have already been identified among the group of oxidized lipid mediators. Here, we report involvement of oxidized lipids in Taxane-evoked CIPNP. Lipidomic analyses revealed increased synthesis of the oxidized linoleic acid metabolite 9,10-EpOME in sensory neurons of mice following paclitaxel treatment causing sensitization of TRPV1 via a cAMP-PKA-mediated mechanism, resulting in increased TRPV1 dependent sEPSC-frequency in lamina II neurons in the dorsal horn of the spinal cord. Moreover, treatment of sciatic nerves and DRG-neurons with 9,10-EpOME leads to increased release of the proinflammatory peptide CGRP, and peripheral injection of this lipid causes a reduction of both mechanical and thermal thresholds in wild type but not TRPV1-deficient mice. We conclude that synthesis of oxidized lipids in sensory neurons contributes to paclitaxel-induced CIPNP and inhibition of lipid oxidizing pathways may be a strategy for the development of novel analgesics.

Title: The role of multi-whisker integration during active sensation to the cortical representation of somatotopic space

Authors: *S. PLUTA[1], E. H. LYALL[2], E. S. RYAPOLOVA-WEBB[3], G. I. TELIAN[3], H. ADESNIK[1];
[1]Mol. Cell Biol., [2]Biophysics, [3]Neurosci., Univ. of CA - Berkeley, Berkeley, CA

Abstract: The receptive field of cortical neurons are formed by a complex integration of feedforward and horizontal input. The somatotopic, columnar organization of the rodent barrel cortex provides a powerful model for testing the relative contribution of these inputs to the neural representation of space. When performing an object discrimination task, rodents palpate the object with multiple whiskers, and their performance is greatly reduced or abolished when the whisker pad is experimentally trimmed to only a single whisker. Nonetheless, the role of multi-whisker integration to the cortical representation of space is not well understood, particularly in an awake, actively sensing animal. We addressed this problem by developing a novel method in the awake-behaving mouse for determining the contribution of principal (primarily feedforward) and surround (primarily horizontal) whisker input to the cortical representation of space. We found that most neurons can be categorized by two major groups: (1) surround-whisker facilitated and (2) surround-whisker suppressed, while a smaller subset of neurons were both facilitated and suppressed as a function of object location. Recording activity simultaneously across multiple barrel columns reveals how a population code derived from the multi-barrel distribution of firing rates could discern object location.

Title: A direct translaminar inhibitory circuit tunes cortical output

Authors: *A. NAKA, S. R. PLUTA, J. VEIT, G. I. TELIAN, L. YAO, R. M. HAKIM, D. TAYLOR, H. A. ADESNIK;
UC Berkeley, Berkeley, CA

Abstract: Anatomical and physiological experiments have outlined a 'canonical' blueprint for the feed-forward flow of activity in cortical circuits: signals are thought to propagate primarily from the middle cortical layer, L4, up to L2/3, and down to the major cortical output layer, L5. Pharmacological manipulations, however, have contested this model and suggested that activity in L4 may not be critical for sensory responses of neurons in either superficial or deep layers. To address these conflicting models we reversibly manipulated L4 activity in awake, behaving mice using cell type specific optogenetics. In contrast to both prevailing models, we show that activation of L4 directly suppresses L5 through deep, fast spiking inhibitory neurons. Our data suggest that the net impact of L4 activity is to sharpen the tuning of L5 neurons. Thus we establish a novel translaminar inhibitory circuit in the sensory cortex that acts to enhance the feature selectivity of cortical output.

Title: Predicting the spatial resolution of thalamocortical input from a detailed model

Authors: *M. W. REIMANN, E. MULLER, H. MARKRAM;
Blue Brain Project, Geneve, Switzerland

Abstract: One distinctive feature of primary sensory areas in the neocortex is topographical mapping of inputs, e.g. locations of light stimuli on the retina, or the location of a touch. While it is easy to measure the resolution of the final mapping, it is unclear how this emerges during different stages of sensory processing. We investigated one stage of the process: i.e. the ability of neocortical microcircuits to discriminate thalamic input. We subjected a highly detailed model of a neocortical microcircuit of a rat to simulated thalamic input centered around spatial locations with different separations and tested the responses of neurons for significant differences in terms of their firing rate and the precise timing of their firing. The result was a map of the ability of individual cortical neurons to discriminate between spatially constrained thalamic input, dependent on stimulus separation and amplitude, cortical layer and the activity state of the network. We found that many neurons showed significant discriminatory power for separations over 50 μm, already when only the delay or the firing rate of their response was taken into account. Neurons with strong discriminatory power were found predominately in layers 5 and 6. Finally, we investigated how the measured spatial resolution relates to the ability to discriminate between more complicated spatio-temporal input patterns.

Title: Predictive in silico reconstruction of cell-type specific synaptic anatomy and physiology in the neocortical microcircuit

Authors: *S. RAMASWAMY, J. G. KING, E. MULLER, J. RAHMON, M. REIMANN, H. MARKRAM;
EPFL - Blue Brain Project, Geneva, Switzerland

Abstract: The neocortical microcircuit contains a rich diversity of excitatory and inhibitory neurons. Although previous research has revealed the fundamental characteristics of neocortical neuron types, knowledge of their axonal, dendritic, synaptic, and laminar organization remains very limited. The Blue Brain Project has developed a data-driven process for the *in silico* reconstruction of a neocortical microcircuit. The reconstruction integrates a vast array of biological data on neuronal morphologies and electrical types, ion channel kinetics and axo-dendritic density distributions, synaptic kinetics and dynamics from juvenile rat somatosensory cortex. These data were used to parameterize and validate the *in silico* anatomy and physiology of monosynaptic connections arising from the incidental axo-dendritic overlap of diverse pre- and post-synaptic morphological types. Experimental protocols of whole-cell paired recordings and glutamate uncaging under high extracellular Ca^{2+} concentrations *in vitro* were mimicked *in silico* to uncover a gamut of predictions on the anatomy and physiology of the synaptic connections of principal neocortical neuron types. The reconstruction predicts the complete intrinsic anatomical and physiological wiring diagrams of a microcircuit of neocortical neurons, in depth anatomy and physiology of nearly 2000 inter- and intra-laminar monosynaptic pathways, and functional synaptic maps for 55 identified neuron types based on afferent and efferent morphological, electrical, and synapse types. In addition, the reconstruction also predicts the physiology of synaptic transmission under low extracellular Ca^{2+} conditions observed *in vivo*. Component models of single neurons, synaptic transmission with stochastic transmitter release, and pairs of synaptically connected neurons of the *in silico* reconstruction are publicly available through the Neocortical Microcircuit Collaboration Portal (https://bbp.epfl.ch/nmc-portal) for community use and collaborative refinement. The spectrum of predictions obtained from the reconstruction can be challenged and validated through the design of targeted experiments. The resulting validated reconstruction can fill gaps in our knowledge on the precise roles of local synaptic transmission and neuronal function in modulating global circuit dynamics. The *in silico* reconstruction is therefore proposed as a complementary approach to current experimental techniques for the systematic characterization of neocortical synaptology.

Title: Data-driven construction of mouse whole-brain models

Authors: C. EROE, D. KELLER, H. MARKRAM, *M.-O. GEWALTIG;
EPFL - Ctr. For Brain Simulation, Geneva, Switzerland

Abstract: We present a semi-automatic process for constructing whole-brain models at the point neuron level from different sets of image stacks. Our process has two parts, each with several steps. In the first step, we determine the positions of all cells, using high-resolution Nissl stained microscope image stacks Allen Mouse Brain Reference Atlas [1]. In the second step, we determine the type of each cell, using *In situ* hybridization (ISH) image data from the Allen Mouse Brain Atlas. To increase the spatial resolution of the data, we re-aligned the ISH images to the reference atlas. Here we present differentiation into glia, excitatory neurons and inhibitory neurons. More fine-frained differentiation is possible by adding more genes to this step. We compare the resulting cell and neuron numbers to literature data [2,3]. Our estimates of cell numbers are best for the isocortex (relative error 5%) and worst for the cerebellum (60%), where the cell density in the images is too high to distinguish individual cells. After differentiating glia

Deleted: In situ

and neurons, our estimates differ from the literature value by an average of 12% for the isocortex and 63% for the cerebellum. In the next step, we use two-photon tomography images of rAAV labeled axonal projections from the Allen Mouse Connectivity Atlas to determine the mesoscale connectivity between the neurons in different brain regions. For this step, a comprehensive comparison to experimental data is difficult, due to lack of comparable connectivity data. Finally, we obtain a network model that can be simulated with state-of the art simulators like NEST and NEURON. We show results from a simulated whisker stimulation experiment and compare the evoked activity patterns to data from comparable calcium imaging experiments. We also present results from our ongoing research on reconstructing the microscale connectivity between the neurons in a small volume from appropriate data-sets. Abstract: Despite recent experimental advances in cortical anatomy and physiology *in vivo*, the functional significance of cortical laminar architecture and the diversity of neuronal morphologies, electrophysiologies, and synaptic interactions for cortical information processing *in vivo* remains largely a mystery. The Blue Brain Project has developed a data-driven in silico reconstruction of juvenile rat somatosensory cortex which integrates the current state of experimental knowledge on the anatomy and physiology of the microcircuit at the cellular and synaptic levels of organization. The in silico reconstruction contains 6 synapse types, and 55 morphological neuron types, 11 electrical types, 207 morpho-electrical sub-types, distributed according to experimentally observed proportions across the 6 cortical layers, optimized to fit somatic patch-clamp recordings to standardized protocols, and simulated in full morphological detail. Synaptic anatomy and physiology of the reconstructed microcircuit are presented in a companion abstract (Ramaswamy et. al.). While most integrated experimental data employed *in vitro* techniques on acute cortical slices, simulation of the reconstruction shows a spectrum of emergent network activity states. Baseline extracellular Ca2+ concentration is found to control the balance of excitation and inhibition in the network, and can be adjusted towards a state of criticality where bursting events have a range of amplitudes and frequencies around Ca2+ levels *in vivo*. We performed a range of in silico experiments to compare this critical network state to recent *in vivo* findings on spontaneous and evoked activity of cortical circuits. In silico results were found to be qualitatively comparable to their experimental counterparts without parameter tuning, and enabled predictions of the mechanisms at play beyond what was possible using current experimental techniques.

Title: Recent improvements towards the accurate modeling of the rat brain using detailed morphologies on supercomputing technologies

Authors: *J. G. KING[1], F. DELALONDRE[1], B. MAGALHAES[1], P. KUMBHAR[1], T. EWART[1], A. OVCHARENKO[1], S. YATES[1], F. CREMONESI[1], A. DEVRESSE[1], M. HINES[2], E. MULLER[1], H. MARKRAM[1], F. SCHUERMANN[1];

Abstract: The Blue Brain Project (BBP) aims at developing models and software to support the building and simulation of large-scale morphologically detailed and biologically accurate models of neocortical tissue that include hundreds of millions of neurons. Such an endeavor must leverage state-of-the-art high performance computing technology to attain the desired level of detail and model fidelity with a usable time-to-solution. Here we describe our recent developments towards the provision of a stack of scientific software to be made available to the Human Brain Project community. To improve our circuit building process, additional parameters have been added to better capture biological features of interest. Proximal contacts between neurons, or “touches“, are allowed some degree of variability in the space between cells. This space has been considered an allowance for spines along the morphologies and a recent additional filter now limits those spine lengths such that the final distribution matches those observed in tissue. Next, simulating the built circuit requires development of scalable software for supercomputing architectures to manage run time. Our new simulation package, CoreNeuron, consists of the core functionalities of the NEURON software refactored using OpenMP threading, vectorization, and efficient memory layout. On leading-class supercomputing system the JUQUEEN IBM Blue Gene/Q, this implementation utilizes 458,752 computing cores and 1,835,008 threads to model a network made of 155 million neurons. Further developments have been carried out in conjunction with the Dynamic Exascale Entry Platform (DEEP). Such a platform consists of an x86-based “Cluster” with InfiniBand interconnect to run less scalable parts of an application while an Intel MIC based “Booster” with Terabit EXTOLL interconnect runs highly scalable compute kernels. Following code analysis, CoreNeuron computing needs were mapped to the appropriate parts of the heterogeneous DEEP system for increased node performance. Finally, to make these new features and optimizations accessible to users and ensure reproducibility, an automated continuous integration and deployment infrastructure is installed which makes all versions of software available to users.

Title: Ipsilateral sensorimotor integration: Is it an upper limb phenomenon?

Authors: ***K. L. RUDDY**[1], W. TAUBE[2], E. JASPERS[1], M. KELLER[2], N. WENDEROTH[1]; [1]Neural Control of Movement Lab., ETH Zurich, Zurich, Switzerland; [2]Univ. of Fribourg, Fribourg, Switzerland

Abstract: Somatosensory information from the limbs reaches the contralateral (contra) primary sensory cortex (S1) with a delay of 23ms for finger, and 40ms for leg (somatosensory N20). Upon arrival of this input in the cortex, motor evoked potentials (MEPs) elicited by transcranial magnetic stimulation (TMS) are momentarily inhibited. This phenomenon is called 'short-latency afferent inhibition (SAI)' and can be used as a tool for investigating sensorimotor interactions in the brain. Here we tested whether SAI could also be elicited in the hemisphere ipsilateral (ipsi) to the sensory stimulated limb (ipsi SAI) and determined the precise onset of inhibition in the ipsi primary motor cortex (M1). We electrically stimulated the limb either contra or ipsi to the hemisphere receiving TMS, using a range of different interstimulus intervals (ISI). In Exp 1 (n=23), we tested finger muscles (first dorsal interosseous, FDI) and elicited robust contra SAI for ISIs corresponding to N20+7ms ($p<0.001$) and N20+22ms ($p<0.001$). By contrast, significant ipsi SAI was only observed for ISI N20+22ms ($p<0.05$). This pattern of outcome occurred regardless of whether the dominant or non-dominant hemisphere was tested. In Exp 2 (n=15), contra SAI was detected in the tibialis anterior muscle (TA) when stimulation occurred at ISIs corresponding to N20+5, N20+10 and N20+15ms (all $p<0.001$), but not at corresponding timepoints in the ipsi leg. In a third experiment (n=12) we directly compared ipsi SAI between hand and leg muscles for a large range of ISIs. No ipsi SAI was detected in TA, while ipsi SAI was present in FDI for ISIs between N20+15 to N20+40ms with strongest group-level reductions in MEP size at N20+20ms. Our data suggests a transcallosal route for ipsi sensorimotor integration for hand but not for leg muscles. The early emergence of ipsi SAI at

N20+20ms is consistent with the timing expected by a direct S1-S1 or contra S1-ipsi M1 pathway, precluding the involvement of much slower S2 interhemispheric communication. The absence of ipsi SAI in TA suggests that sensory input to the lower limbs may be processed predominantly contralaterally, as no evidence was found for ipsi sensorimotor integration.

Abstract: The multiple body representation within somatosensory cortex provides a good opportunity to study structural and functional correlates of areal diversification and ultimately cerebral cortical functionality at a microscopic scale. Area 3b and area 1, two closely related regions, play critical roles in tactile perception and each possess an enlarged hand representation. We tested the hypothesis that the horizontal and laminar distribution of anatomical connectivity exhibit differential characteristics similar to some known functional differences between the two areas as for instance receptive field size and cortical magnification. We used bidirectional tract tracing via injections of BDA into distal finger pad representations of area 3b and area 1 of the squirrel monkey. The sizes of injections (about 300 µm in diameter) matched the size of

submodality specific tactile modules in areas 3b and 1. Irrespective of the origin, both retrograde and anterograde labeling exhibited supragranular dominance, making these cortical layers the main site of interactions between the two areas. Kernel density analysis of the lateral extension of retrograde labeling suggests that similarly sized neuronal populations provide input to column-size cortical regions within and between areas 3b and 1. However, considering the different magnification factors the cortical territory with high density labeling represents a larger skin area in area 1 than in 3b. Anterograde labeling revealed an anisotropic distribution of terminal axon arborizations that extended across the finger representations in both areas. Interestingly, terminal axon arborizations spread over a larger distance within an area when compared to that of the inter-areal projections. The broad interdigit interactions within an area may serve as the means for multidigit integration at single hierarchical levels, while homotopic distal finger pad representations mediate fast information exchange between areas via the existing thick axonal processes. The results point to the importance of intra-areal connections in integrative processing and the specialization of some inter-area connections for fast information exchange. Title: Visual responsiveness of neurons in the secondary somatosensory area and its surrounding parietal operculum regions in awake macaque monkeys

Authors: ***M. TAOKA**[1,2], S. HIHARA[1,2], M. TANAKA[1,2], A. IRIKI[1,2];
[1]RIKEN Brain Sci. Inst., Wako-Shi, Japan; [2]Section of Cogn. Neurobiol., Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: It is believed that the secondary somatosensory cortex (SII), located in the upper bank of the lateral sulcus (LS), is principally engaged in the processing of somatosensory information. Previous neurophysiological studies performed on awake macaque monkeys demonstrated the

existence of neurons responsive to visual stimuli in the upper bank of LS caudal to the SII; however, sensory inputs other than somesthetic information have not been reported in the SII. In contrast, recent human brain imaging studies have revealed the effects of visual and auditory stimuli on SII activity, which suggest multisensory integration in the human SII. To determine whether multisensory responses of the SII also exist in nonhuman primates, we recorded single-unit activity in response to visual and auditory stimuli from the SII and surrounding regions in eight hemispheres from six awake macaque monkeys. We used three types of visual stimulation in this study: 1) moving the experimenter's hand in front of the animal within its reach range (<40cm); 2) the same stimuli outside the reach range; and 3) observations of human actions (such as "reaching for a food container and picking up a piece of food"). Among the 1157 recorded neurons, we found 306 neurons that responded to visual stimuli. They rarely responded to simple object presentations (the static presentation of the experimenter's hand, 1.6%), but did respond to rather complex stimuli, such as the stimulation of the peripersonal space (40.5%), observation of human action (29.1%), and moving-object stimulation outside the monkey's reach (23.9%). These visual neurons often responded to somatosensory stimuli (37%) and monkeys' self-initiated reaching and grasping actions (26%). We were able to test the responsiveness of a fraction of the visual neurons (about one-third of the 306 neurons) to auditory stimuli and found 10 neurons showing auditory responsiveness. Furthermore, all of them responded to somatosensory stimuli (trimodal neurons). Next, we investigated the distribution of the visual neurons in the LS upper bank. The visual neurons were usually recorded along with somatosensory responsive neurons that are distributed throughout the upper bank of LS; from the regions caudally bordering with area 7b/Ri (retroinsular area) to the region rostrally bordering with the PR (parietal rostroventral area) covering the entire SII. These results clearly show that the SII of macaques is a multisensory area. This emphasizes the need for a novel definition of the functional role of the SII beyond the currently attributed sensorimotor function arising from the idea that the SII is a unimodal somatosensory area.

Title: Human secondary somatosensory cortex detects tactile novelty under the predictive coding theory

Authors: G. NAEIJE, V. WENS, B. MARTY, T. VAULET, M. OP DE BEECK, S. GOLDMAN, *X. DE TIÈGE;
Unité De Magnetoencephalographie, ULB-Hôpital Erasme, Brussels, Belgium

Abstract: This study investigates using magnetoencephalography the spatio-temporal dynamics and the neural mechanisms of somatosensory mismatch negativity (sMMN) under the predictive coding framework. Somatosensory evoked magnetic fields (SEF) were recorded in 16 right-handed adults while they underwent: (1) Oddball: 100 blocks of four standards followed by a deviant stimuli with 20 blocks of five consecutive standards randomly intermingled (interstimulus interval (ISI): 0.5 sec, interblock interval (IBI): 0.8 sec), and (2) Dual: 80 blocks of one standard immediately followed by one deviant (ISI: 0.5 sec, IBI: 1-6 sec). Standards were pneumatic tactile stimulation on right index fingertip while in deviants, tactile stimulation was applied to the right forefinger distal and middle phalanxes. Ten adults also underwent: (1) Oddball_long_IBI: similar to Oddball but with longer and variable IBI, randomly set between 1-2.5 sec, (2) Expected_Omissions: 100 blocks of four standards followed by an omission with 20 blocks of five consecutive standards randomly intermingled and (3) Rare_Omissions: 180 blocks of five consecutive standards with 35 blocks of four standards followed by one omission randomly intermingled. Non-parametric clustering tests were used for statistics in sensor space. The sMMN generators were localized using conventional equivalent current dipole modeling. Paired t-tests were used to compare the maximal amplitude of source waveforms. In all conditions, significant mismatch responses were elicited at contralateral SII between 75-125 ms post-deviants/omissions. In oddball paradigms, deviants elicited higher SII response than standards whereas in Dual, deviants led to smaller SII response than standards. SII responses to standards in Oddball were similar contrasting with SII response suppression from the second standard in Oddball_long_IBI. No significant SEF difference was observed between standards and omissions but rare omissions led to significantly higher SII responses than expected omissions. These results fit the predictive coding framework. Indeed, at SII cortex, response suppression is observed after a first tactile stimulation, omissions lead to responses similar to those observed after standard stimulation and rare omissions elicit higher responses than expected omissions. Furthermore, response suppression suggests that after a first tactile stimulation, top-down predictions of potential upcoming somatosensory stimuli are dominated by predictions on sensory modality, while after several similar tactile stimuli, the memory trace of tactile stimuli specific features is the main guide of top-down predictions

Title: Prestimulus oscillatory state differentially influences cerebral processing of attended versus unattended somatosensory stimuli

Authors: *N. FORSCHACK[1,2], T. NIERHAUS[3,4], M. M. MÜLLER[2], A. VILLRINGER[3,4]; [1]MPI For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Dept. of Psychology, University of Leipzig, Germany; [3]Max-Planck-Institute for Human Cognitive and Brain Sci., Leipzig, Germany; [4]Mind Brain Inst. and Berlin Sch. of Mind and Brain, Charite and Humboldt-Universität zu Berlin, Germany

Abstract: Background oscillations have been shown to influence the perceptibility of weak attended and unattended stimuli as well as mid-latency ERP components such as the N1. We have recently shown that subthreshold somatosensory stimuli are associated with an evoked potential after 60ms (P1, Nierhaus et al., 2015) which is modulated by selective attention. Here we investigate whether background Rolandic alpha rhythm modulates P1 and - if so - whether this modulation depends on attention, both for subthreshold as well as for suprathreshold stimuli. Subjects (n=40, average age=25 years, 20 females), received subthreshold (imperceptible) and rare suprathreshold (perceptible) electrical pulses over 26 two-minutes blocks to the left index finger while 32 channel EEG was recorded. Subjects were instructed to respond to perceived stimuli only at the cued side. The stimulus locked somatosensory evoked potential (P1-compoent, SEP) was related to power binned pre-stimulus Rolandic alpha. As expected attention strongly modulated overall Rolandic alpha power, with higher amplitudes contralateral to the unattended side. For attended imperceptible as well as perceptible stimuli, there was a positive relationship between pre-stimulus background Rolandic alpha power and the amplitude of the P1. A different pattern was seen for unattended stimuli: Pre-stimulus Rolandic alpha power was negatively associated with P1 amplitude for unattended suprathreshold stimuli and no clear relationship was seen for unattended imperceptible stimuli. The influence of prestimulus Rolandic alpha power on the SEP seems to differentially depend on the presence of attention both for subthreshold as well as suprathreshold stimuli. Since attention itself modulates baseline alpha, this effect is reminiscent of previous findings reporting an inverse U-shaped relationship between sensory perception and the amplitude of prestimulus alpha (Linkenkaer-Hansen et al., 2004; Zhang & Ding, 2009). Alternatively, the effect might be mediated by a third, but so far

unknown, mechanism, changing the functional role of prestimulus alpha according to the current attentional state.

Title: Simultaneous calcium imaging of identified feedforward and feedback cortico-cortical neurons during behavior

Authors: J. L. CHEN[1], F. F. VOIGT[1], R. KRÜPPEL[2], *F. HELMCHEN[1];
[1]Brain Res. Inst. / Univ. of Zurich, Zurich, Switzerland; [2]Deutsche Forschungsgemeinschaft (DFG), Bonn, Germany

Abstract: Cortico-cortical processing is essential for neocortical function during behavior. Understanding the dynamics in information flow across cortex requires simultaneous functional measurements across distant areas. However, it has not been possible to restrict such recordings to neuronal subpopulations that anatomically project between areas. Here, we report the application of a multi-area two-photon microscope in combination with anatomical tracers for simultaneous calcium imaging from identified neurons in distant cortical regions. We used virus-mediated conditional expression of fluorescent reporters, in primary (S1) and secondary (S2) somatosensory whisker cortex to label subsets of ”feedforward” S1 neurons projecting to S2 (S1FF) and “feedback” S2 neurons to projecting S1 (S2FB) in layer 2/3 neurons along with the genetically-encoded calcium indicator, YCNano140. Simultaneous calcium imaging was

performed across the corresponding whisker barrel column in S1 and S2 of mice (n = 7 mice, ~1000 neurons per area) engaged in a texture discrimination task or during passive texture presentation. Using linear discriminant analysis and pair-wise correlation analysis, we identify task-dependent dynamics between S1FF and S2FB neurons evolving during the trial period and differing across trial conditions that correlated with texture coding and behavior responses. Our results indicate anatomically-specific coordination of cortico-cortical dynamics under behavior.

Title: Sevoflurane modifies information transfer across the cerebral cortex

Authors: *J. KURATA;
Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Introduction: Peripheral sensory information reaches the cerebral cortex and induces sensory evoked potentials even under general anesthesia. General anesthesia might possibly induce loss of consciousness by inhibiting sensory information integration at the cerebral cortex resulting in the failed perception of sensation. Propofol and midazolam suppressed activity at the parietal sensory association cortex and transcortical information transfer, respectively. To obtain direct evidence of transcortical suppression, we examined electrocorticogram and corticocortical evoked potentials by grid electrodes under general anesthesia. Methods: Three adult patients underwent implantation of cortical grid electrodes to localize epileptic foci. Several cortical grids were placed on the cortical surface over suspected epileptic foci under sevoflurane anesthesia. End-tidal sevoflurane concentration was kept at 1.5%, sedation evaluated with modified observer's assessment of alertness/sedation scale (mOAA/S); and somatosensory (SSEP), corticocortical evoked potentials (CCEP), and spontaneous electrocorticogram (ECoG) were recorded. The same observation and recording were repeated at 1.0%, 0.7%, and 0% of sevoflurane concentration. Results: The patients regained consciousness at 0.7% or 0% of sevoflurane with the mOAA/S scores of 4-5. The CCEP, but not SSEP, amplitude increased remarkably on awakening (Figure). The ECoG showed the minimum cross-electrode coherence

and phase reversal at 1% of sevoflurane. Conclusion: Sevoflurane affected the corticocortical information transfer as evidenced by the CCEP and ECoG coherence. Sevoflurane-induced unconsciousness could possibly involve suppression of corticocortical information transfer.

Title: Disrupted sensorimotor communication during ketamine anesthesia

Authors: *K. E. SCHROEDER[1], Z. T. IRWIN[1], M. GAIDICA[2], J. BENTLEY[4], P. G. PATIL[4,5,1], G. A. MASHOUR[2,3,6], C. A. CHESTEK[1,2,3];
[1]Biomed. Engin., [2]Neurosci. Grad. Program, [3]Ctr. for Consciousness Sci., Univ. of Michigan, Ann Arbor, MI; [4]Neurosurg., [5]Neurol., [6]Anesthesiol., Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: The neural mechanisms of anesthetic-induced unconsciousness have yet to be fully elucidated. Most clinically-used general anesthetics act by potentiating the transmission of γ-aminobutyric acid (GABA), which would predictably lead to depression of neuronal function and conscious processing. Ketamine, however, does not depress the cortex and fails to conform to most mechanistic frameworks of general anesthesia: it does not bind with high affinity to the GABAA receptor or depress thalamic metabolism, among other differences. Identifying common neural features of ketamine and GABAergic anesthetics would therefore be an important step

toward a foundational understanding of anesthetic-induced unconsciousness. During the waking state, sensory representation in primary somatosensory cortex (S1) is shared directly with primary motor cortex (M1); they are anatomically and functionally connected. We recorded and analyzed multi-unit thresholded activity, as well as single unit activity, from M1 and S1 of two monkeys while applying sensory stimulation to the finger pads before, during, and after ketamine anesthesia. Before ketamine administration, the identity of the stimulated finger (1 of 3 choice) could be correctly classified from thresholded neural activity at the M1 and S1 electrodes using a Naïve Bayes decoder with a mean accuracy of 74.9% from M1 electrodes and 83.5% from S1 electrodes. During ketamine-induced unconsciousness, however, decoding performance in M1 decreased to chance levels, with a mean of 27.5% correct, while S1 decodes remained unchanged. Furthermore, single-unit firing rate correlations decreased significantly ($p<.05$) between M1 and S1 cells in the anesthetized state, indicating a functional breakdown in communication. Given past studies showing that GABAergic drugs inhibit surrogate measures of cortical communication, this finding suggests functional disconnection of cortical areas represents a common network-level mechanism of anesthetic-induced unconsciousness.

Title: Characterization of the resonance responses in eeg and forepaw movements to the rhythmic peripheral versus cortical stimulations

Authors: ***D. LEE**, J. CHOI;
Korea Inst. of Sci. and Technol., Seongbuk-Gu, Seoul, Korea, Republic of

Abstract: The tactile exploration is highly related to the synchronous neuronal activities within the somatosensory-motor system (S-M system). However it is still unveiled that how tactile features such as roughness of the surface are represented in the neuronal activities of the S-M

system. Recent studies have shown that in the tactile space, represented by a spatial-frequency parameter space, the frequency is preserved within the S-M system, particularly in the low frequency range (10 - 50 Hz), but the frequency response properties within the S-M system are not fully described. Here, we investigated the natural and driven oscillation properties and resonance characteristics of S-M system, and compared the following responses within the cortex. The tactile stimulation was given to the forepaw of the lightly anesthetized mice, and the optogenetic stimulation was applied to the forelimb region of the primary somatosensory cortex of freely moving animal to mimic the cortical response to the rhythmic tactile perception. Extracranial high density electroencephalogram (hdEEG) was measured and compared at various frequencies ranging 1 - 60 Hz, and the paw movement was analyzed using paw tracker. Our main findings are (i) the cortical regions corresponding to primary somatosensory and motor cortex responded to paw and cortical stimulation with their maximal responses at beta band frequency (~ 30 Hz) in both cases, (ii) the forepaw motion exhibited resonance response as well but at lower frequency range (~ 20 Hz). These results indicate that the frequency resonance properties are well preserved to the primary somatosensory cortex, but the frequency is down-shifted in signal transduction from the primary somatosensory to muscle. We will discuss the potential role of resonant oscillations in the tactile exploration and potential reason of the frequency downshift in the S-M system.

Title: Intrinsic and synaptic properties of excitatory neurons in layer 2/3 somatosensory cortex of CK1d migraine mice

Authors: ***P. M. SAWANT**[1], K. BRENNAN[2];
[1]Neurosurg., Univ. of Utah, Salt lake city, UT; [2]Neurol., Univ. of Utah Sch. of Med., Salt Lake City, UT

Abstract: A mutation in casein kinase 1delta (CK1d) was identified in two families with advanced sleep phase syndrome and typical migraine with aura. Mice genetically engineered to express this mutation showed a reduced threshold for cortical spreading depression (a phenomenon that underlies both migraine aura and brain injury) and an increased sensitivity to nitroglycerine-induced mechanical and thermal hyperalgesia (both considered migraine relevant pain phenotypes). Cellular mechanisms underlying hyperexcitability are unclear. We examined the intrinsic and synaptic properties of layer 2/3 neurons of mouse somatosensory cortex, using *in vivo* whole-cell current-clamp recordings in wild-type and CK1d mutant mice. Neurons from CK1d mice showed a hyperpolarizing shift in the resting membrane potential and an increase in input resistance, compared to wild-type animals, suggesting enhanced intrinsic membrane properties. To characterize the synaptic activity, we recorded up and down states in layer 2/3 neurons. We showed an increased duration and amplitude with a lower frequency of spontaneous post-synaptic potentials. In conclusion, CK1d animals have altered baseline excitability, consistent with a migraine-relevant phenotype. CK1d mice represent the transgenic model of non-hemiplegic migraine, thus they may be helpful in elucidating mechanisms that are relevant to normal migraineurs. Support: CDMRP 55900428, R01 59311100

Title: Identifying hand, foot and face sensorimotor U-fibers using DTI

Authors: *E. BORDBAR[1], C. BUCKLESS[2], D. PETERSON[4], S. MOSTOFSKY[2], D. CROCETTI[3];
[1]neurology, Johns Hopkins Sch. of Medicine/ Kennedy Krieger, Baltimore, MD; [3]Neurol., [2]Kennedy Krieger Inst., Baltimore, MD; [4]Integrated Brain Imaging Ctr., Univ. of Washington, Seattle, WA

Abstract: Introduction: U-shaped white matter bundles ("U-fibers") represent short association fibers connecting adjacent gyri and are critical to cortico-cortical integration. Sensorimotor U-fibers are comprised of connections between primary somatosensory and motor regions. Mapping sensorimotor U-fibers and segmenting these fibers into functionally distinct clusters that correspond with the foot, hand, and face could provide insight into white matter development and aid in elucidating underlying white matter abnormalities in developmental and neurodegenerative disorders. Few studies have attempted to segment sensorimotor U-fibers using diffusion imaging; however, their ability to demonstrate anatomic validity and intra- and inter-rater reliability is limited. In this study, we leverage fMRI motor execution literature with diffusion imaging to reconstruct sensorimotor U-fibers corresponding with the foot, hand, and face and demonstrate a high degree of reliability. **Methods:** Fiber tracking was performed on 10 participants: 4 autism, 3 ADHD, and 3 controls, aged 8-12 yrs. fMRI-based seeds served as centroids for spheres used to segment the sensorimotor fiber map into foot, hand, and face regions (figure 1). Extraneous fibers not connecting sensorimotor cortices were removed. The procedure was performed by two raters. Intra- and inter-rater reliability was calculated using Dice's coefficient. **Results:** The mean Dice's coefficients for intra-rater reliability were 0.99, 0.99, and 0.98 for foot, hand, and face, respectively; inter-rater reliability for foot, hand, and face was 0.98, 0.98, and 0.95, respectively. **Conclusions:** In this study we combined motor activation coordinates with DTI fiber tracking and demonstrate feasibility and a high degree of reliability using this approach. This approach could provide valuable insight into the underlying white matter microstructure of developmental disorders and further aid in revealing associations between sensorimotor microstructure and diagnostic and behavioral characteristics of these disorders.

Title: Optogenetic mapping of translaminar functional connectivity in the somatosensory cortex of rodents

Authors: *M. C. QUIQUEMPOIX[1,2,3], S. L. FAYAD[1,2,3], K. BOUTOURLINSKY[1,2,3], N. LERESCHE[1,2,3], R. C. LAMBERT[1,2,3], T. BESSAIH[1,2,3];
[1]Neurosci. Paris Seine, Univ. Pierre & Marie Curie, Paris, France; [2]Umr 8246, CNRS, Paris, France; [3]U1130, INSERM, Paris, France

Abstract: While the six-layered structure of the neocortex is one of the most prominent features of the mammalian brain, the role of this laminar architecture in information processing is still

elusive. Multiple simultaneous intracellular recordings as well as glutamate uncaging and laser scanning photostimulation in brain slices allowed the emergence of a picture of the wiring diagram between cortical layers. However, these approaches do not allow evaluating the relationships between the strength of translaminar connectivity and the response properties to sensory stimuli of individual neurons. We used *in utero* electroporation in mice to deliver ChannelRhodopsin-2 to layer 2/3 pyramidal neurons in the barrel cortex of mice. This technique allows the specific, fast and reliable control of the temporal pattern of activity in the transfected neurons, while recording simultaneously the spiking activity of several layer 5 cortical neurons *in vivo*. We found that optogenetic stimulation of layer 2/3 pyramidal neurons enhances the activity of only a subset of layer 5 neurons, which have particular response properties to tactile stimulations.

Title: Morphological and Functional Characterization of Non-fast spiking GABAergic Interneurons in layer 4 microcircuitry of rat barrel cortex

Authors: ***V. SIVARAJAN**[1,2], G. QI[2], D. FELDMEYER[2,1,3];
[1]Dept. of Psychiatry, Psychotherapy and Psychosomatics, RWTH Aachen Univ. Hosp., Aachen, Germany; [2]Inst. of Neurosci. and Med. - 2, Forschungszentrum, Juelich, Germany; [3]Translational Brain Med. (JARA Brain), Jülich Aachen Res. Alliance, Aachen, Germany

Abstract: Inhibitory GABAergic interneurons (INs) are notorious for their heterogeneity. Classification of INs is crucial for understanding their functions. GABAergic INs can be broadly classified into fast spiking (FS) and non-fast spiking (nFS) INs based on their intrinsic firing patterns. Recently, the functional and structural properties of nFS INs (e.g. somatostatin-positive INs) have received more attention. In this study, we focused on the quantitative morphological classification of nFS INs in layer 4 (L4) of the rat primary somatosensory (barrel) cortex and

their connectivity profiles. Single and paired whole-cell patch-clamp recordings were performed on acute barrel cortex slices of juvenile rats. Following histochemical processing, biocytin-filled neurons were morphologically reconstructed using the Neurolucida system. Fluorescent dyes conjugated with biocytin were used to investigate the molecular marker expression in patched L4 nFS INs. Unsupervised cluster analysis (Ward's method) was adopted to classify L4 nFS INs based on their quantitative electrophysiological and morphological parameters. Principal component analysis was used to eliminate the correlated parameters. We identified 4 morphologically distinct L4 nFS IN types. These types differed with respect to their intralaminar, intracolumnar and translaminar axonal projection patterns. The majority of L4 nFS INs were somatostatin-positive. We also found that L4 nFS INs show diverse firing patterns such as late-spiking, stuttering and irregular spiking. Results from paired recordings from synaptically coupled nFS INs and other L4 neurons showed that nFS INs establish weak synaptic connections, with a low release probability and low amplitude; the connections showed paired-pulse facilitation. This is markedly different from the FS INs, which form strong synaptic connections that exhibit invariably paired-pulse depression. Based on the above findings, we conclude that nFS INs have very distinct morphological and physiological characteristics compared to FS INs and are an important element in the L4 microcircuitry. Elucidating the structure and function of nFS INs is critical for the understanding of the role of inhibitory microcircuits in health and disease.

Title: Behavioral rewards impact sensory cortical representations via their effect on apical dendrites in Layer 1 of mouse barrel cortex

Authors: ***C. LACEFIELD**[1], E. PNEVMATIKAKIS[6,2], L. PANINSKI[2,3,4], R. M. BRUNO[1,5]; [1]Neurosci., [2]Statistics, [3]Ctr. for Theoretical Neurosci., [4]Grossman Ctr. for the Statistics of Mind,

Abstract: Layer 1 of mammalian sensory cortex is potentially one of the most important sites where sensory signals and internal signals are integrated. In the rodent vibrissal primary somatosensory “barrel” cortex, Layer 5 pyramidal neurons send apical dendrites to the surface of the cortex in Layer 1, where they receive excitatory synaptic contacts from the vibrissal motor cortex (vM1), thalamic medial posterior nucleus (PoM), and secondary somatosensory cortex (S2), as well as a host of contacts from diverse inhibitory interneurons and neuromodulatory nuclei. These connections have the potential to influence the processing of whisker sensory information within the cortical circuit in the context of information about self-generated motion, higher-order features of a stimulus, behavioral state, or the relevance of a sensory stimulus to behavior. To elucidate the impact of these connections onto Layer 1 apical tuft dendrites during behavior, we imaged dendritic calcium activity in a broad population of dendrites from Layer 5 pyramidal neurons in the mouse barrel cortex using two-photon imaging of the genetically encoded fluorescent calcium indicator GCaMP6 while mice performed a whisker-based head-fixed operant task. We find that calcium activity within Layer 1 correlates with timing of rewards given during a stimulus presentation, as well as with random rewards given during non-stimulus epochs. Examining the activity of individual apical tufts reveals that the effect of reward is non-uniform across neurons, rather than a singular broad influence over the entire population. This finding suggests that reward may play a role in modulating subpopulations of neurons that underlie sensation during behavior. These influences could lead to enhancement of sensory representations for behaviorally relevant stimuli, or alternately, for learning associations between stimuli or with behavioral responses necessary for attaining rewards.

Title: VIP interneurons in the barrel cortex of VIPcre/tdTomato mice

Authors: A. PRÖNNEKE[1], B. SCHEUER[1], R. J. WAGENER[1], M. MOECK[1], M. WITTE[1], *J. F. STAIGER[2];
[1]Neuroanatomy, Georg-August-University, Göttingen, Germany; [2]Georg-August-Univ, Göttingen, Germany

Abstract: The vast heterogeneity in the population of neocortical GABAergic interneurons provides a major obstacle in identifying and studying distinct subgroups. This hampered the understanding of their individual properties and functional impact onto cortical circuitry and information processing. Now, distinct and virtually non-overlapping subgroups of inhibitory interneurons can be targeted by the expression of cre under the promotor of certain proteins, like parvalbumin, somatostatin and vasoactive intestinal polypeptide (VIP). Among these, VIP expressing interneurons sparked substantial interest since these neurons seem to operate disinhibitory circuit motifs found in all major neocortical areas. However, only very little is known about neurochemical specificity and electrophysiological as well as morphological properties of neurons tagged in transgenic Vip-ires-cre mice. Therefore, the potential to specifically target the population of VIP expressing interneurons in this mouse line was evaluated. We quantitatively analyzed the co-localization of cre-driven fluorescence with labeling deriving from in-situ hybridization using Vip RNA probes or αVIP immunohistochemistry in the barrel cortex of VIPcre/tdTomato mice in a layer-specific manner. Our results indicate a high sensitivity (complete coverage of the target cell population) and specificity (virtually a 100% of co-localization in immunostainings) of cre expression for VIP neurons, and also verified that these are GABAergic interneurons (i.e., Gad1 positive). Furthermore, we determined the distribution pattern of VIP interneurons in the barrel cortex of mice, which are predominantly found in layer (L) II/III (58.7%). However, a substantial fraction (39.4%) is located in L IV to VI. Interestingly, we found differentially distributed morphological features of single VIP neurons from L II/III when compared to L IV-VI. The most conspicuous difference was that the dendritic input domain of L II/III neurons was restricted to L I-III whereas the axonal output was distributed across all layers. In contrast to this, the dendrites of VIP neurons in L IV-VI were significantly more extended vertically, often reaching the upper layers, whereas the axon remained virtually confined to the layers V-VI. Furthermore, VIP neurons displayed a variety of firing patterns, which did not correlate with a broad spectrum of electrophysiological properties or morphological characteristics. VIP neurons in L IV-VI, however, were more hyperpolarized, had a greater amount of fast inward rectification and larger amplitudes of AHPs compared to those in L II/III.

Title: Fast modulatory activity of serotonergic cortical afferents mediated by $5HT3_AR$-expressing interneurons

Authors: *F. MARKOPOULOS, S. PAGÈS, V. KEHAYAS, C. GILLET, S. FRAZER, A. DAYER, A. HOLTMAAT;
Univ. of Geneva, Geneva, Switzerland

Abstract: Serotonin (5-HT) is thought to play a critical role in neuromodulation during specific brain states and behavioral contexts. In the mouse cerebral cortex, 5-HT is released from Raphe Nuclei (RN) afferents and acts on a plethora of excitatory or inhibitory 5-HT receptors expressed on pyramidal (Pyr) neurons as well as on GABAergic interneurons. The vast majority of these receptors are metabotropic. The only ionotropic serotonergic receptor ($5HT3_AR$) is excitatory and is expressed in almost one third of cortical GABAergic interneurons. Thus serotonin may exert fast modulatory effects on and play a pivotal role in shaping cortical activity. To unravel the role of $5HT3_AR$ interneurons in serotonergic modulation in cortical microcircuits, we performed targeted patch recordings in the barrel cortex, in acute brain slices of transgenic mice in which $5HT3_AR$ interneuron population or its vasoactive intestinal peptide (VIP)-expressing subset is fluorescently labeled. Combining optogenetics with local electrical stimulation and pharmacology, we characterized serotonergic inputs to $5HT3_AR$ interneurons and explored the modulatory roles of these inputs as well as of VIP-expressing interneurons in cortical microcircuits. Local application of the potent high affinity $5HT3_AR$ agonist 1-(m-chlorophenyl)-biguanide (mCPBG) elicited excitatory post-synaptic potentials (EPSPs) and spiking activity in both VIP-positive and VIP-negative $5HT3_AR$ interneurons confirming the depolarizing action of $5HT3_ARs$ in those cells. Moreover, optogenetic stimulation of RN cortical afferents elicited excitatory responses in a significant fraction of the $5HT3_AR$-GFP interneurons. These responses

persisted in the presence of glutamatergic receptor blockers, providing evidence for direct serotonergic depolarization of these cells via synaptic transmission. Simultaneous optogenetic stimulation of RN afferents and electrical stimulation of layer 4 (L4) elicited greatly different responses in Pyr, somatostatin (SOM)-expressing and parvalbumin (PV)-expressing neurons, suggesting that that serotonin release has distinct short-latency effects on those neurons. Interestingly, similarly distinct responses were observed upon combined optogenetic stimulation of VIP-expressing neurons and electrical stimulation of L4. Altogether, our work provides evidence that serotonin release from RN afferents in the barrel cortex recruits $5HT3_AR$ interneurons, affecting synaptic inputs to principal neurons and other GABAergic interneurons.

Title: The effect of sensory deprivation and the role of perineuronal nets

Authors: P. CHU[1], K. BUDHU[2], *J. C. BRUMBERG[3];
[1]Psychology, The Grad. Center, CUNY, New York, NY; [2]Neuroscience, Major, Queens College, CUNY, Flushing, NY; [3]Dept Psychology, Queens Col., Flushing, NY

Abstract: Perineuronal nets (PNNs) are specialized extracellular matrix structures of the central nervous system that predominantly ensheath inhibitory interneurons. The development of PNNs is activity dependent relies on sensory input to mature to normal levels and is correlated with the closure of the developmental critical period. It remains unknown how PNNs affect electrophysiological intrinsic properties of neurons and how that may influence sensory deprivation induced plasticity. After 30 days of global bilateral sensory deprivation of the barrel cortex we found prolonged reductions in PNNs density in the somatosensory barrel cortex. Even after a period of sensory recovery for another 22 days following deprivation, we do not see any recovery off PNN levels. Our results provide support for the idea of a developmental critical period for PNN development. *In vitro* whole cell patch clamp recordings from barrel cortex following one month of deprivation resulted in changes in the response properties of fast-spiking

Deleted: In vitro

interneurons consistent with the known cellular distribution of PNNs. To further study the role PNNs have in modulating intrinsic and synaptic properties of barrel cortex neurons we used an *in vitro* model of PNN reduction via enzymatic digestion by Chondroitinase ABC (chABC) in adult mice, followed by whole cell patch clamp recordings. We found that intrinsic physiology of PNN regulation of GABAergic inhibitory cells i.e., Fast spiking and Low threshold spiking cells, was impacted to a greater extent than that of excitatory neurons i.e., Regular spiking, Regular spiking doublet, and Bursting cells. Regular spiking-Single and Regular spiking-doublet cells were not found to be greatly impacted by PNN digestion. These findings suggest that PNNs are critical regulators of intrinsic physiological plasticity in a cell type specific manner.

Title: Inter-barrel synaptic connections involving layer 4 spiny neurons and interneurons in rat barrel cortex

Authors: ***G. QI**[1], D. FELDMEYER[1,2];
[1]Res. Ctr. Jülich, Jülich, Germany; [2]RWTH Aachen Univ., Aachen, Germany

Abstract: In the primary somatosensory (barrel) cortex of rodents, the neuronal network in a single layer 4 (L4) barrel has been considered to be a self-contained entity with little interaction with adjacent barrels; this is significantly different from all other cortical layers where long-range horizontal synaptic interactions are known to exist. In the present study we present direct evidence for the existence of monosynaptic connections between L4 neurons located in two separate barrels and characterise their electrophysiological and morphological properties using paired recordings and simultaneous biocytin fillings. Monosynaptic connections (n=18) between L4 neurons located in two neighbouring barrels were obtained. They include 8 excitatory-excitatory (E-E), 8 excitatory-inhibitory (E-I) and 2 inhibitory-excitatory (I-E) connections. Once a postsynaptic neuron was patched in one barrel, normally less than 10 (1 - 12) putative

presynaptic neurons located in the adjacent barrel need to be searched before one connection was found. The distance between the somata of pre- and postsynaptic neurons is in the range of 126 - 272 µm. E-E connections (n=8) including two reciprocal ones have an average unitary EPSP (uEPSP) amplitude of 0.71 ± 0.50 mV, coefficient of variation (CV) of 0.42 ± 0.21 and failure rate (FR) of 22.3 ± 25.2%. The amplitude was depressing in most (6 out of 8) connections during repetitive presynaptic suprathreshold stimulations at 10 Hz. The 20-80% rise time and decay time constant are 1.59 ± 0.48 ms and 33.2 ± 15.0 ms, respectively. All of the aforementioned parameters for inter-barrel connections are not statistically different from that of intra-barrel ones. However, the latency of 1.71 ± 0.21 ms is significantly longer than that of intra-barrel ones (~1 ms). There is no preference for two L4 spiny neuron subtypes, i.e., spiny stellate cell (SSC) and star pyramidal neuron (SPN), to be pre- (5 SSCs vs. 3 SPNs) or postsynaptic (4 SSCs vs. 4 SPNs) neurons. E-I connections (n=8) have an average uEPSP amplitude of 0.70 ± 1.13 mV, CV of 0.56 ± 0.21 and FR of 25.3 ± 23.0%. They are much weaker than intra-barrel connections (≥ 1 mV). The uEPSP amplitude was either depressing or weakly facilitating with a paired-pulse ratio of 0.96 ± 0.19. The rise and decay time are 0.53 ± 0.22 ms and 9.9 ± 3.1 ms, respectively. The latency is 1.92 ± 0.83 ms, which is significantly longer than that of intra-barrel ones (~0.5 ms). Pre- and postsynaptic neurons are predominantly SSCs (7 out of 8) and fast spiking (FS) interneurons (7 out of 8), respectively. In addition, two monosynaptic inhibitory synaptic connections from FS interneurons in one barrel to SSCs in the other barrel were recorded.

Title: Excitatory and inhibitory inputs to vasoactive intestinal polypeptide-expressing neurons in the mouse barrel cortex

Authors: *J. SOHN[1], S. OKAMOTO[1], N. KATAOKA[2], K. NAKAMURA[2,3], T. KANEKO[1], H. HIOKI[1];
[1]Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan; [2]Dept. of Physiol. 2, Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]PRESTO, JST, Nagoya, Japan

Abstract: Vasoactive intestinal polypeptide-positive (VIP+) neurons, morphologically characterized as bipolar cells, are one of the subclasses in γ-aminobutyric acid (GABA)-ergic inhibitory neurons in the neocortex. Recently, excitation of VIP+ neurons has been revealed to trigger the local cortical activation via inhibition of other types of inhibitory neurons. The presynaptic inputs to VIP+ neurons are, therefore, responsible for the activated state of local cortical network. We morphologically investigated synaptic convergence to the subcellular compartments of VIP+ neurons in layer (L) 2/3 of the mouse barrel cortex. We developed a new adeno-associated virus (AAV) vector; this AAV vector forced neurons to strongly express reporter protein. Injection of AAV2/1-SynTetOff-DIO-FGL into the barrel cortex of VIP-Cre mice resulted in specific labeling of local VIP+ neurons with somato-dendritic membrane-targeted green fluorescent protein (FGL). Reconstruction imaging of VIP+ neuron dendrites showed their bipolarity in the vertical orientation, and their apical branches were longer and ramified at more distal portion than basal branches. We subsequently investigated input patterns to VIP+ neurons; both cortico- and thalamocortical excitatory inputs were frequently found on the distal dendrites of VIP+ neurons, and corticocortical excitatory inputs were nearly two-fold denser than thalamocortical inputs. These dense excitatory inputs on the distal dendrites were not just because of the layer-specific distribution of presynaptic axon terminals, but excitatory inputs preferentially targeted the distal dendrites. Since their ‘apical branches’ abundantly ramified at the distal portion in L1, VIP+ neurons can be strongly recruited by integrative excitatory projections from other neocortical areas and paralemniscal thalamic nuclei. On the other hand, inhibitory inputs were almost equally distributed on the somato-dendritic domain of VIP+ neurons. We finally evaluated the axonal arborization of L2/3 VIP+ neurons; their axons arborized translaminarly from L1 to L6, running in L4 preferentially through interbarrel ‘septa’. Those input-output characteristics may be inherent in VIP+ neurons for their translaminar activation of local cortical networks.

Title: Circuit mechanisms underlying tactile gating during active sensation

Authors: ***J. YU**, D. GUTNISKY, A. HIRES, K. SVOBODA;
HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Movement activates peripheral mechanosensors, giving rise to 'reafferent' signals, whereas contacts with objects produce 'exafferent' signals. Reafferent and exafferent signals are often multiplexed in the same pathway. The brain needs to disentangle these different streams of information for perception. Movement itself can sculpt tactile signals in the sensory cortex, extracting task-relevant signal at the expense of extraneous signals. The locus and mechanisms of this sensory gating are not fully understood. We investigated the circuit mechanisms of tactile gating in mice performing an object localization task with their whiskers. Neurons in the ventral posteromedial nucleus of thalamus (VPM) are sensitive to both whisker movement and touch. Long-range input from VPM targets primarily layer 4. VPM afferents synapse onto both excitatory neurons (L4_e) and fast-spiking GABAergic interneurons (L4_fs), which in turn inhibit the excitatory neurons. In behaving mice, L4_e neurons responded selectively to touch with temporally sharp, large-amplitude membrane depolarization and spikes, whereas whisker movements by themselves produced little membrane potential change and increase in spike rate. In contrast, L4_fs interneurons responded strongly to touch and whisker movements, similar to VPM neurons. Silencing VPM or cutting the infraorbital nerve abolished whisking-correlated activity in L4_fs neurons, indicating that the inhibition is driven by sensory input via the thalamus. Suppressing activity in L4_fs neurons using eNpHR3.0 revealed whisking-related excitation and enhanced touch responses in L4_e neurons. Thus, fast-spiking interneurons cancel movement-related input in cortical excitatory neurons to extract a sparse and selective representation of touch in the somatosensory cortex.

Abstract: Sensory cortex integrates external sensory input with internally generated spontaneous activity across 6 layers of interconnected neurons. The synaptic and cellular mechanisms of trans-laminar sensory integration in behaving animals, however, are poorly understood. Here we made single and dual whole-cell recordings in primary somatosensory forepaw cortex of behaving mice to compare the cellular properties and membrane potential dynamics of L2/3 and L5 excitatory neurons. We show that L2/3 and L5 neurons have distinct intrinsic properties with L5 neurons having larger input resistance and higher firing rates than L2/3 neurons during current injection. Higher firing rates of L5 neurons were also present during spontaneous activity during quiet resting periods, during active periods of forepaw movement and in response to sensory stimulation. We show that these differences in firing rates were signaled by a smaller difference between the peak spontaneous Vm or sensory-evoked reversal potential and action potential threshold in L5 neurons as compared to L2/3 neurons. Dual, simultaneous recordings allowed a direct comparison of the timing of synaptic input and action potential firing across layers. Slow depolarizing events during quiet states were broadly correlated across layers but were more reliable and had an earlier onset in L5. In contrast, synaptic input triggered by movement onset or sensory stimulation had similar latencies and was highly correlated across layers. Movement and sensory evoked subthreshold input therefore showed a different temporal structure across layers compared to spontaneous activity. We conclude that laminar specific

membrane potential properties are central to spike rate differences recorded across cortical layers during active sensory processing.

Title: Effects of excitation wave induced by forelimb stimulation on the propagation pattern of excitation wave induced by hindlimb stimulation in the rat sensorimotor cortex recorded with an optical recording system

Authors: ***N. HAMA**, M. KAWAI, S.-I. ITO, A. HIROTA;
Shimane University, Sch. of Med., Izumo, Japan

Abstract: Optical recording system using a voltage-sensitive dye has well documented that the sensory-evoked cortical response is of a concentric propagating wave emerging from the focal site rather than a simultaneous activation of the area of response. Thus, when two distant cortical sites are concurrently activated, the two waves should interact with each other. Details of this interaction, however, remain largely unknown. In this study, we examined the influence of forelimb stimulation-induced excitation wave (wave F) on the hindlimb stimulation-induced one (wave H). The sensorimotor cortex was exposed and stained with a dye (RH-414). Electrical stimulation (1 mA, 0.5 ms) was given first to the hindlimb then to the forelimb with an interstimulus interval (ISI) of 0, 10 or 20 ms. We compared the latency of wave H at the initiation site with and without forelimb stimulation. Without forelimb stimulation, the first response to the hindlimb stimulation occurred with the latency of 46.5 ± 10.2 ms (mean ± SD). With forelimb stimulation the latency of wave H was significantly shortened for the ISI of 0 ms. The wave F arrived at the wave H initiation site, 57.0 ± 7.83 ms after the forelimb stimulation. It should be noted that this value was longer than the value of shortened latencies of wave H. We also compared the amplitude, full width at half maximum (FWHM) and slope of the rising phase of wave H with and without forelimb stimulation, at the collision portion of two propagation

waves. To estimate the portion, we constructed the isochrone maps based on the difference in latency of each pixel. And then, the collision portion was defined as the recording portion including the local maximum of the isochrone map within the area between forelimb- and hindlimb-response initiation sites. The FWHM was significantly shorter for all ISIs. The slope of rising phase was significantly steeper but only for the ISI of 0 ms. No significant difference was found in the amplitude for any ISIs. We conclude that this interaction is not linear summation and that the spatio-temporal pattern of neural activity as resulting from the interaction between two waves in the sensorimotor cortex is complex depending on the change of the timing of another sensory input.

Title: Representation of two-whisker sequences in L2/3 of mouse S1

Authors: ***K. J. LABOY-JUAREZ**[1], D. E. FELDMAN[2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA

Abstract: Most studies of sensory coding in rodent whisker somatosensory cortex (S1) have focused on understanding the encoding of single whisker stimuli. However, natural whisker sensation involves complex spatiotemporal patterns of whisker contacts, suggesting that multi-whisker stimuli are processed and represented in S1. Here we tested how S1 represents two-whisker combinations, which are the simplest multi-whisker feature. We presented single-whisker stimuli and two-whisker sequences in urethane-anesthetized mice, while performing single unit extracellular recording in layers 2-4 of the D1 column of S1. We interleaved single whisker deflections of a 3x3 grid of whiskers centered on D1 plus all possible two-whisker sequences at ±2 ms intervals (72 sequences). Optimal sequences evoked higher firing rates and response probabilities than optimal single whisker deflections. For 85% of units, optimal

combinations involved adjacent whiskers with a clear preference for sequences involving D1 (columnar whisker) or their best whisker (BW, the whisker that evoked the most spikes). Selectivity among 2-whisker sequences (measured by lifetime sparseness) was higher than predicted from the linear sum of single whisker responses. Selectivity was greater in L2/3 than in L4. L2 units responded linearly to the best sequence but sublinearly to other sequences. L4 units responded sublinearly to all sequences, with non-optimal sequences often being strongly suppressed. Thus, sublinear integration of single whisker input sharpens tuning for 2-whisker sequences. Whisker map topography differed for single-whisker stimuli vs. 2-whisker combinations. Mapped with single-whisker stimuli, the large majority of L4 neurons were tuned to the CW for their column (D1), but L2/3 neurons exhibited heterogeneous tuning for multiple whiskers. This is consistent with a recent mapping study using calcium imaging (Clancy et al., 2015). However, when mapped using 2-whisker sequences, many L2/3 neurons responded best to sequences involving the D1 whisker. Further, some L2 single units that were not tuned to D1 when mapped with single whisker deflections responded more strongly to D1 than any other whisker when 2-whisker sequences were presented. These initial results suggest that many L2/3 neurons are tuned for specific 2-whisker sequences, and that multi-whisker representation may increase between L4 and L2/3. We speculate that a major role of S1 circuits may be to process multi-whisker information.

Title: Sensory stimulus evoked responses in layer 2/3 pyramidal neurons of the hind paw-related mouse primary somatosensory cortex

Authors: *G. BONY, A. A-BHASKARAN, K. LE CORF, A. FRICK;
INSERM, Bordeaux Cedex, France

Abstract: The mouse primary somatosensory cortex (S1) processes tactile sensory information and is, with a surface area of ~30%, the largest sensory neocortex area, emphasizing the importance of this sensory modality for rodent behavior. Most of our knowledge regarding information processing in S1 stems from studies of the whisker-related barrel cortex (S1-BC), yet the processing of tactile inputs from the paws is largely unknown. We used *in vivo* whole-cell patch-clamp recordings from layer (L) 2/3 pyramidal neurons of the S1 hind-paw (HP) region of anaesthetized mice to investigate their intrinsic properties, spontaneous activity, and evoked sub- and supra-threshold activity. We found that L2/3 neurons displayed up- and down-states characteristic of sleeping mice, and low spontaneous firing rates (~0.1 Hz). Approximately 45% of L2/3 pyramidal neurons responded to contralateral HP stimulation in a sub-threshold manner, ~5% with on average 0.4 action potentials per trial, while ~50% of neurons did not respond at all. The evoked subthreshold responses had a long onset (23 ms) and peak latency (61 ms), and 86% of L2/3 neurons responded to prolonged stimulation with on- and off-responses. HP stimulation responsive neurons had a greater intrinsic excitability compared to non-responding neurons, as shown by an increase in the action potential output as a function of current injected. In conclusion, while S1-HP L2/3 pyramidal neurons share certain physiological properties with their counterparts in the S1-BC, they also have unique features specific for the sense of paw touch. Our findings support a sparse coding scheme of operation for S1-HP L2/3 pyramidal neurons, and suggest that response latencies are not crucial for paw sensation and sensory aspect of locomotion.

Title: Feedforward motor information enhance sensory responses in S1 barrel cortex neurons

Authors: M. KHATEB, J. SCHILLER, *Y. SCHILLER;
Technion Med. Sch., Haifa, Israel

Abstract: The whisker barrel system functions as a sensory-motor loop, with tight interconnections between the sensory S1 barrel cortex and the vM1 motor cortex. During physiological whisking, neurons in the barrel cortex receive information regarding whisker movements from vM1 followed by upstream sensory information arriving from the whiskers via the thalamus. The goal of this study is to investigate the effect of motor inputs arriving from vM1 on sensory processing in the S1 barrel cortex. Under physiological conditions the activity in the vM1 motor and sensory barrel cortexes are tightly linked. To dissociate between the activity in these two cortexes we stimulated whiskers either passively (ramp and hold stimulation) or with artificial whisking paradigms (facial nerve stimulation induced artificial whisking against P320 sandpaper), and independently activated the motor cortex using channel rhodopsin 2 (ChR2) mediated optogenetic stimulation. We monitored the response in S1 barrel cortex neurons using a 16-contact single shaft silicon probe that simultaneously recorded single units from layers 2-5. Pairing optogenetic activation of VM1 (20 ms laser pulse) with whisker activation (either passive or artificial whisking) yielded a prominent supra-linear summation of the two responses. On average the response of paired optogenetic vM1 activation with passive whisker deflection and artificial whisking against sand paper was 178±49 % and 168±56 % of the expected for linear summation of the two responses ($P < 0.005$). This supra-linear summation response was largest in layer 5 neurons and smallest in layer-4 neurons fitting previously known functional neuroanatomical data about vM1-S1 connectivity. When we changed the relative timing of optogenetic stimulation and whisker activation we found that the response of both passive whisker stimulation and artificial whisking activation can be enhanced supra-linearly when vM1 was optogenetically activated 75 ms before up to 20 ms after the initiation of whisker stimulation. In these experiments, maximal supra-linear enhancement was achieved when vM1 was activated 20 ms before whisker activation (both for passive and artificial whisking paradigms). In conclusion, our findings suggest that as whisking is initiated, vM1 sends parallel "attentional" information to S1 barrel neurons, preparing them for the sensory cues expected to arrive from the periphery.

Title: Sensory modulation by whisker movement in the rat brainstem trigeminal complex

Authors: S. CHAKRABARTI, *C. SCHWARZ;
Univ. Tuebingen, Tuebingen, Germany

Abstract: In order to make sense of input acquired by mobile sensors, information about movement and sensory input needs to be integrated. In the rodent whisker system this interaction happens as early as in the brainstem trigeminal nuclei (TN). The TN house the second order tactile neurons, but also a quite extensive and only partially known intrinsic network. Lesions in one part of the TN, the ncl. spinalis interpolaris caudalis (SpVic) lead to blockade of movement effects in the lemniscal pathway ascending from the principal nucleus (PrV). We aimed at elucidating the hypothesis that SpVic is the origin of motor effects in PrV by recording unit and LFP data in both sub-nuclei in head-fixed rats trained to perform active whisker movements to touch an object (Schwarz et al., 2010, Som. & Mot. Res., 27:131). The animals were implanted with mobile multielectrode arrays to record unit and evoked LFP data in PrV and SpVic. We find that during active whisker movements both nuclei show a depression of the sensory response to object contact with concomitant increment of (pre-touch) movement-related activity. The majority of neurons in both the PrV and SpVic showed a bimodal response to touch, perhaps indicating direct input from primary afferents and an indirect one from the well-described corticobulbar projections. The identical modulation of the two sub-nuclei in unit and LFP data does not support the notion that SpVic is responsible for sensory modulation in the lemniscal pathway. Currently we aim at identifying the intermingled ascending projection neurons and intrinsic neurons in SpVic to gain more detailed insight into SpVic's role for active touch.

Title: Receptive fields and response characteristics of neurons in the S1 whisker representation of the short-tailed opossum, Monodelphis domestica

Authors: *D. L. RAMAMURTHY[1], L. A. KRUBITZER[2];
[1]Ctr. for Neurosci., UC Davis, Davis, CA; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: The innovation of hair in mammalian evolution allowed for the development of a unique form of movable tactile sensors in the form of sinus hairs, or whiskers. Whiskers are present in all marsupials and placental mammals. However, to date, neural response properties in the cortical whisker representation have been studied in only two species of rodents (rats and mice), and to a small extent in lagomorphs (rabbits). Using single unit extracellular recording, we examined the receptive fields and response properties of neurons in the whisker representation of the short-tailed opossum, a marsupial that shared its last common ancestor with placental mammals over 160 million years ago. Single neurons in layer IV of the S1 whisker representation in the opossum predominantly respond to a single best whisker. In addition, these neurons also display a lower magnitude response to 1-15 surrounding whiskers. Thus, opossum S1 neurons have a receptive field organization with a center and an excitatory surround, similar to the neurons in S1 barrel cortex of rodents. Peristimulus time histograms indicate that S1 neurons display a transient response to stimulus onset and offset. In general, the offset response has a lower magnitude compared to the onset response. On average, neurons respond to stimulus onset with a short latency of 5-10 ms, similar to neurons in S1 barrel cortex of rodents. The population mean response profiles were examined for neural responses to the best whisker, compared to the surrounding whiskers, and were found to have similar response latencies. The short latency in the neural responses to the best whisker as well as the surrounding whiskers suggests the contribution of direct thalamocortical inputs to the excitatory surround component of the receptive fields of neurons in the opossum S1 whisker representation. In rodents, the receptive field surround is mainly driven by intracortical relays rather than direct thalamocortical input. The distribution of spike waveform durations in opossum S1 was bimodal, with an average spike duration of 0.3 ms for one set of neurons, and 0.6 ms for the other. This is similar to previous findings in somatosensory cortex of mice, rats and rhesus macaques, where these two categories of neurons are referred to as fast spiking units and regular spiking units. Taken together, the results of our study suggest that receptive field structure and response properties of neurons in layer IV of the S1 whisker representation are conserved in marsupials and placental mammals. Further research is necessary to elucidate potential differences in the underlying circuitry, which may be related to species-specific behavior and the lifestyle of the animal.

Title: Perception of partial slips under tangential loading of the fingertip

Authors: ***A. BARREA**[1], B. DELHAYE[2], P. LEFEVRE[1], J.-L. THONNARD[1];
[1]Univ. Catholique De Louvain, Louvain-la-Neuve, Belgium; [2]Univ. of Chicago, Chicago, IL

Abstract: When a fingertip is pressed against a surface and moved laterally, slippage does not occur instantaneously but rather in a progressive fashion as established by a classic result in contact mechanics. In previous studies we showed that this transition starts with slips occurring at the periphery of the contact area and then propagating towards its center until the whole contact area slips. The stick ratio (SR) allows us to quantify this phenomenon. It is defined as the ratio of the stuck area over the whole contact area. When slip occurs, SR varies from 1 (no slip) to 0 (full slip). While the mechanical behavior of a slipping fingertip has already been characterized, the perception of this phenomenon by human subjects has not been investigated yet. Here, we designed a psychophysical experiment to examine human ability to detect partial slips. We used a robotic platform to make a transparent glass plate slide tangentially in the radial-ulnar direction against the right index fingertip of five subjects. For each trial, the glass plate was first loaded against the finger pad at a given normal force (NF), which was kept constant during the whole trial. Once NF stabilized at the prescribed level, the plate moved tangentially over a given distance with a constant speed of 5 mm/s. The plate was then moved away from the fingertip. Seven levels of plate displacement were used, ranging linearly from 0.5 mm to 5 mm. Each displacement was repeated eight times for each normal force level (2N or 5N), for a total of 112 trials per subject. At the end of each trial, subjects reported whether or not they detected that the plate had slipped under their fingertip. Position and forces exerted on the plate were recorded during the trials. In addition, images of the finger pad contact were also recorded during each trial through the glass plate using an imaging system embedded in the robotic platform. SR was computed from the recorded images using image processing techniques. Results showed that all subjects reported slippage before full slip, i.e. for an average SR of 0.6 (SD = 0.1), corresponding to a plate displacement of 2.3 mm (SD = 0.6 mm). We also tested three predictors they might have used to detect these slips: the plate displacement, the

tangential force or SR. Among the three predictors, SR appeared as the best one allowing subjects to detect partial slips since it was the only one for which NF had no significant effect on the detection threshold of the subjects. In conclusion, this demonstrates that human subjects are able to detect partial slips at the fingertip under tangential loading.

Title: Differential modulation of sensory input from three forearm afferent nerves to the spinal cord of the primate during delayed wrist movements

Authors: ***J. CONFAIS**[1], G. KIM[1,2], S. TOMATSU[1], T. TAKEI[1,2], K. SEKI[1,2,3];
[1]Natl. Ctr. For Neuroscience, NCNP, Tokyo, Japan; [2]Dept. of developmental physiology, Natl. institute for physiological science, Okazaki, Japan; [3]Presto, Japan Sci. and Technol. Agency, Tokyo, Japan

Abstract: During voluntary movements, descending motor command and sensory reafferent input converge at the level of the spinal circuits, and their interaction determine the net drive to the motoneuronal pool. The sensory afferent signal must thus be regulated, so that it does not interfere with the motor command. Previous reports already showed that the input from pure cutaneous afferent is suppressed during the dynamic epoch of a wrist movement task (Seki et al. 2003). This task-dependent suppression of afferent inputs could be induced by either a general inhibition of afferent inputs irrespective of their modality or receptive area, or by a targeted modulation of specific afferents. According to this latter view, input from distinct modalities or nerves could be differently modulated according to behavioral needs. To examine this possibility, we stimulated (1 to 3 Hz) multiple sensory afferents with different receptive area/

modality in the forearm using implanted cuff electrodes, as macaque monkeys (n=4) were performing a delayed wrist flexion-extension task. The effect of nerve stimulation on spinal interneurons was then computed (peak area of the PSTH) and compared according to task epochs. Neurons in which the peak response started 1.5ms or less after the peak of cord-dorsum volley were identified as a putative first-order interneurons, and were used for further analysis (N=203). The stimulated nerve were the Superficial Radial nerve (SR, N=56), a cutaneous nerve innervating the dorsal aspect of the hand, the Deep Radial nerve (DR, N=95), a proprioceptive nerve innervating the extensor muscles of the wrist and fingers, and the Median nerve (M, N=52), a mixed nerve innervating the palmar aspect of the hand and fingers. The effect of nerve stimulation on first-order interneurons was strongly modulated according to task epoch, and differed according to the stimulated nerve. As in our previous report, the input from the cutaneous nerve SR is suppressed during movement, especially during flexion movements. The input from the mixed nerve M is similarly suppressed during movement. By contrast, the input from the proprioceptive nerve DR is facilitated during movement as well as during the instructed delay preceding it, exclusively during extension movements (that is, the direction corresponding to the activation of the target muscles). Sensory inputs seem thus to be differently modulated according to movement direction and input modality, hinting at a fine-tuned input control mechanism at the spinal level rather than a general suppression. As some of these modulations take place before the onset of the movement, they might be the result of a descending anticipatory command.

Title: Predictions for parietal cortex from a neural-network model of state estimation

Authors: *J. G. MAKIN, B. K. DICHTER, P. N. SABES;
Ctr. for Integrative Neurosci., Univ. of California, San Francisco, San Francisco, CA

Abstract: How does the brain learn to track the dynamical state (position, velocity, etc.) of objects, including one's own limbs, as well as external stimuli? In higher mammals, these skills are clearly adaptive and likely learned, rather than inborn. A central locus of this learning is likely to be parietal cortex. We have recently proposed a computational model for how parietal cortex could learn to perform such state estimation. The model is an artificial neural network that is trained by quasi-Hebbian, unsupervised rules--which appear to be ubiquitous in cortex--to become a good "generative" model of its inputs. The key insight is to include among these inputs the recent activity of the model's own hidden layer, which allows the network to learn temporal dependencies in the data. When the rest of the inputs are the responses of sensory units to the moving stimulus, this means learning, implicitly, the dynamics of the object being tracked. This in turn facilitates optimal inference about its dynamical state. When the input also includes units that report a "copy" of the efferent command, the network learns (again without supervision) to interpret the signal as such, as well as how the command influences the trajectory of the moving object. The resulting inference to the position of that object--in this case, the limb--is again nearly optimal. The solution to the state-estimation problem learned by the network is not obvious; it therefore makes predictions for real neural networks in cortex. Here we examine the nature of that solution; the receptive fields (RFs) learned by the model; and how these compare to electrophysiology in MSTd and in Area 5 of posterior parietal cortex. Learning to track external stimuli from position-encoding units causes the network's hidden units to encode position at various temporal lags--i.e., to be tuned for past positions--rather than, for example, simply encoding the current posterior mean and variance, as in the standard engineering solution, the Kalman filter. The resulting RFs resemble those in MSTd in macaques. Moreover, when the task is instead to track the arm during center-out reaches, and the inputs are both position and efference-copy units, the distribution of the hidden units' temporal lags becomes instead roughly symmetric about zero. A very similar distribution has been found in macaque Area 5, which is thought to be responsible for learning the model of arm dynamics. In fine, the network model and the solutions it learns offer explanations for otherwise puzzling electrophysiology in parietal and related areas.

Title: Stick-slip movements of whisker depend on multiple variables - some determined by the touched object and some by the actively touching subject

Authors: *M. OLADAZIMI[1,2,3], C. SCHWARZ[1,2];
[1]Systems Neurophysiology, Werner Reichardt Ctr. F, Tuebingen, Germany; [2]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tuebingen, Germany; [3]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: Friction is an important determinant of touch related perception. In whisker mediated touch, friction leads to stick-slip movements ('slips') already with light touch - well in the range of variables that is deemed to govern realistic touches performed by rodents. If slips should ever tell the subject something about the touched surface, the dependencies of occurrence should be uniquely related to the touched object- i.e. any other dependencies, e.g. on the way the touch is performed by the subject, must be either minimized or predicted by the subject. We used natural rat vibrissae mounted on a rotating axis and swept by a stepper motor across surfaces to videotape whisker vibration in the plane of whisking (2 kHz frame rate). Slip events were extracted using threshold speed criteria. The occurrence and kinematic profile of slips dependent on, texture roughness (particle size of sandpaper), whisker identity (C2, C4, C6, E2, A2, ɣ), touch distance (5mm, quarter and half whisker length from the whisker tip), and sweeping velocity (200-1800 deg/s) was assessed (200 sweeps for each condition). We found dependencies of slip occurrence and kinematics on surface roughness as reported before. Small numbers of events with high slip amplitude/velocity were generated by rough surfaces, while ubiquitous small slips were observed with smooth textures. Importantly though, we also found that slips can be dependent on touch distance and sweeping velocity: greater distance and velocity generated larger slips. From our findings, we predict that two selected textures may evoke the same slip profile if touch dependent variables are set accordingly. Thus, assuming that slip kinematics are decisive for tactile perception, rodents need to carefully adjust their active touch strategy to find out the difference between any two surfaces.

Title: Modulation of somatosensory evoked potentials after transcranial static magnetic field stimulation over primary and supplementary motor cortices

Authors: *H. KIRIMOTO, H. TAMAKI, H. ONISHI;
Niigata Univ. of Hlth. & Welfare, Niigata, Japan

Abstract: Introduction: Current research by two groups has reported that the primary motor cortex (M1) in the human brain can be modulated by the application of static magnetic fields, and not only time-varying (electromagnetic) fields, through the scalp (Oliviero et al., 2011; Silbert et al., 2013). Moreover, we previously reported that transcranial static magnetic field stimulation (tSMS) over the sensorimotor cortex (C3) reduces the amplitudes of the N20 component of somatosensory evoked potentials (SEPs) (Kirimoto et al., 2014). In transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS) studies, the M1 is considered an important target with proven efficacy in chronic pain treatment. On the other hands, supplementary motor area (SMA) is thought to one of the generator of SEPs, however the effect of tSMS on the excitability of SMA has never been examined. Objective: This study aimed to investigate the possibility of non-invasive modulation of SEPs by the application of tSMS over the M1 and SMA in healthy humans. Methods: tSMS and sham stimulation over the M1 or SMA were applied to 14 subjects for periods of 15 min. SEPs following right median nerve stimulation were recorded before, immediately after, 5 min after, and 10 min after tSMS from sites C3' and F3. Using a Gauss meter, magnetic field strength of a cylindrical neodymium magnet (NdFeB) was measured, both through the human skull specimen and directly. Results: Amplitudes of the P25 and N33 component of SEPs at C3' significantly decreased immediately after the 15-min period of tSMS over the M1 by up to 20%, returning to baseline by 10 min after intervention. However, tSMS over the SMA did not influence any of the components of SEP amplitude. At a distance of 2-3 cm (rough depth of the cortex), magnetic field strength was in a range between 110-190mT, regardless of the presence or absence of the skull. Conclusions: Our results suggest that different components of SEPs are reduced according to the tSMS stimulation site: for instance, tSMS over the C3 modulates the N20 component of SEPs, while the amplitude of N33 is affected by tSMS over the M1. This result, showing that tSMS over the M1 can reduce the N33 component of SEPs at C3' is consistent with repetitive transcranial magnetic stimulation and transcranial direct current stimulation over M1 studies (Lefaucheur et al., 2008; Sugawara et al., 2014). Therefore, tSMS could be a useful tool for modulating cortical somatosensory

processing. SMA is likely to be a more difficult area to target with tSMS than M1, since it is located in the interhemispheric fissure, which would result in the magnetic field strength of tSMS being attenuated to on-effective levels.

Title: Regression of the expression of growth associated genes after chronic nerve injuries

Authors: *T. GORDON[1], W. TETZLAFF[2];
[1]Div. of Physical Med. and Rehabiltation, Ctr. for Neurosci., Univ. of Alberta, Edmonton, AB, Canada; [2]ICOR and departments of Zoology and Surgery, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The regenerative capacity of injured neurons and the regenerative support provided by Schwann cells declines after delayed surgical repair and over time and distance. Injured neurons undergo morphological changes that reflect altered gene expression including the upregulation of regeneration associated genes (RAGs) that include the cytoskeletal proteins, actin and tubulin, and neurotrophic factors such as glial and brain derived neurotrophic factors. The question that we asked is whether this expression is sustained or whether there is a regression with time that might, in turn, account for the progressive reduction in the capacity of chronically injured neurons to regenerate their axons. In Sprague Dawley rats, sciatic nerves were transected and the nerve stumps ligated and sutured to innervated muscle to prevent regeneration for periods of up to 6 months and, in a subgroup of rats, the proximal nerve stump was refreshed and again ligated to prevent nerve regeneration. At 7 days and months after axotomy, the expression of actin, tubulin, neurofilament, and GAP-43 in the motoneurons that supplied the experimental axotomized sciatic nerve and those that supplied the contralateral intact sciatic nerve was determined using *in situ* hybridization. When expressed relative to the RAG expression in the motoneurons supplying the contralateral intact sciatic nerve, the expression of tubulin, actin and GAP-43 mRNA was increased to a maximum and that of neurofilament was reduced within 7 days. Thereafter the RAG expression of each of the upregulated genes declined and the down-regulated genes increased with an exponential time course to reach basal levels equal to the contralateral sciatic motoneurons. This decline was reversed when the ligated nerves were

Deleted: in situ

refreshed by a transection injury but the expression of the tubulin, actin, and GAP-43 genes declined and the neurofilament genes increased, the rate of the change in expression being significantly faster than after the first injury. These findings demonstrate the transient nature of expression of RAGs and that, whether or not the ligated nerves were refreshed, the exponential decline in the expression reaches basal levels, the decline corresponding with the time course of decline in the regenerative capacity of chronically injured neurons. Therefore, the transient expression of RAGs accounts, at least in part for the relatively short window of opportunity when the regenerative response of injured neurons is maximum and when, in turn, functional return is optimal.

Title: Chronic electrical muscle stimulation (EMS) immediately after nerve transection and repair increases reinnervated muscle force but does not prevent misdirection of regenerating nerves

Authors: ***M. WILLAND**, J. CATAPANO, T. GORDON, G. H. BORSCHEL;
Div. of Plastic Reconstructive Surgery, The Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Introduction: Functional recovery after surgical repair of transected nerves is reduced when axons are misdirected to reinnervate muscles other than their original and appropriate targets. Canine models of laryngeal nerve transection injury have suggested that EMS during the period of nerve regeneration promotes reinnervation of original targets. However, these conclusions were based on functional measurements and there remains no direct evidence that the muscles are reinnervated by motoneurons from the original motoneuron pool following EMS. In this study, we investigated whether EMS using a natural activation pattern increases the number of motoneurons regenerating to innervate their original target muscle. Methods: Prior to injury, soleus muscles in two groups of Sprague Dawley rats were injected with True Blue tracer to label the original motoneuron pool in the spinal cord. One week later, the lateral gastrocnemius soleus (LGS) nerve was transected and immediately repaired and the soleus muscle was implanted with intramuscular wire electrodes attached to implanted mini-stimulators. In one group of rats the denervated soleus muscle was subjected to EMS with a paradigm

mimicking the natural activation of the soleus muscle: 12 hours (h) of continuous daily EMS at 20 Hz (10 seconds on, 20 sec off) followed by 12 h of intermittent EMS (10 sec on, 1 h off). Two months after the LGS nerve transection and repair, the motoneurons that had regenerated axons into the soleus nerve were retrogradely labelled with FluoroRuby just proximal to the soleus muscle. The motoneurons of the contralateral uninjured lateral gastrocnemius (LG) and soleus muscle were labelled to compare the spatial distribution of the contralateral motoneuron pool with that of the injured side. A second group of rats, undergoing the same procedure, were used for isometric force recordings. Results: Intramuscular injection of soleus muscle resulted in a labeling efficiency of 75% of the uninjured contralateral side which was labeled using the gold standard well technique. Double labeled motoneurons, representing reinnervated axons that originally innervated the soleus muscle, were no different between groups (EMS: 10.9 ± 2.3 % vs Sham: 15.5 ± 9.9 %). Visualizing 3D spatial distributions of labeled neurons indicated that more axons originated from the LG motoneuron pool which has 3x more motoneurons than the soleus. Muscle twitch forces were greater in the EMS group (33 ± 4.6 % vs 20 ± 2.5%). Conclusions: In our model, EMS does not counteract the misdirection of nerve regeneration but it does enhance muscle force in line with our previous finding that EMS accelerates muscle reinnervation.

Title: Optical activation of cut axons in mouse peripheral nerves enhances regeneration and muscle reinnervation

Authors: ***A. W. ENGLISH**, P. J. WARD, S. PARK;
Dept Cell Biol., Emory Univ. Sch. Med., Atlanta, GA

Abstract: To evaluate whether increasing neuronal activity is sufficient to promote axon regeneration and functional recovery following peripheral nerve injury, we activated peripheral

axons using optogenetics. In thy-1-ChR2/YFP mice, in which channelrhodopsin is expressed at para-nodal regions of nearly half of the sensory and motor axons in peripheral nerves, neural activation was achieved by application of short (1 ms) pulses of 473nm light at 20 Hz for one hour prior to transection and surgical repair of the right sciatic nerve. Mice with similar injuries that were untreated (UT) served as controls. All mice were implanted with stimulating cuffs around the right sciatic nerve, distal to the injury site, and EMG recording electrodes in the gastrocnemius and tibialis anterior muscles bilaterally. The time course of axon regeneration and muscle fiber reinnervation were studied from EMG potentials evoked by electrical stimulation of the right sciatic nerve. Recordings were made weekly in awake animals for as long at 18 weeks after nerve injury. Even though treatment with optical stimulation (OS) results in activation of only half of the sensory and motor axons in the sciatic nerve, OS at the time of injury resulted in an earlier reappearance of compound muscle action potentials (M responses) and monosynaptic H reflexes in reinnervated muscles than in UT mice, and a significantly more rapid restoration of the pre-transection M response amplitude. These outcomes are similar to data from animals exposed to one hour of 20 Hz supramaximal electrical stimulation at the time of nerve transection and repair, a treatment which is expected to activate all axons in the nerve. The isolated activation of neurons whose axons have been transected is sufficient to promote enhanced axon regeneration and improved functional recovery after peripheral nerve injury.

Title: Pharmacogenetic enhancement of functional recovery from sciatic nerve transection

Authors: ***P. B. JAISWAL**, A. W. ENGLISH;
Emory Univ., Atlanta, GA

Abstract: Designer receptors exclusively activated by designer drugs (DREADDs) are a pharmacogenetic tool that could be used to modulate neuronal excitability in the peripheral nervous system. We hypothesized that activation of excitatory (Gq) DREADD by the physiologically inert ligand, clozapine-N-oxide (CNO), will increase the excitability of

DREADD-infected neurons whose axons have been transected and that this will lead to enhanced axon regeneration and improved functional recovery. The gastrocnemius (GAST) muscle of young female Lewis rats was injected unilaterally with AAV9::hM3Dq-hsyn-mCherry (7.6x109 viral genomes/µl). The contralateral muscle served as a control. Six weeks after intra-muscular injection, direct muscle (M) responses and monosynaptic H reflexes were elicited from sciatic nerve stimulation, under isoflurane anesthesia (1-2% in oxygen) before (Baseline) and after intra-peritoneal injection with 1mg/kg CNO (Post CNO). The sciatic nerve was then transected and repaired bilaterally and rats were treated with 1mg/kg CNO by daily intra-peritoneal injection for three days after injury. Electrophysiological data were collected at 2 weeks and 4 weeks after injury. A prolongation of both the latency and duration of evoked responses was observed at 2 and 4 weeks after transection. However, these responses were shorter in the DREADD-infected than in the contralateral GAST muscles. Recovery of elicited responses was observed at 2 weeks after transection injury in animals treated with CNO on the DREADD-infected but not the contralateral GAST muscle. The Baseline amplitude of the maximal M-response was greater on the DREADD infected but not the contralateral GAST at 4 weeks after injury in all animals. Post CNO amplitude of the evoked M-response and H reflex in the DREADD-infected muscle was greater than the contralateral GAST muscle, compared to their respective Baseline, at Intact and 4 weeks after transection. This novel use of DREADD technology in the peripheral nervous system caused sustained increases of neuronal excitability, which was sufficient to produce enhanced recovery of the evoked muscle responses after sciatic nerve transection.

Abstract: Purpose: Recently, surgeons have been using decellularized nerve allografts to bridge nerve gaps, but these grafts lack therapeutic levels of neurotrophic factors and therefore do not support regeneration to the same extent as autografts. Here we investigated a local delivery system for glial cell line derived neurotrophic factor (GDNF) controlled release to the implanted decellularized nerve allografts using drug-loaded poly(lactic-co-glycolic acid) (PLGA) microspheres (MS) embedded in a fibrin gel. The hydrogel composite served to localize MS around the nerve allografts and allows sustained GDNF release. Methods: In a nerve gap model, a 10 mm decellularized nerve graft was used to bridge a 5 mm common peritoneal (CP) nerve gap. In negative control groups, animals received no treatment or received fibrin gels with empty MS at both suture sites of the nerve graft. Fibrin gels loaded with MS encasing GDNF with 2 weeks or 4 weeks release period served as the primary experimental groups. Rats receiving nerve isografts served as the positive control group. 8 weeks after repair, nerve regeneration was assessed using retrograde labeling and collecting nerve samples 10 mm distal to the graft for histomorphometric analysis. Results: Regeneration for both motor and sensory neurons in all the groups with GDNF MS treatment and isograft treatment were indistinguishable and significantly higher compared to the negative control groups. Qualitative and quantitative analysis of nerve samples obtained at 10 mm distal from the nerve grafts revealed that groups receiving GDNF MS had similar nerve morphology to the isograft receiving group, with significantly higher myelinated axons present in the nerve cross sections compared with the negative control groups. Fiber frequency analysis indicated enhanced nerve maturity for the GDNF MS and isograft treated groups as the number of fibers with larger diameter (4 μm - 6 μm) was higher compared to the negative control groups with more smaller diameter fibers (2 μm - 4 μm). Conclusion: GDNF local administration using a biodegradable and biocompatible drug delivery system makes the decellularized nerve allografts as effective as the isografts in supporting nerve regeneration. The biomaterial developed in this study has the potential to provide an “off the shelf” alternative in the current management of severe nerve injuries.

Title: Large-diameter sensory neurons require androgen receptor signaling for activity-enhanced axon regeneration

Authors: *P. J. WARD, A. ENGLISH;
Dept of Cell Biology, Emory Univ., Atlanta, GA

Abstract: Signaling through androgen receptors is required for the effects of increased neuronal activity on enhancing axon regeneration following peripheral nerve injury. The targets of androgenic activity required to promote axon regeneration are unknown. Here, we evaluated whether androgen receptor signaling in sensory neurons is necessary for enhancing axon regeneration following nerve transection and repair that is produced by increased neuronal activity. In wild type (WT) mice that received electrical stimulation for 1 hour (20 Hz) prior to sciatic nerve transection and repair, we observed an increased number of retrogradely-labeled, large diameter sensory neurons in the L4 dorsal root ganglia two weeks later, compared to untreated WT mice. We compared these results to the effects of increased activity in Adv-Cre::ARff mice, in which the androgen receptor is knocked out selectively (via tamoxifen administration at 8 weeks of age) in a subset of sensory neurons (primarily large diameter sensory neurons). Although the mice received one hour of 20 Hz electrical stimulation just prior to injury, we observed fewer retrogradely-labeled, large diameter sensory neurons two weeks later. These results suggest that neuronal androgen receptor signaling is required for the effects of activity-induced axon elongation of large diameter sensory neurons following nerve injury.

Title: Modulation and inhibition of M-response and H- reflex activity using kilohertz electrical stimulation

Authors: *Y. PATEL[1], R. J. BUTERA[1], A. W. ENGLISH[2];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Cell Biol., Emory Univ., Atlanta, GA

Abstract: Kilohertz electrical stimulation (KES, 3-70 kHz) has been shown to be effective at blocking action potential propagation in whole nerves, which contain both myelinated (A) and unmyelinated (C) fibers. The threshold for C-fiber KES block is lower than the threshold for A-fiber KES block at sufficiently high frequencies. To evaluate whether KES block could be selective towards afferent and efferent fibers in peripheral nerves, we stimulated the sciatic nerve (test stimulation) in urethane-anesthetized mice and measured evoked EMG potentials in the gastrocnemius and plantar foot muscles in the presence or absence of KES. If KES is applied distal to the test stimulation, the direct muscle (M) responses are blocked completely at frequencies from 4-20 KHz. At higher frequencies, KES is ineffective in blocking motor action potential propagation. If KES is applied proximal to the test stimulus, both the M response and the monosynaptic H reflex are blocked at frequencies that are effective in blocking efferent action potentials, but at higher frequencies (20-40 KHz) the H reflex is lost, but the M response persists. These findings are interpreted to mean that KES can be used to produce selective block of action protential propagation in afferent or efferent axons in peripheral nerves. It could prove useful either as an experimental tool or as an experimental treatment to regulate activity in peripheral nerves.

Abstract: Spinal root traction or avulsion leads to a progressive loss of axotomized motoneurons (MNs) which sometimes avert warranty for surgical nerve repair. Since the molecular mechanisms involved in this neurodegenerative process are non-apoptotic and unknown, we performed an unbiass and comparative proteomic study coupled to System Biology approach for data using two pre-clinical rat models: a Root Avulsion (RA) model that produces retrograde motoneurodegeneration, and a Distal Axotomy (DA) model that promotes MNs survival and regeneration. We generated topological maps with associated mathematical algorithms for protein interactions that characterized each condition. We wanted to find patentable drug combinations capable to change the degeneration-related map into the regeneration-based one. For that purpose, we used a computational tool called the therapeutic performance mapping system (TPMS) technology which is based on artificial neural intelligence to predict biological responses to different stimuli. We selected drug combinations with the highest scores and validated its neuroprotective potential. The treatment also let to a reduction of gliosis in the ipsilateral side of the spinal cord and promoted the apparition of regenerative markers such as GAP43. In addition, the use of TPMS allowed the prediction of the mechanisms of action (MoA) for each combination. Thus, we validated that the treatment with combination number 3 was capable to regulate key proteins related to MN survival. In conclusion, we verified that the present overall approach is promising as novel methodology to design effective treatments for complex pathological conditions.

Title: VEGF administration maintains normal discharge characteristics on axotomized abducens motoneurons in adult cats

Authors: ***R. M. DE LA CRUZ**, P. M. CALVO, A. M. PASTOR;
Dept. de Fisiología, Univ. de Sevilla, Facultad de Biología, Sevilla, Spain

Abstract: VEGF was discovered by its effects on the vasculature, such as vasculogenesis, angiogenesis and increased capillary permeability. However, recent evidences point to this molecule as an important neurotrophic factor, particularly on motoneurons. For example, transgenic mice with reduced levels of VEGF develop an adult-onset motoneuronal degeneration similar to amyotrophic lateral sclerosis. Moreover, the exogenous administration of VEGF to animal models of this disease leads to beneficial effects. However, information linking this factor to phsysiological or synaptic activity on motoneurons *in vivo* is lacking. Our objective was to evaluate the action of VEGF exogenous administration on lesioned motoneurons in order to determine to what degree firing properties and synaptic inputs could be protected by this factor. First of all, we carried out an immunocytochemical study that determined that all abducens motoneurons are endowed with the two types of receptor of the VEGF: VEGFR1 (or Flt-1) and VEGFR2 (or Flk-1). Secondly, we prepared animals for the chronic recordings of identified abducens motoneurons under alert conditions. In control, these motoneurons show a typical tonic-phasic discharge pattern that correlates with eye position and eye velocity, giving rise to two neuronal sensitivities, eye position sensitivity (k, in spikes/s/degree) and eye velocity sensitivity (r, in spikes/s/degree/s), respectively. Axotomized cells discharged at lower rates both during fixations and saccades, yielding a significant decrease in both parameters. VEGF was administered through a home-made devise that allowed to introduce the distal end of the VI nerve on a camera through which the factor was delivered (0,2 µg/kg on alternated days). Axotomized motoneurons treated with VEGF showed normal firing characteristics during the different types of eye movements and presented normal k and r values. Since the different types of eye movement relies on particular synaptic inputs, the present data are the first to describe that VEGF completely prevents the firing and synaptic alterations on axotomized motoneurons.

Title: Peripheral injury induces Ca^{2+} permeable AMPA receptor-mediated maladaptive spinal plasticity

Authors: ***J. R. HUIE**[1], K. MORIOKA[1], E. STUCK[1], D. FONG[1], L. VAN CITTERS[1], C. GUANDIQUE[1], J. HAEFELI[1], V. DEGOS[2], M. MAZE[2], H. SU[2], A. FERGUSON[1]; [1]Brain and Spinal Injury Ctr., [2]Anesthesiol., UCSF, San Francisco, CA

Abstract: Nociceptive input from peripheral injury can lead to the development of chronic neuropathic pain, impaired cognitive function, and perturbations in locomotor function. The expression of these lasting changes in the central nervous system suggests that peripheral injury broadly impacts CNS plasticity. A large body of work has demonstrated that peripheral nociceptive input can alter dorsal horn neurons through cellular mechanisms that are similar to those underlying hippocampal learning and memory, inducing a form of 'pain memory'. A key mediator of these effects on pain plasticity is the increased expression of calcium-permeable, GluA2-lacking AMPA receptors (CP-AMPARs). It is unknown whether peripheral injury also induces a similar mechanism in ventral motor neurons. In this study we used a tibia fracture model to determine whether spinal motor neurons are susceptible to CP-AMPAR-mediated maladaptive plasticity induced by peripheral musculoskeletal injury. Wild-type C57BL/6J mice received open tibia fracture of the right hind limb under isoflurane anesthesia. Control animals (n=5) received equivalent anesthesia without tibia fracture. Lumbar spinal cord was then extracted either 30 minutes (n=4) or 6 hours (n=6) following tibia fracture. Systematic algorithmic sampling of lumbar motorneurons was performed on histological sections, followed by unbiased automated image analysis of high-resolution 3D confocal images. Quantification of GluA1 and GluA2 AMPA receptor subunit puncta revealed no significant change in tibia fracture animals at 30 minutes post-injury compared to control animals, but did show a significant increase in both synaptic and extrasynaptic GluA1 expression at 6 hours post-injury. There was no significant increase in GluA2 at 6 hours post-injury, suggesting an increase in CP-AMPAR expression. Interestingly, the increase in GluA1 was observed in motor neurons both ipsilateral and contralateral to the injured hindlimb, indicating a broad effect on central spinal cord plasticity. These findings provide evidence for a synaptic mechanism underlying

maladaptive spinal plasticity in motor neurons in response to peripheral bone fracture, and may provide a spinal CNS target for promoting recovery of neural function after such injuries.

Abstract: Facial nerve axotomy (FNA) in immunodeficient mice causes significantly more motoneuron loss than in wild type (WT) mice, indicating that the immune system serves a neuroprotective function. Further studies reveal that CD4+ T cells and interleukin-10 (IL-10) are both critical for motoneuron survival after injury, but the neuroprotective IL-10 does not come from CD4+ T cells. The objective of this study is to investigate both the roles of CD4+ T cells and IL-10 in neuroprotection after FNA. To study the neuroprotective effects of CD4+ T cells, WT, immunodeficient recombinase-activating gene-2 knockout (RAG-2 KO), and CD4+ T cell-reconstituted RAG-2 KO mice received a FNA, and qPCR analysis of the facial motor nucleus was conducted to compare gene expression profiles. Expression of genes associated with axonal regeneration, glial activation, cell death receptor pathways, and inflammation was measured. Across the three experimental groups, there was no significant difference in the axonal regeneration or cell death receptor gene expression profiles after axotomy. However, there was a significant decrease in glial activation in RAG-2 KO mice compared with WT and CD4+ T cell-

reconstituted RAG-2 KO mice. Additionally, tumor necrosis factor-alpha (TNFα) expression was significantly decreased in RAG-2 KO mice compared to WT and reconstituted mice, implying that TNFα may also benefit motoneuron survival. Overall, these data suggest that CD4+ T cells improve motoneuron survival by modulating the glial response to axotomy. Additionally, the expression of TNFα for the first 2 weeks after injury may be critical for attracting and activating the immune response that leads to neuroprotection. Further studies will be done to explore the importance of TNFα in immune-mediated neuroprotection. To determine the cellular source of IL-10, a mouse model that expresses IL-10 protein hybridized to green fluorescent protein (GFP) received a FNA, and fluorescent immunohistochemistry was conducted to determine colocalization of the IL-10/GFP protein with cellular markers for astrocytes and microglia. The results showed that microglia, and not astrocytes, produce IL-10 after FNA. Time-course analysis revealed that IL-10 is expressed constitutively, and production peaks at 10 days post-axotomy. Overall, these data support the hypothesis that CD4+ T cells interact with the glia in the facial motor nucleus to regulate their activation post-axotomy and induce microglia to produce IL-10, generating an anti-inflammatory environment that promotes motoneuron survival.

Title: Adipose-derived stem cell-conditioned medium as a systemic therapy in a mouse model of amyotrophic lateral sclerosis

Authors: ***C. L. WALKER**[1,4], R. M. MEADOWS[1], Y. DU[2], K. MARCH[3,4], K. J. JONES[1,4]; [1]Anat. & Cell Biol., [2]Neurol., [3]Med., Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Res. and Develop., Richard L Roudebush VAMC, Indianapolis, IN

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating progressive disease involving the loss of motor neurons (MN), which ultimately results in paralysis and death. The superoxide dismutase 1 (SOD1) transgenic mouse model of ALS exhibits similar clinical progression of pathology, including pre-symptomatic, symptomatic, and end stages. Disease onset is thought to begin during the pre-symptomatic stage when axons of spinal MNs retract from target musculature through axonal die-back. Prior research indicates denervation of hindlimb muscles occurs by 47 days of age in SOD1-G93A mutant mice, with progressive loss over time. This early pathological period may represent both a key mechanistic stage in disease progression and an optimal window of time to assess potential therapies for efficacy with clear anatomical outcome (denervation) as a measure of treatment effects. Our data show similar gastrocnemius muscle innervation between wild-type and 35 day old SOD1-G93A mice, but significant gastrocnemius muscle denervation in 47 day old SOD1 mice compared to wild-type ($p < 0.05$) and 35 day old SOD1 ($p < 0.05$) mice based on quantification of neurofilament and synaptophysin, a pre-synaptic marker, co-localization with α-bungarotoxin, which labels post-synaptic acetylcholine receptors (AchRs). We have already performed systemic daily therapy with medium conditioned (CM) in culture with adipose-derived stem cells (ASCs) beginning at symptom onset (110 days of age). Our results showed that daily ASC-CM ameliorated characteristic progressive motor neuron loss in the lumbar spinal cord ($p < 0.005$), and prolonged survival ($p < 0.05$) compared to SOD1-G93A mice treated with vehicle medium. Our current pre-symptomatic disease onset data sets the stage for testing whether this systemic ASC-CM therapeutic paradigm can prevent gastrocnemius denervation and promote long-term functional and survival benefits in the SOD1-G93A mouse model of ALS.

Title: Dealing with uncertainty: binary decision making in the cerebellum

Authors: *A. KHILKEVICH, J. E. CANTON-JOSH, M. D. MAUK;
Univ. of Texas At Austin, Austin, TX

Abstract: The world is an uncertain place. Brain systems must operate properly, despite noisy and variable sensory inputs. The cerebellum is known to receive vast sensory and proprioceptive inputs, thus it is critical to know how the cerebellum deals with uncertainty in these inputs. The question is the following: if the cerebellum has learned a response of a certain size to a particular input, how should it respond to an input that is partially similar to the trained input? To answer this question, we used a combination of cerebellar-dependent behavior, full control over inputs to the cerebellum and simultaneous in-vivo tetrode recordings from the cerebellar cortex. Specifically, New Zealand albino rabbits were implanted with two stimulation electrodes in the middle cerebellar peduncle and a 16 tetrode microdrive in the left anterior lobe of the cerebellar cortex. They were trained using a delay eyelid conditioning paradigm using electrical stimulation of mossy fiber inputs (100 Hz, 100 μs pulse width, 500 ms burst width, 100 μA) as the conditioned stimulus (CS). Such design gave us full control over the intensity and temporal characteristics of input to the cerebellum. Animals were trained until they showed robust conditioned responses (CRs) of a target amplitude. After that, we introduced CS-alone probe trials, where input to the cerebellum was systematically altered in three different ways from the original CS. We either decreased the frequency of stimulation, shortened the duration of the stimulus or decreased the current on the electrode used for training while adding competing stimulus through previously unused electrode. Our results show that under all conditions the cerebellum makes a binary choice at the behavioral level: either to make a CR with amplitude and timing appropriate to its previous training, or to not make a response at all. In all three cases, as the stimulus on probe trials became more distinct from the original CS, the probability of observing a CR decreased. However, the size of CR was independent from the CR probability, indicating two separate mechanisms for 1) the decision of whether the cerebellum should make a CR and 2) the size of CR on trials when it is present. Simultaneous recordings from Purkinje cells (PCs), the output neurons of the cerebellar cortex, allowed us to localize such decision to be the result of cerebellar cortex computation. Recordings from other cerebellar cortex neurons suggest that the decision about the presence or absence of CR is made prior to PCs, but PCs amplify this difference to a binary choice. Together, these data demonstrate a novel computational principle that the cerebellum implements when faced with uncertainty in its inputs.

Title: Following learning-related activity in Purkinje cells and interpositus nucleus during the transition from delay to trace eyelid conditioning

Authors: *H. E. HALVERSON[1], A. KHILKEVICH[2], M. D. MAUK[2];
[1]Ctr. for Learning and Memory, Univ. of Texas At Austin, Austin, TX; [2]Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: The cerebellar cortex and anterior interpositus nucleus are necessary for acquisition and expression of properly timed conditioned eyelid responses (CRs). Much of what is known about the cerebellar mechanisms supporting eyelid conditioning has focused on delay conditioning, although the same areas of cerebellum necessary for delay also appear to be engaged during trace conditioning. It is not known whether Purkinje cells and/or interpositus neurons contribute to CR expression during trace conditioning in a similar way as their contributions during delay conditioning. The rules dictating which neurons are contributing during CR expression could be different for each paradigm with respect to population activity or at the single neuron level. Before training a 12 tetrode hyperdrive array was implanted dorsal to the ipsilateral anterior lobe or the anterior interpositus nucleus. Neuronal activity was recorded during initial CR expression with delay conditioning using a 500 ms tone conditioned stimulus (CS) and 50 ms periorbital shock (2-3 mA) unconditioned stimulus (US). After training with delay conditioning, rabbits were switched to trace conditioning with the same 500 ms tone and 500 ms stimulus free trace interval to obtain recordings from the same population of Purkinje cells and interpositus neurons. A few individual neurons in each area were followed throughout the switch from delay to trace conditioning. Eyelid Purkinje cells were identified by the presence of US-evoked complex spikes. Eyelid interpositus neurons were identified by stimulating through tetrodes showing learning-related activity and evoking eyelid movements. Recordings in each area showed that at the population level the same group of neurons are involved with the expression of properly-timed delay and trace CRs. Following individual neurons during the switch from delay to trace conditioning provided compelling evidence that the same neurons in each area were also involved with generating well-timed CRs for both paradigms. The same neurons are engaged during delay and trace conditioning, however learning-related responses in each area of the cerebellum changed slightly to produce appropriately timed CRs during each paradigm, even at the individual neuron level.

Title: Functional characterization of identified mossy fiber synaptic inputs in the input layer of cerebellar cortex

Authors: ***F. LANORE**[1], A. HANTMAN[2], A. SILVER[1];
[1]UCL, LONDON, United Kingdom; [2]Janelia Farm Res. Campus, Howard Hughes Med. Inst., Ashburn, United States, VA

Abstract: The input layer of the cerebellar cortex receives sensory inputs from almost every sensory system, together with information from different cortical areas about motor commands and sensory feedback. Sensory and motor command signals are conveyed by mossy fibers (MFs), which arise from multiple brainstem nuclei and make glutamatergic synapses onto inhibitory Golgi cells (GoCs) and excitatory granule cells (GCs) in the granule cell layer. GoCs provide the sole neuronal source of inhibition to GCs. Although the gross structure of the cerebellum is well characterized, the fine scale connectivity between MFs arising from the different precerebellar nuclei and GoCs and GCs have only partially been studied. Fine scale connectivity is important as it ultimately determines how sensory and motor signals are combined and transformed. To investigate the connectivity and functional properties of MFs arising from specific precerebellar nuclei we expressed channelrhodopsin-2 (ChR2) in spinal trigeminal nuclei (Sp5; which conveys sensory information about the face) or in the pontine nucleus (PGN; which carries motor and sensory signals from the cortex) using an adeno-associated virus (AAV) under a synapsin promotor. We recorded light-evoked excitatory synaptic responses in voltage-clamped GoCs and GCs in acute slices containing Crus I and II regions. In the absence of GABAA and Glycine receptor antagonists, GCs innervated by Sp5 or PGN MF inputs also received a rapid inhibitory synaptic response from GoCs activated by the same MF inputs indicating the presence of input specific feedforward inhibition. The average amplitude of unitary MF-GC EPSCs arising from Sp5 was larger than those from the PGN (Sp5:

81 ± 18 pA and PGN: 34 ± 6 pA; P<0.05, unpaired t-test). Moreover short-term synaptic depression of MF-GC EPSCs was larger for Sp5 MFs than for the PGN MFs at 20 and 50 Hz. In contrast, MF-GoC EPSCs exhibited little short-term depression irrespective of their origin. Our results have begun to reveal the fine scale connectivity rules and functional properties of identified MF inputs, thereby providing a better understanding of how incoming information is combined and transformed in the cerebellum.

Title: Multimodal sensorimotor processing in mammalian cerebellar granule cells

Authors: ***T. K. DOYKOS**, B. D. HOUCK, A. L. PERSON;
Univ. of Colorado Denver, Aurora, CO

Abstract: Theoretical models suggest that cerebellar computations benefit from access to outgoing motor commands, called corollary discharge (CD), to quickly and accurately control coordinated movements. The nucleocortical pathway, which carries collaterals of premotor output neurons to the cerebellar cortex, serves as an experimentally accessible CD pathway, allowing empirical tests of the role of CD in sensory processing. We used both *in vitro* and *in vivo* physiological approaches in mice to test the role of nucleocortical CD information in granule layer processing. In acute cerebellar mouse brain slices, optogenetically evoked nucleocortical EPSCs and IPSCs were recorded in adult granule cells. Surprisingly, we found a complete lack of overlap between cells exhibiting evoked monosynaptic EPSCs (7/13) and polysynaptic IPSCs (6/13), arguing against a simple time-windowing role for feedforward inhibition by cerebellar Golgi cells. To test how the nucleocortical pathway influences sensory processing *in vivo*, we made extracellular, single-unit recordings from granule cells in ketamine/xylazine anesthetized mice while stimulating cutaneous receptors with an air puff (200 ms; ~150 kPa) to the whiskers with and without concurrent optogenetic activation of nucleocortical terminals (~30-70 mW/mm2). We found that granule cell sensory responses were sensitive to coincident optogenetic activation of nucleocortical motor afferents. Individual cells

Title: Granular cells CRFR1 depletion expedites cerebellar associative learning

Authors: ***G. EZRA-NEVO**[1,2], H.-J. BOELE[3], M. TSOORY[1], A. CHEN[1,2];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Max Planck Inst. of Psychiatry, Munich, Germany;
[3]Erasmus Univ., Rotterdam, Netherlands

Abstract: Corticotropin-releasing factor (CRF), and its cognate receptor, CRF receptor type 1 (CRFR1) play an important and well-established role in the response to stressful challenges. The expression of CRF and CRFR1 in the cerebellar system, including in the granular cell (GrC) layer and in mossy fibers innervating it, have been reported in many species. However, the emotional and cognitive role of the cerebellar CRF system remains elusive. In order to explore the behavioral role of CRFR1 expression in GrCs, we have established a new genetic mouse model specifically depleted of CRFR1 in these cells (GrCs-CRFR1KO), which accounts for more than 90 percent of CRFR1 expressed in the cerebellum. GrCs-CRFR1KO did not show altered baseline motor behavior when compared to control littermate. However, when tested in specific cerebellar dependent classical conditioning, namely delay eye-blink conditioning (EBC), GrCs-CRFR1KO mice presented accelerated learning compared to control mice. This phenotype was dissociated from anxiety related behaviors. GrCs-CRFR1 depletion was correlated with changes in several genes expression, including genes related to intra-cellular calcium homeostasis. We conclude that GrCs CRFR1 plays a role in cerebellar-specific learning, and may be linked to intra-cellular calcium dependent mechanisms. Our findings shed light on the interplay between stress related central components and classical conditioning.

Title: Synaptic interactions between interneurons and Purkinje cells in cerebellar cortex *in vivo*

Authors: ***C. ARLT**, C. D. WILMS, M. HAUSSER;
Wolfson Inst. For Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Molecular layer interneurons (INs) make monosynaptic GABAergic synapses with postsynaptic Purkinje cells in the molecular layer of the cerebellar cortex. *In vitro* experiments have shown that interneurons are excited directly by parallel fiber input, and indirectly by glutamate spillover from climbing fibers, and that they in turn can inhibit the spike output of Purkinje cells. How single INs are excited and interact with Purkinje cells under *in vivo* conditions remains poorly understood. Here we addressed these issues using simultaneous cell-attached recordings from IN-PC pairs guided by two-photon imaging in head-fixed mice under isoflurane anaesthesia. We recorded both spontaneous as well as sensory-evoked spiking activity, using an airpuff to the ipsilateral perioral region. Crosscorrelograms of spontaneous IN spikes and PC simple spikes showed a spike-triggered decrease in PC spiking, time-locked to the IN spikes (n=12 out of 56 pairs, mean reduction to 70% of baseline rate). Triggering single IN spikes with direct stimulation of the interneuron resulted in a similar decrease of PC firing (n=6), demonstrating that single INs can efficiently inhibit their targets. Crosscorrelograms of PC complex spikes and IN spikes revealed an increase of IN activity triggered on complex spikes (n = 26 out of 56 pairs, mean increase of 65% above baseline rate), indicative of glutamate-spillover-mediated IN depolarization. Analysis of complex spike waveforms showed that the increase in IN rate scales with complex spike duration and spikelet number. Sensory stimulation could trigger fast excitatory responses in both INs and PCs (n=11 out of 14 pairs) and could synchronize IN-PC pairs. In some cases, PCs responded mainly with inhibition to the sensory stimulus (n=3 out of 11). A trial-by-trial analysis revealed that trials in which the IN responded to the stimulus had a higher baseline IN firing rate, and that sensory-evoked IN spikes could strongly reduce the fast excitatory response in PCs, effectively gating the excitatory PC response to sensory stimulation. These results demonstrate that INs are activated by both parallel fiber and climbing fiber activity *in vivo* in a graded manner and that they exert powerful influence on PC output both during spontaneous activity and during sensory processing. Our findings put the INs

Deleted: *in vivo*

Deleted: *In vitro*

Deleted: *in vivo*

Deleted: *in vivo*

in a position to efficiently modify PC output during climbing fiber-induced plasticity and thereby are consistent with predictions from adaptive filter models of cerebellar function.

Title: Responses of Purkinje cells in Crus I/II to repetitive whisker pad stimulation in anesthetized mice

Authors: ***S. BROWN**, I. M. RAMAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The rodent whisker system is extensively represented in the cerebellar cortex in lobules Crus I/II and provides a context for studying sensory information processing by the cerebellum. To study how input to the whisker pad is represented in Purkinje neurons of Crus I/II, we have made *in vivo* somatic and dendritic whole-cell recordings from Purkinje cells in ketamine/xylazine anesthetized mice and measured responses to air puff stimulation (25 ms, 10 PSI) of the ipsilateral whisker pad. Purkinje cell recordings were confirmed by the presence of both simple and complex spikes. Consistent with previous reports, Purkinje cells in this region show robust responses to passive stimulation of the whisker pad. We found that, in response to a single air puff stimulation, a subpopulation of Purkinje cells produced a well-timed inhibitory postsynaptic potential (IPSP) (~30 ms latency relative to the onset of stimulation, 20-30 ms duration) followed by a barrage of excitatory postsynaptic potentials (EPSPs), which could be resolved in records in which Purkinje cells spontaneously hyperpolarized. As a result of the short latency IPSP and longer-lasting EPSPs, Purkinje cell spiking was reorganized such that a typical response consisted of a pause in simple spiking followed by a well-timed resumption of firing. In cells with lower baseline rates, the post-inhibitory simple spikes tended to include a cluster of action potentials that exceeded the baseline rate; the relative increase post-inhibitory in firing rate was greater in cells with lower baseline rates. To start to investigate how Purkinje cells in Crus I/II transmit more complex patterns of stimuli, we recorded responses to trains of five consecutive air puffs at stimulus frequencies of 1, 2, 4, and 8 Hz. At lower stimulation

Deleted: in vivo

frequencies, the IPSP response characteristics were constant for each stimulus in the train. At higher stimulation frequencies, the IPSP response became smaller in amplitude and less reliable with successive stimuli. The decrement of the IPSP at higher stimulation frequencies resulted in a decrease in the reliability of the pause in simple spiking associated with the stimulus. Thus, over this frequency range, Purkinje cells showed adaptation to this type of somatosensory stimulation. These data provide evidence for a major role of inhibition in setting the strength and pattern of Purkinje cell responses to repetitive whisker pad stimulation.

Title: Inhibition of Purkinje cell firing induces motor learning

Authors: *H. L. PAYNE[1], B. NGUYEN-VU[2], J. L. RAYMOND[2];
[2]Neurobio., [1]Stanford Univ., Stanford, CA

Abstract: Recent evidence suggests that the simple spike output from cerebellar Purkinje cells (PCs) can instruct motor learning (Lee et al., 2015; Nguyen-Vu et al., 2013). Here, we analyzed the role of decreases in Purkinje cell firing in the induction of vestibulo-ocular reflex (VOR) learning. We optogenetically controlled PC firing using transgenic mice expressing ArchT under control of the PC-specific L7 promotor. Inhibition of PCs in the cerebellar flocculus with 532 nm light elicited robust eye movements. To assess whether pauses in PC output are sufficient to induce motor learning, L7-Arch mice underwent 30 min of training consisting of a vestibular stimulus (rotation about an earth-vertical axis at 1 Hz, with 10°/s peak velocity) paired with optogenetic inhibition of PCs in the flocculus (500 ms light pulses). Light was delivered either during head turns towards the side of stimulation ("ipsiversive PC suppression"), or away from the side of stimulation ("contraversive PC suppression"). Before and after training, the VOR was tested by measuring the eye movements elicited by the vestibular stimulus in the absence of the

optogenetic stimulus. Compared to a habituation control with only the vestibular stimulus delivered during training, ipsiversive PC suppression induced a significant increase in the gain of the VOR, measured in the absence of optogenetic stimuli. In contrast, contraversive PC suppression induced no change in the VOR relative to control. Taken together with previous findings, this indicates that activation or suppression of floccular PCs are both sufficient to induce learned increases in VOR gain, and that such learning depends on the specific timing of PC modulation relative to the sensory input. We assessed the site of plasticity underlying PC-induced learning. Before and after training, Purkinje cells in the flocculus of L7-Arch mice were bilaterally inactivated for 60 s while a vestibular stimulus was delivered to test the flocculus-independent component of the VOR. Preliminary results indicate that the learning induced by ipsiversive PC suppression is mediated, at least in part, by plasticity in the flocculus-independent VOR pathway. In contrast, the flocculus-independent component of the VOR was relatively unchanged after training with contraversive PC suppression. Therefore, pauses in PC simple spikes can induce learning via plasticity downstream of the cerebellar cortex.

Title: Skilled voluntary motions activate a cerebellar state of intrinsically synchronized neural dynamics

Authors: *M. J. WAGNER[1], J. SAVALL[1], J. LI[1], M. J. SCHNITZER[1,2];
[1]Stanford Univ., Stanford, CA; [2]HHMI, Stanford, CA

Abstract: It has long been hypothesized that to coordinate voluntary movements the cerebellum enters a physiologic state of internally synchronized neural dynamics. This predicts cooperative neural activity anticipating movement initiation, greater neural synchronization promoting superior motor performance, and encoding of motor information by concerted neural activity that cannot be fully deciphered using single cell recordings. We tested these predictions by two-photon calcium imaging of cerebellar Purkinje neurons' complex spiking patterns in mice making targeted forelimb reaches on a robotic manipulandum. Our custom-designed robot can

record and manipulate arm movements in real-time. In the basic task version, mice moved the robotic arm to a target region to receive a water reward. In more advanced versions, to permit studies of unexpected self-motion we used real-time control of the robot to physically perturb the arm-reaching trajectory. Mice made hundreds of reaches per behavioral session. From the two-photon imaging data we determined the timing of individual complex spikes to an accuracy of 6-11 ms (s.d.); this accuracy was essential for evaluating whether the cells were using concerted codes. Reaching evoked large-scale synchrony near movement initiation followed by coordinated neural silence peaking after initiation. By using shuffled datasets, our analyses showed that task- or sensory-driven modulations of complex spiking do not account for the synchrony increases. This insufficiency points to internal synchronization as being necessary to account for the concerted dynamics. Testifying to the importance of internal synchrony for movement quality, the greater the neural synchrony at reaching onset, the straighter and less variable was the ensuring arm motion. When the robot unexpectedly perturbed reaching mid-trajectory, concerted spiking conveyed information about the perturbation direction that was absent from single cell spiking patterns. Thus, the cerebellum coordinates skilled motions in a large-scale, internally synchronized state. Other motor circuits might also employ intrinsic synchrony and silence to choreograph movement.

Title: Encoding of action by the Purkinje cells of the cerebellum

Authors: ***D. J. HERZFELD**[1], Y. KOJIMA[2], R. SOETEDJO[2], R. SHADMEHR[1];
[1]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Physiol. and Biophysics, Washington Natl. Primate Ctr., Seattle, WA

Abstract: Execution of accurate eye movements depends critically on the cerebellum, as evidenced by inactivation and lesion studies, suggesting that Purkinje cells (P-cells), may predict the state of the eye. Yet, this encoding has remained a long-standing puzzle: firing of P-cells show little consistent modulation with respect to saccade speed or direction, and critically, lasts significantly longer than duration of a saccade. Given that the cerebellum is thought to play a critical role in terminating saccades, how can P-cells be involved in predicting or controlling the eye if their response persists so much longer than the saccade? We analyzed simple spike activity of 72 oculomotor vermis (OMV, cerebellar lobules VI and VII) P-cells from five monkeys during saccadic eye movements. Our population included cells that during the saccade period exhibited either increased activity (bursting; n=39), or decreased activity (pausing; n=33). These cells project to the caudal fastigial nucleus (cFN), where about 50 P-cells converge onto a single cFN neuron. We computed the population response by choosing 50 P-cells randomly (both bursting and pausing cells) and then computed the change in firing rate of the population. When we averaged across all saccade directions, the time course of the population activity predicted the time course of saccade speed in real-time; an encoding that was not present in either population alone. A population response makes the fundamental assumption that a random selection of the recorded neurons converges onto a single output neuron. However, in the cerebellum the P-cells that project onto a single cFN neuron are not selected randomly, but are likely organized by their inputs from the inferior olive. In this scenario, the olive projections divide the P-cells into modules where projects onto one cFN neuron. We found that if we organized the simple spikes of the P-cells based on each P-cell's complex spike (CS) properties, additional features of the population response were revealed. When we aligned the simple spike activity of each P-cell to a coordinate system that depended on that cell's CS tuning, the result unmasked a pattern of inhibition at cFN that encoded saccade speed and direction via a multiplicative gain-field. Therefore, our results suggested three new ideas: reliable encoding of saccade metrics does not occur in the firing of individual P-cells, but via synchronized inputs of bursting and pausing cells onto cFN; in this encoding, speed and direction are multiplicatively represented via a gain-field; and the anatomical projections of P-cells to cFN neurons are not random, but organized by the CS tuning of the P-cells.

Title: Application of antagonist drugs of inhibitory receptors in the macaque ventral paraflocculus changes the response of Purkinje cells during oculomotor behaviors

Authors: *P. M. BLAZQUEZ, T. A. YAKUSHEVA;
Otolaryngology, Washington Univ., Saint Louis, MO

Abstract: Inhibition is ubiquitous in the cerebellar cortex. In the granular layer, Golgi cells release GABA and glycine to inhibit information transfer from mossy fibers (mf) to granule cells at the glomerulus. In the molecular layer, GABA released by stellate and basket cells act over Purkinje cells (PCs), which are themselves GABAergic interneurons that contact nearby PCs. Our current understanding of the role of inhibition in cerebellar cortex function has come mainly from studies carried out in in-vitro and anesthetized preparations. These studies have greatly advanced our understanding of cerebellar signal processing, but they face the challenging task of extrapolating their result to the awake animal. Here we examined the role of inhibition in cerebellar ventral paraflocculus (VPFL) function in awake macaques while they perform oculomotor tasks known to engage the VPFL. We used custom made carbon fiber multibarrel electrodes to examine the effect of injecting drugs that interrupt specific information pathways on the response of PCs. Our experimental approach has the advantage of examining cerebellar processing while the animal performs behavioral relevant computations. Our drug application affected a small portion of the VPFL (less than 1%), thus it has no effect on pursuit or saccade behavior. Moreover, we recorded the response of eye movement related mf with and without drug application and further verified that the efferent copy pathway is not affected by drug application. We found that injection of GABA-A receptor antagonist gabazine increased the gain of PCs to pursuit and VOR cancellation and made PCs responsive to saccades eye movements regardless of saccade direction. Injection of glycine blocker strychnine produced similar increases in gain than gabazine application, but had a lesser effect in PC saccade related responses. In contrast, injection of GABA-B receptor antagonist phaclofen reduced the response gain of PCs to pursuit. Overall, our result suggests that control of inhibition is a powerful mechanism to regulate the input-output gain of cerebellar cortex and spatial response properties of PCs. We hypothesize that the observed PC response gain changes during pursuit and VOR cancellation with application of gabazine and glycine are the result of modulating inhibition at the mf to granule cell synapses. In agreement, it has been shown that increasing inhibition reduces the gain of granule cells to mf stimulation. We also hypothesize that the effect over saccades responses is due to a different mechanism, perhaps involving molecular layer inhibition.

Title: Temporal integration in an interneuron circuit model

Authors: ***R. MAEX**[1], B. GUTKIN[1,2];
[1]Ecole Normale Superieure, Paris, France; [2]Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Inhibitory interneurons are integral parts of all brain circuits, and are commonly assumed to provide brisk control of spike timing, synchronization, circuit oscillations, etc. Theoretical studies have shown, however, that inhibitory circuits may also act as temporal integrators through a slow process of progressive disinhibition (Cannon, Robinson and Shamma, Biol. Cybern., 1983). We simulated a circuit of molecular layer interneurons, comprising a volume of about 100 (parallel-fibre axis) x 700 (sagittal) x 300 (depth) micrometers of cerebellar cortex. Each interneuron was implemented as a 22-compartment unit (an active soma and three passive dendrites, following Abrahamsson et al., Neuron, 2012). A population of 400 to 800 interneurons were interconnected through chemical (GABAA receptor) and electrical synapses, and activated by a pool of more than 10,000 parallel fibers firing Poisson spike trains. A narrow beam of parallel fibres conveyed the time-modulated, rectangular or sinewave stimulus. In the complete absence of inhibition, all interneurons spiked very fast with little variation across the network (mean ± s.d. 102 ± 10.4 spikes per second, CV 0.1), and they modulated their spike rates in-phase with the parallel-fibre stimulus. When the inhibition was strengthened, however, the overall spike rate decreased and could vary markedly across the network (13.5 ± 17.8, CV 1.3). Moreover, the most responsive interneurons spiked with a considerable phase lag of about 45 degrees at 0.2-0.5 Hz stimulation, corresponding to an integration time-constant of about 4 seconds. Three factors were able to enhance this integration time-constant: the strength of inhibition, the strength of electrical coupling, and the interneuron density. Electrical coupling depressed the overall spike rate, by spreading inhibition, but enhanced the response amplitude. In conclusion, the present simulation results indicate that networks of interneurons may act as low-pass filters, and they suggest that interneurons may be a component of the neural integrator thought to be distributed across the cerebellar - brainstem circuit.

Title: Encoding of virtual reality locomotion kinematics in vermis lobules V and VI of the mouse cerebellum

Authors: ***S. MITOLO**, T. MUZZU, S. R. SCHULTZ;
Imperial Col. London, London, United Kingdom

Abstract: The cerebellum has a well-established role in motor planning, execution and control. Recent imaging studies have shown that populations of cerebellar neurons are topically activated during locomotion (Ozden et al, PLoS ONE 7(8): e42650, 2012) and that optogenetic stimulation of Purkinje cells can affect the coordination of limb and trunk movements (Hoogland et al, Current Biology 25(9):1157-65, 2015). However to date it is still not well understood how the cerebellar network achieves movement control. We therefore aimed to characterize the activity of cerebellar neurons using high-density silicon electrode arrays in awake mice engaged in a locomotion task. We recorded from lobule V and VI of the cerebellar vermis of mice navigating in a virtual reality environment and we isolated more than 500 units. The cells were classified according to their electrophysiological properties (Hensbroek et al, J Neurosci Meth 232:173-80, 2014): the majority of the cells were identified as Purkinje cells, ~20% as Basket or Stellate cells and ~12% as granule cells. We then characterized the spiking activity of the cells in response to movement and found three main response profiles: speed-sensitive neurons, yaw-sensitive neurons and step cells. Speed-sensitive neurons could be further divided in positively tuned, negatively tuned and preferred speed neurons. Yaw-sensitive neurons modulated (50-200%) their activity with respect to the clockwise or anticlockwise direction. Step cells displayed a bursting activity synchronized with quick acceleration events caused by the animal stride. By recording simultaneously a large population of cerebellar neurons in a behaving animal we were able to encode locomotion-related parameters of cerebellar neurons. Further characterization of the

cerebellar network with our approach will increase our understanding on how movement control is achieved through the cerebellum.

Title: Response of the cerebellar nodulus and uvula Purkinje cells to vestibular stimulation in wild-type and LTD-deficient mice

Authors: ***T. A. YAKUSHEVA**[1], R. G. HERNANDEZ[2], C. I. DE ZEEUW[3], P. M. BLAZQUEZ[1];
[1]Dept of Otolaryngology, Washington Univ. in St.Louis, Sch. of Medi, Saint Louis, MO; [2]Dept. de Fisiología, Facultad de Biología, Univ. de Sevilla, Sevilla, Spain; [3]Dept. of Neurosci., Erasmus Univ. Med. Ctr., Rotterdam, Netherlands

Abstract: One of the most remarkable advances towards understanding cerebellar cortex computations in recent years has come from studies on the role of the cerebellar Nodulus and Uvula (NU, lobules IX and X) in spatial navigation in macaque monkeys. Macaque data suggest that NU are part of a neuronal circuit that transforms vestibular information, provided by our vestibular organs (semicircular canals and otolith organs), into heading direction (translation) and orientation with respect to gravity (tilt) using clearly defined mathematical operations. Most remarkably, genetically modified mice that lack postsynaptic LTD at parallel fiber to Purkinje cell synapses (L7-PKCI) have problems with spatial navigation when relying exclusively on internal cues (e.g. vestibular information). This finding strongly suggests that plasticity at parallel fiber to PC synapses enables the structure to optimize computations and generate predictions of self motion necessary for path-integration. In this study we characterize the

response of NU Purkinje cells in wild-type alert mice using similar vestibular stimulation protocols to those we have previously employed in the macaque monkey. We tested the hypothesis that cerebellar LTD is necessary to enable the NU circuit to perform reliable estimations of heading direction (translation) and head orientation (tilt). Specifically, we characterized the response of NU Purkinje cells in the L7-PKCI transgenic mouse that expresses a protein kinase C (PKC) inhibitor in Purkinje cells, thus preventing normal PKC activity and LTD at parallel fiber to Purkinje cell synapses. We found that similar to macaques, NU Purkinje cells of wild-type alert mice carry the internal estimate of tilt and translation by combining transformed semicircular canal and otolith information. However, we found that mice and macaque NU Purkinje cells show differences in their dynamic response properties. Finally, our results suggest that plasticity at parallel fiber to PC synapses is essential to allow the temporal and spatial match of semicircular canal and otolith related information in NU. We conclude that some computational steps required estimating of tilt and translation occurred at parallel fiber to Purkinje cell and shaped by cerebellar plasticity.

Title: Selective encoding of unexpected head tilt by the deep cerebellar nuclei

Authors: ***J. CARRIOT**[1], M. JAMALI[2], J. X. BROOKS[1], K. E. CULLEN[1];
[1]Physiol., [2]McGill Univ., Montreal, QC, Canada

Abstract: The ability to distinguish sensory inputs that are a consequence of our own actions from those that result from changes in the external world is essential for perceptual stability and accurate motor control. We have previously shown that vestibular output neurons of the cerebellum, contributing to vestibulo-spinal reflexes and motion perception, robustly encode passively applied head rotation in the horizontal plane, while their responses are attenuated during comparable self-generated head motion. However, natural head movements are not restricted to one plane and generate more complex vestibular stimuli because of the presence of

the gravity. Therefore, we hypothesized that the brain uses an internal model that includes gravity to distinguish between self- versus externally- generated head motion. Interestingly, the ability to control posture and estimate unexpected self-motion depends strongly on the integration of vestibular, proprioceptive, and motor-related signals in cerebellum and is significantly disrupted in cerebellar patients. Thus, we tested our proposal by recording from single neurons from the rostral fastigial nuclei of the cerebellum in alert macaques during passive and active i) head-on-body tilts, as well as ii) head-on-body translations. We found that responses related to actively-generated tilts were significantly attenuated (relative to passively applied tilts). Moreover, this attenuation was comparable to that observed for active versus passive head translations (67 vs 74%, $p>0.05$). Taken together, our findings show that the neuronal coding of natural self-motion comprises an elegant computation of an internal model of active head motion that accounts for gravity.

Title: Most caudal fastigial neurons of the monkey respond to saccades as well as smooth-pursuit eye movements

Authors: *Z.-P. SUN[1,2,3], P. W. DICKE[4], P. THIER[4];
[1]Hertie Inst. for Clin. Brain Research, Univ. of Tübingen, Tuebingen, Germany; [2]Grad. Sch. of Neural and Behavioural Sci., [3]Intl. Max Planck Res. Sch. for Cognitive and Systems Neuroscienc, Univ. of Tübingen, Tuebingen, Germany; [4]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tuebingen, Germany

Abstract: Saccades and smooth pursuit eye movements (SPEM) are two forms of goal directed eye movements with different kinematics, a difference that has contributed to the notion of largely segregated neuronal circuits for saccades and SPEM. Also previous work on the oculomotor role of the cerebellum seemed to suggest that distinct modules might be dedicated to the two types of goal directed movements, namely the flocculus/parafloccullus to SPEM and the oculomotor vermis (OMV) to saccades. However, first evidence requiring a modification of this

view became available already in the 80's, when Suzuki and Keller (Suzuki & Keller, J Neurophysiol , 1988) described Purkinje cells (PC) in the OMV responsive to both saccades and smooth-pursuit, a characteristic that meanwhile turned out to be the rule rather than the exception (Smilgin, Dicke, & Thier, SFN abstract, 2012). The caudal fastigial nucleus (cFN) is a major target of PC axons originating from the OMV, serving as gateway for the oculomotor centers of the brainstem. Not surprisingly in view of the dependence of the cFN on the OMV, previous work has described both saccade- and SPEM-related single units in this nucleus, yet, without addressing the question if the two pools overlap. In other words, does the cFN continue the joint representation of SPEM and saccade-related signals found in the OMV or does it function as a track switch serving two independent pathways for SPEM and saccades starting here? To solve this question, we recorded 74 saccade-related neurons from the cFN. Of these, 28 were tested also for SPEM and, actually, 21 of them exhibited also clear SPEM-related activity. To estimate the sensitivities of these neurons for the major kinematic variables characterizing eye movements, we fitted their discharge with a linear combination of eye acceleration, velocity and position, independently for saccades and for SPEM. We found that the relative weights of the three variables were clearly different for saccades and SPEM. Saccade-related discharges were largely dominated by the position term without any difference between the subgroups of units tested for saccades only or for saccades as well as SPEM. On the other hand, SPEM-related responses were much more dependent on eye velocity. Sensitivity profiles for eye movement kinematics that are dependent on the type of eye movement executed with very similar properties as the one found in the cFN are also characteristic of OMV PCs. Hence, the cFN maintains a high degree of functional continuity with the OMV, offering saccade as well as SPEM-related signals to brainstem nuclei, hitherto usually assumed to be specific for saccades.

Title: Cerebellar nuclear neurons use time and rate coding to transmit Purkinje neuron pauses

Authors: ***S. SUDHAKAR**[1,2], B. TORBEN-NIELSEN[1], E. DE SCHUTTER[1,2];
[1]OIST, Okinawa, Japan; [2]Univ. of Antwerp, Wilrijk, Belgium

Abstract: Neurons of the cerebellar nuclei convey the final output of the cerebellum to their targets in various parts of the brain. Within the cerebellum their direct upstream connections originate from Purkinje neurons. Purkinje neurons (PNs) of the cerebellar cortex have two distinct firing signatures: simple and complex spikes. The simple spikes are due to the intrinsic mechanisms of the cell and synaptic inputs coming through the parallel fibers and molecular layer interneurons (Gundappa-sulur, Schutter, & Bower, 1999; Palay & Chan-Palay, 1974; Raman & Bean, 1999). The PNs also emit complex spikes, which are due to strong excitation coming from the axons of the inferior olive cells, the climbing fibers (Palay & Chan-Palay, 1974). The simple spikes are highly regular intertwined with short pauses (Shin & De Schutter, 2006) while complex spikes occur sporadically and consist of burst of spikelets (Eccles, Llinas, & Sasaki, 1966). How can the cerebellar nuclei neurons downstream of the PNs make sense of this complex firing pattern? In this study we analyze how PN synchrony in the context of "pauses" in simple spikes affects different coding mechanisms of the neurons of the cerebellar nuclei. To this end, we use a computational model of a cerebellar nuclear neuron (Steuber, Schultheiss, Silver, De Schutter, & Jaeger, 2011) and synthetic PN spike trains. The coding mechanisms of cerebellar nuclear neuron can be broadly categorized as rate (Armstrong & Rawson, 1979; McDevitt, Ebner, & Bloedel, 1987) and time coding (Person & Raman, 2012). We define PN synchrony as synchronized Purkinje neuron pauses with either pause beginning or pause ending spikes precisely synchronized (Shin & De Schutter, 2006). With varying amount of pause synchrony for the above mentioned synchrony types, we analyzed its effects on time locking and rate coding in a nuclear cell. We find that Purkinje neuron synchrony is mainly represented as changes in the firing rate of cerebellar nuclei neurons. Pause ending type synchrony causes increased firing modulation. Pause beginning spikes produce better time locking of nuclear neurons compared to their pause ending counterparts for shorter length pauses but not for longer length pauses. We characterize the dependency of pause length and spike jitter on the coding strategy of the nuclear neuron. Additionally, we find that the rate of rebound responses in nuclear neurons after a synchronized pause is controlled by the firing rate of Purkinje neurons preceding it. We argue that these results lead to better understanding of how PN pause synchrony is processed in its target nuclear neuron.

Title: A functional monosynaptic connection from the cerebellum to the ventral tegmental area

Authors: *C. H. CHEN[1], S. DORIZON[2], I. CARTA[2], K. KHODAKHAH[2];
[2]Dominick P. Purpura Dept. of Neurosci., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: The cerebellum is known for its coordination of movement, though it has also been implicated in non-motor behaviors. Converging evidence from neuroimaging and neuroanatomical studies suggest that the cerebellum contributes to a wide range of cognitive tasks, and dysfunction of the cerebellum may lead to cognitive disorders. Anatomical tracing studies suggest that the cerebellum has some inputs to the ventral tegmental area (VTA), a region where many dopaminergic pathways originate. Several of these pathways innervate areas that are known to be involved in cognitive processing, such as reward, and motivation. Therefore, we examined the connection between the cerebellum and the VTA. To test the functionality of this connection, we used optogenetics in mice to selectively excite cerebellar axons in the VTA while we monitored the activity of VTA neurons with extracellular recordings. Preliminary data show that the optical activation of cerebellar fibers *in vivo* increased the firing rate of neurons in VTA with a short latency of approximately a few milliseconds. To further investigate the nature of this connection, we optically stimulated cerebellar axons terminating in VTA in acutely prepared slices and found that it also resulted in short latency EPSCs in voltage-clamped VTA neurons. The sub-millisecond delay and the reversible blockade of these light-evoked currents by AMPA and kainate receptor antagonist CNQX *in vitro* suggest the existence of a monosynaptic excitatory pathway. Our data support the hypothesis that the cerebellum modifies the activity of the VTA and suggests that the cerebellum may play a role in modulation of the reward pathway. The behavioral consequences of manipulating this pathway are presented in another poster.

Title: Synchrony is key. Olivocerebellar control of deep cerebellar nuclear (DCN) activity

Authors: ***T. TANG**[1], C. Y. SUH[1], T. A. BLENKINSOP[2], E. J. LANG[1];
[1]Neurosci. & Physiol., New York University, Sch. of Med., New York, NY; [2]Mount Sinai, Sch. of Med., New York, NY

Abstract: Determining how DCN activity is modulated is central to understanding the signals the cerebellum sends to the rest of the CNS. Yet, the synaptic control of DCN activity is not well understood. For example, the large majority of synapses onto DCN cells are from Purkinje cells (PCs), yet, at least on a population level, simple spike and DCN firing rates are often found to co-modulate, suggesting that simple spikes have a relatively weak effect. Here, we explored the effect of complex spikes (CS) on DCN activity as an alternate control mechanism. CSs were recorded from PC arrays along with a single DCN neuron. CS-triggered correlograms of DCN activity were used to identify synaptically-connected PC-DCN cell pairs that formed narrow groups of 4-7 PCs. These correlograms showed that CS activity predominantly has an inhibitory effect on DCN activity. We tested whether the strength of the inhibitory effect of a CS varied as a function of its being synchronized with other cells in its group. The inhibitory effect was found to increase with the number of PCs in the group having synchronous CSs, such that isolated CSs produced little to no change in DCN activity, whereas highly synchronous CSs could cause a 60-80% drop. However, analysis of single trials showed the inhibitory effect was quite variable, even for the same synchrony level. A possible source of this variability is the variability of the CS waveform, as that may affect the number of axonically-propagated action potentials in a CS. We used signal variance to measure CS waveform, as this variance correlates with the number of spikelets in a CS; however, when synchrony is held constant, no consistent relationship between signal variance and the strength of the inhibitory action has been found thus far. Therefore, changes in waveform do not seem to alter the CS's action on the DCN significantly, and therefore could be modulated for other purposes, such as gating cortical plasticity, while changes in synchrony could be used to help shape DCN activity directly. Thus, by having distinct targets for their action, CS waveform and synchrony level, may allow the olivocerebellar system to perform its proposed roles in motor control and learning independently of each other.

Title: Cellular classification of fastigial/medial cerebellar nucleus output circuits

Authors: *H. FUJITA, T. KODAMA, S. DU LAC;
Johns Hopkins Univ., Baltimore, MD

Abstract: The midline cerebellum is involved in a wide range of functions including body posture, paced gait, eye movements, physiological homeostasis, attention, cognition, and emotion. The medial cerebellar (fastigial) nucleus (MCN), the sole output from the medial cerebellum, is responsible for this functional diversity, and is divided into rostral and caudal parts, which give rise descending and ascending projection, respectively. However, the critical diversity at a cellular level within the MCN is unclear. To molecularly classify individual MCN neurons and identify individual circuits, we quantitatively profiled expression of genes related to neurotransmitters, ion channels, and marker gene candidates for individual mouse MCN neurons. As a result of cluster analysis, sampled MCN neurons were functionally dichotomized by major quantitative differences in genes for ion channels as Kv3, which enables fast spiking. Further distinction of each group by qualitative or minor quantitative differences in other gene expression finally classified excitatory MCN neurons into four distinct groups. This classification was supported by distinct morphology of their neurons visualized with immunostaining for marker candidate proteins as Fzd7 and Spp1. Moreover, neurons in each group was localized to either rostral or caudal part of the MCN. For the ascending projection from the caudal MCN, retrograde tracing from VM thalamus or superior colliculus labeled distinct subset of MCN neurons, whose features were similar to those indicated in our molecular classification. Distinct projection targets for molecularly distinct neurons were so far also confirmed in the descending projection from the rostral MCN. With these results, we are investigating framework for each MCN function.

Title: Lobule-specific contribution of cerebellum to executive functions in mice

Authors: *A. M. BADURA[1,2], J. W. METZGER[1], B. DEVERETT[1], S. KOAY[1], J. L. VERPEUT[1], D. W. TANK[1], S. S.-H. WANG[1];
[1]Princeton Neurosci. Inst. and Dept. of Mol. Biol., Princeton Univ., Princeton, NJ; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Cerebellar lobules VI/VII and crus I/II form reciprocal loops with neocortical regions associated with executive functions (Wang, Kloth, & Badura 2014, Neuron 83:518–532), but the functional significance of those connections is not well explored. We hypothesized that the disruption of these cerebellar regions would lead to disruption in one or more executive domains: (1) social choice and behavioral inhibition, as measured using a 3-chamber test and an elevated plus maze; (2) cognitive flexibility as measured by the ability to change the preferred arm in a Y-maze swim task; and (3) working memory, as measured using a novel head-fixed visual evidence-integration task. Our results are consistent with specific roles for lobule VI in cognitive flexibility, and a role for crus II in behavioral inhibition. To achieve cell-type-specific inactivation of defined cerebellar regions, we took a pharmacogenetic approach using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs). We used AAV8-hSyn-hM4D(Gi)-mCherry to express the inhibitory DREADD hM4D in molecular layer interneurons (MLIs). Inactivation of MLIs removes a major source of modulation of firing of Purkinje cells, which are inhibitory, putatively leading to net disinhibition of thalamus and neocortex. Mice were injected with the virus at 6 weeks of age and behavioral experiments followed 2 weeks later. Prior to each behavioral session mice were intraperitoneally injected with Clozapine-N-oxide (CNO), a DREADD agonist. In mice with DREADD expression in lobule VI, inactivation by CNO led to increased perseveration. Mice could learn to find an hidden platform in a swimming Y-maze, but showed impaired switching when the platform was moved to the other arm of the maze. The mice also showed prolonged individual bouts of grooming. In contrast, in a 3-chamber social choice between a novel mouse and a novel object, preferences were unchanged. We observed converse results in mice with DREADD expression in crus II, which is reciprocally connected with medial prefrontal cortex. CNO did not impair Y-maze reversal, but

did lead to increases in mouse-vs-object preference in the 3-chamber test, as well as increases in open-arm entries in an elevated-plus maze. These findings indicate a specific loss in behavioral inhibition. To probe executive function with greater temporal resolution, we are now testing mice using a head-fixed version of a working memory task (see abstract by Koay, Deverett et al., this meeting). In preliminary results, lobule VI-inactivated mice show reduced correct-performance trials and increased bias during evidence integration.

Title: Cerebellar projections to VTA: a potential role for cerebellum in reward and social behavior

Authors: *I. CARTA[1], C. H. CHEN[2], S. DORIZAN[2], K. KHODAKHAH[2];
[2]Dominick P. Purpura Dept. of Neurosci., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: Cerebellum is an important structure for movement. However, some of its projections terminate in brain areas that are not exclusively related to movement. Cerebellar fibers are found throughout the midbrain, including the ventral tegmental area (VTA). The VTA, through dopaminergic signaling, participates in reward, motivation and social related behaviors. In order to determine whether the cerebellar input to VTA can influence these complex behaviors we expressed either Channelrhodopsin2 or Archaerhodopsin (ArchT) in the deep cerebellar nuclei (DCN) of mice, and bilaterally implanted optical fibers above VTA. We then performed behavioral testing to assess reward seeking and sociability. In a simplified self-stimulation test we found that optical stimulation of cerebellar terminals in VTA is sufficient to encourage the mice to self-stimulate. Moreover, in the widely used three chamber social task, we found that the natural preference of mice for social contexts is reduced if stimulation is offered as an

alternative. The social preference is also decreased if the cerebellar input to VTA is silenced during the three chamber social task. Our data suggest that the cerebellum is an important upstream structure capable of shaping VTA responses to salient stimuli and might thus influence VTA function in processing reward and social behavior.

Title: Speed modulation of locomotor gait in the adult mouse

Authors: ***N. JOSSET**[1], M. LEMIEUX[1], M. ROUSSEL[1], S. COURAUD[1], F. BRETZNER[1,2]; [1]Ctr. De Recherche Du CHU De Québec, Quebec, QC, Canada; [2]Dept. de psychiatrie et neurosciences, Univ. laval, Québec, QC, Canada

Abstract: Most quadrupeds exhibit a wide range of locomotor gaits from walk, to trot, to gallop. Interestingly, while the mouse can jump for 1 to 2 consecutive strides during flight reaction, there is little evidence that they can really gallop. Upon genetic manipulations of the spinal interneuronal circuit, some mutant mice can gallop with hindlimb synchronization, however, their wild-type littermates continue to walk even at high locomotor speed, thus raising some concerns as to whether the wild-type mouse can gallop and bound. Combining kinematic, angular excursion and electromyographic studies, we assessed locomotor gaits in 9 adult C57BL/6 mice (>3 weeks old) during steady-state locomotion at treadmill speeds ranging from 5 to 150 cm/s. Based on the symmetry/asymmetry of the gait (i.e. the presence or absence of hindlimb alternation) and the inter-limb coupling (e.g. between forelimbs, hindlimbs, as well as lateral limbs), we identified and characterized 2 symmetrical and 6 asymmetrical gaits during locomotion. Among symmetrical gaits, which were defined by hindlimb alternation, mice

displayed lateral walk and trot, but never diagonal walk or pace. Lateral walk was characterized by an anti-phase coupling in hindlimbs and forelimbs but an out-of phase coupling in lateral limbs, while trot showed an anti-phase coupling in all pairs of limbs. Among asymmetrical gaits, two sub-types of locomotor gaits were identified according to either an in- or out-of- phase coupling in hindlimbs. Half-bound, full-bound, and hop were identified by hindlimb synchronization. Forelimbs were out-of phase during half-bound and in-phase during full-bound, while they appeared disorganized during hop. Moreover, we also identified asymmetrical gaits with an out-of phase coupling in hindlimbs such as in the rotary gallop, transverse gallop and asymmetrical walk. Using phase-frequency analysis, we found that mice exhibited a large spectrum of locomotor gaits across specific ranges of locomotor speed with episodes of lateral walk from 1 to 4 Hz (9 % of gait events) and trot from 1 to 10 Hz (40.2%), all gallops above 7 Hz and up to 15 Hz, with the rotary gallop (3.6 %), transverse gallop (5.9 %), half-bound (10.8 %), and full-bound (16.8 %). Hop and asymmetrical walk showed a bimodal distribution with a peak at low speeds below 3Hz and high speeds above 6 Hz, thus suggesting that they might be transition gaits. In summary, our study demonstrates that mice display a continuum of gaits as function of the locomotor frequency, ranging from walk to trot and then to gallop with various sub-types of gaits at the slowest and highest speeds.

Title: Motor control of forward accelerations versus steady swimming in bluegill sunfish

Authors: ***M. A. SCHWALBE**, A. L. BODEN, T. N. WISE, V. VIKAS, E. D. TYTELL; Biol., Tufts Univ., Medford, MA

Abstract: Muscle can produce energy for movement, but can also change the effective stiffness or damping properties of a joint by co-contraction or eccentric contractions. Animals can shift muscles between these roles by changing relative timing of antagonist muscles. In particular, high speed behaviors require high muscle forces, but may also require an overall stiffer body because the reaction forces from the environment are also higher. How do animals control force production and stiffness modulation during high speed movements? We compared muscle activity during steady swimming and forward acceleration in bluegill sunfish (*Lepomis macrochirus*). We hypothesized that fish may increase the effective stiffness of their bodies by co-contracting left- and right-side muscles during acceleration, and may also activate more muscle during lengthening (eccentric contractions). To determine the muscle activity of a swimming fish, we implanted bipolar electromyographic electrodes in the superficial red axial muscle of bluegill sunfish and recorded muscle activation during forward accelerations and steady swimming between 0.5-2.5 body lengths/second. We used a new digital accelerometer to quantify the acceleration and 3D orientation of a fish's body and also quantified swimming kinematics using high speed video. In forward accelerations, the muscles were active for a larger fraction of the tail beat cycle and came on at a different time compared to that in steady swimming. Further, duty cycles (percentage of strain cycle period) was greater in forward accelerations than in steady swimming. These results suggest that muscle on both sides of a fish's body may co-contract during accelerations but not in steady swimming. Fishes likely control their effective body stiffness and enhance efficiency of both acceleration and steady swimming by shifting the timing and duration of muscle activity. By investigating the motor control of swimming in fish, we gain insights into how vertebrates control both high speed, high force movements and low speed, steady movements.

Title: The Quakemill: A computer vision based actuated treadmill for rapid, precisely controlled mechanical perturbations of freely running animals

Authors: *A. VAHEDIPOUR, C. D. VALENTI, B. D. ROBERTSON, O. HAJI MAGHSOUDI, A. J. SPENCE;
Bioengineering, Temple Univ., Philadelphia, PA

Abstract: Locomotion is critical to survival and reproduction in most animals. As such it provides a powerful lens with which to view and subsequently understand the nervous system. Individuals often encounter obstacles and perturbations during locomotion. The mechanisms enabling recovery from these unexpected perturbations have not been fully described. A central difficulty is the integrated nature of this phenomenon. Feedforward neural commands, sensory feedback, and self-stabilizing aspects of the musculoskeletal system and whole body dynamics likely all contribute to recovery. A powerful paradigm with which to tackle this difficulty would be the application of external mechanical perturbations with and without simultaneous manipulation of the nervous system: so called “neuromechanical” perturbations. For example, these perturbations could target how gait is regulated to maintain stability after perturbation, or the function of sensory feedback in compensating for the unexpected. Here we present a computer vision controlled treadmill system capable of applying rapid, precisely timed, and spatially confined mechanical perturbations to freely running animals including mice and rats. We leverage robotic technologies developed by the Kod*Lab (University of Pennsylvania; G.C. Haynes et al., Proc. SPIE 8387, 2012), to create a fast, vertical displacement of the treadmill surface in closed-loop. We present data on the behavioral, gait, and postural kinematic response of C57BL/6 mice to sudden mechanical perturbations. We determined these responses with a multi-camera high-speed video system. Because the perturbations are triggered by a real-time feed of animal speed and position, confounding effects due to variation in these quantities were minimized. Combined with optogenetic manipulation of sensorimotor pathways, our long-term goal is to understand the integrated neuromechanical basis of robust legged locomotion. The system we present here represents a significant contribution to this aim. Through a better understanding of the neuromechanical basis of robust movement in the face of disturbances, we can improve outcomes for individuals with neurological disorders and musculoskeletal injuries, and provide inspiration for legged robots.

Title: Applying mediolateral pelvis force perturbation during treadmill training improves dynamic balance and overground walking in Children with Cerebral Palsy

Authors: ***M. WU**[1,2], J. KIM[2], D. J. GAEBLER-SPIRA[2], P. ARORA[2];
[1]Dept Physical Med. & Rehabil, Northwestern Univ., Chicago, IL; [2]Sensor Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Cerebral palsy (CP) is the most prevalent physical disability originating in childhood with an incidence of 2-3 per 1,000 live births. Ninety percent of children with cerebral palsy have difficulty in walking. In addition, children with CP typically present with compromised balance control. Impaired balance control limits their walking capacity and negatively impacts their daily activities. Current standing balance training paradigms may improve standing balance but may have limited transfer to postural control during locomotion in children with CP. As a consequence, there is a need to develop a dynamic balance training paradigm for improving postural control during walking in children with CP. Previous study indicated that hip abductors/adductors plays a key role for maintaining lateral balance control during locomotion. In addition, muscle strength of hip abductors in children with CP was significantly less than in their able-bodies peers and appeared to be most closely related to walking function than any other lower-extremity muscle group. Thus, treatment techniques that focus on improving the motor control of the hip abductor/adductor muscles may improve lateral balance during locomotion in children with CP. We hypothesize that adding a lateral perturbation force to the pelvis during walking will increase the muscle activation of hip abductors/adductors, and repeated exposure of pelvis lateral perturbation loading will result in an improvement in dynamic balance and walking in children with CP. Ten children with CP (6 boys) have been recruited to participate in this study. The average age of these children was 10.2 ± 2.8 years old. The Gross Motor Function Measure ranged from I to III. A controlled force perturbation was applied to the pelvis in the mediolateral direction through a custom designed cable-driven robotic system while subjects walking on a treadmill. Muscle activities and kinematics of the pelvis and lower limbs were recorded during treadmill walking. In addition, standing balance, measured using a force-plate, and overground walking speeds were also measured before and after treadmill walking paired with pelvis force perturbation. Results indicated that pelvis force perturbation induced an enhanced muscle activities of hip abductors/adductors during treadmill walking in children with CP. In addition, overground walking speed and step width also improved in children with cerebral palsy following one session treadmill training paired with pelvis force perturbation.

These techniques could be used as an intervention to improve the dynamic balance and walking function in children with cerebral palsy.

Title: Constraints on stance-phase force production and muscle coordination during overground walking in persons with chronic incomplete spinal cord injury

Authors: ***H. B. HAYES**, S. L. TIRADO, R. D. TRUMBOWER;
Dept of Rehabil. Med., Emory Univ., Atlanta, GA

Abstract: Persons with incomplete spinal cord (iSCI) struggle with community ambulation. They exhibit decreased walking speed, reliance on assistive devices (ADs), and increased fall risk, suggesting forces for propulsion, weight support, and stability are impaired. Muscle weakness and inappropriate muscle coordination may impede force production, but how altered muscle coordination constrains force production remains unknown. The purpose of this study is to investigate constraints on force production during the stance phase of overground walking in persons with iSCI and the underlying muscle coordination deficits. We hypothesize that persons with iSCI exert smaller forces than age-matched able-bodied controls (AB) walking at matched cadences and fail to modulate forces with increased cadence. We hypothesize that differences in iSCI forces coincide with maximum muscle co-activity. To test our hypotheses, persons with chronic iSCI and AB walked overground at self-selected and fast cadences. AB also walked at the matched cadences and ADs of iSCIs. Ground reaction forces generated by the more impaired limb were recorded along with surface electromyography of 12 leg muscles. Non-negative matrix factorization identified groups of consistently co-activated muscles, or modules, and their activation across stance. Persons with iSCI exhibit reduced forces due to muscle co-activity and weak extensor activation. iSCI persons exert significantly lower braking and propulsive impulses

in the fore-aft axis and lower peak vertical forces during late stance compared to AB walking at matched cadences and ADs. Reduced braking aligns with activation of co-activity modules composed of muscles across the ankle, knee, and hip. Reduction in late-stance propulsive forces scale with lower extremity motor scores and align with weak plantarflexion module activation. Force reductions are exaggerated with ADs, even compared to AB walking at the same cadences and ADs. Finally, when walking at faster cadences, iSCI show limited force modulation as compared to AB. Those with ADs even show opposite modulation compared to AB, suggesting force impairments and reliance on ADs increase with effort. Consistent with our hypotheses, ground reaction forces are constrained during overground walking in persons with chronic iSCI resulting from both muscle weakness and inappropriate co-activity. When using ADs, walking faster as often sought in rehabilitation, may actually exaggerate muscle dis-coordination and compensation. Understanding these force and coordination impairments is vital for targeted rehabilitation strategies to improve overground walking ability in chronic iSCI.

Title: Muscle actions on task performance and joint integrity in the rat hindlimb

Authors: ***M. C. TRESCH**[1], T. SANDERCOCK[2], Q. WEI[3], Y. DHAHER[4], D. K. PAI[5];
[1]Biomed. Eng, Physical Med. and Rehab, Physiol., [2]Physiol., Northwestern Univ., Chicago, IL;
[3]Bioengineering, George Mason Univ., Fairfax, VA; [4]Rehabil. Inst. of Chicago, Chicago, IL;
[5]Computer Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Although the neural control of movement is usually considered in terms of the control of task relevant variables, neural systems might also control the state of other variables that have a less visible impact upon behavior. In particular, we are examining the hypothesis that the nervous system actively monitors and regulates the state of internal joint variables in order to minimize excessive stresses and strains on joint cartilage and ligaments. We are examining these issues in the rat, evaluating whether the nervous system activates hindlimb muscles to control both task performance (i.e. locomotion) and joint integrity (i.e. knee joint structures). We

examine the biomechanics of the patellofemoral joint in the rat and its control by quadriceps muscles. In acute experiments we measured the kinetics and kinematics of hindlimb movements evoked by stimulation of the three main quadriceps muscles in the rat: rectus femoris (RF), vastus lateralis (VL), and vastus medialis (VM). The pelvis was held in place using bone screws and the distal tibia attached to a 6 axis force transducer. Retroreflective markers were rigidly attached to the patella and femur and their 3D position was tracked. Each quadriceps muscle was then stimulated and the evoked isometric forces and kinematic motions were recorded. We found that the isometric forces evoked by VM and VL were very similar to one another (3D forces differing by ~5 degrees). Consistent with this similarity, there was minimal mediolateral movement of the patella in the femoral groove produced by stimulation of any of quadriceps muscle. However, each muscle produced opposing rotations of the patella within the groove, suggesting that these muscles exerted opposing torques on the patella. Additional experiments confirmed these results, showing that VM and VL evoked similar hindlimb trajectories when the limb was allowed to move freely but that they evoked opposing mediolateral forces on the patella when the force transducer was attached directly to the patella. These results demonstrate clearly that although VM and VL have redundant contributions to task performance, producing similar endpoint forces and joint kinematics, they have antagonistic contributions to joint regulation, producing opposing mediolateral and rotational forces on the patella. These biomechanical experiments allow us to make strong predictions on neural control strategies across a range of perturbations and thereby to evaluate how the nervous system controls both task and joint variables during behavior.

Title: Feedback and feedforward control during walking in individuals with chronic ankle instability

Authors: *S.-C. YEN[1], M. B. CORKERY[1], A. DONOHOE[1], M. GROGAN[1], Y.-N. WU[2]; [1]Dept. of Physical Therapy, Northeastern Univ., Boston, MA; [2]Univ. of Massachusetts Lowell, Lowell, MA

Abstract: Lateral ankle sprains (inversion injuries) are a common injury encountered in physical activities. Up to 70% of individuals who have an ankle sprain eventually develop chronic ankle instability (CAI), which is characterized by residual pain, weakness, and most problematically, recurrent ankle sprains. The cause of recurrent ankle sprains remains unclear, but has been linked to impaired feedback and feedforward control of the ankle joint. The purpose of this study was to compare the feedback and feedforward control between healthy individuals and individuals with CAI when they walk with a perturbation inverting the ankle joint. We hypothesized that the feedback and feedforward control are different between the two groups. Twelve young subjects with CAI and 12 healthy subjects participated in this study. They were asked to walk on a treadmill in 3 sequential periods. The first period was the baseline period where subjects walked normally on a treadmill without any intervention for 1 minute. The second period was the adaptation period where subjects walked with a 1-lb weight placed on the dorsal-lateral side of the foot (inversion perturbation) for 5 minutes. Subjects' reaction to the weight can generate insight into the feedback control strategy. The third period was the post adaptation period where the weight was removed while subjects continued to walk for 1 minute. Subjects' kinematic change detected in this period (i.e., aftereffect) can generate insight into the feedforward control strategy. Subjects' ankle kinematics was recorded and calculated using 3D motion capture system. The kinematic analysis was focused on 30 ms before and after heel contact where ankle sprains are most likely to occur. We found that healthy individuals increased ankle eversion to counteract the perturbation during both early and late adaptation period. After the weight was removed during the post adaptation period, they showed a significant aftereffect consisting of increased ankle eversion. In contrast, subjects with CAI only increased ankle eversion in the early adaptation period. In the late adaptation period, the ankle angle in the frontal plane returned to the baseline. After the weight was removed, they showed no significant aftereffect. The results suggest that CAI is associated with changes in feedback and feedforward control of the ankle joint during walking. The results may help explain why individuals with CAI recurrently sprain the ankle during daily walking.

Title: Locomotor control in mutant mice lacking DSCAM: a kinematic and EMG study

Authors: ***M. LEMIEUX**[1], F. BRETZNER[2];
[1]Ctr. De Recherche Du CHU De Québec, Quebec, QC, Canada; [2]Ctr. De Recherche Du CHU De Québec, Québec, QC, Canada

Abstract: Quadrupedal locomotion is an adaptable behavior requiring coordination within each limb, between the left and the right side of the pectoral and pelvic girdles and between girdles. The proper orchestration of spinal networks operating at each level depends on local and long-range connectivity that is genetically determined during development. Down Syndrome Cell Adhesion Molecule (DSCAM) is an immunoglobulin that has been involved in several neurodevelopmental processes. Interestingly, mice lacking DSCAM stood with hyperextended limbs and a flexed back at rest reminiscent of the scaredy cat posture. However, little is known about their functional locomotor and postural impairments. Combining kinematic and electrophysiological studies in mice, we have investigated the impact of a spontaneous mutation of DSCAM (DSCAM2J) on locomotor control. Reflective markers were placed on hindlimbs joints to analyze limb movements. Mice were videotaped during treadmill locomotion at steady speeds ranging from 0.05 to 0.9 m/s. Based on individual strides, we identified different locomotor gaits: asymmetrical walk (out of phase hindlimbs), lateral walk (anti-phase hindlimbs, low homolateral couplet), trot (anti-phase forelimbs, hindlimbs and homolateral limbs), hop (in-phase hindlimbs) or pace (anti-phase hindlimbs and in-phase homolateral limbs). WT mice exhibited predominantly asymmetrical walk at very low speed, lateral walk at low to moderate speed and trot at higher speeds. In contrast, DSCAM2J mice predominantly used asymmetrical walk at low and moderate speeds and lateral walk instead of trot at higher speeds. DSCAM2J mice also hopped at moderate speeds and paced at all speeds whereas WT mice used these two gaits only at low speed. DSCAM2J were more frequently supported on two limbs rather than on three limbs like WT mice. At the intralimb level, DSCAM2J mice generally presented a larger stride height and length than WT mice. We found a larger and more variable angular excursion for proximal and intermediate joints for DSCAM2J mice. The occurrence of the hyperextended posture of DSCAM2J typically seen at rest and during hops decreased during asymmetrical walk and was rarely observed during lateral walk, trot and pace. Our electrophysiological recordings showed that the amplitude of electromyographic responses and the coordination between flexor and extensor muscles were impaired at low speed but improved at high speed. We conclude that the DSCAM mutation alters the output of neural networks involved in intralimb and interlimbs coordination during locomotion.

Abstract: A close relation between hippocampus and locomotion has been described by several authors. After a penetrating injury in hippocampus, tamoxifen promotes the recovery of the hindlimb kinematics and the brain cortex electrical activity. The present experiments were performed in 2 months old female rats to determine the kinematic changes after a penetrating injury (PI) in the left hippocampus. Hindlimb and forelimb kinematics were studied: before, 7, 15 and 30 DPI. A total of 13 subjects were studied (cortex group n=3, hippocampal non-treated group n=5 and hippocampal tamoxifen group n=5). After 30 days the subjects were anesthetized and intracardiacally perfused to obtain the hippocampal tissue and cell counts were performed. We observed kinematic changes in the ipsilateral and contralateral hindlimbs as well as in the ipsilateral forelimb due to the hippocampal lesion, which were not present in the cortex group. Tamoxifen effect was noticeable at 7 and 30 DPI, reducing in a significant manner the kinematic changes present in the non-treated group. Tamoxifen favored the preservation of the hippocampal pyramidal neurons on the CA1 region, this could be related to the better kinematic outcome of the tamoxifen treated group.

Title: Predictive and one-step-behind algorithms for self-paced split-belt treadmill

Authors: *M. BOOTS[1], S. YAKOVENKO[2];
[1]West Viriginia Univ., Morgantown, WV; [2]Neurosci., WVU, Morgantown, WV

Abstract: Trauma to the nervous system or even to the musculoskeletal system generally results in asymmetric movement and adaptations in animals, including humans. Common rehabilitation of asymmetric gait is locomotor training that may involve walking on an instrumented split-belt treadmill to accommodate the interlimb asymmetry. The rational of this study was to develop a self-paced split-belt treadmill that adapts to individual performance with independent belt control without the use of motion capture. Using real-time analysis of ground reaction forces (GRF) we extracted the following step parameters: swing and stance phase durations, stride length, and ground contact on the treadmill for each leg. The speed of each leg was calculated at phase transitions (swing to stance & stance to swing) detected by thresholding vertical GRF components. The limb speed was then calculated as a ratio of stride length divided by the cycle duration, where the stride length was a sum of the difference in interstride contact positions and the integrated speed signal over the past cycle duration. Two components, based on the interstride differences in gait phases, were also added to reduce uncontrolled belt speed drift. The resulting signal was then used in a closed-loop one-step-behind controller to update independently the speed of each treadmill belt. In addition, we have augmented this controller with an acceleration-based prediction. These two types of controllers were tested during locomotion over a range of velocities to evaluate their performance. Subjects were instructed to walk symmetrically; therefore, the interlimb speed difference could be used to access the overall controllability of the treadmill. Both algorithms were sufficiently robust to allow self-paced locomotion at desired pace and speed, with the predictive algorithm showing the best performance.

Title: Auditory cue modifies the fractal dynamics of human gait during treadmill walking

Authors: ***K. MASANI**[1,2], H. ROUHANI[1,2], M. O. ABE[3], K. NAKAZAWA[4], D. NOZAKI[5]; [1]Toronto Rehab Inst., Toronto, ON, Canada; [2]Inst. of Biomaterials and Biomed. Engin., Univ. of Toronto, Toronto, ON, Canada; [3]Grad. Sch. of Educ., Hokkaido Univ., Sapporo, Japan; [4]Dept. of Life Sci., [5]Grad. Sch. of Educ., The Univ. of Tokyo, Tokyo, Japan

Abstract: Stride interval fluctuation during walking has unique dynamics called long-range correlation or fractal dynamics. It was described that the fractal dynamics disappear when one walks with rhythmic auditory cues, such as metronome sounds. Here we quantitatively investigated the dynamics of the stride interval fluctuation during treadmill walking with auditory cues to reveal how the fractal dynamics is modified by the cue. Ten healthy subjects (18 - 24 yrs) participated in this study. Each subject was requested to walk on a treadmill with his/her natural cadence and speed (natural walking). The average cadence was calculated in the first trial, and then the subject was asked to walk with the same speed while a metronome sound with average cadence was added (metronome walking). Detrended fluctuation analysis (DFA) was performed to examine the fractal dynamics of each gait condition. Agreeing with previous studies, the DFA plot for metronome walking showed a curve at around a window period of 30 steps. Thus, we calculated the slope of DFA plot before (1st period) and after (2nd period) the window period of 30 steps, separately. Further, we performed a simulation study based on the assumption that stride interval fluctuation during metronome walking is a summation of innate fractal rhythm and an error of the current rhythm from the metronome sound. The alpha value for natural walking was 0.96±0.09, suggesting that natural walking has fractal dynamics even with a constrained speed (i.e., walking on a treadmill), which agrees with previous studies. In contrast, metronome walking showed alpha value of 0.37±0.16 for the entire range, suggesting that long-range correlation disappeared. For metronome walking, the alpha value was 0.56±0.08 and 0.21±0.21 for the 1st and the 2nd periods, respectively. These alpha values were different from each other, indicating that the DFA plot for the metronome walking was curved with a convex shape. In the simulation study, we found that the simulated stride interval fluctuation showed a curved DFA plot very similar to the one in the experiment. This result suggests that fractal dynamics were preserved even during metronome walking while an error correction based on the previous step modifies the stride interval.

Title: Use of inertial sensors for determining kinematic characteristics of infant leg movement

Authors: *I. A. TRUJILLO PRIEGO[1], B. A. SMITH[2];

[2]USC Div. of Biokinesiology and Physical Therapy, Univ. Of Southern California, Los Angeles, CA

Abstract: Our overall goal is to use data from inertial sensors to determine the quantity, type and quality of infants' leg movements performed across a full-day measurement for further use in the differentiation of infants with typical, delayed or impaired neuromotor development. Here we describe an algorithm to calculate kinematic characteristics of leg movements. Inertial sensor data were collected from 12 infants with typical development for a period of 8-13 hours per day. There were 2 months between visits and a total of 3 visits per infant. An inertial sensor was attached to each leg, recording simultaneously accelerometer and gyroscope measurements at 20Hz. In previous work, we developed and validated a threshold-based algorithm where each pause or change of direction of the limb is counted as a discrete movement. Here we determined the duration, average acceleration, and peak acceleration of each movement. The duration of each movement was computed by counting the number of samples when the acceleration magnitude was above baseline until it crossed the baseline for a second time. Consequently, acceleration magnitude was obtained for each of these samples and average acceleration and peak acceleration of each movement was calculated. Infants produced average movement durations that ranged from 0.23 to 0.33 seconds per movement, with average accelerations ranging from 1.59 to 3.88 m/s^2 and average peak accelerations from 3.10 to 8.83 m/s^2. Mean (M) and standard deviation (SD) of movement duration (D), average acceleration (AA) and peak acceleration (PA) for each infant at each visit, for right and left legs, are shown in Table 1. Our results showed that there is a range of leg movement duration and acceleration values produced by infants across visits. Future work will focus on the analysis of movement features based on

the developmental level of infants and identification of the differences between infants with typical, delayed or impaired neuromotor development.

Title: Stepwise shifts in the set of modules for human locomotion with speed change

Authors: ***H. YOKOYAMA**[1], T. OGAWA[1], N. KAWASHIMA[2], K. NAKAZAWA[1]; [1]The Univ. of Tokyo, Tokyo, Japan; [2]Res. Inst. of Natl. Rehabil. Ctr. for Persons with Disabilities, Saitama, Japan

Abstract: Spinal neural circuits can generate locomotor movements in a wide-range of speeds. Recent studies in vertebrates have revealed that different spinal circuits are activated depending on locomotor speeds. Although there are a few behavior-based studies, it is unknown whether different spinal neural circuits are responsible for generating different speeds of locomotor movements in human. To answer this question, factorization algorithms were used for extracting

locomotor modules: functional units implemented in spinal neural circuits. By applying this technique, we tested the hypothesis that human locomotor modules shift with changing speed. Eight healthy adults and eight collegiate runners walked or ran on a treadmill linearly increasing speed from 0.3 to 4.3 m/s and from 0.3 to 5.0m/s, respectively (ramp speed condition, acceleration of the belt was set to 0.01m/s^2). Subjects were instructed to either walk or run on the basis of their preference under the given speed. Surface EMGs were recorded from 16 muscles on the one side of the trunk and leg. Locomotor modules were extracted from the EMGs by using the non-negative matrix factorization algorithm. Then, commonality of modules among subjects and speeds was evaluated based on the correlation coefficients. In addition, to evaluate the influence of the differences of modules among speeds on generation of muscle activity, the combined method of EMG reconstruction method and cluster analysis were executed. Assuming that similar module sets generate similar EMG activity, EMG activities across all speeds were repeatedly reconstructed by using modules at each speed. After that, the characteristics of the reconstruction quality were grouped by cluster analysis. The results showed that the number of modules and the components of modules were different among speeds. Further, the characteristics of EMG reconstruction were different between walking and running. Then, those of walking and running were respectively divided into two subgroups: slow and fast one. Namely, discrete modules are activated with speed change. These results strongly confirmed our working hypotheses, and the results clearly support the view that neural circuits for human locomotion shift in a speed-dependent manner.

Title: Knee joint impedance optimizations for design of transfemoral prostheses

Authors: *H. ARGUNSAH BAYRAM[1], M. B. BAYRAM[1], B. L. DAVIS[2];
[1]medical engineering, Acibadem Univ., istanbul, Turkey; [2]Biomed. Engin., Univ. of Akron, Akron, OH

Abstract: Knee joint impedance describes the knee resistance to rotations and possible buckling. It is defined as the ratio of the kinetics of the joint, (i.e., the torque applied to the knee to rotate it), and its kinematics (i.e., the angular velocity at the knee) during static and dynamic situations. Muscles are the key impedance suppliers. In exploring the time intervals, when the energy is harvested and dissipated at the knee, impedance analysis is extremely important. A prosthetic knee, which can store energy in the spring when it is available and then release the appropriate amount of it at the appropriate time during the daily activities, could potentially greatly enhance ambulation. Information regarding impedance of knee is important for understanding the energy flow at the knee and designing energy regenerative prostheses. This study examined knee mechanics in 12 healthy subjects to explore impedance in the energy harvest and return phases during the activities of daily living (ADL's). The reason for assessing different ADL's is because it is possible that impedance of the knee is dependent on the musculoskeletal task being performed. During the energy return phases, high impedance is obtained due to the resistance to motion. Therefore, the stored energy is absorbed at the knee during these periods. Conversely, during the energy harvest phases, low impedance is obtained due to the knee's intention to assist to motion. Thus, energy is harvested during these periods. These findings are helpful for identifying prosthetics design strategies, so that by using modern computational tools, prosthetic knees could be simulated even before initiating the hardware design process. Impedance is calculated by performing a regression of sagittal plane knee flexion moment and knee angular velocity curves for the energy harvest and return phase intervals of the activities. The slopes of the torque versus angular velocity regressions are defined as the impedance. Energy return phase impedance varied between -0.005 Nm s/kg deg. and 0.047 Nm s/kg deg., and energy harvest phase impedance varied between -0.002 Nm s/kg deg. and 0.004 Nm s/kg deg. The erratic impedance values indicated the difficulty of achieving high efficiency during all activities in a simple mechanism.

Title: Reducing gait asymmetry after stroke with strength training

Authors: *J. W. STINEAR, A. J. C. MCMORLAND, M.-J. JEON;
Univ. of Auckland, Auckland, New Zealand

Abstract: Hemiparesis is a common sequel to stroke that typically results in an asymmetrical gait pattern. We designed an experiment to test the hypothesis that plantarflexor (PF) and dorsiflexor (DF) strength training reduces gait asymmetry. Fifteen chronic stroke patients with a walking velocity between 0.6 and 0.8 m/s conducted strength training using Therabands three days a week over six weeks. Two pre-intervention measures of PF and DF strength were taken 2-4 weeks apart. Timing of muscle activity was also assessed using surface electromyography (EMG) during walking, while a Vicon motion capture system recorded patients' kinematic and kinetic data. One set of post-intervention measures was taken immediately after the training period followed by another six weeks later. The study will conclude at the end of May, 2015. Preliminary results are as follows. Strength training improved paretic limb PF strength by approximately 45%. Only minimal gains in DF strength were observed. There was a trend for paretic limb step time to decrease by 9%, and double support time to decrease by 15% when the paretic limb trailed; this was also accompanied by a 19% reduction in the duration of paretic limb PF muscle activity. These data partially support our hypothesis, and suggest that after stroke, strength training for muscles activating the ankle reduces some measures of gait asymmetry.

Title: Alterations in sagittal and frontal gait kinematics in patients with subacute stroke following high-intensity stepping training

Authors: *T. G. HORNBY[1,2], G. MAHTANI[3], M. CONNOLLY[3], C. HOLLERAN[3], P. HENNESSY[3], J. WOODWARD[3];
[1]Dept. of Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL; [2]Sensory Motor Performance Program, [3]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Background: Development and reinforcement of abnormal gait kinematics is a primary concern for therapist treating patients post-stroke. A common goal of locomotor training strategies is to approximate “normal” kinematic patterns and walking speeds, although the negative outcomes of robotic and therapist-assisted gait training strategies raise questions regarding the importance of this strategy. Recent strategies that focus on providing large amounts of high-intensity stepping practice in variable contexts have not focused on minimizing abnormal gait patterns, but have resulted in substantial improvements in clinical locomotor outcomes. Allowing patients to explore different kinematic solutions to successfully complete stepping tasks could lead to development of compensatory gait strategies, although the resultant kinematic outcomes have not been well described. The present study investigated changes in sagittal and frontal plane kinematics following high intensity locomotor training in patients < 6 mo post-stroke as compared to conventional strategies. Methods: The present data represents a subgroup analysis of kinematic outcomes from two separate, completed studies (Holleran 2014, 2015). Eligible subjects included those who ambulated at overground gait speeds < 0.90 m/s. Subjects completed up to 40 1-hr sessions of high intensity stepping training in variable contexts, with focus only on completing walking tasks. The control group completed up to 40 sessions of low-intensity variable task training. Kinematic data collection was performed during graded treadmill testing (start at 0.1 m/s, increased by 0.1 m/s every 2 minutes) at pre- and post-training (22 experimental, 13 controls). Data were collected at 1000 Hz with an 8 camera motion capture system with 32 lower limb, reflective markers (modified Cleveland Clinic set). Primary outcomes included sagittal plane joint excursions and frontal plane hip hiking/circumduction. Results: Subjects in the experimental group achieved greater increases in peak speeds (0.56 vs 0.13 m/s), cadence, paretic step length and sagittal plane hip excursion than the control group. Frontal plane hip hiking was significantly increased at peak speeds post-training in the experimental vs control group (3.0 vs 0.3 deg). Increases in frontal plane changes were related to baseline impairments (Fugl-Meyer). Conclusions: Significant but small changes in frontal plane kinematic strategies were observed following high-intensity stepping training in variable contexts. Such changes may be due to initial impairments and lack of residual motor function to successfully retrain normal gait patterns.

Title: Visual feedback allows altered muscle phasing during pedaling for both the paretic and non-paretic leg following stroke

Authors: *C. H. MULLENS[1], D. A. BROWN[2];
[1]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL; [2]Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Stroke is a major cause of locomotor disability. Nearly 800,000 people experience a stroke yearly, with 50% of ischemic stroke survivors showing lasting reductions in functional locomotor capacity. Inappropriate muscle phasing is a critical contributor to this incapacity, and occurs when a muscle is inappropriately active at a phase of the locomotor cycle during which it will interfere with limb progression, or inactive when it might otherwise contribute to limb progression. Prior work in pedaling, which provides a mechanically-constrained cyclical locomotor-like task that allows well-controlled study of phasing, has demonstrated prolonged activation in the paretic limb of vastus medialis (VM), a uniarticular knee extensor, that is the major contributor to progression of the limb during the downstroke. This prolonged activation also appears in walking, and impairs appropriate initiation of knee flexion during swing. In this pedaling study, following a control period, we presented individuals poststroke with visual feedback of activity in the VM, and a deactivation target at the earliest behaviorally-relevant angle found in the literature (seen during very high-frequency pedaling) for five 3-minute trials at 40rpm. We hypothesized that individuals would advance deactivation in both paretic and non-paretic VM, but that the shift would be reduced in the paretic limb. Using a novel method presented previously by the authors at SfN 2014, the overall relative timing of activation during each individual cycle was calculated relative to control period activation. Participants (n=12), who had experienced a stroke ≥5 months before the study, demonstrated a significantly earlier median muscle phasing during the feedback condition compared to control, for both the non-paretic and paretic limb (Wilcoxon rank-sum, $p<0.005$). The non-paretic limb showed advancement of 16.4±21.9° across participants, with 10/12 medians advanced. Surprisingly, the paretic shift showed advancement of 24.5±31.3°, with 11/12 medians advanced. The larger shift in the paretic limb is likely to reflect a greater difference between deactivation during the control period (in which the paretic limb shows delayed deactivation) and the final target. However, this result clearly shows that despite impaired phase of activation during typical behavior, individuals poststroke demonstrated a considerable ability to manipulate muscle phasing in the paretic limb, contrary to current theories suggesting that the poststroke nervous system has reduced capability for flexible activation/deactivation of muscle activity during movement.

Title: Dynamics inherent to bipedal locomotion constrain active control of foot placement

Authors: ***S. L. BARTON**[1], J. S. MATTHIS[3], B. R. FAJEN[2];
[2]Dept. of Cognitive Sci., [1]Rensselaer Polytechnic Inst., Troy, NY; [3]Ctr. for Perceptual Systems, Univ. of Texas, Austin, Austin, TX

Abstract: When walking over complex terrain, humans use visual information to exploit the passive physical forces inherent to bipedal locomotion. We previously showed that control of stepping to a target foothold relies critically on visual information of that target during the end of the preceding step (Matthis & Fajen, 2013; Matthis, Barton, & Fajen, 2015). Visual information about target position presented during this "critical control phase" was sufficient for subjects to accurately step to a target, while the same information presented before or after the critical phase resulted in stepping errors. These findings reflect a control strategy based on the mechanical structure of the body, in which visual information is used to initialize a ballistic trajectory of the body for the upcoming step. Although visual information about target position is critical during the end of the preceding step, it remains unclear if humans use visual information about target footholds during a step to make adjustments to the foot's trajectory mid-flight. Such active control may be important for responding adaptively to changes in the environment that render a previously safe target foothold undesirable or unobtainable. However, mid-flight corrections during continuous walking, where stability and efficiency are largely governed by the passive dynamics initialized prior to each step, are likely to be constrained by the forces inherent in bipedal locomotion. In the present study we explored the contributions of active and passive modes of control by asking subjects to walk along a path of irregularly spaced targets projected onto the ground while their movements were recorded with motion capture. On a subset of trials, the location of one of the six targets was perturbed in either a medial/lateral or anterior/posterior direction as subjects approached. Perturbations were applied at one of four points during

subjects' approach, three of which occurred during the step to the target, and one that occurred during the preceding step. We found that subjects' ability to respond to the perturbation depended strongly on the point at which the perturbation occurred. When the perturbation occurred at less than half a step from the target, subjects demonstrated no corrective movements, leading to large stepping errors. As the perturbation was applied earlier in the approach, stepping error decreased systematically. However, stepping error did not return to baseline in any condition in which the target was perturbed. This suggests that the ability of a walker to assert active control of foot placement during continuous walking is constrained by the dynamics of continuous locomotion.

Title: Effect of cue timing and modality on gait initiation in Parkinson's disease

Authors: ***C. LU**[1,2], S. L. AMUNDSEN HUFFMASTER[1,2], P. J. TUITE[2], J. M. VACHON[1,2], C. D. MACKINNON[1,2];
[1]Movement Disorders Lab., [2]Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: The purpose of this study was to examine the effect of different cue timings and modalities on anticipatory postural adjustments (APAs) preceding and accompanying gait initiation in Parkinson's disease (PD) patients with and without freezing of gait (FOG). Sensory cues can markedly facilitate movement initiation in people with PD, even when they are off medication. These observations provide compelling evidence that PD patients retain the capacity to initiate movement via non-dopaminergic pathways. Currently it is unknown how the timing of the cue or the cue modality impacts gait initiation in PD patients. Twentytwo patients with PD (11 freezers) were studied in the off medication state. Step initiation was cued using instructed--delay (warning-go) timing protocols: fixed delay period (3 s), random delay period (4-12 s), and countdown (3-2-1-go, 1 s between cues) in three sensory modalities: visual, acoustic and

vibrotactile (applied to the lateral malleolus of the stance leg). Subjects also performed self-initiated stepping trials. The APA variables were the timing and peak amplitude of: stepping leg loading force, stance leg unloading force, and initial excursions of the net center of pressure in both the mediolateral (COPml) and anteroposterior (COPap) directions. The change in APA performance between the self-initiated and cued conditions was calculated in each individual. Changes in APAs were analyzed using a repeated measures analysis of variance with factors of group, cue timing, and cue modality. There was a significant main effect ($p < 0.05$) of cue timing on the timing of APA generation. Post-hoc tests showed the time to peak loading of the stepping leg ($p = 0.004$) and peak excursions of the COPml ($p = 0.002$) and COPap ($p < 0.001$) were significantly increased in the countdown compared with the random delay condition. There was no significant effect of cue timing on the magnitude of change in the APA. A significant main effect ($p < 0.05$) of cue modality was found on the amplitude of the COP excursion. Peak excursions of the CoPml ($p = 0.042$) and COPap ($p = 0.003$) were significantly reduced in the tactile compared with the visual condition. Group effects were not significant for all variables. The data demonstrate that cueing protocols that incorporate predictable timing improve the timing, but not the amplitude of APAs compared to random timing in PD patients. In contrast, cue modality affects the magnitude but not the timing of APAs. Visual cues improve the amplitude of gait initiation compared to tactile cues in both freezers and non-freezers.

Title: Effects of external cue timing on the variability of gait initiation in people with Parkinson's disease

Authors: *S. L. AMUNDSEN HUFFMASTER[1,2], C. LU[1,2], J. M. VACHON[1,2], P. J. TUITE[1], C. D. MACKINNON[1,2];
[1]Neurol., [2]Movement Disorders Lab., Univ. of Minnesota, Minneapolis, MN

Abstract: External cues can improve gait initiation in people with Parkinson's disease (PD) and help those with freezing of gait (FOG) overcome a freeze, but the effectiveness of cues is often highly variable within individuals, thus reducing the clinical utility of this intervention. This study examined how the timing of auditory cues affects the variability of the anticipatory postural adjustments (APAs) that precede and accompany gait initiation. Self-initiated and cued gait initiation trials were performed by 24 PD subjects off medication (12 with FOG). Three cue timing conditions were tested (6 trials each) using an instructed-delay (warning-"go") paradigm: fixed delay (3s), random delay (4-12 s), and countdown (3-2-1-go, 1 s between cues). Ground reaction forces (GRFs) and center of pressure (CoP) excursions from two force plates and bilateral EMG from 10 leg muscles were recorded. Filtered forces and CoP were time normalized from APA onset to step leg toe-off. The coefficient of variation (CV) of the medial-lateral (CoPml) and anterior-posterior (CoPap) CoP and vertical GRFs (GRFv) were calculated for each condition. The mean and standard deviation of peak filtered EMG were determined bilaterally for tibialis anterior (TA) and gluteus medius (GMs) EMG in each set of trials. The effect of Cue Timing and Group was tested via repeated measures ANOVA. Results showed a significant ($p<0.05$) main effect of Group for the CV of CoPml. Post-hoc analysis showed the CV of CoPml was higher in the FOG group. The effect of Group for the variability of the stance leg GM EMG approached significance ($p = 0.07$). There was a significant effect of Cue Timing for the CV of CoPml, GRFv and variability of the peak TA EMG for the step and stance legs. Post-hoc analysis showed the CV of CoPml significantly decreased for the random and fixed delay cues relative to self-initiated, and for the fixed delay relative to the countdown condition. The CV of the GRFv for the step leg was lower in the fixed delay than the self-initiated or countdown conditions. Peak TA EMG variability increased in both legs for all cueing conditions compared to self-initiated gait. Our findings demonstrate that patients with FOG have more variability in medial-lateral gait initiation profiles compared to those without FOG. External cues improved the consistency of lateral weight shift in both groups. Cues increased the variability of TA activation compared to self-initiated gait largely due to an increase in magnitude. Our results show that cues improve the reliability of gait initiation, particularly force generation in the medial-lateral plane. A fixed delay cueing paradigm provides the most consistent gait initiation performance.

Title: The feasibility and efficacy of a standing continuous tracking task: Exploring the dosing of postural task practice in Parkinson's disease

Authors: *S. Y. SCHAEFER[1,2], H. A. HAYES[2], L. E. DIBBLE[2];
[1]HPER, Utah State Univ., Logan, UT; [2]Physical Therapy, Univ. of Utah, Salt Lake City, UT

Abstract: Although Parkinson disease (PD) impairs motor learning, the paradigms documenting such deficits have not necessarily been salient to the postural dysfunctions associated with PD, particularly when unmedicated by dopamine replacement. Saliency aside, however, excess exogenous dopamine may further impair motor learning in PD despite improving motor signs themselves. The purpose of this study was to test the feasibility and efficacy of a standing continuous tracking task (CTT) for measuring motor learning. To account for age, disease, and dopamine replacement effects, we tested two groups of individuals with PD on (n=10) or off (n=9) medication, compared to two control groups of healthy elderly (n=10) and healthy young (n=10) adults. We hypothesized that the prescribed dose of practice (12 blocks of 10 repetitions over two days) would be feasible for all participants, and that the healthy control groups (HE and HY) would learn the standing CTT faster than either PD group (On or Off med), such that the prescribed dose would be less efficacious for learning in participants with PD. The CTT required anterior-posterior postural sway to track a visual target trajectory that contained a repeating pattern; root mean square error (RMSE) was recorded as the difference between this and the participant's trajectory. Feasibility was measured as the percentage of participants who completed the required practice dose without adverse events (e.g. fatigue/falls). Furthermore, exponential decay functions were fitted to the RMSE data across practice blocks for each participant, with the decay constant indicating the number of blocks needed to achieve an asymptote in performance (i.e. steady state). Efficacy was then determined by the percentage of participants who achieved this steady state within the prescribed practice dose. We found that the dose was feasible for 100% of all groups with no adverse events. This dose was not, however, efficacious for 100% of any group to achieve a steady state in performance. In light of our hypothesis, the HY group had more participants (90%) achieve steady states within the dose compared to the other groups (HE=70%, PD On=78%, PD Off=33%). These results suggest that our standing CTT was feasible for people with and without PD. Furthermore, our practice dose was only selectively efficacious for promoting learning, and even less so off dopamine replacement medication than on. Nevertheless, future research is needed to address the

interactions between practice dose, exogenous dopamine, and age on the treatment of Parkinsonian motor deficits through non-pharmacological, learning-based interventions.

Title: Effectiveness of self-triggered versus externally-triggered cueing for improving gait initiation in persons with Parkinson's disease and freezing of gait

Authors: ***M. PETRUCCI**[1], C. MACKINNON[2], E. HSIAO-WECKSLER[1];
[1]Univ. of Illinois Urbana-Champaign, Urbana, IL; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Freezing of gait (FOG) is a disorder that affects approximately one half of people with Parkinson's disease (PD) and may be related to a diminished ability to couple posture and locomotion. An example of this impairment is the absence or reduction of anticipatory postural adjustments (APAs) during gait initiation. APAs are necessary to propel the body forward and laterally towards the stance foot as the stepping foot comes off the ground. Exogenous sensory cues can significantly improve the magnitude and timing of APAs and reduce the incidence of FOG episodes. However, the utility of these cues is often compromised by the inability to determine the timing and context during which the cue should be delivered. For this reason, a self-triggered cue (e.g., the user is able to press a button to receive a go-cue) might solve this problem. However, it is unclear if a self-triggered cue can be as effective as an externally-triggered cue. In the current study, we evaluated the effectiveness of an acoustic and a mechanical assistance cue using these two cue delivery paradigms. Five participants (64± 12 yrs, H-Y 3-3.5) with FOG symptoms were tested OFF medication. Four test conditions were evaluated in both the self and externally-triggered paradigms: [Baseline] - self-initiated stepping without a cue, [Acoustic] - acoustic cue (80 dB, 1 KHz tone for 500 ms), [Assist] mechanical assistance cue provided by a powered ankle-foot orthosis (sequence of dorsiflexor and

plantarflexor torque, 330 ms and 83 ms, respectively) worn on the stepping foot, and [Acoustic-Assist] both acoustic and mechanical assistance cue provided simultaneously. Participants were asked to take several steps forward on the go-cue starting with their right foot, for all trials. All externally-triggered go-cues were presented 2.5 s after a ready-cue. Vertical ground reaction forces (vGRF) and center of pressure (COP) data were collected. Preliminary results showed that APA magnitudes were increased in the externally-triggered paradigm. Compared to Baseline, vGRF and medial lateral COP (ML-COP) magnitudes were increased in the Acoustic (64% vGRF, 37% ML-COP), Assist (50% vGRF, 52% ML-COP), and Acoustic-Assist (82% vGRF, 77% ML-COP) conditions. However, decreases in these same parameters were found in the self-triggering paradigm in the Acoustic (-22% vGRF, -8% ML-COP), Assist (-32% vGRF, -29% ML-COP), and Acoustic-Assist (-4% vGRF, -9% ML-COP) compared to Baseline. These findings suggest that self-triggering may result in decreased APAs compared to the externally-triggered paradigm. Thus, a self-triggered cue may not be as effective at restoring normative gait initiation behaviors in persons with PD and FOG.

Title: Variability in frequent, objective postural sway measures in mild cognitive impairment

Authors: *J. M. LEACH[1], M. MANCINI[2], J. A. KAYE[2], T. L. HAYES[1], F. B. HORAK[2]; [1]Biomed. Engin., [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Background: There are fundamental insufficiencies in infrequent measures as they reflect one instance of performance, cannot detect changes in performance variability over time, and may mask true changes in both cognitive and motor function. Motor changes have been shown to coincide with or precede cognitive changes. Because postural control (a specific motor function) and cognitive status have been evidenced as covariates, and because both postural and cognitive performance become increasingly more variable during the initial stages of decline, the longitudinal variability in postural sway (i.e., static postural control) may serve as a sensitive marker of early cognitive decline. Frequent, objective postural sway measures may differentiate older adults with mild cognitive impairment (MCI) from older adults with no cognitive impairment (NCI). Methods: 22 subjects (11 MCI, 11 NCI) enrolled in ongoing Oregon Center for Aging and Technology (ORCATECH) studies were recruited. A Nook tablet and Wii balance board (WBB) were integrated into ORCATECH's current in-home technological platform to quantify postural sway daily for 30 days. Subjects stood on the WBB (positioned on the floor) and performed a 3-minute daily exercise via the tablet (mounted on the wall). A cognitive load was utilized to increase the overall difficulty of the simple standing-in-place task (i.e., quiet stance). The tablet immediately transferred center of pressure (CoP) data (acquired by the WBB) and cognitive data (acquired by the tablet) to ORCATECH's data repository via a wireless internet connection. Objective postural sway measures were derived from the CoP data and were used to quantify postural control. Cognitive data was used to make inferences regarding the subjects' effort exerted on the cognitive dual-task. Postural dual-task costs will be calculated and postural sway will be assessed between groups. A latent class trajectory analysis will be used to assess longitudinal trends across the 30-day monitoring period. Results: Data analysis is currently underway. If the variability in frequent, objective postural sway measures differentiates MCI from NCI, it may be used as a sensitive predictor of cognitive status and early cognitive decline. Conclusions: This pilot study will characterize postural sway in MCI, will determine the utility of frequent, objective postural sway measures, and will lay the foundation for longitudinal, in-home monitoring of postural sway. Future work may enable early detection of cognitive decline and yield opportunities for intervention, treatment, compensation, coping, sustained independence, and prevention of irreversible damage.

Title: Balance control is improved in children with cerebral palsy through classical-ballet based instruction

Authors: ***C. LOPEZ-ORTIZ**[1,2,3], T. EGAN[4], D. J. GAEBLER-SPIRA[4,2];
[1]Kinesiology and Community Hlth., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL; [3]Joffrey Ballet Academy, The Official Sch. of the Joffrey Ballet, Chicago, IL; [4]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Cerebral palsy (CP) is the most common developmental motor disorder in children. The prevalence of CP in children in the United States is estimated to be between 3.1 to 3.6 cases per 1000 live births. Individuals with CP demonstrate abnormal muscle tone and motor control. These deficits contribute to impaired posture and control and movement coordination that in turn compromise balance control. The main goals of rehabilitation include promoting function while decreasing the risk for skeletal deformity and muscular dysfunction later in life. Rehabilitative therapies for cerebral palsy include most commonly orthopedic surgery, botulin toxin injections and physical therapy. Physical therapy interventions consist mainly of intensive stretching and strengthening exercises and more recently, high dosage robotic training aimed at restoring locomotion, reaching ability and ankle mobility. Reviews of literature fail to show meaningful clinical improvements after robotic interventions or, at best, the improvements are comparable to those of regular physical and occupational therapies. Enhancing selective motor control is at the cornerstone of this investigation and targets the ability to produce movements without unwanted, detrimental motor activity in the moving limb or in other areas in the body. Our classical ballet based intervention for movement rehabilitation targets motivation and attention as part of the rehabilitation strategy. All procedures were approved by the local IRB and informed consent and assent were obtained. Fourteen children ages 6-15, 8 male, 4 female with Gross Motor Function Classification System Scores I-IV participated in this experiment and were randomly assigned to a control or a treatment group. The treatment group participated in a one-hour class, three times per week over four weeks. Both groups received traditional physical therapy at school during the experimental period. The Pediatric Berg Balance Test (PBBT) was performed in both groups before, after, and one month after the intervention. Paired t-tests showed statistically significant improvements in the PBBT with $p<0.05$ after the intervention and one month after the intervention for the treatment group and not for the control group. Classical Ballet's training principles align with physical therapy practices. The participants did not view the ballet classes as therapy but more as a fun activity to share with their peers. This targeted dance class proved successful in improving balance beyond the outcomes of routine physical therapy.

Title: Feasibility and effect of task-specific fall prevention training strategies to improve postural and stepping responses in patients with cerebellar dysfunction

Authors: *S.-J. IM, J.-H. PARK;
Korea Univ., Seoul, Korea, Republic of

Abstract: Cerebellar dysfunction typically induces increased body instability and poor coordination of movements, which leads to high incidence of falls and fall-related injuries. There is a lack of evidence-based recommendations for effective fall prevention trainings in cerebellar patients. The present study investigated the feasibility and effect of a specific rehabilitation strategy that aims to improve dynamic balance and postural reactions against external perturbations in patients with cerebellar disease. A total of 21 patients with degenerative cerebellar disease participated in a 12-week training program, 2 times per week for 1.5 hours per session (total 24 training sessions). The rehabilitation program consisted of intensive practice of balance and gait activities that facilitate sensorimotor processing to scale the magnitude of postural responses to compensate for external perturbations. The results showed a significant reduction in the rate of falls and fear of falling after intervention. In addition, kinematic measures indicated that the training decreased the size of the postural response (i.e., body sway) and time before returning to an equilibrium point. After intervention, therefore, the patients appear to reacquire the capability to perceive and control displacement of center of gravity when challenged with external perturbations. Taken together, the present study has provided preliminary evidence that task-specific motor rehabilitation programs to prevent falls may be beneficial to enhance more timely stepping strategies in response to gravitational changes in patients with cerebellar dysfunction.

Title: Synergistic changes in muscle activity post-stroke during split-belt treadmill walking

Authors: ***P. ITURRALDE**[1], D. DE KAM[2], G. TORRES-OVIEDO[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Split-belt walking in which legs move at different speeds improves gait symmetry in patients who have suffered a stroke (Reisman et al. 2013). Previous work has focused on kinematic changes during this task in post-stroke patients, but little is known about the underlying changes in muscle activity. It is important to investigate the latter to understand the actual plasticity of neural mechanisms in these patients. Thus, in this study we investigated changes in muscle coordination of 16 post-stroke subjects during split-belt walking. Subjects initially walked with both legs moving at the same speed (baseline condition), then speeds were abruptly changed so that they had to walk twice as fast with their non-paretic leg than their paretic one (adaptation condition), and then once again abruptly changed to walk in the same baseline environment (post-adaptation condition). We measured electromyographic activity in 15 muscles on each leg, and compared the steady-state adapted condition measurements vs. both the baseline and the post-adaptation conditions. Statistical testing of mean activity per gait cycle phase was performed for each subject, and we used a Bonferroni correction to account for multiple comparisons. We found consistent activity changes on muscles on both legs during specific times of the gait cycle in at least 50% of the patients. Interestingly, we observed spatial and temporal symmetricity in these changes. Increased activity on one side was matched by decreased activity on the other side (spatial symmetricity) and changes in muscle activity for each leg occurred during the same phase of the ipsi-lateral gait cycle (temporal symmetricity). Specifically, we observed increased activity of hamstrings (i.e. semimembranosus, semitendinosus, and biceps femoris) in the paretic side during its swing phase matched by decreased activity contra-laterally. We also observed decreased activity of plantarflexors (soleus, medial and lateral gastrocnemius) and dorsiflexors (peroneus and tibialis anterior) in the paretic side during its stance phase matched by increased activity contra-laterally. Non-paretic rectus femoris and hip muscles were the only muscles that showed increases in activity not matched by changes in the paretic side. Because most changes in muscle activity occurred bilaterally and not only in the sound limb, our results suggest that post-stroke patients are able to modulate their muscle activity when learning a new walking pattern on the split-belt treadmill. Therefore,

chronic post-stroke patients may still have the flexibility to change their muscle coordination to improve their walking despite of their cortical lesions.

Title: Missing muscle synergies for balance control in paretic side after stroke

Authors: ***D. DE KAM**[1], V. WEERDESTEYN[1], G. TORRES-OVIEDO[2];
[1]Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: ***Objective:*** Postural instability is a major risk factor for falls in people after stroke. Defective muscle coordination of balance recovery responses may contribute to their greater fall risk. We aimed to identify stroke related impairments in muscle control during balance recovery. ***Methods:*** Ten people after unilateral stroke (> 6 months) and 9 healthy controls were subjected to translational balance perturbations in 12 directions resulting in a feet-in-place balance correcting response. Activity of eight muscles was recorded bilaterally: erector spinae (ERSP), gluteus medius (GLUT), biceps femoris (BFEM), semitendinosis (SEMT), soleus (SOL), rectus femoris (RFEM), peroneus (PER) and tibialis anterior (TA). After averaging muscle activity over 3 time bins of 75 ms, muscle synergies were extracted for each leg separately. Averaged synergy coefficients (W) and activation coefficients (c) of healthy subjects were used as a reference. To identify differences in directional tuning of synergies between patients and controls, we compared c-values in a repeated measures ANOVA for each time bin and for each synergy with LEG (paretic, non-paretic and control) and direction (DIR) as independent variables. ***Results:*** While three muscle synergies (W1-W3) were consistently found in healthy controls, we found differences in these synergies and their recruitment in the paretic leg of post-stroke patients. Muscle synergies W3 (BFEM, SEMT, ERSP and PER) and W2 (TA, RFEM) that responded to forward translations were either missing or had lower activity compared to controls. Namely, muscle synergy W3 was absent in paretic legs of 4 stroke patients with lower clinical motor score (Motricity Index and Fugl-Meyer). Also, the activation of W3 was missing in response to

forward translations on the non-paretic side (LEG x DIR p=0.001). Similarly, the activation of muscle synergy W2 in response to forward floor translations was lower in the paretic leg compared to controls (LEG x DIR p=0.018 in bin 1 and p=0.008 in bin 2). Finally, while synergy W1 (SOL, GLUT) was present in all stroke patients, its activation C1 was higher in patients than in controls in response to medial floor translation during later time bin 3 (LEG x DIR p<0.001). ***Conclusion:*** Stroke related impairments in postural muscle responses include absence of the 'hamstring synergy' W3 and lower recruitment of the 'anterior synergy' W2 in response to forward floor translations, when balance is mostly challenged. These deficits may contribute to the high fall rates in stroke patients.

Title: It's all uphill from here: incline split-belt walking increases locomotor adaptation in unimpaired subjects and post-stroke patients

Authors: *C. J. SOMBRIC[1], J. S. CALVERT[1], P. A. ITURRALDE[1], D. M. MARISCAL[1], D. DE KAM[2], G. TORRES-OVIEDO[1];
[1]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [2]Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Promising studies have shown that patients can correct their gait asymmetries after walking on a split-belt treadmill, which forces their legs to move at different speeds (e.g., Reisman et al. 2013). Thus, there is an interest in enhancing learning of the split-belt walking pattern (i.e., after-effects) to improve patient's gait. We hypothesized that learning split-belt walking is modulated by the forces experienced at the feet (i.e., the ground reaction forces). To test this, we assessed the after-effects following split-belt walking when the treadmill was in an inclined, flat, or decline condition - which are situations known to modulate ground reaction forces during walking (Lay et al. 2006). 23 unimpaired subjects (24.7±5.2 years old) and 4 stroke patients (65.9±9.5 years old) participated in the study. Unimpaired subjects were divided into three groups: flat (n=9), incline (n=8), and decline (n=6). Each stroke patient served as their own

control by experiencing flat and incline conditions in two separate sessions. Split-belt perturbations and slopes were smaller for stroke patients to ensure they would be able to complete the split-belt inclined condition. Specifically, 3:1 split-belt perturbation and 8.5 degree slopes were used for controls, whereas 2:1 and 5.0 degree slopes were used for stroke patients. Kinematic data were recorded in all groups with a motion tracking system via reflective markers placed bilaterally on the trunk and legs. We computed step length symmetry in each group, which is a measure of clinical interest known to adapt during split-belt walking (Reisman et al. 2007). We evaluated the steady state reached during split-belt walking (i.e., average of the last 40 strides of adaptation) and the after-effects (i.e., average of first 5 steps of post-adaptation) as compared to baseline walking. Split-belt walking in the inclined conditions results in the greatest adapted state ($p<0.001$) and after-effects ($p<0.001$) in unimpaired subjects. Stroke patients also reached a significantly higher steady state in the incline condition compared to the flat ($p=0.03$), but after-effects did not change in all subjects ($p=0.29$). A larger sample size might result in significant differences in after-effects across conditions. In sum, incline walking on a split-belt treadmill significantly increased the extent of adaptation in unimpaired and post-stroke patients. This increase in gait adaptation is important because not all stroke patients change their movements in flat split-belt walking (Reisman et al. 2013). Therefore, it is important to identify ways to facilitate the effect of split-belt walking across patients.

Title: Effects of strength training the hip abductor-adductor muscles on protective stepping: a pilot study

Authors: ***M.-L. MILLE**[1,2,3], M. PAPAIORDANIDOU[1], G. FLORENT[1], K. EL KOULALI[1], R. C. FITZPATRICK[4];
[1]Inst. of Movement Sciences, UMR 7287, Marseille, Cedex 9, France; [2]Ufr staps, Toulon Univ., La Garde, 83957, France; [3]Dpt Physical Therapy & Human Movement Sci., Northwestern Univ., Chicago, 60611, IL; [4]Univ. of New South Wales, Sydney, NSW 2052, Australia

Abstract: Protective stepping is a common strategy to avoid falling. Control of lateral stability during stepping is challenging, particularly for elderly subjects. It requires an inter-limb coupling of the hip abductors-adductors (AB-AD) muscles that are known to undergo age-related strength losses. Thus, strengthening of these hip muscles is hence called for since it could improve balance recovery in older people. The aim of this preliminary study was to examine the effects of hip AB-AD muscle strengthening on protective stepping. Twelve elderly subjects in good health (≥ 60 years old) were randomly assigned to a training group (TG) or to a control group (CG). Training sessions of the AB-AD muscles were performed twice a week for 8 weeks. Before (PRE) and after (POST) the 8-week period, participants underwent a battery of tests comprising AB-AD force measurements as well as protective stepping abilities. Three perpendicular synchronized rotary motors under computer control allowed forces to be applied at the waist in the forward or lateral (left or right) directions to induce protective stepping. Subjects performed 7 trials for each of the 3 perturbation directions in a random order. For each perturbation, the number of steps, the side of the first step and the first step characteristics (onset, duration, length, width and clearance) were determined. Training improved maximal contraction force of AB by 12% (Wilcoxon $p<0.046$) and AD by 19% (Wilcoxon $p<0.046$) in the TG between PRE and POST testing whereas these maximal forces were unchanged in the CG (Wilcoxon $p>0.5$). The percentage of trials in which only one step was made to recover balance increased from 39% to 54% in the TG (Wilcoxon $p<0.027$) but remained the same in the CG (PRE: 33%; POST: 39%; Wilcoxon $p>0.5$). Finally, first step duration decreased in the TG (PRE: 416ms; POST: 371ms; Wilcoxon $p<0.027$) but did not change in the CG (PRE: 427ms; POST: 397ms; Wilcoxon $p=0.142$). These results indicated that improving the strength of the hip abductor-adductor muscles also improves balance recovery to postural perturbation in the elderly. Thus targeting these muscles by simple strength training could be beneficial for balance and help prevent falls.

Title: Time course of nanoparticle drug delivery to prevent or reverse functional and structural changes of proprioceptors in short-term hyperglycemic rats

Authors: ***V. K. HAFTEL**[1], J. LAKE[2], R. BUTLER[1], T. JOHNSON[1], M. PRIEST[1], K. MOTON-MELANCON[3], C. EADDY[1];
[1]Dept of Biol., [2]Psychology, Morehouse Col., Atlanta, GA; [3]Biol., Spelman Col., Atlanta, GA

Abstract: Short term hyperglycemia leads to dysfunction of peripheral neurons leading to numbness, tingling, decline in H-reflexes, and difficulty walking. This study was done to determine the appropriate time course of drug application via biodegradable nanoparticles (NP) to prevent/reverse changes seen in proprioceptor function in a model of Type I diabetes. Several groups of rats were injected with streptozotocin, and blood glucose monitored to allow 2 or 3 weeks of hyperglycemia (> 250 mg/dL; dpn). Then, NPs encapsulating human recombinant insulin were injected into left triceps surae muscles. One or two weeks following NP injection, terminal experiments were performed in the following groups: 3wk dpn/then 2wk NP; 3wk dpn/1wk NP; 2wk dpn/2wk NP; 2wk dpn/1wk NP. These time points were chosen based on changes in structure and function seen by us at 3 and 6 wks of hyperglycemia in previous experiments, and the time course of drug released from the formulation of NP used (insulin release of 110-10 ng/mL over 2-14 days from 75:25 of poly-lactide-co-glycolide NPs). Intra-axonal electrophysiological measurements were made in anesthetized rats, and immunohistochemistry was done to determine sciatic axon:myelin diameter ratio, dorsal root ganglion soma area, and sodium channel distribution in the peripheral nerve. Data show NP injection improves muscle spindle afferent responses to muscle stretch in a time-dependent manner, e.g., afferents from 3wk dpn rats show very high no. action potentials (N) and maximum firing rate (Mx) upon muscle stretch; 6 wk dpn afferents show very low N and Mx (previous data from this lab); NP treated afferents in 3wk dpn/1wk NP, 3wk dpn/2wk NP, 2wk dpn/2wk NP resulted in gains toward untreated control values of N and Mx. Structural changes were found in dpn rat nerves, and 3wk dpn/1 wk NP and 3wk dpn/2wk NP dorsal root ganglia soma areas move closer to untreated control. Measurements are being collected from the other NP groups. Axon:myelin diameter ratios of 3 wk and 6 wk dpn nerves were larger than control, and 3wk dpn/1wk NP treated side were greater than those, suggesting an inflammatory response that requires further examination. 3wk dpn/1wk NP untreated side, and 3wk dpn/2wk NP untreated side measurements were closer to control, even slightly larger. These results require more thorough examination and reanalysis. Also, sodium channel distribution in sciatic nerves from in each group are being examined immunohistochemically. Further tests will be done on additional time points of NP treatment and different methods of delivery of NP to the affected neurons in order to fine tune treatment methods for peripheral changes in short term diabetes.

Title: A novel use of commerically available technology to assess balance impairment in mild traumatic brain injury

Authors: *W. WRIGHT[1], J. MCDEVITT[1], R. TIERNEY[1], F. J. HARAN[2], K. APPIAH-KUBI[1]; [1]Temple Univ., Philadelphia, PA; [2]Naval Exptl. Diving Unit, US Navy, Panama City, FL

Abstract: Mild traumatic brain injury (mTBI) can cause diffuse axonal injury, which can affect cognitive, and emotional, and sensorimotor processes such as balance impairment. Assessments of balance following mTBI often include the Sensory Organization Test (SOT) and the Balance Error Scoring System (BESS). The SOT has shown that visual-vestibular processing deficits may underlie post-concussion balance impairment, but this test is less sensitive to unremitting symptoms that do not spontaneously resolve within a week. The BESS is most sensitive to symptoms only in the first few days post-injury. Our current project involves demonstrating validity and reliability of a novel low-cost, portable virtual reality-based balance screening device that employs established principles of sensorimotor reweighting and visual-vestibular integration. The goal is to determine if it can replace existing tools that are either prohibitively expensive or lack reliability or sensitivity. Healthy young adults (n=27) were tested to establish healthy norms. Individuals with recent mTBI (n=8) were compared to the healthy norms. The new VR-based balance assessment system consists of a Wii balance board (WBB), a large screen television, and a custom-designed software user interface which collects and processes data. Subjects performed six upright postural tasks modeled after the Clinical Test of Sensory Organization and Balance (CTSIB) with 3 visual conditions either standing directly on the WBB or on foam placed on the WBB. The three visual conditions were Static Scene, Dark Scene, and Dynamic Scene (Roll at 60 deg/s). Subjects viewed a VR scene displayed on a 60” TV. The WBB recorded center-of-pressure (COP) at 100Hz for 30 sec, and COP velocity, RMS, and sway area were calculated. Subjects also performed the BESS and SOT. Within-group repeated-measures ANOVA showed the device reduced postural stability as sensory input reliability and availability decreased. Between-groups ANOVA reveal that individuals with mTBI have significantly worse balance scores on the new VR-device ($p<0.001$). Criterion validity of the new device measured using ROC curves reveal sensitivity/specificity higher than BESS and

equal to SOT (AUC=0.83, $p<0.01$). In conclusion, this study demonstrates that our new VR-based assessment tool is a valid measure for detecting balance related changes in neurologically impaired individuals and can potentially replace much more expensive equipment. Including sensitive and specific postural control measures after brain injury may help improve identification of individuals with sub-acute symptoms which can guide rehabilitation and clinical decision-making.

Title: Assessing the effect of repeated sub-concussive head blows on balance control in football defensive linemen

Authors: ***M. CINELLI**, N. FIGUEIRA;
Dept. of Kinesiology & Physical Educ., Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Previous research has revealed that concussed athletes experience balance deficits that are more prominent in the anterior-posterior A/P direction as indicated by increased Center of Pressure (COP) displacement and velocity which persist even when they return to activity. This deficit may be due to potential damage to the vestibular system, primarily the impairment of the lateral vestibulospinal tract which sends signals to control ankle extensors. This may lead to increased compensatory torques about the ankle. The purpose of this study was to determine if there is a sensitive enough balance measure that is able to quantify any negative cumulative effects of sub-concussive head blows on balance control of football defensive linemen. It was hypothesised that as the balance task became more challenging, a higher order analysis would be able to demonstrate any cumulative effects of sub-concussive blows. Seven varsity defensive linemen participated in balance testing every week following their Saturday game. To assess static balance during quiet stance, ground reaction forces were collected for 45s at 100Hz using a Nintendo Wii board. Participants stood on the Wii board using a narrow Romberg stance with their hands by their side during five conditions: 1) eyes open (EO); 2) eyes closed (EC); 3) math

dual task (Math); 4) an iPad dual task (iPad); and 5) horizontal head turns for 15s followed by 30 additional seconds of static stance with eyes closed (HeadTurn). Results revealed that there was no change in COP displacement or M/L COP velocity over the course of a competitive football season. However, A/P COP velocity significantly decreased ($p<.05$) in three of the conditions (EC, Math, HeadTurns) over time indicating an improved level of balance control over the course of the season. As previously reported, AP COP velocity is a sensitive enough measure to detect balance control changes over time. However, the findings from the current study indicate that exposure to repeated sub-concussive head blows during a competitive football season did not have a negative concussion-like cumulative effect. The improvement in balance control is most likely due to the neural adaptations occurring as a result of the sport specific training over the course of the season. It is possible that the improvement in strength as a response to the physical training improved both the neural and physical aspects necessary for an improvement in overall balance control. Unfortunately, the current findings are not able to determine whether or not long-term negative effects on balance control will develop following exposure to sub-concussive head blows.

Title: Locomotion and interhemispheric motor connectivity in mTBI

Authors: *L. A. KING[1], B. W. FLING[1], C. SWANSON[1], J. CHESNUTT[2];
[1]Neurol., [2]Orthopedics and Rehabil., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Despite recent data suggesting that gait coordination may be impaired after mild traumatic brain injury (mTBI), gait is not typically assessed post-concussion. Abnormality in gait coordination could 1) indicate abnormal brain functioning and 2) impair physical function and predispose the person to additional injury. The purpose of this pilot study is to objectively measure gait coordination along with structural and functional measures of inter-hemispheric motor connectivity in subjects with chronic mTBI. Three people with chronic mTBI (23, 44, and 59 years old) performed standardized gait task. Gait coordination measures included 1) phase

coordination index (PCI), and 2) stride width obtained using inertial sensors (APDM system) and Gait Rite. Resting state functional and diffusion-weighted images were collected to assess functional and structural connectivity between the right and left supplementary motor areas (SMA). Functional and diffusion images underwent well-established preprocessing techniques measuring 1) functional connectivity strength between the right and left SMA and 2) fractional anisotropy of fibers connecting those areas. Results are presented as mean (+/- SD) and are compared to normative data as appropriate. People with mTBI had reduced gait performance with larger PCI [3.7 +/-2.5 vs. 2.5 +/-0.59] and stride width [13.6 cm +/-1.6 vs 10.0 cm] compared to normative data. Fractional anisotropy of fibers connecting the bilateral SMA was reduced in all people with mTBI compared to age-matched controls [FA = 0.55 +/-.15 vs 0.68 +/-0.06]. Furthermore, two people with mTBI had functional hyperconnectivity between the right and left SMA compared to age-matched controls [r = 0.72 +/-0.07 vs 0.53 +/-0.08]. The third person with mTBI had reduced integrity of connecting fiber tracts to such an extent that they showed a near complete loss of functional connectivity between the SMA (r = 0.11). Consistent with existing literature we show that people with mTBI have reduced fiber tract structural quality within the body of the corpus callosum. However, this pilot data suggests that this decreased structural connectivity is related to increased functional connectivity between the higher-order motor areas. These results support the notion of a release from GABA-ergic mediated inhibition with declining interhemispheric fiber tract structure. Further, this small group of people with chronic mTBI had impaired interlimb coordination during gait possibly related to impaired interhemispheric communication. Future work will investigate associations between inter-hemispheric sensorimotor connectivity and gait performance.

Title: Neural correlates of dual-tasking in young and old adults

Authors: *S. PAPEGAAIJ[1], T. HORTOBÁGYI[2], B. GODDE[3], P. ERHARD[4], C. VOELCKER-REHAGE[3];
[1]Univ. of Groningen, Univ. Med. Ctr., Groningen, Netherlands; [2]Ctr. for Human Movement Sci., Univ. of Groningen, Univ. Med. Ctr. Groningen, Groningen, Netherlands; [3]Jacobs Univ., Bremen, Germany; [4]Univ. Bremen, Bremen, Germany

Abstract: The ability to perform two tasks simultaneously has been shown to decrease with age. One proposed neurological mechanism explaining these findings is that the age-related increase in neural recruitment to perform a single task results in a reduced residual capacity in shared brain resources when performing a dual-task (Van Impe et al., 2011). The purpose of the study was to determine whether this structural interference indeed mediates the age-related decrease in dual-task performance. Functional magnetic resonance imaging (fMRI) was used to investigate 23 young adults (20-29 years) and 32 old adults (66-89 years) performing a calculation and balance-simulation task separately or simultaneously. The calculation task consisted of serial subtraction by seven. Standing balance was simulated by a plantar flexion force control task with the goal of keeping an avatar on the screen from swaying forward or backward. Motor and calculation performance decreased during the dual-task compared with the single tasks in both age groups. There were no significant age-related differences in dual task costs. Brain activation was more extended in old than young adults during all conditions (balance, calculation and dual-task). This increased brain activation was more prominent in the old adults with low compared with high balance performance. However, brain activation did not differ between old adults with low or high dual-task costs. Moreover, dual-task costs did not seem to be related to the magnitude of upregulation in brain activity between single and dual-tasks within shared brain regions. Under the present experimental conditions the age-related increases in brain activation were related to single task performance but not to dual-task costs. Van Impe, A., Coxon, J.P., Goble, D.J., Wenderoth, N., Swinnen, S.P., 2011. Age-related changes in brain activation underlying single- and dual-task performance: visuomanual drawing and mental arithmetic. Neuropsychologia. 49, 2400-2409.

Title: Dynamic parameters of postural control during reaching tasks: which are linked to fall risks for older adults living in the community?

Authors: ***M.-H. HUANG**[1], K. NEWMAN[1], T. SHILLING[1], A. RIGHTER[1], K. MILLER[2], K. SMITH[3], K. FREDRICKSON[4];
[1]Univ. of Michigan-Flint, Flint, MI; [2]Beaumont Hlth. Syst., Royal Oak, MI; [3]Life In Balance Physical Therapy, Nile, MI; [4]Mary Free Bed Rehabil. Hosp., Grand Rapids, MI

Abstract: Age-related changes in postural control are major risk factors of falls, leading to fall-related injuries, increased morbidity and mortality in older adults. No consensus has been established on the measures of postural stability during movements to identify those at risks of falling. This study investigated whether center of pressure (COP) parameters during reaching to objects of different loads would differ between young, older adults without (non-fallers) and with (fallers) a history of falls. 17 young adults (25±2.1 years), 11 non-fallers (65±9.2 years), and 12 fallers (68±7.3 years) living in the community volunteered. All were able to walk >50 ft without another person's assistance and with no history of neurologic conditions. Participants reached forward to grasp a basket placed at 30 cm in front of the feet on the floor using both hands, and returned to an upright posture while holding the basket. Participants were instructed to perform the task as fast as possible. The basket's weight was altered in the following sequence: 2.2 Kg, 0 Kg, and 2.2 Kg. Participants performed 3 trials in each load condition while data from the 1st and 3rd trials of a condition were analyzed. Center of pressure (COP) was analyzed during 3 phases of the task: anticipatory postural adjustments (APA), reaching to the target, and returning to upright. Parameters included COP displacement during APA, as well as maximum COP forward displacement, COP peak velocity, and COP trajectory smoothness during reaching and returning. Linear Mixed Model was used to analyze postural parameters, with group as between subject factor, trial as within subject factor, and Tukey's LSD for post-hoc comparisons. Significance level was $p<0.05$. COP parameters were comparable across trials. APA amplitudes and durations were significantly larger in fallers compared to non-fallers and young adults ($p<0.01$). During reaching and returning, fallers had significantly smaller COP forward displacement than non-fallers ($p<0.05$) and young adults ($p<0.01$). In contrast, all groups achieved maximum COP forward displacement at comparable timings and had similar COP peak velocities. Moreover, COP trajectory smoothness was significantly reduced in fallers compared to non-fallers and young adults ($p<0.01$). Older adults retain the ability to modulate APA according to the weight of reaching targets. However, fallers achieved this by altering APA amplitudes and durations. The control of COP trajectories during movement execution is compromised with aging and a history of falls. COP variables may be sensitive and precise parameters in identifying older adults with fall risks.

Title: Does aging with a cortical lesion increase fall-risk: Examining effect of age versus stroke on intensity modulation of reactive balance responses from slip-like perturbations

Authors: *P. PATEL, T. BHATT;
The Univ. of Illinois At Chicago, Chicago, IL

Abstract: Background: We examined the effect of aging with cortical lesions on postural stability and compensatory stepping response to increasing intensity of sudden slip-like stance perturbations among older stroke survivors. We hypothesized that although older stroke survivors and healthy controls would demonstrate greater postural instability at higher perturbation intensities, older healthy adults and stroke survivors as compared with young adults would show impaired modulation of reactive balance response for recovery from perturbation. Further, at higher perturbation intensities, older stroke survivors would demonstrate least postural stability at touchdown resulting from an inefficient compensatory step and reduced ability to control trunk extension. Methods: Ten chronic older stroke survivors (56 ± 6.48 yrs), healthy age-similar controls (AS, 57.9 ± 6.4yrs), and young adults (YA, 24.5 ± 3.8 yrs) were exposed to 3 levels of forward perturbations (accelerations 7.5, 12, and 16.75 m/s2 for levels I, II, and III respectively) in a random order. Stability at liftoff (LO) and touchdown (TD) was measured as the shortest distance of instantaneous center of mass (COM) state [position and velocity relative to base of support (BOS)] from a theoretical threshold for backward balance loss. Compensatory step length and trunk angle at TD were recorded. Results: All three groups showed greater instability at LO with increasing perturbation intensity (main effect of intensity, $p \leq .05$). At TD, while the YA had a linear improvement in stability with increasing perturbation intensities, such a trend was absent in AS and stroke groups (intensity x group interaction, $p \leq .05$). Thus, between group differences in stability at TD were observed at level III (YA>AS>stroke group, $p \leq .05$). At level III, while the YA group increased step length and reduced trunk extension to maintain COM more anterior to BOS, the stroke group was unable to do so. Although the AS group was unable to modulate step length, they reduced trunk extension at TD to achieve greater stability at level III as compared with stroke group. Conclusion: The findings reflect impairments in reactive balance control among older stroke survivors compared with their healthy counter parts, particularly at higher perturbation intensities. While aging had

an effect on intensity modulation of postural stability, the effect of aging superimposed with a cortical lesion elevates the balance deficits, explaining the increased fall risk in chronic ambulatory stroke survivors. Balance assessment and intervention in this population should incorporate more challenging environmental threats to unmask and retrain reactive balance.

Title: Thinking and walking while thinking outcomes of exercise interventions in older adults with age-related psychomotor slowing

Authors: K. A. LOWRY[1], W. J. FARRINGTON[1], *J. M. VAN SWEARINGEN[2];
[1]Des Moines Univ., Des Moines, IA; [2]Univ. Pittsburgh, Pittsburgh, PA

Abstract: Purpose: Walking problems are common and often cooccur in older adults with executive cognitive deficits. We compared aerobic and motor skill, task-oriented walking exercise on cognitive, and integrated walking while thinking outcomes. Participants: Fourteen adults>65 years old with slow gait (≤1.0m/s, but >0.60m/s) and psychomotor slowing (Digit Symbol Substitution Test <age-adjusted norm),randomized to motor skill or aerobic gait exercise interventions, 12weeks, 2 times/week. Materials/Methods: All measures completed pre and post intervention. Computerized cognitive tasks: 1) Flanker, determine direction of middle arrow in a row, interference suppression, 2) Update, add 2 for a blue circle, or subtract 1 for a red square, cognitive flexibility, 3) GoNoGo, inhibitory control, 4) 2Back, determine if number matches number two back, working memory. The same cognitive tasks were completed while walking around a track viewing the tests displayed on easels. A triaxial accelerometer secured at the waist recorded anteroposterior (AP) and vertical (V) trunk accelerations to determine smoothness, a measure of the motor control of walking. Accuracy scores were determined pre and post intervention for the computerized cognitive tasks and during the walking while thinking tasks. Results: Descriptive prepost changes in cognitive accuracy and smoothness during the walking while thinking tasks were determined; lower/negative numbers indicate greater improvement. Mean prepost changes in accuracy scores for the cognitive tasks were: 1) motor skill group,

Flanker=.05, Update=.04, GoNoGo=.01, 2back=.06; 2) aerobic group, Flanker=.02, Update=.06, GoNoGo=.04, 2back=.04. Mean pre-post changes in cognitive accuracy during the walking while thinking tasks were: 1) motor skill, Flanker=.01, Update=-.05, GoNoGo=no change, 2back=-.03; 2) aerobic, Flanker=no change, Update=-.02, GoNoGo=no change, 2back=-.02.Mean prepost changes in AP and V smoothness during walking while thinking were: 1) motor skill, Flanker AP=.14, V =.004, Update AP=.16, V=.24, GoNoGo AP= .38, V=.50, nback AP=.50, V=.51; 2) aerobic, Flanker AP=.12, V=.06, Update AP=.26, V=.26, GoNoGo AP=.12, V=.27, nback AP=.05, V=.35. Conclusions : While the aerobic group had more consistent improvement in cognitive task accuracy, the motor skill group tended to exhibit greater and more consistent improvement of walking smoothness and cognitive accuracy during walking while thinking. Based on the preliminary data motor skill training may reduce cognitive resource burden during walking by improvements in motor control and automaticity of gait in older adults.

Title: Interaction effect of Vision and Unstable base of support with Age on postural sway frequency

Authors: *E. PARK[1], G. SCHÖNER[2], D. REISMAN[3];
[1]Sch. of Applied Physiol., Georgia Inst. of Technol., Atlanta, GA; [2]Ruhr-Universität, Institut für Neuroinformatik, Germany; [3]Univ. of Delaware, Newark, DE

Abstract: The postural control process requires a complex integration of visual, somatosensory and vestibular sensory information about the orientation and position of body segments relative to each other, and to the surrounding environment. Age effects on postural control get attention in motor control research because the ability to maintain upright standing posture declines with aging. However, most of the findings from previous studies to investigate age effects on postural control do not address whether the effect of age comes from the control of certain joints (e.g. ankle joint), or from a different coordination strategy to stabilize posture. In addition to that, our

understanding of the interactions between factors affect postural control is still not sufficient to address the decreased postural control observed with aging. Young (YA) and older adults (OA) groups were asked stand on normal floor (NO) and soft foam base of support (FO) with eyes-opened (EO) and eyes-closed (EC) for 3-min. We applied the UCM analysis in frequency space to investigate the effect of age, vision and proprioception on coordination between joints. We distinguished the COM sway into two different frequency bands (e.g., 0~0.1Hz, and 0.1~0.5Hz) to understand whether one frequency band has more effect on postural control with age, vision and proprioceptive control. Results showed that removing visual information does not affect all frequency bands (0~0.5Hz) when both age groups stand on normal floor, however, if subjects stand on foam condition, both variance components of the UCM analysis increase in the PSF (0.1~0.5Hz) frequency band. When subjects stand on an unstable base of support, the system uses more flexible joint coordination (i.e., increase of Vucm) in all frequency bands (0~0.5Hz), accompanied with the increase of the error component of variability (Vort). In conclusion, regardless of any age group, perturbation of proprioceptive information affects COM sway in all important frequency band (0~0.5Hz), but removing visual information effect on the PSF (0.1~0.5Hz) of COM sway, only when subject stand on unstable base of support.

Title: Age-related deterioration in multi-joint coordination increases center of mass acceleration during quiet standing in humans

Abstract: Elderly individuals usually exhibit greater postural sway during quiet standing. In particular, the amplitude of the translational acceleration of the body's center of mass (CoM) has been demonstrated to be much greater in the elderly than in young adults. This study investigated a kinematic mechanism by which CoM acceleration during quiet standing increases with advancing age, given a recent observation that the human quiet standing is a multi-joint motor task. Seven healthy young and eight healthy elderly participants were required to stand quietly on a dual-plate force platform. Angular motions of the ankle, knee, and hip joints were measured in the sagittal plane with an optical motion capture system. As expected, the root mean square (RMS) of the translational CoM acceleration was significantly greater in the elderly than in the young; however, there were no significant differences in the RMSs of the individual joint angular accelerations between the two age groups. The combined variance of the joint angular accelerations (in the angular acceleration space) along a direction in which the variance affects the translational CoM acceleration was significantly greater in the elderly group. These results suggest that changes in multi-joint coordination, rather than increased variability of individual joint motions, are a major cause of the impaired postural steadiness common in elderly individuals.

Title: Deficits in medio-lateral balance control, leg strength and reaction time contribute to the increased risk of falling in persons with multiple sclerosis

Authors: *S. MORRISON[1], J. J. SOSNOFF[2], C. RYNDERS[3];
[1]Physical Therapy, Old Dominion Univ., Norfolk, VA; [2]Kinesiology and Community Hlth., Univ. of Illinois, Urbana-Champaign, IL; [3]Sch. of Med., Univ. of Colorado, Aurora, CO

Abstract: A major health risk faced by persons with Multiple Sclerosis (MS) is the heightened risk of suffering a fall. The reason for this increased risk can often be traced back to a general decline in neurophysiological mechanisms underlying optimal balance control and/or strength. The aim of the current study was to assess differences in falls risk, strength, reaction time (RT), and postural control between fallers with and without MS (MS: n=20, age 43-74 years;

comparison group: n=16, age 60-79 years). Falls risk was measured using the Physiological Profile Assessment (PPA). The PPA is a validated tool which includes tests of vision, sensation, posture, and leg strength. Values from each test are combined to provide an overall risk score with higher scores denoting greater falls risk. Balance was assessed using a force platform under the following conditions: 1) eyes open/firm surface, 2) eyes closed/firm surface, 3) eyes open/foam surface, and 4) eyes closed/foam surface. Simple reaction time was assessed for the hand and foot (15 trials). Results demonstrated that, in comparison to healthy older adults classified as fallers, those persons with MS had a significantly higher falls risk, slower reaction times (with the hand) and weaker lower limb musculature. For the balance measures, persons with MS exhibited greater overall postural sway compared to the comparison group. Interestingly, for the MS group their increased sway was characterized by motion in the medio-lateral (ML) direction whereas the comparison group tended to sway more in the anterior-posterior (AP) direction. Overall, the results confirm that persons with MS are often at a heightened risk of falling, due to the multitude of neuromuscular changes brought about by this disease process. However, the increased ML sway seen for the MS group could reflect a decreased ability to control motion in this direction in comparison to being able to control AP motion. Targeted interventions aimed at improving ML sway in MS may reduce the number of falls in this population.

Title: Effect of assistive force applied to the center of mass during walking on peak plantarflexor kinetics of older adults and an individual with poststroke hemiparesis

Authors: *C. HURT, D. BROWN;
Univ. of Alabama At Birminghma, Birmingham, AL

Abstract: BACKGROUND/PURPOSE: Older individuals and individuals poststroke walk slowly, in part due to decreased plantarflexor power production. Assistive forces applied directly to the lower limb are shown to increase walking speed; however, these forces only affect the

swing phase of gait. Using robotic technology, we developed a paradigm that applies assistive forces to an individual's center of mass, thus allowing undisturbed control of the lower limb throughout the gait cycle. The purpose of this study was to quantify peak plantarflexor power absorption and production while older individuals and an individual with poststroke hemiparesis walked at a comfortable speed while experiencing assistive forces. We hypothesized that assistive forces would result in decreased power production for older adults, and further, that experiencing assistive forces while walking would reduce plantarflexor power asymmetry for the individual poststroke. METHODS: To date, we have analyzed five older individuals (62.4 years±9.9) and one individual poststroke (24 years). The robotic system, coupled with a split-belt instrumented treadmill, allows individuals to self-select walking speeds. Assistive forces of 30%, 60%, 90%, and 120% of the average force generation required to walk at a given speed were provided by altering the amount of average forward-directed force required by the robotic system to move at a particular speed. Individuals maintained their comfortable speed across conditions using visual feedback, and motion capture and kinetic data were collected. RESULTS: We observed a linear trend in fore-aft ground reaction forces, indicating decreased propulsive and increased braking forces with higher levels of assistive force, but no change in power generation. We observed increased power absorption during the first half of the stance phase with increased assistive forces in 4/5 older adults. For the individual poststroke, we noted a decrease in propulsive force generation with 30% and 60% assistive force, followed by an increase at the higher levels. There was also an increasing trend in power absorption of the nonparetic limb. DISCUSSION/CONCLUSION: For older adults, we observed increased power absorption with the addition of assistive forces, which presumably acts to slow gait speed. This may explain the lack of change in power production even though assistance was provided. For the individual poststroke, some moderate level of assistance allowed for more similar levels of power production between limbs; however, the increased power absorption of the nonparetic limb may have contributed the increase in power generation at the higher levels of assistance.

Title: Atypical muscle coordination present in hemiparetic walking as an explanation for impairment

Authors: ***W. BOEHM**[1], K. G. GRUBEN[2];
[1]Univ. of Wisconsin Madison, Madison, WI; [2]Kinesiology, Biomed. Engineering, Mechanical Engin., Univ. of Wisconsin, Madison, WI

Abstract: Following a stroke, humans with hemiparesis often present with impaired walking. Currently published perspectives of how stroke disrupts walking indicate rehabilitation methods should focus on removing kinematic deviations to restore walking, however, therapies centered on this objective have failed to produce the expected improvements for patients. Our lab has shown the plausibility of an alternative explanation for the observed behavior deviations that accounts for both the occurrence of the behaviors as well as the failure of state-of-the-art therapeutic approaches to remove them. Leg muscle coordination deviation has been observed in hemiparetic individuals during a non-balancing task. That deviation, if present during walking, would necessitate compensatory strategies such as the behaviors observed in hemiparetic gait. It was hypothesized that muscle coordination deviation is indeed present during hemiparetic walking. The ground reaction force on the foot (F), which reflects the coordination of muscles crossing the joints of the leg, was measured in stroke patients walking on a custom force treadmill. Deviation in F compared to the participant's non-paretic limb was observed and had consistent character across all eight study participants. These findings suggest that the limb coordination used in hemiparetic walking is altered in a specific manner. Appropriate F is needed to prevent falling down or over, so the atypical F observed is likely to interfere with balancing and could elicit compensatory behaviors. Common therapeutic interventions, such as body weight supported treadmill training, provide balance support while attending to kinematic patterns. The limited success of these therapies, then, may be due to 1) not addressing learning coordination to produce appropriate F and 2) acute kinematic improvements only occurring due to external support reducing the need for compensatory behaviors and not motor learning. These findings suggest that future therapy should be developed to focus on correcting an underlying coordination mechanism rather than only addressing kinematic deviations.

Title: The influence of sensorimotor deficits on unexpected lateral perturbations after stroke

Authors: *V. L. GRAY, C.-L. YANG, S. MCCOMBE WALLER, M. W. ROGERS; Physical Therapy & Rehabil. Sci., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Protective stepping is commonly used as a strategy to recover and stabilize the body when one's balance is disturbed. Increasing the base of support, with a lateral step, is the most effective means, however, crossover and medial steps are often used by people with poor balance. After a stroke, balance recovery is difficult, many falls occur as weight is transferred laterally, with an equal number of falls reported during unexpected disturbances as there are during voluntary movements. The recovery of one's balance is impacted by the residual sensorimotor deficits, such as sensory impairments, paresis and impaired coordination. Little is known about the factors that influence step behavior when perturbed unexpectedly laterally. The purpose was to determine whether cutaneous sensation or isokinetic peak torque of the ankle (plantarflexors (PF) and dorsiflexors (DF)) and hip (abductors (ABD) and adductors (ADD)) has an impact on the step type in response to an unexpected lateral waist-pull. Fourteen community dwelling individuals (> 6 months post-stroke) were tested using a lateral waist-pull system at 3 perturbation magnitudes. Step type was recorded during 18 randomly ordered trials (3 magnitudes x 2 sides x 3 trials). Participants were instructed to react naturally and prevent themselves from falling. The peak isokinetic torque of hip ADD/ABD and ankle PF /DF was measured with a dynamometer. The paretic limb torque was calculated as a percentage of non-paretic torque. Primary outcomes were step type, hip ABD/ADD torque, ankle PF/ DF torque and cutaneous sensation. Cutaneous sensation was assessed on the plantar aspect of the foot with monofilaments. ANOVA was used to examine the differences in primary outcomes by step type. Three step types were used, crossover, medial and lateral step. The perturbation magnitude did not influence the step type. When participants were pulled towards the paretic side, a medial step was commonly used by those individuals with greater deficits in sensation and torque of the paretic ankle PF and hip ABD. A lateral step with the paretic leg was used by those with minor deficits in sensation and paretic hip ABD and ADD torque. When pulled to the non-paretic side, neither sensation nor paretic torque deficits were significantly related to the step type. The results suggested, a medial step is more frequently used to recover lateral balance when pulled towards the paretic side for persons with weaker hip abductor torque and greater sensory impairments.

This may indicate a compensatory strategy that is biomechanically less effective, however, provides a quicker response to stabilize the body.

Title: Compensatory stepping in people with multiple sclerosis

Authors: *D. S. PETERSON[1,2], J. HUISINGA[3], F. HORAK[1,2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Veterans Affairs Portland Hlth. Care Syst., Portland, OR; [3]Landon Ctr. on Aging, Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Our objective was to characterize compensatory stepping in people with multiple sclerosis (MS) in order to identify possible targets for stepping rehabilitation. Fifty four people with MS and 21 age-matched healthy adults underwent forward and backward support surface translations. Slow- “in-place” perturbations (4cm in amplitude, 15cm/s in velocity) and faster- “stepping-response” perturbations (15cm in amplitude, 56cm/s in velocity) were carried out. Body kinematics and shank electromyography were captured. Persons with MS also completed clinical outcomes including the European Database for Multiple Sclerosis Disability Score (EDMUS-DSS) and 25ft timed walk. People with MS exhibited more center of mass movement after perturbations and more pronounced deficits in compensatory stepping characteristics than healthy adults (e.g. step latency, number of steps, anticipatory postural responses). Stepping

deficits in MS were observed primarily during backward stepping and were correlated to clinical outcomes (EDMUS-DSS; 25ft walk time). Both healthy subjects and persons with MS exhibited slower muscle onset time after fast translations compared to slow translations. Compensatory steps are altered in people with MS, however these deficits are more pronounced during backward stepping than forward stepping which suggests backward stepping may be more effective at identifying stepping dysfunction in MS. Step latency and anticipatory postural responses are particularly altered during backward stepping in people with MS and may be appropriate targets for neurorehabilitation.

Title: Preferred sense for static balance in people with diabetes and sensation loss

Authors: R. WILKINS[1], M. MARTIN[1], *S. D. MOTTS[2];
[1]Physical Therapy, Arkansas State Univ., Jonesboro, AR; [2]Physical Therapy, Arkansas State Univ., State University, AR

Abstract: Diabetes can cause neurologic problems such as peripheral neuropathy. People with diabetes can have decreased foot sensation which may lead to balance impairments. Some suggest that people with sensation loss rely more on their visual system than somatosensation for balance. However, diabetes also affects the small blood vessels of the eye (retinopathy), thus vision could be declining along with foot sensation. We hypothesize that people with diabetes and sensation loss continue to rely on somatosensation for balance. This study was approved by the IRB at Arkansas State University. After obtaining consent, we tested balance and sensation in subjects who had diabetes. Subjects were tested for balance on the NeuroCom using the sensory organization test. This test consisted of six different activities that challenged somatosensation, vision, and vestibular senses. This tool determines which sense subjects rely most upon to maintain balance. Subjects were also tested for sensation using Semmes-Weinstein monofilaments on the plantar surface of both feet. Eleven persons with diabetes were tested. All subjects had diminished light touch sensation. Normal sensation is measured by the 3.61 monofilament, which requires 0.4 grams of force to bend. Two subjects had a lack of protective sensation measured by the 5.07 monofilament. The 5.07 monofilament requires 10 grams of

force to bend. The grand mean of monofilament measurements was 4.62. For balance, the sensory organization test was completed using the NeuroCom. The average equilibrium composite score was 78.78 with a range of 37-93. We hypothesized that subjects with diabetes and sensation loss would continue to rely on somatosensation for balance. We found that the majority of our subjects (7 out of 11) relied on somatosensation for balance. There is no correlation between sensation loss and sense preference for balance (Spearman's rho correlation coefficient = -0.060). Understanding the preferred sense used for balance will allow clinicians to develop better treatment plans to help patients with diabetes deal with their neuropathy and balance deficits. One of the limitations of this study was lack of subject participation. For higher level evidence future studies need to be completed with a larger group of subjects. Another limitation to our study is that we did not know which sensation the subjects relied on before they lost sensation. Knowing previous preference of sense (somatosensation, vision, or vestibular) for balance would enable the identification of a change in sense preference as somatosensation is lost.

Title: Determination of the optimal error-augmented feedback schedules for enhancing acquisition of novel motor skills

Authors: *P. N. PARMAR[1,2], J. L. PATTON[1,2];
[1]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [2]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Error-based learning mechanisms are believed to play a key role when acquiring novel motor skills and adapting to perturbations. Recently, Patton et al. (2013) demonstrated how visuomotor learning in human might be enhanced by artificially augmenting the size of perceived mistakes (Error-Augmentation or EA) in point-to-point reaching. They observed nonlinear influence of different EA gains, with faster learning rates for only the intermediate values (gain 2) and higher post-training performances for lower values (gain 1). What has not been explored is the variations in outcome that might be accomplished by allowing the EA gain to change across trials. Here, we demonstrate an optimal control modeling approach to determine the optimal EA gain schedule that best enhances visuomotor learning. We used previously acquired experimental data (Patton et al. 2013) to model a phenomenological process of visuomotor learning using Gaussian process regression. We then used Pontryagin's minimum principle to achieve the optimal EA gain schedules that yield the fastest learning and the highest performance. Our results reveal that EA gain should be nearly doubled (×1.92) throughout training for the fastest learning. However if the highest post-training performance is desired along with the fastest learning, the optimal feedback gain schedule should gradually vary from 1.92 to 1 across training. This study explores a novel approach to optimize skill acquisition for learning to operate machines such as robotic tools, and prosthetics/assistive technologies. It also sheds light on relationships of tradeoffs between speed and final error in motor learning.

Title: Introducing variability to elicit changes in bimanual coordination

Authors: *R. RANGANATHAN;
Dept of Kinesiology, Michigan State Univ., East Lansing, MI

Abstract: The ability to coordinate multiple degrees of freedom is critical to successfully perform everyday motor tasks. This coordination is often disrupted in neurological conditions such as stroke and the goal of rehabilitation is primarily to alter these coordination patterns to improve both functional outcomes and promote biological recovery. Here we look whether introducing variability during practice can successfully change the coordination patterns used to perform a motor task. We recruited 16 college-aged individuals with no history of neurological impairment. The goal of the participants was to make reaching movements with a cursor toward three targets shown on a screen (placed at 40 degrees, 90 degrees and 135 degrees with respect to the horizontal) as fast and accurately as possible. The cursor position was computed as the average location of the individual hands, which meant that the task could be achieved using different contributions of the left and right hands. If participants reached the target within 500 ms, the target turned yellow and they received a pleasant tone. Participants initially completed a baseline block consisting of 90 trials (Baseline 1). After the baseline block, we had a rotation block where we gradually introduced a visuomotor rotation on the right hand in one of two ways -- in the first group of participants, the rotation was always constant at +60°. In the second group of participants, the rotation had the same mean angle of +60° but on any given trial it was variable and picked randomly from a uniform distribution ranging from +30° and +90°. Participants adapted to this rotation for 4 blocks (360 trials) before being gradually brought back to the baseline condition (Baseline 2) again. Results showed that even though we manipulated properties of only one hand, participants adapted to both the constant and variable visuomotor rotations with curved trajectories in both hands. These changes tended to maintain symmetrical motions of the two hands. Moreover, when comparing Baseline 1 to Baseline 2, we observed changes in the contribution in the involvement of the left and right hands in the first few trials, but these differences tended to wash out with more trials. These results suggest that introducing variability resulted in reorganization of bimanual coordination, although the tendency for making symmetric movements persisted. These have implications for stroke rehabilitation where one side of the body is affected.

Title: Inverse identification of motor deficits using movement distributions and mixtures of expert models

Authors: *J. R. LANCASTER[1], F. C. HUANG[2], J. L. PATTON[1];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Motor deficits resulting from stroke and other neurological disorders significantly decrease quality of life and produce a wide variety of unusual motor behaviors in affected patients. Although the clinical literature contains many terms used to describe stereotypical motor behaviors seen in this patient population, characterizations of motor impairments have generally been confined to coarse, ordinal measures of general function such as the Fugl-Meyer Assessment of Motor Recovery after Stroke. Our goal in this work is to determine if idealized models of motor deficits can be identified by observing subjects' movement tendencies. In order to access these tendencies, we have developed a novel experimental paradigm called "free exploration." In this protocol, subjects were instructed to grip a robotic end effector and freely explore the workspace of the robot, varying their movements through many different positions and speeds while trying to avoid repetitive motions. We used healthy control data from one of these experiments to drive a simulation of a planar two-link arm model similar to that used in Shadmehr and Mussa-Ivaldi, 1994, which was used to produce movement distributions. We also developed three idealized models of pathology (weakness, rigidity and spasticity) governed by a total of ten "pathoparameters," which we varied in our simulation to produce "impaired" arm models. By varying each pathoparameter from zero (healthy) to one (maximally impaired), we constructed a "library" of impairment distributions that we could search in order to identify the pathoparameters underlying an unidentified distribution. We discovered using only single-impairment library elements did not give sufficient information to identify models containing combinations of impairments. In addition, as the severity of an impairment increased, more library elements were needed to provide the desired resolution. By implementing these changes, we were able to successfully identify the pathoparameters corresponding to unidentified movement distributions. This is a proof-of-concept for quantitative identification of motor impairments using measurements of movement tendencies. The framework developed here can be used with any computational model of motor impairment and can be generalized to three-dimensional space. We hope that this work will allow better characterization of motor impairments in patients suffering from neurological disorders and that this will, in turn, lead to better customization of treatments.

Abstract: Error feedback is critical for supporting motor adaptation in rehabilitation, sports, piloting, and skilled manual tasks. Error augmentation interventions, in which participants' errors are amplified with either visual or haptic feedback during training has shown success over repetitive practice. Here we show that the statistical tendencies arising from free movement exploration can improve error augmentation with customized training forces that vary across the trajectory. We hypothesized that with error- augmentation customized to individual distributions of reaching errors, or error fields, participants will adapt faster to learning a visual-motor distortion and have greater improvement than participants receiving standard error-augmentation and participants repetitively practicing the task. We tested twenty-one participants using a robotic exoskeleton device restricted to two degrees of freedom. We found that the time constant of decay (measured by number of trials) was significantly lower for the EF Group (12±6 trials) than the EA and Control Groups (32±16 and 36±15 respectively). The change in error was greatest for participants receiving customized forces. These promising results support the need for customization to target subject specific errors.

Title: Analysis of simple motor performance and complex procedural skill in simulated surgery tasks

Authors: *F. C. HUANG[1], D. RUTHERFORD[2], R. RAY[2], F. A. MUSSA-IVALDI[1], C. PUGH[2];
[1]Sensory Motor Performance Prog, Rehabil Inst. of Chicago, Chicago, IL; [2]Dept. of Surgery, Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI

Abstract: Skill in surgery relies on perceptual and motor abilities, but also requires the ability to perform complex sequences and cope with unexpected events. Our goal in this study was to examine how metrics of simple motor tasks can be used to predict performance in complex procedural tasks. Our unique study design included testing with virtual environment stations and clinical scenario simulation (physical apparatuses) stations, allowing for measurement of several types of skills. We devised an interactive virtual environment using haptic devices and video displays, in which participants could perform multiple testing modules, including movements within visual distortion, force perturbation, as well as a simulated tissue puncture task. Our experimental apparatus also featured physical stations that simulated common clinical procedures for a general surgery resident. These included a laparoscopic ventral hernia (LVH) repair, bowel anastomosis, central venous catheterization, and bladder catheterization. We considered several metrics that reflected basic sensorimotor capabilities, for example, overall movement accuracy, task completion time, and maximum speed. We also considered high-level descriptions of behavior, including coping with changes in task conditions and decision-making. Our preliminary analysis has focused on performance in the virtual environments tests. We found that surgery residents (n=47) were sensitive to changes in specific task conditions, including the starting location of movement, heading angle of movement, the degree of visual distortion, and coping with changes in the force threshold of the puncture task. Interestingly, the changes in movement heading and starting location were significant factors across different tasks. The identification of these key metrics of motor performance will allow for analysis of the relationships between skills in simple motor tasks versus complex procedural tasks. Future work will also consider how such metrics can be used to predict clinical performance in terms of error recovery and decision-making processes. Our findings will help formulate methods not only for evaluation of surgical performance, but also for targeting specific skill deficits in surgical trainees.

Title: Methods to train a Kalman filter to decode body motions into the control of a 2D cursor

Authors: *I. SEÁÑEZ-GONZÁLEZ[1], C. PIERELLA[2], E. THORP[1], A. FARSHCHIANSADEGH[1], F. ABDOLLAHI[1], F. MUSSA-IVALDI[1];

Abstract: Despite progress in the field of assistive devices for people who suffered a spinal cord injury (SCI), most of the current devices to control computers and wheelchairs are set in place to require as little physical effort from the user as possible, and little attention has been paid to maintaining and strengthening the neural and muscular resources that survived the injury. We recently developed a body-machine interface (BMI) that allows users to control a 2D cursor by engaging the majority of the motor system that remained intact after paralysis. A calibration paradigm where unimpaired human subjects followed a cursor on a screen as if they were controlling it with their shoulders was used to generate a map between shoulder motions and cursor kinematics. This map was based on Kalman's method for state estimation and we used it to derive the desired cursor coordinates from upper-body motions. Although this study demonstrated promising results on 2D cursor and virtual wheelchair control by a BMI, the design of the experiment instructed the same specific movements in the calibration phase for all subjects in order to reduce variability introduced by different body-to-cursor maps. People with high-level SCI will have individual-specific residual movements, so in the application of this BMI,

they must have the ability to choose their own movements to control the cursor. We expect that the chosen map will have an effect on task performance. However, we still don't understand what characteristics make it a good map vs. a poor map. In this study, we instructed subjects to follow the cursor with their shoulders using three distinct methods. After familiarizing themselves with each map, subjects performed one block of a center-out reaching task. We determined how the different characteristics of each map (orthogonality, reconstruction, mutual information) correlated with different performance metrics (movement time, variability, path length, minimum jerk) during the reaching task. Having a method that allows us to predict whether a subject's chosen map will result in good performance is advantageous to the subjects and their therapists. This knowledge allows us to make recommendations to the subject_based on their residual ability_that will maximize their performance. Moreover, having a clear understanding of the relationship between a map and performance can serve as a test bed for the field of body and brain-machine interfaces to experiment on alternative mapping algorithms and predict their performance offline.

Title: A predictive model pointing to speed for post-stroke neurorehabilitation

Authors: *Y. ABDEL MAJEED[1], J. L. PATTON[2,3];
[1]Bioengineering, Univ. of Illinois At Chicago, Chicago, IL; [2]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL; [3]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: We took up the challenge of using robotic devices to assess and predict clinical recovery after stroke. Our lab proposed a new method for teleoperation through a bimanual task that uses the healthy arm to train the affected arm. We extracted features from the point-to-point reaches and ran a forward model-selection algorithm, which considered these features along with all demographic information we had on the first day of the study. Our goal was to predict the

change in their clinical performance (as measured by their Fugl-Meyer motor ability score). Our model results show that there is an affinity to maximum speed as the feature of choice for predicting changes in clinical performance. Further analysis revealed that maximum speed was negatively correlated, so that patients moving at lower speeds on the first day tended to have higher Fugl-Meyer change. Such multi-featured models not only provide prognostic tools, but also may also guide therapy by shedding light on the areas that may improve the most.

Title: Effect of intermittent isometric contractions on transcranial direct current stimulation induced alterations in force generating capacity

Authors: ***E. P. WASHABAUGH, IV**[1,2], L. SANTOS[1], E. CLAFLIN[1], C. KRISHNAN[1,2,3]; [1]Physical Med. and Rehabil., [2]Col. of Engin., [3]Col. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Transcranial direct current stimulation (tDCS) is a noninvasive brain stimulation technique that is capable of altering motor cortical excitability in a polarity-dependent fashion. Our previous work has shown that a single bout of anodal tDCS significantly increases the force generating capacity of the upper-extremity muscles. Similar findings have been reported in the lower extremity, showing enhanced force production of knee extensor muscles following anodal tDCS. However, when tDCS is concurrently combined with another excitability-increasing event, such as motor practice, interference (aka metaplasticity) may occur that hinders tDCS dependent neuroplastic effects. In this study, we explored the interaction and longitudinal effects of anodal tDCS on force production when paired with a motor learning task. We also tested the time-course of interference following tDCS intervention. For the experiment, nineteen healthy subjects participated in two experimental sessions that were separated by a week. On one session subjects received conventional anodal tDCS over the quadriceps hotspot (determined using transcranial magnetic stimulation) while they were at rest, while during the other session they received tDCS paired with a motor learning task that required them to intermittently perform a

low-level (5% of maximum) force matching task using their knee extensors. The order of the testing conditions was randomized a priori. In both sessions, the subject's maximal voluntary isometric torque of the knee extensor muscles was measured both before and for up to a half hour following the stimulation using a biodex isokinetic dynamometer. Our preliminary results indicate that, when tested immediately following tDCS, a low-level force matching task interferes with the normal force enhancing effects of anodal tDCS, resulting in a 9.3 N-m decrease in torque output when compared with conventional tDCS. However, this interference effect was short-lived and subjects started to show a trend towards greater torque production within 10 minutes after stimulation. At around 25 minutes, there was virtually no difference in the tDCS mediated changes in maximum voluntary torque values between the two conditions (2.0 N-m). These results suggest that a low-level motor training task during tDCS can interfere with the force enhancing capability of anodal tDCS; however, only for a short-period of time.

Title: The "queen" computational model: learning new distributions through costly encounters

Authors: *A. K. SHAH[1], J. L. PATTON[2];
[1]Univ. of Illinois @ Chicago, Chicago, IL; [2]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Movement variability can be a problem in human performance, especially in the recovery following stroke or other neural trauma. Excessive variability can cause people to exceed task limits and cause danger or discomfort to the individual, such as falls (Hausdorff et al., 2001), accidents in the workplace (Branton, 1970) or other costly events. As a result of neural trauma, people need to learn and shift their distributions of movement patterns to avoid costly events because their limits have been altered. Few models predict the learning process and how humans reshape their distributions from costly encounters. Here we present a novel motor controller inspired by the Multi-Armed Bandit (Koulouriotis and Xanthopoulos, 2008) paradigm of explore and exploit. In this case, we use the principle of explore and avoid. This motor

controller develops a motor plan to probabilistically avoid prior experienced regions of high cost that are represented using radial basis functions (Atkeson et al., 1997). We compare the controller's performance in an environment similar to that of healthy subjects who performed a complex interception task in a recent experiment. During the middle portion of the experiment, we created a high-cost and zero cost region of space to move. Subjects reacted by constraining their distribution of movements within the zero cost region. Our motor controller produces behavior similar to that of subjects who perform this task and other tasks when exposed to the invisible boundary constraint. The model predicts *distributions* and learning. With further development, this controller can form a new class of motor controllers for robotic control and predictions of human control.

Title: Optimal design of a passive planar multi-directional resistive robot for upper-extremity rehabilitation

Authors: A. GWOZDZIOWSKI[1,2], E. P. WASHABAUGH[1,2], C. D. REMY[2], *C. KRISHNAN[1,2,3];

[1]Physical Med. & Rehabil., [2]Col. of Engin., [3]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Many patients with brain injury (e.g., stroke) experience debilitating loss of upper-limb function. Several lines of research indicate that a large amount of goal-directed reaching movements are critical to promote brain plasticity and recovery. Conventional therapy, however, is often limited due to decreasing third-party coverage. Rehabilitation robots can assist in meeting the increasing demand for therapy; however, existing robots are often large and expensive. Further, because of the importance of muscle strength in recovery of motor function, portable robots that are capable of providing functional strength training could greatly amplify therapy. The portability and safety of a resistive robot can be enhanced if a dissipative passive damping system could be used instead of active actuators. However, there are many possible options for planar manipulandums - though, there is an inherent trade-off between design complexity (i.e., number of links) and steerability. Hence, the purpose of this study was to perform a theoretical analysis verified with simulations to obtain an optimal solution for a passive 2D planar resistive robot. We first examined a 2-link 2R planar manipulator with magnetic braking using theoretical analysis derived from the principle of virtual work. Our analysis indicated that an exact solution was impossible due to the inability to achieve independent control of the x and y components of the resistive force. We then performed a simulation analysis to simulate the forces experienced during a straight-line trajectory reaching in order to determine the least-error solution. We found that the angle between least-error and desired forces was substantially large (frequently $\geq 45°$), thus ruling out the possibility of a single 2R manipulator. We then examined a 4-link 4R planar manipulator consisting of two 2-link 2R manipulators connected at the end effector. This model was chosen due to its improved steerability, as demonstrated by Gao et al. We determined a system of equations relating the joint braking to the workspace force field. The braking coefficients were then found using the Moore-Penrose pseudo-inverse of the system. Solutions in the nullspace of the system were then added to the resulting solution until all braking coefficients were positive. Our simulations indicated that the computed braking coefficients provided the desired resistance force across the intended workspace. Our preliminary analysis also indicates that control effort could be improved using additional parallel 2R manipulators. Our results have meaningful implications for the design of passive planar robots. Grants: UM FIGs grant, UMOR grant, NIH R01EB019834

Title: Real-time feedback of estimated intent in the presence of random disturbances increases operator performance and reduces arm stiffness

Authors: *J. R. HOROWITZ[1,2], T. MADHAVAN[2], C. MASSIE[2], J. L. PATTON[2];
[1]Rehab Inst. of Chicago, Chicago, IL; [2]Bioengineering, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Unstable and uncertain environments are an everyday problem that affects piloting and input devices in human-machine interaction. Here we experimentally evaluate intent feedback (IF), which estimates and displays the human operator's underlying intent in real-time. IF is a filter that combines a model of the arm with position and force data to determine the intended position. Subjects performed targeted reaching motions while seeing either their hand position or their intent estimate as a cursor while they experienced white noise forces rendered by a robotic handle. We found significantly better reaching performance during force exposure using the estimated intent. Additionally, IF reduced estimated arm stiffness to about half that without IF, indicating a more relaxed state of operation. While visual distortions typically degrade performance and require an adaptation period to overcome, this particular distortion immediately enhances performance. In the future, this method could provide novel insights into the nature of control. IF might also be applied in driving and piloting applications to best follow a person's desire in unpredictable or turbulent conditions.

Title: Customized force field training based on stroke survivors' individual movement distributions

Authors: *Z. WRIGHT[1,2], J. L. PATTON[1,2], F. C. HUANG[2], E. LAZZARO[2];
[1]Bioengineering, Univ. of Illinois At Chicago, Chicago, IL; [2]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Variation in upper extremity motor impairments among stroke survivors creates challenges for the design of robot-assisted therapies. One approach to enhance treatment is to customize based on individual assessments of motor capabilities. However, current strategies are limited by the use of traditional assessments (e.g. Fugl-Meyer, goal-directed performance) for informing customization. Our approach characterizes typical motor behavior through distributions of self-directed motor exploration. We then design unique force fields that push participants towards their neglected movements in the velocity domain. In this study, we investigated how stroke survivors' (n = 6) movement patterns evolve with customized force field training and compared this to a control group that trained without forces (n = 6). Our results showed that both training groups improved Fugl-Meyer UE scores (2.5 ± 1.0 point and 1.5 ± 0.7 point improvements for the force field group and control group, respectively) and increased their movement capabilities in the velocity domain (104.1 ± 28.1% and 169.8 ± 101.4% increases for the force field group and control group, respectively). These results provide preliminary evidence that patient-specific force fields could be developed into a treatment that expands movement capabilities. To our knowledge, this study is the first to directly link assessments to therapy.

Title: A computational model of learning in a body-machine interface

Authors: *F. A. MUSSA-IVALDI[1,2], C. PIERELLA[1,3], M. CASADIO[3];
[1]Rehabil. Instiotute of Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL; [3]Univ. of Genoa, Genoa, Italy

Abstract: In the human motor system there is an evident imbalance between the large number of degrees of freedom available to control a particular movement and the smaller number of variables that are needed to specify and plan that movement. Body-machine interfaces (BMI) display the same type of imbalance as they map redundant set of movement related signals into control variables. Redundancy provides the disabled BMI users with the opportunity to identify a comfortable and natural subset of their residual motion abilities that is optimal, or at least adequate, to operate an external device. Understanding the mechanisms that lead to motor function reorganization when subjects learn to use a BMI is crucial to improve its design in terms of usability and adaptability. We used a state-space model to represent how the interface users through practice learn to form an inverse internal model of the BMI mapping. This internal model is the user's representation of the cursor-to-body map, that is a right-inverse of the map implemented by the interface from body configurations to cursor positions. The BMI performs a dimensionality reduction by mapping different body configurations into the same cursor position. Hence, users face the task of learning an ill-posed inverse problem. We represented the inverse internal model used by the subject at any time as a state vector that changes under the influence of the current reaching error in the low-dimensional task space. At every reaching block we calculate the gradient of the reaching error and with that we update the state. Preliminary results show that the data simulated with the model and the empirical data have a similar trend. In particular, we focused on the error in the task space, calculated as the distance of the cursor after 1 second from the target to reach, and the similarity of the inverse map with the forward map, calculated as the Euclidean norm of their product. The error in the task space decrease as the subject performs more reaching movements. Concurrently, the internal model of the subjects becomes more stable. Understanding the dynamics of human motor learning in a BMI is of critical importance for co-adapting the interface to the individual evolving abilities of its user.

Title: Evaluation of the efficacy of body machine interface for rehabilitation of spinal cord injury survivors: a pilot study

Authors: *C. PIERELLA[1,2], A. DE LUCA[2], F. CERVETTO[2], E. TASSO[2], S. GAMBA[3], L. LOSIO[3], A. VENEGONI[3], S. MANDRACCIA[3], I. MULLER[3], A. MASSONE[3], F. A. MUSSA-IVALDI[1,4], M. CASADIO[2];
[1]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [2]Dibris, Univ. of Genoa, Genoa, Italy; [3]Unità Spinale Unipolare, Ospedale Santa Corona, ASL2 Savonese, Pietra Ligure, Italy; [4]Biomed. Engin., Northwestern Univ., Chicago, IL

Abstract: A body-machine interface (BMI) is a powerful instrument that allows people with severe motor impairments to access assistive devices, perform functionally relevant and/or entertaining activities while concurrently focusing on the achievement of rehabilitative goals. BMIs map the user's residual mobility onto a control signal for external devices, such as a cursor on a computer screen. The dimensionality of the signals coming from the body is higher than the one of the device control variables. This is a critical feature that allows us to combine assistive and rehabilitative purposes because the map we created between body and device spaces is not unique and it can be modified in order to gradually push the subjects to modify specific characteristics of their movements. Previous studies showed improvements in the clinical tests used to measure strength and mobility at the upper body of spinal cord injured (SCI) survivors. However, the instrumental evaluations to quantify changes occurring pre and post rehabilitative treatment are still limited. Here, we present a method for better characterizing the residual motor abilities following a spinal cord lesion and a possible technique to evaluate motor improvements after a rehabilitation treatment based on the use of the BMI. The evaluation method consists on acquiring kinematic and electromyographic (EMG) data from the upper body during the execution of some functional tasks, like reaching for an object placed at different locations in space, or moving an object between two locations. In this preliminary study we recruited two cervical SCI subjects and 2 control subject of matching age. Only SCI subjects practiced with the BMI 3 times per week, for 5 weeks. From the preliminary data we evaluated task completion time, movement speed and smoothness. We were also able to identify strategies that subjects used to perform different tasks using particular muscle activation patterns, before and after the BMI treatment. After the training SCI subjects improved in the functional tasks in terms of smoothness and completion time. They also exhibited a change in muscle activations used to execute the tasks. While we should emphasize again that these are preliminary observations, the patterns of EMG activations in SCI participants at the end of training had a higher similarity with

those seen in the control subjects. The kinematic and EMG analysis used in this study allowed us to identify and describe some strategies used by SCI subjects during the completion of functional tasks. Moreover it offered a tool for a deeper evaluation of possible changes and improvements that can occur during a rehabilitative treatment through the use of the BMI.

Title: Kinetic energy optimization in object manipulation

Authors: *A. FARSHCHIANSADEGH[1], R. RANGANATHAN[2], F. MUSSA-IVALDI[3]; [1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Michigan state university, East Lansing, MI; [3]Northwestern Univ., Chicago, IL

Abstract: Studies of reaching movements in the horizontal plane have found that straight line trajectories are persistent motor behaviors that are robust to different kinematic and dynamic perturbations. The results of these studies suggest that there are kinematic costs associated with the trajectory formation. However, in the majority of these studies a circular cursor was employed to represent the system under control and the dynamic perturbations were typically in the form of force fields. Here, we suggest that such a simple and symmetric visual representation creates a strong bias towards Euclidean trajectories. We asked human subjects to reach different targets while holding a simulated mechanical linkage. The mechanical properties of this system were set so that the paths of least action were substantially different from straight line paths. Our results demonstrate that subjects exploited the passive dynamics of the manipulated object and moved along curvilinear trajectories that matched the path of least action, which was also the path of minimum kinetic energy of the manipulated object. However, this behavior was contingent upon receiving concurrent and consistent visual and haptic information of the system under control. When either form of feedback was absent or when visual and haptic information

were not mutually consistent, subjects reverted to generating the default pattern of smooth and rectilinear movements.

Title: Spinal cord injury survivors take control with a novel Body-Machine Interface

Authors: ***F. ABDOLLAHI**[1,2], A. FARSHCHIANSADEGH[2,1], C. PIERELLA[1,3], I. SEÁÑEZ-GONZÁLEZ[2,1], E. THORP[2,1], M.-H. LEE[4], R. RANGANATHAN[4], J. PEDERSON[1], D. CHEN[1], E. J. ROTH[1,2], M. CASADIO[3], F. A. MUSSA-IVALDI[1,2];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL; [3]Univ. of Genoa, Genoa, Italy; [4]Michigan State Univ., East Lansing, MI

Abstract: This study tested the use of a customized body-machine interface (BMI) for enhancing functional capabilities in persons with cervical spinal cord injury (cSCI). The interface allows cSCI survivors to operate external devices by reorganizing their residual motion abilities. Eight cSCI participants wore a custom-made garment with motion sensors placed on the shoulders. Signals derived from the sensors controlled a two-dimensional computer cursor. Principal component analysis was used to extract the combinations of sensor signals that best captured each participant's capacity for controlling a computer cursor. Participants practiced with the BMI for 24 sessions over 15 weeks, by practicing three tasks: reaching, typing and game playing. Learning and performance were evaluated by quantifying the movement errors, smoothness and timing, in addition to performance metrics specific to the game and typing tasks. Through practice, participants were able to reduce the movement time ($p = 0{\cdot}002$) and the final error ($p<0{\cdot}001$) in the reaching task. All participants became more skilled in the typing task and in game playing, as the pong hit rate ($p = 0{\cdot}006$) increased significantly with practice. Cursor trajectories became shorter and straighter -i.e. smoother- in most participants. The results provide

proof-of-concept for the customized BMI as a means for people with absent or severely impaired hand movements to control assistive devices that would be normally manually operated.

Title: Differences in motor skill learning across lifespan

Authors: ***M.-H. LEE**[1], A. FARSHCHIANSADEGH[2];
[1]Michigan State Univ., East Lansing, MI; [2]Northwestern Univ., Chicago, IL

Abstract: When is the best time to learn a new motor skill? Although it is commonly thought that children have superior abilities when it comes to learning skills, this question is difficult to answer using real-world motor tasks because differences in learning abilities are also confounded by physical differences in body size and body composition. Therefore, we sought to minimize these physical confounds by using a novel virtual task and investigate if there were differences in learning a novel motor task across lifespan. We examined differences in learning to operate a novel body-machine interface (BoMI) task across a continuum of the lifespan -- between 9 and 75 years of age. Inertial measurement units were attached to the upper body and these movements were mapped to the position of a computer cursor. The goal of the participants was

to learn to move the cursor in a center-out reaching task to 8 different targets. Given that the body space is higher dimensional than the task space, we used principal component analysis (PCA) to map the first 2 principal components to the task space. Importantly, this mapping ensured that each participant was capable of doing the task with his or her own movement abilities. There were 160 trials in total toward 4 targets during practice session. Three generalization tests were interleaved during learning (pre, during and post-practice), where participants reached toward all 8 targets. These tests were used to evaluate performance and learning with practice. Overall, the results showed an inverted-U shape with the young adults showing the best performance. Children and elderly tended to have longer movement times (~2x longer) compared to young adults. The analysis of trajectories also showed that children and elderly had less ability to control the cursor, and that children and elderly participant also exhibited greater variability between individuals, which was manifested in the large within group variance. Overall, these differences suggest that young adults are better at learning a new motor task compared to both children and older adults, and this may reflect the time course of development of neural mechanisms for learning.

Title: Is signal dependent noise an effective tool for shaping motor learning?

Authors: *E. B. THORP[1,2], F. A. MUSSA-IVALDI[3,2,1];
[1]Sensory Motor Performance Program, Rehabil. Inst. of Chicago, Chicago, IL; [2]Biomed. Engin., Northwestern Univ., Evanston, IL; [3]Physiol., Northwestern Univ., Chicago, IL

Abstract: The human motor system often must control a high number of degrees of freedom to accomplish a low dimensional task. From this there often exist infinite movement patterns or control policies for completing a task. How and why people choose their movement patterns

when facing this redundancy is not totally clear. One current hypothesis is that people choose movement patterns that maximize task performance in the face of motor noise. Many studies have demonstrated that motor noise is signal dependent, and thus scales with increased contractions. Theories such as the minimum intervention principle suggest that people select movement patterns that are optimal with respect to minimizing the motor noise that directly impacts task performance, while ignoring motor noise which is irrelevant to the task. Here, we asked the question whether we could use artificial signal dependent noise to shape peoples' control policies when learning a novel redundant motor task. Subjects learned to control the orientation of their two hands, as measured by roll and pitch of each hand, to control a two dimensional cursor on a screen. They were required to make coordinated hand movements that would move the cursor between specific target locations. During the learning process, we imposed artificial signal dependent noise on each of the input channels. Specifically, the variance of the noise imposed on each input channel was proportional to the magnitude of the signal from that channel. Thus, different movement patterns produced differing levels of cursor noise, which directly affected task performance. This paradigm allowed for the calculation of a single optimal policy, the movement pattern that minimized cursor noise. We found that even in the presence of artificial signal dependent noise, subjects were able to learn to control the interface quickly and effectively, as demonstrated by decreased movement time and increase smoothness through training. We did not, however, find that all subjects converged to the optimal control policy during learning. Overall this work presents a framework for looking at how individuals select an appropriate control policy when learning to resolve redundancy in a novel motor task.

Title: The dynamics of kinematic, kinetic and electromyography parameters of competitive exercise bench press powerlifting in athletes with disabilities

Authors: *A. B. TREMBACH, D. LEVCHENKO, I. FEDOROVA, I. PAVELYEV, I. KOMLEV, Y. SHKABARNYA;
Univ. of Physical Educ., Krasnodar, Russian Federation

Abstract: Aims: Spatial-temporal parameters of competitive exercise bench press powerlifting is an objective indicator of sport technique and are due to the specifics of the pathology in athletes with disabilities. However, the dynamics of the external and internal structure of this exercise is not sufficiently studied. The aim of the study was to to structure sequential time intervals of bench press on the kinematic, dynamic and electromyographic characteristics in athletes with disabilities. Methods: The participants were 20 disabled lifter-athletes of high qualification. Biomechanical parameters and EMG of symmetrical M. Pectoralis major, Latissimus dorsi, Biceps and Triceps brachii during bench press were recorded by complex in powerlifting on the basis of power coordinated platforms making an independent ballistograms (kinetic) and video motion (kinematic). Results: An analysis of the dynamics of speed, acceleration, displacement barbell and ballistogram, found that the significant time intervals of exercise were lowering barbell to the chest, hold it and press. Lowering barbell on the chest included 2 periods and 4 phases. The first period - dispersal barbell had two phases: from the beginning of barbell down to the maximum acceleration, ballistogram (1) and from the development of maximum acceleration, ballistogram to the maximum speed of development (2). Second period - brake barbell had two phases: from the development of the maximum speed to the minimum acceleration, ballistogram (1) and from the minimum speed to the termination of the movement of the barbell (2). Hold the barbell on the chest. Bench press had 2 periods and 4 phases too. First period- acceleration barbell had two phases: from the beginning of movement of the barbell up to the maximum acceleration, ballistogram (1) and the maximum acceleration, ballistogram of the barbell to the maximum speed. In the second period - brake barbell had two phases: from of the maximum speed of the barbell to speed up the development of the minimum (1) and the minimum acceleration to lock the barbell at arm's length (2). The values of the spatial-temporal parameters of the bench press mainly due to the activity of M. Pectoralis major, Latissimus dorsi, and were less M. Biceps and Triceps brachii. Maximum values and expressed synchronization of acceleration, ballistogram and square EMG M. Pectoralis major, Latissimus dorsi detected in first period- acceleration barbell. Duration phase and the values the acceleration and ballistogramm efforts in each of them are individual markers that characterize the level of training of disabled athletes and sports results, respectively.

Abstract: Direct cortical control of hand and arm neuroprostheses has long been posited as a key achievement for intracortical brain-computer-interfaces (iBCIs). As part of the Braingate2 Pilot Clinical Trial, Case Western Reserve University / University Hospitals (Cleveland, OH) is investigating the use of iBCIs to control Functional Electrical Stimulation (FES) neuroprostheses for restoring arm and hand movements to persons with chronic high cervical spinal cord injury (SCI). One individual with C4 level SCI was implanted with two 96-channel microelectrode arrays in the precentral gyrus. The participant has demonstrated robust modulation of single-unit and high frequency spike power (> 300 Hz) sufficient to achieve, using a virtual anthropomorphic limb in stereoscopic space, two and three dimensional control of the wrist position, four dimensional control of the shoulder and elbow joints, and one or two dimensional control of pronation/supination, wrist flexion/extension, and hand aperture. We subsequently implanted 16 percutaneous fine-wire electrodes into the contralateral upper extremity for direct

stimulation of muscles of the arm and hand. To enhance muscle resistance to fatigue, we implemented preprogrammed FES exercises patterns for whole hand grasping (lateral grip), elbow flexion/extension, and shoulder horizontal flexion/extension. During FES exercise, expected channel-specific stimulation artifact was observed on the cortical electrodes. We utilized multiple strategies for reducing and/or eliminating the stimulation artifact, including blanking, signal post-processing, and varying the size and location (including surface vs. percutaneous) of the anode. The participant demonstrated cortical control of the percutaneous FES system in performing a grasp force tracking task, as well as cued single-joint and multi-joint arm reaches. These early indicators of success pave the way for a fully implanted iBCI+FES system to restore complete arm movements to persons with chronic paralysis due to high cervical SCI.

Abstract: Dimensionality reduction techniques, applied to neural spike trains, have revealed structure in the motor cortex of non-human primates (NHPs, e.g. Yu et al, 2008, Sadtler et al, 2014, Vargas-Irwin et al, 2015). Local field potential oscillations have been shown to contain information about attempted or imagined movements in NHPs (e.g. Murthy and Fetz, 1992, Sanes and Donoghue, 1993) and people with tetraplegia (e.g. Perge et al, 2014). We propose a method to identify frequency bands of interest in local field potential activity recorded intracortically with a multielectrode array placed in motor cortex. First, we compute LFP power across time using multi-taper spectral analysis. We then apply factor analysis and k-means clustering to these power spectra and compute the distance between clusters in the frequency domain. We apply this method to data collected from nine people with tetraplegia during a 2D point-and-click cursor control task. These include two people with tetraplegia resulting from spinal cord injury (S1 and T8), two people with tetraplegia and anarthria resulting from brainstem stroke (S3 and T2), and five people diagnosed with amyotrophic lateral sclerosis (T1, A1, T6, T7, and T9). The analysis recovers the prominence of the beta band (10-40 Hz) and suggests differences in beta activity between participants. The results point towards new ways to interpret local field potentials in motor cortex, including in comparisons across task contexts and between etiologies of paralysis.

Abstract: Brain-computer interfaces (BCIs) aim to restore communication and independence to people with severe motor disabilities by translating decoded neural activity directly into control of a computer cursor. However, nonstationarities in recorded brain activity can degrade the quality of neural decoding over time. Periodically interrupting ongoing use of the BCI to perform

decoder recalibration tasks would be time-consuming and impractical. Previously, we showed that typing performance in a self-paced, neurally controlled point-and-click communication interface can be maintained for hours, despite underlying signal nonstationarities, without requiring the user to pause to perform disruptive calibration tasks. This was accomplished by incorporating 3 decoding software innovations that address different aspects of neural signal nonstationarities: feature mean and variance tracking, decoder output bias correction, and retrospective target inference-based (RTI) decoder calibration, which uses data acquired during practical, ongoing BCI use to recalibrate the decoder. The current study extends self-calibration of the BCI to multiple days. On day 1, a participant diagnosed with amyotrophic lateral sclerosis (ALS) in the BrainGate2 clinical trial (participant T6) performed the usual open-loop and closed-loop decoder calibration center-out tasks with presented targets, and then proceeded to self-paced typing. Then, on days 3, 5, 14, 35, and 42, with the aid of feature tracking and bias correction, the participant was able to proceed directly into self-paced typing using the previous session's last directional and click decoders. The decoders were updated periodically over the course of the day using data acquired during typing, without ever requiring the participant to perform explicit calibration tasks again after day 1. Multi-day self-calibration was also replicated in a 2nd participant with ALS (T9). By eliminating the need for the user to perform daily calibration tasks with prescribed targets, despite nonstationarities in the underlying neural signals, this approach advances the potential clinical utility of intracortical BCIs for individuals with severe motor disability.

Title: User state-based modulation of intracortical activity: distinguishing the idle state

Authors: *D. LESENFANTS[1,2], J. SAAB[1,2], B. JAROSIEWICZ[3,4,2], D. M. BRANDMAN[3,2], B. SORICE[5], A. A. SARMA[1,4,2], E. N. ESKANDAR[6], S. S. CASH[5,7], J. D. SIMERAL[4,1,5,2], J. P. DONOGHUE[4,3,1,2], L. R. HOCHBERG[4,1,5,7,2];
[1]Sch. of Engin., [2]Inst. For Brain Sci., [3]Dept. of Neurosci., Brown Univ., Providence, RI; [4]Ctr. for Neurorestoration and Neurotechnology, Rehab. R&D Service, Dept. of VA Med. Ctr., Providence, RI; [5]Neurol., [6]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [7]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Background: Brain-computer interfaces based on intracortical recordings (iBCI) have allowed people with tetraplegia to reliably control a computer cursor on a screen and perform actions with a robotic limb (Hochberg et al., 2006, 2012; Simeral et al., 2011; Kim et al., 2011). Long-term goals of this technology include the ability to switch automatically between volitional neural control of assistive technologies and idle time ("asynchronous" BCI). Idle state detection has been examined in EEG-based BCI (Zhang et al., 2007; Hasan et al., 2011; Lee et al., 2015). Here, we report the ability to distinguish motor cortical activity in task-related blocks from idle inter-task periods in an individual with tetraplegia using an iBCI. **Methods**: The participant in this study (T9) was a 52-year-old man in the BrainGate2 trial with amyotrophic lateral sclerosis. During research sessions, neural signals were recorded from two 96-channel microelectrode arrays (Blackrock Microsystems, Salt Lake City, UT) implanted into his motor cortex. Average multi-unit spike rates were extracted for each channel during centered-out-and-back radial-8 task blocks and during inter-task periods from two sessions (session 1: 2015.04.22; session 2: 2015.04.23). Channels with statistically significant changes in spike rates between task- and inter-task periods were identified (Wilcoxon signed rank test, $p<0.01$) and further quantified (e.g., spike rate modulation in %). **Results**: Spike rate modulation between a block and consecutive inter-block period could be visually observed on many channels. Of the 192 channels, 29 (session 1: 17 on lateral array, 12 on medial array) and 56 (session 2: 48 on lateral array, 8 on medial array) showed a spike rate decrease from task block to consecutive inter-block period (mean±std; session 1: lateral array, -15±4%; medial array, -14±3%; session 2: lateral array, -18±9%; medial array, -15±6%). Only 1 (session 1; lateral array) and 4 (session 2; 2 on each array) channels illustrated a spike rate increase (mean ± std; session 1: lateral array, 18±0%; session 2: lateral array, 33±38%; medial array, 10±1%). **Conclusion**: In an individual with tetraplegia, intracortical multi-unit activity exhibited statistically significant spike rate changes

between iBCI task periods and intervening idle periods. This suggests that the user's active engagement with the iBCI system could be distinguished from idle periods. Detecting this engagement could provide greater independence and utility using iBCI communication and permit people with severe motor disabilities to asynchronously control assistive devices.

Title: Comparing coordinate frame representations in human primary motor cortex for control of reaching

Authors: ***D. YOUNG**[1,2], R. F. KIRSCH[1,2], L. R. HOCHBERG[3,4,6,7,5], A. AJIBOYE[1,2]; [1]Case Western Reserve Univ., Cleveland, OH; [2]Louis Stokes Cleveland Dept. of Veterans Affairs Med. Center, FES Ctr. of Excellence, Rehab. R&D Service, Cleveland, OH; [3]Dept. of Veterans Affairs Med. Center, Ctr. for Neurorestoration and Neurotechnology, Rehab. R&D Service, Providence, RI; [4]Sch. of Engin., [5]Inst. for Brain Sci., Brown Univ., Providence, RI; [6]Dept. of Neurol., Massachusetts Gen. Hosp., Providence, RI; [7]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Single neuron activity from motor cortices has been shown to encode various parameters of natural arm movements, including global arm endpoint position, movement direction, movement speed, and joint velocities. Studies of human intracortical closed-loop control have decoded extrinsic Cartesian endpoint velocities for cursor and robotic control (Hochberg, et al, 2012, Collinger, et al, 2013). However, human arm movements may be better represented and/or controlled in a body-centric joint velocity coordinate frame. Additionally, a decoding scheme in joint velocity space is similar to control schemes implemented in current functional electric stimulation (FES) devices, and hence may be more easily implemented into existing upper extremity prosthetics. In this work, we compared cortical control of a multi-joint anthropomorphic virtual arm using a Cartesian endpoint velocity decoder to a joint velocity decoder. We hypothesized that because evidence of both coordinate frames exist in M1 neural activities, the participant would be able to perform closed-loop control of the virtual arm, though with differing rates of learning of the two decoders. One participant with C4 level spinal cord injury was implanted with two 96-channel intracortical electrode arrays in the dominant precentral gyrus. Using 3D visualizations, the participant watched and controlled coordinated virtual arm movements in a standard center-out reaching task. The user practiced controlling the arm for multiple weeks using two separate control schemes, a 3D endpoint velocity and a 4D proximal joint velocity decoding paradigm. Endpoint and joint velocity decoders were each built in open-loop, followed by standard closed-loop recalibration. The participant trained in each decoding scheme separately using multiple workspaces to learn and improve performance. We then tested the user's ability to control the virtual arm in Cartesian and joint velocity space on the same day and in the same 3D reaching task. Our participant achieved similar performance using both decoders, hitting above 80% of the targets in both decoder interfaces, but had lower path efficiencies when controlling in joint velocity space. Our work suggests that a paralyzed user can control coordinated reaching in closed loop using both 3D endpoint and 4D joint velocity decoding strategies.

Ctr., Providence, RI; [7]Neurosurg., [8]Electrical Engin., [9]Neurosci., Stanford Univ., Stanford, CA; [10]Neurol., [11]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [12]Neurol., Harvard Med. Sch., Boston, MA

Abstract: The BrainGate2 clinical trial has demonstrated that individuals with tetraplegia can control prosthetic limbs using neural signals processed from implanted electrodes in the precentral gyrus (Hochberg et. al. 2012). This work was recently expanded to high-dimensional prosthetic limb control (Collinger et. al. 2013, Wodlinger et. al. 2015). These studies used continuous decoding strategies for grasp control; however, an alternate approach for grasp decoding would be to discretely decode only the most common grasps used during everyday activities: the pinch, key and power grips. A discrete decoding strategy focused on these relevant grasps would have several benefits. First, such decoding strategies would not only provide a decoded command (i.e. the maximum-likelihood estimate) but also a level of confidence of the command; if a particular grasping action is detected with a high level of confidence, it can be enacted by an external effector without having to continuously control kinematic parameters on-line. Second, using a discrete decoding strategy could potentially allow releasing a grasp based on a generic hand-opening command vs. a grasp-specific command. The purpose of this experiment was to explore the feasibility of discrete grasp decoding and the potential advantages outlined above. Methods: Two research participants (T6 and T7) with amyotrophic lateral sclerosis (ALS) were implanted with Blackrock microarrays in the dominant precentral gyrus as part of the BrainGate2 clinical trial. In an open-loop block-randomized instructed-delay session paradigm, they were asked to “perform, or attempt to perform” one of four actions: power, pinch, or key grasp, or supination. Results: A total of 737 actions were analyzed for the two participants

over five sessions. Raw spike rates were analyzed using a Gaussian Naïve Bayes classifier with 5-fold cross-validation. The action performed could be decoded with greater than 95% confidence during the action epoch. It was possible to decode the grasp-release state equally well using either a generic or grasp-specific class. Conclusion: Wrist supination and the commonly used power, key and precision grasps (the most common grasps used for daily activities) can be decoded with high accuracy from the precentral gyrus in humans. Triggering grasping movements based on high-confidence discrete classification of neural signals offers a robust and functional alternative to continuous control of hand kinematics for neuroprosthetic application, which could bring neural control of prosthetic devices closer to clinical utility.

Abstract: Many brain machine interfaces (BMIs) decode motor action from cortical ensemble recordings and thus may suffer from issues such as over-fitting. Traditionally, the full neuronal population is used as input into the decoder, which may lead to decreased performance when the ensemble includes neurons that contain little information about the decoded variables. Dimensionality reduction can be a useful preprocessing step for preferentially extracting relevant information from large (>50) populations of neurons. Here, we examined how low dimensional dynamics extracted from different statistical procedures such as Poisson linear dynamic system (PLDS) state-space models, principal component analysis (PCA), and spike train similarity space (SSIMS) methods (Vargas-Irwin et. al., 2015) affected neural decoding performance. Specifically, we compared the performance of gait decoding of Rhesus Macaques during a

variety of locomotion tasks. Neuronal activity from the hind limb area of primary motor cortex was recorded via a 96-microelectrode array simultaneously with recordings of hind limb joint positions and muscle EMGs while monkeys walked across a corridor, a ladder, or on a treadmill at varying speeds. Low dimensional dynamics of the neural ensemble extracted by PLDS showed robust cyclical trajectories which were phased locked to the locomotion gait cycles. These state-space trajectories reflected the kinematic trajectories despite variability in task type and speed. In addition, SSIMS differentially clustered specific tasks and different gait phases in a low dimensional space. A linear decoder with history was used to compute expected joint positions, muscle activations, and phase of the gait cycle (stance vs swing) from both full population neural spike trains and reduced dimensionality inputs. Compared to using the full population, low dimensional inputs improved overall decoding performance with increases in R2 of 0.71 in some tasks. This improvement was observed especially during trials where decoding performance based on the full population was particularly poor. In our data, improvement in decoding performance based on low dimensional neural state trajectories reached a plateau at about 8 dimensions. These results suggest that future BMI design may benefit from incorporating dimensionality reduction approaches for neural decoding.

Abstract: Although human hands are capable of performing a very large variety of dexterous movements, most activities of daily living can be accomplished using a small set of basic grips including power, precision, and key. Formulating high-accuracy neural decoders for these basic grips is therefore an important goal for the development of assistive brain computer interface devices. Performing this type of decoding in a daily-life setting poses a set of unique challenges. Ideally, it should be possible to generate a decoder using a minimum of training data, so the user does not have to go through a lengthy data collection period in order to train or recalibrate the device. We evaluated the performance of linear (linear discriminant analysis) and non-linear (nearest-neighbor) decoding methods applied to spike counts and spike train similarity metrics. For each method we also examined the effect of augmenting the training data using synthetic spike trains derived as follows for each grip category: First, the distribution of spike counts per trial for each unit is fit using a gamma distribution. The number of spikes fired for each synthetic spike train is randomly chosen from this distribution. Once the desired number of spikes is chosen, n times as many spikes are selected from the full set available in all trials with the same grip (following temporal alignment). The spikes are then jittered using normally distributed temporal shifts. Finally, every nth spike is selected (in order to approximate a refractory period). Our test data included cortical recordings from non-human primates performing the three canonical grips as well as human participants in the BrainGate clinical trial attempting to perform the same grips. Our results show that it is possible to achieve high accuracy grip classification using limited training data (with only about 5 exemplars per category) and a small number of single units (around 15). We also demonstrate that it is possible to significantly increase decoder accuracy by using bootstrapping to augment the training data sets when few training exemplars are available. These results are consistent in all datasets examined, demonstrating similar features of grasp-related neural activity in able-bodied NHPs and humans with longstanding paralysis.

Title: Mechanical fatigue testing of an implantable intrafascicular electrode system

Authors: A. E. PENA[1], *S. S. KUNTAEGOWDANAHALLI[2], J. J. ABBAS[3], R. JUNG[1]; [1]Biomed. Engin., [2]Biomed. Engin. Dept, Florida Intl. Univ., Miami, FL; [3]Biol. & Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: We have developed an implantable device that uses longitudinal intrafascicular electrodes (LIFEs) to stimulate/record from small groups of fibers in peripheral nerve fascicles in upper-limb amputees. Since the electrodes and leads must maintain functionality when exposed to stresses during routine activities like walking or lifting, mechanical fatigue testing is necessary to assess the long-term reliability before clinical deployment. Our device consists of a stimulator/recorder unit with a 15-wire lead assembly. The assembly consists of a primary sheathed bundle (15 coiled wires) that leads to a trifurcation to form 3 sheathed bundles (5 coiled wires/bundle), each of which further separates into individual wires (LIFEs). Each LIFE is a 23μm insulated Pt/Ir wire with a 1mm long active zone. Using a needle, each LIFE is sewn longitudinally into the fascicle and sutured to the nerve at the entry and exit points. When implanted, high stresses may occur on the primary bundle near the trifurcation, at the point where the individual wires exit the sheath, or at the nerve suture points. Mechanical fatigue at these points could trigger device failure such as breakage of electrode wires or cracks in the sheath or insulation. We have developed equipment and procedures to expose the device to stress conditions that mimic the anticipated stress profiles in the upper arm. One setup imposes bending stress on the lead bundle near the trifurcation while it is under tension. Another setup imposes longitudinal strain on a compliant structure that models the nerve; LIFEs were sewn into the model nerve and anchored using sutures to mimic surgical installation. Electrode continuity was measured periodically and the status of the lead bundles and wires was assessed using a

microscope. Two mechanical fatigue test paradigms were used: a high cycle/low amplitude paradigm to mimic activities such as walking (7.3 million cycles based on a 2-year design life at 10,000 steps/day) and a low cycle/high amplitude paradigm to mimic strenuous activities such as lifting (1.2 million cycles; based on OSHA guidelines). Bending amplitudes of ±15° (low) and ±45° (high) were chosen based on ISO standards for a similar device. Strain amplitudes of 5% (low) and 15% (high) were chosen based on nerve strain studies. To-date, the high cycle individual wire test has reached 5 million cycles and all other tests have been completed. All wires in all samples (n≥3 samples per test condition) have retained electrical continuity and passed visual inspection. These results suggest that this set of leads and fine wires can maintain functionality in the stressful environment of the upper arm. Supported by NIH-R01-EB008578

Title: Experimental assessment of fitting procedures for a neural enabled prosthetic hand system

Authors: *L. RINCON GONZALEZ[1], S. S. KUNTAEGOWDANAHALLI[1], J. J. ABBAS[2], K. W. HORCH[1], R. JUNG[1];
[1]Florida Intl. Univ., Miami, FL; [2]Arizona State Univ., Tempe, AZ

Abstract: Stimulation of intact peripheral afferents in upper limb amputees can elicit somatosensory percepts, but prosthetic systems that use peripheral nerve stimulation are not yet available for chronic use outside the lab by amputees. To address this gap, we have developed a Neural-Enabled Prosthetic Hand (NEPH) system, which is based on a fully implantable stimulator and longitudinal intrafascicular electrodes (LIFEs) that deliver electrical stimulation to small groups of peripheral nerve fibers. It includes external electronics for transcutaneous wireless communication, custom-designed firmware to determine appropriate stimulation commands, an instrumented EMG-controlled prosthetic hand (force, position sensors), and custom-designed PC-based software for system calibration and testing. In addition, we have designed experimental paradigms for system calibration and testing. One paradigm has the

subject press a pinch grip force sensor (or a position sensor) and use visual feedback to match a target level that is presented on a screen; the other has the subject use visual feedback to match the target (as described above) and then reproduce the action (force or position) using the other hand, but with no visual feedback. In initial experiments, 7 able-bodied subjects performed the unilateral force task to validate the experimental procedures. The display had a white thermometer bar (scaled to the subject's calibrated force range), a moving red bar to indicate the applied force, and a green horizontal bar (width = 6% range) to show a target value of 0, 25, 50, 75, or 100%. Subjects were instructed to apply force to match the target level and maintain it for 1 second. Across 72 trials, the target alternated between one of the outer targets (0 or 100%, presented randomly) and one inner target (25, 50, or 75%, presented randomly). Subjects performed the experiment with their right and left hand separately. Performance was assessed using success rate, accuracy, and time to reach the zone. On average, subjects had a success rate of 97% and 95% with their dominant and non-dominant hands, respectively. In addition, it took subjects 1.4±0.2 sec to reach the target zone. A one-way ANOVA indicated an effect of target level on acquisition time; no other significant effects were noted. These results demonstrate that subjects were able to complete the task and the results provide baseline performance data for comparison with data from amputees fitted with our NEPH system. We plan to fine-tune elements of the protocol (e.g. trial time, target zone width) and validate the position task and bilateral tasks on able-bodied participants prior to testing with amputees using the NEPH system.

Title: Evaluation of an implantable intrafascicular electrode System in rodents

Authors: ***A. K. THOTA**[1], S. KUNTAEGOWDANAHALLI[1], R. SIU[1], J. ABBAS[2], R. JUNG[1]; [1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Electrical stimulation of peripheral nerve afferents can elicit sensations of touch and hand opening in upper limb amputees. To deliver meaningful stimuli that are derived from sensor signals on the prosthetic limb, we have developed a Neural-Enabled Prosthetic Hand (NEPH) system. To the best of our knowledge, this is the first system developed for chronic use by amputees that uses implantable direct nerve interface technology that is controlled via wireless communication from prosthesis-mounted sensors/electronics. The NEPH system consists of an implantable stimulator that directly interfaces with small groups of peripheral nerve fibers via longitudinal intrafascicular electrodes (LIFEs), external electronics that digitize sensor signals from an instrumented prosthetic hand, custom designed firmware to determine appropriate stimulation commands, a link for transcutaneous wireless communication with the implanted stimulator, and PC-based software (CustomTouch) for system calibration and testing. It has been designed, developed, validated and verified via bench testing in accordance with FDA and ISO-10993 standards. In this work, an in-vivo rat model was used to test the system capabilities for impedance measurement, and for stimulation pulse specification, sequencing and delivery. For these tests, an implant emulator was externalized and leads were routed percutaneously to LIFEs (25µm diameter Pt/Ir wire with 4µm thick Teflon coating) implanted in rat sciatic nerve fascicles (2 adult male Sprague-Dawley rats). Wireless protocols were used for bidirectional communication between the PC-based software and the implant emulator. The rat was placed on a pedestal with limbs hanging freely. Stimulation responses were monitored using bipolar fine wire intramuscular electrodes in tibialis anterior (TA) and gastrocnemius (GM) and a video based kinematic tracking system. The strength-duration curve for each electrode was established (threshold amplitude at various pulse widths) and fusion frequency was determined by testing pulse trains at frequencies from 10-100Hz. Two channels were programed to activate TA and GM alternatively (burst duration of 110ms and 310ms, respectively; cycle period of 500ms; 100 cycles; inter-burst intervals at 20ms and 60ms, respectively). Stimulation pulse parameters used for rat 1 were: TA 20 µA, 60 µs; GM 30 µA, 40 µs; for rat 2: TA 105 µA, 150 µs; GM 30 µA, 40 µs. Results demonstrated repeatable reciprocal activation of TA and GM. These studies provide and *in vivo* confirmation of NEPH system capabilities for calibration and for stimulation pulse specification, sequencing and delivery.

Title: Biocompatibility testing of an implantable intrafascicular electrode system in rabbits

Authors: A. THOTA[1], S. KUNTAEGOWDANAHALLI[1], K. HORCH[1], J. ABBAS[2], *R. JUNG[1];
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Longitudinal intrafascicular electrodes (LIFEs) have been used to stimulate or record from small groups of fibers within a peripheral nerve fascicle. These electrodes can be used in sensorimotor prostheses or electronic medicine applications that require a highly specific peripheral nerves interface. We have constructed LIFEs from fine wires (23µm diameter Pt/Ir wire with 4µm thick insulation) with approximately 1 mm long active area and a tungsten needle (75µm diameter) that is used to thread the LIFE into a fascicle and then removed after implantation. Here, we report on biocompatibility studies in rabbits that were performed at a GLP certified facility to evaluate the local neural tissue response to LIFE electrodes. The study used 22 rabbits sacrificed at either 4 weeks (n=11) or 12 weeks (n=11). Using aseptic techniques, LIFEs were implanted in the peroneal and tibial fascicle of the left sciatic nerve. Distal and proximal ends of the individual wires were securely sutured to the epineurium with non-absorbable sutures. For surgical control, tungsten needles were inserted into and removed from right sciatic nerve fascicles. Nerve tissue and electrodes were extracted from all nerves without explanting the electrodes. Three tissue blocks (entry, exit and central parts) of both the left and right sciatic nerves were embedded in plastic resin. Two additional tissue blocks (proximal and distal to entry and exit areas) were embedded in paraffin. Cross and longitudinal sections (thickness = 5µm for plastic; 4-6µm for paraffin) from each block were stained with hematoxylin and eosin, and luxol fast blue. Macroscopic and microscopic evaluations were performed by a board certified pathologist and histological analyses were performed according to part 6 of ISO 10993. Macroscopic evaluation showed no indications of erythema, edema, or other adverse tissue responses. Histological evaluation after 4 weeks showed responses that depended on whether the electrode was within the fascicle or between fascicles at the analysis site. Sites with intrafascicular LIFE showed minimal to mild fibrous tissue and very occasional macrophages and sites with an interfascicular LIFE showed minimal to mild or moderate fibrous tissue, low numbers of macrophages and occasional giant cells. Axonal degeneration, traumatic fibrosis, and seroma formation occurred at comparable incidences and severities at the location of LIFE and surgical control sites. In conclusion, other than slight tissue irritation, there were no adverse clinical or neurological effects or microscopic evidence of local toxicity or adverse reactions following implantation of the LIFEs in the sciatic nerve of rabbits.

Title: A brainet for whole-body navigation

Authors: ***R. SANKARANARAYANI**[1], P. TSENG[1], A. YIN[2], M. LEBEDEV[1], M. NICOLELIS[1];
[1]Neurobio., [2]Biomed. Engin., Duke Univ., Durham, NC

Abstract: Much neurophysiological research has been done over the years on the properties of cortical neurons to represent both self-initiated actions and the observation of actions performed by others. Yet, it is not well understood whether such neuronal representations could be utilized to enable brain machine interfaces (BMIs) to handle concurrent execution and observation. Even less is known about the possibility of using these representations in Brainets (i.e. BMIs comprised of several brains) first developed by our laboratory. Here we demonstrate a Brainet design where wheelchair navigation is controlled by cortical neuronal ensembles simultaneously recorded in two rhesus macaques. In one version of this design, one monkey (driver) is seated on top of a robotic wheelchair while the second monkey (observer) is stationary and observes the wheelchair movements. Since both the driver's and observer's cortical ensembles are directionally tuned to the wheelchair translational and rotational velocity, the activity of both brains can be used to control the wheelchair navigation. In this Brainet control, the driver is motivated by a food reward at the navigation target location, and the observer is similarly motivated by a food reward which it receives when the driver reaches the target. In the second Brainet design, both monkeys drive wheelchairs, and, again, the activity of both brains is integrated to achieve this control. We suggest that such Brainets in the future will be used for clinical applications where a therapist's brain activity is merged with the brain activity of a patient to rehabilitate function lost to neurological injury or disease.

Title: A brainet for cortico-spinal communication

Authors: *A. P. YADAV[1,2], M. A. L. NICOLELIS[1,2,3,4,5];
[1]Dept of Biomed. Engin., [2]Ctr. for Neuroengineering, [3]Neurobio., [4]Psychology and Neurosci., Duke Univ., Durham, NC; [5]Edmond and Lily Safra Intl. Inst. of Neurosci. of Natal, Natal, Brazil

Abstract: Dorsal Column Stimulation (DCS) is an effective therapy for a number of neurological conditions, including Parkinson's disease and spinal cord injury. Although DCS has been used in clinic for decades, its full potential has not been realized. In particular, there has been no implementation of a therapist-patient interface, where neural signals derived from a healthy brain would control stimulation applied to the spinal cord of a patient. Here we modeled such an interface using a Brainet that interconnected two rats: an encoder and a receiver. While the encoder rat performed a tactile discrimination task with its whiskers, its cortical signals were recorded, processed by a neural decoder and transmitted to the spinal cord of the receiver rat using DCS. In this Brainet, both rats learned to successfully exchange multiple tactile patterns and improve their behavioral performance. As the rats learned the Brainet task, we observed interdependent adaptations in both the encoder and receiver animals, which suggested that a complex plasticity occurred at the Brainet level. Our study demonstrated for the first time a cortico-spinal communication between different organisms. The obtained results suggest that such a Brainet could be used in the future to enable a healthy brain to directly modulate neural activity in the nervous system of a patient, facilitating plasticity mechanism needed for efficient recovery.

Title: Wireless brain-machine interface operated by freely behaving monkeys

Authors: ***M. J. LEE**, S. RAJANGAM, L. OLIVEIRA, M. LEBEDEV, M. NICOLELIS; Ctr. For Neuroengineering, Duke Univ., Durham, NC

Abstract: Neurophysiological experiments in nonhuman primates typically utilize a chair restraint, which limits the range of behaviors and does not allow recordings to last longer than 1-2 hours. This is a significant limitation for brain-machine interface (BMI) research, where long-term performance needs to be achieved under natural conditions. To address this problem, we implemented a wireless BMI in two freely behaving monkeys. Monkeys were housed in a large plexiglass enclosure, where they could continuously control a virtual avatar arm through a BMI that processed neuronal ensemble activity recorded from multiple cortical areas and converted it into the avatar movements. The recordings were conducted using our recently developed wireless multichannel system. Activity of several tens of neurons was decoded using continuous neural decoders. Continuous access to the task was provided for a period of up to eight hours during the day. We observed that the prolonged access to the BMI enhanced the behavioral performance. Both monkeys successfully acquired the ability to operate the BMI as they freely roamed about their cage. This learning was accompanied by adaptive changes in cortical modulations to the avatar arm movements. We suggest that such long-term BMI control facilitates an incorporation of the avatar into the brain representation of the body. As such, our wireless BMI is applicable to neurological conditions that require brain reorganization to occur for the treatment to be effective.

Abstract: Previously we have demonstrated visual responses in monkey somatosensory (S1) and motor (M1) cortical areas during a rubber hand illusion (Shokur et al. 2013). Here we explored whether stead-state visual evoked potentials (SSVEPs) could be recorded in the same areas and whether they would be modulated by visual attention. SSVEPs were incorporated into a two-alternative reaching task. In each trial two circular targets were presented on the computer screen. Each targets flickered at a unique frequency (e.g. 9Hz or 13Hz). Non-flickering targets were displayed in 30% of the trials to establish a baseline. Rhesus monkeys manipulated a hand held joystick to reach targets with a computer cursor. Spikes and local field potentials (LFPs) were recorded simultaneously using chronically implanted multielectrode arrays. The neural data were processed using a non-parametric multitaper spectral estimation method to assess frequency modulations at a single trial resolution. Spectral peaks at the flicker frequency were found in both spike and LFP data. These results for the first time show that intracranial recordings from S1 and M1 can be utilized to continuously record visual responses, which are relevant to motor behavior, incorporation of avatar arm, and visual attention. As such, this approach can be useful to build better neural prostheses.

Title: Extracting high-frequency features of neural activity from µECoG surface electrodes

Authors: *C. BARTON[1], S. KELLIS[2], P. HOUSE[3], B. GREGER[1];
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Biol., Caltech, Pasadena, CA; [3]Neurosurg., Univ. of Utah, Salt Lake City, UT

Abstract: While non-penetrating surface electrodes tend to provide recording longevity and minimal tissue response, penetrating electrodes must normally be used to record individual action potentials from cortical neurons. However, general spiking activity has been shown to be associated with increased energy from 300 - 6000 Hz in the frequency spectrum (Pezaris, 2000). More recently, surface electrodes have been developed that were able to record isolated spikes with features of superficial cortical neurons (Buzsaki, 2014). Here, we examine data previously recorded from subdural micro-electrocorticography arrays implanted in human patients over the face-motor cortex and Wernicke's area. Classification of spoken words had previously been achieved by decoding LFP data recorded from these arrays. Several channels also exhibit a small but consistent increase in frequency spectrum energy extending as high as 1 kHz, which could potentially indicate spiking activity. This increase in high-frequency power could represent an additional feature of neural activity that could be extracted from µECoG surface electrodes. By developing a decoding algorithm incorporating these features in addition to lower-frequency spectra associated with LFP, it may be possible to determine whether useful information encoded in higher frequency bands may be detected from µECoG arrays.

Abstract: Severe motor disorders or brain stem damage can leave individuals severely paralyzed but fully aware and unable to communicate by most natural means. For these individuals a direct cortical interface may provide more rapid and intuitive control over a communication prosthesis. Brain-computer interfaces (BCI) have potential for functional restoration and improving quality of life. Decoding natural cortical patterns for individual spoken words would allow for a system which requires very minimal patient training to maintain a high degree of accuracy. Previous attempts have been successful in using principal component analysis to decode single words from cortical activity at levels above chance, serving as a proof of concept. This study reanalyzes micro-electrocorticography (µECoG) data recorded during a repetitive speech task by applying support vector machines (SVM) to increase word prediction accuracy from local field potential (LFP) features. Two µECoG grids were placed on the cortical surface over language areas (Wernicke's area and Face Motor Cortex) of an adult male patient undergoing clinical monitoring for medically refractory epilepsy. LFPs were recorded while the patient was instructed to articulate one of ten words with one second intervals. Trials were aligned to the start of articulation. Snippets from the onset of articulation to 500 ms post articulation were extracted for each trial. Three feature sets were created from the snippets, a time domain series, a frequency domain series and a combined feature set created by concatenating time and frequency domain features. Features from 15 trials for each word were used to train the classifier and 15 subsequent novel trials were used for evaluation. Features were classified using a one-vs-one multiclass SVM classifier with radial basis function kernel. The most successful parameters yielded an accuracy of 83.3% in selecting the correct word from ten possible options and an average of 96.3% accuracy for two word combinations. This is an improvement from the 48% accuracy achieved for ten word classes and average 85% accuracy for two word classes reported with principal components analysis decoding [1]. Decoding spoken words from µECoG recordings using SVM performed well above chance and provide addition support for µECoG as a useful neural interface. [1] Kellis, Spencer et al. Title: Shared control system between a robotic arm and user intent decoded from posterior parietal cortex

Authors: *D. BROWN[1], T. DOBREVA[1], S. KELLIS[1], K. D. KATYAL[2], M. S. JOHANNES[2], C. KLAES[1], R. A. ANDERSEN[1];
[1]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Applied Physics Lab., The Johns Hopkins Univ., Laurel, MD

Abstract: The posterior parietal cortex (PPC) receives sensory information about the location of the body and external objects and outputs planned movement intent. In particular, the anterior intraparietal area (AIP) and Brodmann area 5 (BA5) are responsible for grasp intention and reach movement, respectively. Encoded intention signals from PPC then travel along the motor pathways where the motor cortex develops a more detailed plan for limb movements. Analogously, autonomous robotic systems can integrate sensory data from the environment to determine the detailed kinematics of joint angles necessary to execute high-level commands. Thus, there is a natural fit to use movement intentions from PPC as the high-level commands for a partially autonomous neuroprosthetic. We developed a shared control system that uses decoded PPC intent to guide the movements of a robotic arm. This allows the user to focus on high-level movement intentions, such as grasping or reaching an object, without thinking about the movements of each individual joint. The system includes a Microsoft Kinect for machine vision, a JACO robotic arm as a manipulator, and signals extracted from a neural decoder containing the user’s intent. Microelectrode arrays implanted in AIP and BA5 of tetraplegic human subjects supply neural data to the neural decoder. The goal of the system is to identify objects in the user’s environment and perform activities of daily living, such as drinking a bottle of water, with the assistance of the robotic arm. The system uses the Kinect's image and depth data to identify objects and send their location to the robotic arm. The arm proceeds through the trajectory of motions to pick up the object and performs a context-relevant action. The trajectories composing the task are throttled by the confidence of the neural signal associated with the user's intent to perform that action.The shared control system is currently capable of identifying a bottle of liquid, picking it up, bringing it to the user's mouth, tilting it for drinking, and returning it to its

original position. Progression through the different states of the task is controlled by the subject imagining bringing an object to his mouth. The tetraplegic subject being able to drink from a bottle using intuitive high-level intent shows promise for PPC-based shared control neuroprosthetics as a viable means for individuals with severe motor impairment to regain some independence.

Title: Hand specificity in human parietal neurons and local fields

Authors: *B. REVECHKIS[1], T. N. S. AFLALO[2], C. Y. ZHANG[2], N. POURATIAN[3], E. R. ROSARIO[4], K. PEJSA[2], D. S. OUELLETTE[4], R. A. ANDERSEN[2];

Abstract: Neural signals in the posterior parietal cortex have been shown to encode, among other movement variables, information regarding the state of the arm. This functionality is presumably supported by its substantial connectivity to somatosensory and visual areas. In one of the first extracellular recordings in the human parietal cortex in a tetraplegic subject (six years post-injury), we observed single units and LFPs that preferentially responded to hand-related movement execution and hand-related visual feedback in offline tasks. In an online brain control task performed in 3D virtual reality, we observed changes in spike activity that preferentially improved control of an anthropomorphic hand viewed from the 1st person perspective but not an abstract, disembodied, cursor-like effector. Our findings strengthen the notion that some of the neural machinery in the superior parietal lobule is specialized for feedback control of the hand. Furthermore, this specificity is retained in human parietal activity even years after the loss of motor control of the limb due to high spinal cord injury.

Title: Representation of executed, attempted, and imagined actions in a tetraplegic subject and implications for brain-machine interfaces

Authors: ***C. Y. ZHANG**[1], T. N. S. AFLALO[1], B. REVECHKIS[1], R. A. ANDERSEN[1], E. R. ROSARIO[2], D. OUELLETTE[2], N. POURATIAN[3], K. PEJSA[1], S. KELLIS[1], C. KLAES[1]; [1]Caltech, Pasadena, CA; [2]Casa Colina Hosp. and Centers for Healthcare, Pomona, CA; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: We explored the neural representation of executed, attempted, and imagined actions in the posterior parietal cortex of a tetraplegic subject with a C3-C4 spinal lesion in a BMI clinical trial. We studied imagined and executed shoulder movements, actions she uses commonly to control her wheelchair. We also studied the representation of imagined and attempted hand actions, of a body part she is unable to control. We found some neurons tuned more for execution, some more for imagination, and some with comparable/unbiased tuning for both. The unbiased units showed effector specificity, active only for left or right shoulder actions. This suggests that specificity and cognitive strategy are coded independently. The pattern of results were similar when we compared the representation of imagined and attempted hand movements. Given that different populations were activated by different strategies, we asked which strategy, and therefore which population, was best for online brain control. Using a virtual cursor control task we found both to be viable, with the attempt strategy more successful on days with significant performance differences. Neuron dropping curves showed open loop imagine performance to be better than attempt performance. Interestingly, in closed loop control attempt performance improved while imagine performance did not change significantly, a result that makes physiological sense. To understand these differences we looked at how well each neuron controlled the cursor at each time point in online control. We found that performance differences

were driven by the subpopulation of neurons biased to the attempt strategy. Our results suggest that the imagine strategy may be more open loop and unaffected by the feedback, while the attempt strategy handles feedback better. In able-bodied people the difference between executed and imagined actions is clear, with fMRI scans showing overlapping networks for the two strategies. In paralyzed patients, however, it is unclear if the networks involved are still even intact years after injury. Our results confirm the overlapping networks found in the fMRI results, finding them intact even years after paralysis. The results also suggest that cognitive motor strategy is an important factor in brain control and the choice of strategy can impact performance. In therapies imagined motions are seen as a way to train networks when the subject is unable to move for long periods of time. Our results show that attempted actions are still well represented and different from imagined actions. Understanding the benefits of each strategy may be integral in developing a robust BMI as well as improving rehabilitation techniques.

Title: Representation of decision variables in the human posterior parietal cortex

Authors: ***C. KLAES**[1], S. KELLIS[1], T. AFLALO[1], B. LEE[1,2], B. REVECHKIS[1], C. ZHANG[1], K. PEJSA[1], K. SHANFIELD[3], S. HAYES-JACKSON[3], M. AISEN[3], C. HECK[2], C. LIU[2], R. A. ANDERSEN[1];

Abstract: From Rhesus monkey studies it is known that the posterior parietal cortex (PPC) is involved in decision making and reward processing. In our current human brain-machine interface study we had the opportunity to investigate the involvement of the human PPC in decision making while playing a two player press-your-luck game. Our study participant was implanted with two Utah electrode arrays (UEA), one in a grasp related area (anterior intraparietal area) and one in a reach related area (Brodman area 5). The subject played a simplified two player variant of Black Jack while we recorded brain activity. In this game a series of numbers is presented to the first player sequentially and each time a decision has to be made to either proceed ('hit') or stop ('stay'). The first player's turn ends if the player decides to stop proceeding or the sum of all previous numbers exceeds a certain limit. Afterwards a second player takes his or her turn in the same way. After both players finish their turn the player who was closest to the limit but did not exceed it wins the game round. Our preliminary results indicate that a population of neurons in the PPC tracks the cumulative score during the game. Interestingly we also found neurons which keep track of the opponent's cumulative score. Besides tracking score we could also find neurons that reflect the upcoming decision near the end of a trial. These preliminary findings give a detailed outlook at various variables involved in decision making and how they are represented in the PPC.

Title: Single-unit dynamics match decoder filter dynamics during closed-loop brain-machine interface operation

Authors: ***I. BADRELDIN**[1], M. VAIDYA[3], K. BALASUBRAMANIAN[3], J. SOUTHERLAND[4], A. ELERYAN[5], A. H. FAGG[4], N. HATSOPOULOS[3], K. OWEISS[2];

Abstract: Tuning curves have been traditionally used to quantify how single units represent limb movement covariates. In doing so, however, they ignore the temporal dynamics of a unit's firing rate, making it hard to quantify the extent to which changes in these dynamics may reflect representations of other covariates in the task space. In the context of brain-machine interfaces (BMIs) when no overt natural arm movements are produced, neural decoders are an example of such covariates where simultaneously recorded units are individually weighted by the decoder filter coefficients to extract the desired kinematic variable in near real-time. Maximum output of the decoder is expected when the dynamics of unit firing rates match those of the decoder filter. However, since different firing rate patterns can give rise to the same kinematic pattern, it is unclear whether subjects exploit this strategy when volitionally controlling motor intent signals during BMI operation. In this work, we analyze multiple single-unit firing patterns from a chronically amputated adult female rhesus macaque during the control of a robotic arm in a reach-to-grasp task. Hand velocity and aperture velocity decoders were initialized from spontaneously active neurons using a non-biomimetic approach and held fixed throughout all training sessions. We examined those patterns immediately preceding (1 sec) and following (1 sec) moments when the robotic hand velocity command hit its maximum allowable limit. Using this event, we constructed Peri Event Time Histograms (PETHs) for all the single-units (n=9) that drove the hand velocity decoder. These PETHs were constructed from 20 single day sessions of closed-loop BMI spanning two calendar months. We found that the PETHs of all of the units qualitatively exhibited characteristic shapes during these intervals. Moreover the PETHs of 44% of the units were significantly correlated with the corresponding decoder filter dynamics ($p<0.05$). This evidence suggests that BMI subjects employ a consistent control strategy that matches the characteristic shapes of linear BMI decoders.

Title: Wireless multichannel implant for neuromuscular interfaces

Authors: ***D. MCDONNALL**, C. SMITH, D. MERRILL, S. GUILLORY, S. HIATT; Ripple, Salt Lake City, UT

Abstract: Control of prosthetic arms has been limited by the small number of inputs that are used to control multiple degrees of freedom in the limb. Conventional myoprostheses rely on a pair of signals recorded from surface electrodes on the residual limb. We are developing an implantable multichannel myoelectric device to detect signals from multiple residual muscles that will be sent wirelessly to the prosthetic limb. This approach offers the advantages of recording more channels of isolated muscle signals and providing access to deep muscles that cannot be detected with surface electrodes. We report the results of a proof-of-concept study to verify the *in vitro* performance of the system and an *in vivo* trial to validate device function in an animal model. The implant was constructed on a ceramic circuit board with a bioamplifier ASIC and additional discrete components. The implant was inductively powered by an external transceiver, and digitized signal data were sent from the implant by reflected impedance modulation. Each implant included four pairs of electrodes in epimysial disc, intramuscular bands, and fine wire configurations. The electronic components and ASIC die were coated with a conformal electronics sealant, and the entire assembly was coated in silicone. Benchtop implant performance was verified in a dry configuration and while the devices were soaked in saline. The amplifier was shown to have an input-referred noise of 2.2 µVRMS, a common mode rejection ratio greater than 55 dB, and neighboring channel isolation averaging 66 dB. The system uses an infrared telemetry approach is transmit high-bandwidth transmission (10Mbps) of detected signals. Emitters used for these experiments typically operated with a 30% to 40% power to light conversion efficiency, and optical recovery at the receiver was typically on the order of 0.5% to 5%. These prototype implants were validated in a six-dog study at the University of Utah. Two four-channel devices were implanted bilaterally in the front limb by placing the electronics package behind the shoulder blades with electrodes implanted in deltoideous and lateral head of

Deleted: in vitro

Deleted: in vivo

triceps. One week following implantation, each animal was fitted with a backpack carrying an external transceiver coil and a battery-powered data acquisition system, and the dogs were allowed to freely walk down a hallway. EMG recorded from each animal as it walked down a hallway had very low noise and, in conjunction with recorded video, clearly indicated swing/stance phases of gait.

Title: Corticosterone primes the neuroinflammatory responses to Gulf War Illness associated exposures: Effects of irreversible vs. reversible acetylcholinesterase inhibitors

Authors: ***A. R. LOCKER**, K. A. KELLY, L. T. MICHALOVICZ, D. B. MILLER, J. P. O'CALLAGHAN;
Mol. Neurotoxicology, CDC/NIOSH, Morgantown, WV

Abstract: Following the 1991 Persian Gulf War, as many as 250,000 soldiers returned with symptoms of Gulf War Illness (GWI), a complex disorder with characteristics similar to neuroinflammation-driven “sickness behavior.” These troops were exposed to a variety of cholinesterase inhibitors during deployment, including exposures to irreversible organophosphate (OP) acetylcholinesterase inhibitors (AChEI), in the form of the insecticide [chlorpyrifos (CPO)], or to warfare nerve agent, sarin. The reversible AChEI, pyridostigmine bromide (PB), was self-administered by soldiers as prophylactic treatment for potential nerve agent exposures. Alongside exposure to these AChEIs in the Gulf War were physiological stressors (e.g., high temperatures, physical exercise, or physical threat). Here, we examined effects of exposure to 3 OPs: CPO, DFP (as sarin surrogate), and PB in mice. These AChEIs

were given alone and with pretreatment with the stress hormone corticosterone (CORT) to mimic high levels of physiological stress. We assessed effects of these treatments on brain regional neuroinflammation by qPCR and neuroinflammation-associated microglial/astroglial activation by levels of phosphorylation of STAT3(tyr705). Adult male C57BL/6J mice were exposed to CORT (400mg/L in 1.2% EtOH), or water for 4 days. On the 5th day, mice were exposed to a single i.p. dose of CPO (8.0mg/kg), DFP (4.0mg/kg), or PB (3.0mg/kg). qPCR at 6 hours post-exposure revealed that acute CPO and DFP treatment alone produced neuroinflammation in the cortex and hippocampus that was enhanced by CORT pretreatment. Furthermore, CORT + CPO or DFP exposure enhanced activation of STAT3 in both brain regions. In contrast, acute exposure to PB alone or with CORT pretreatment did not produce significant increases in neuroinflammation or STAT3 activation. Exposure to the irreversible (CPO, DFP) or reversible (PB) AChEI with or without CORT pretreatment did not result in astrogliosis (increases in GFAP) in either the cortex or hippocampus, findings suggestive of an initial lack of neurodegeneration. Overall, exposure to irreversible AChEIs, CPO and DFP, produce neuroinflammatory effects in the cortex and hippocampus that are augmented by CORT pretreatment, an effect not seen with exposure to the reversible AChEI, PB. These effects may be a result of selective CORT priming of the JAK2/STAT3 pathway for specific GWI-related compounds - an effect that does not induce early signs of neurodegeneration. Thus, this study reveals the potential for selective pathway activation by irreversible AChEIs, a stress-hormone primed neuroinflammation in the absence of neurodegeneration that results in symptoms of GWI.

Title: Acute stress activates neurons and microglia across multiple brain regions: impact of adolescent intermittent ethanol treatment

Authors: ***T. J. WALTER**, R. VETRENO, F. CREWS;
Univ. of North Carolina - Chapel Hill, Carrboro, NC

Abstract: Stress affects the brain in many ways, impacting neurons as well as microglia, the resident macrophages of the brain. Furthermore, prior experience can change the way the brain responds to stress. Previous studies suggest that alcohol abuse during adolescence may alter either the neuronal or microglial response to acute stress during adulthood. Therefore, this study examined the response of neurons and microglia to acute stress, as well as the impact of prior adolescent intermittent ethanol (AIE) treatment on this response. This was done by treating Wistar rats with alcohol during adolescence and an acute restraint-water immersion stressor during adulthood. The neuronal response throughout the brain was assessed by immunohistochemical staining for c-Fos and EGR1. This was compared to the microglial response, which was assessed by immunohistochemical staining for CD11b. Acute stress increased c-Fos+ cell counts, EGR1+ cell counts and CD11b+ staining across the brain. While AIE did not impact the c-Fos response to acute stress, it did alter the EGR1 response in the CeA. Prior treatment with AIE enhanced the CD11b response to acute stress in many, but not all, brain regions. Neither acute stress nor AIE altered microglial cell number, and staining for markers of advanced microglial activation, such as CD68, MHCII and iNOS, were negative. The stress-induced increase in CD11b+ staining appeared to be associated with a hyper-ramified microglial morphology. These results suggest that acute stress causes hyper-ramified microglial activation across the brain that is enhanced in select regions by prior binge alcohol treatment.

Title: Combined electrophysiological and behavioral approaches in evaluation of neuro-toxicity due to repeated jet fuel exposure in rats

Authors: *J. G. ROHAN[1,2], M. K. MIKLASEVICH[1,3], S. M. MCINTURF[1], C. P. GUT, Jr.[1,3], K. L. MUMY[1];
[1]Naval Med. Res. Unit, Wpafb, OH; [2]Oak Ridge Inst. for Sci. and Educ., Wpafb, OH; [3]CAMRIS, Wpafb, OH

Abstract: Jet fuel is a typical occupational exposure hazard among civilian and military personnel. Reports have documented significant impairments in attention-based tasks and memory in humans following jet fuel exposures. On the other hand, neuro-behavioral studies performed in animals have reported few neurological effects of prolonged jet fuel exposures, despite significant changes in neurotransmitter levels such as dopamine and serotonin. To date, there are no published data regarding the effects of *in vivo* jet fuel exposures on neuronal function in intact brain slices. Here, we combined electrophysiology techniques with behavioral approaches to assess and correlate neurological effects due to jet fuel exposure in a rat model. We exposed male Fischer rats to 0 (control), 200 (low), 1000 (medium) or 2000 (high) mg/m^3 concentrations of jet fuel (JP-8 or Jet A) using whole-body inhalation chambers for 28 days (5 d/wk, 6 hrs/day). Behavioral assays (acoustic startle response with pre-pulse inhibition and Morris water maze) were performed to assess cognitive effects. Extracellular recordings were performed within 24 hours of exposures, in which we evaluated effects of jet fuel exposures on evoked responses, synaptic plasticity (LTP, LTD, paired pulse facilitation) and spontaneous activity of acutely dissected hippocampal slices. Preliminary findings indicate no dramatic differences in hippocampal function after 28 days of "occupational" *in vivo* exposures to either JP-8 or Jet A. However, we detected small but significant differences in evoked inhibitory response amplitudes surrounding the CA1 region between the control and medium groups. There was a trending decrease in spontaneous activity surrounding the CA1 region of the hippocampus in rats exposed to the highest concentration of JP-8 or Jet A. In contrast, there was a trending increase in spontaneous activity surrounding the dentate region of the hippocampus in rats exposed to high concentration of Jet A. No changes in synaptic plasticity were observed, even in rats exposed to the high concentrations. Consistent with this finding, there was no significant deviation in spatial learning /memory or sensorimotor gating, as evaluated by the Morris water maze and acoustic startle reflex with pre-pulse inhibition tests, respectively. Data gathered to date suggest that current occupational exposure limits (200 mg/m^3) are protective against the neurotoxicity endpoints evaluated. The effects of exposure to very high concentrations of jet fuel, as well as alternative fuels, still warrant further investigation with regard to subtle differences that may occur in humans but not be entirely reflected in the rat model.

Title: Methamphetamine regulates stress-related neuropeptides via diverse epigenetic mechanisms

Authors: *S. JAYANTHI[1], B. GONZALEZ[2], P. WONGPRAYOON[3], M. T. MCCOY[1], B. LADENHEIM[1], A. GODINO[4], J. L. CADET[1];
[1]Mol. Neuropsychiatry Br., NIDA-IRP, Baltimore, MD; [2]Inst. de Investigaciones Farmacológicas, Buenos Aires, Argentina; [3]Res. Ctr. for Neuroscience,, Inst. of Mol. Biosciences, Mahidol University,, Nakornpathom, Thailand; [4]Dept. de Biologie, École Normale Supérieure de Lyon, Lyon, France

Abstract: A single methamphetamine (METH) (10 mg/kg) dose caused time-dependent increases in stress-related neuropeptides, including *Crh*, *Avp* and *Cartpt* in the nucleus accumbens of rats. In general, gene transcription is regulated by complex epigenetic mechanisms that include covalent histone modifications or DNA methylation / hydroxymethylation. Here we show that METH significantly decreased DNA methylation at the CpG-rich sites near the promoter region of *Crh* and at CpG-rich intragenic sites of the *Avp* gene. METH caused no changes in DNA methylation but increased enrichment of pCREB on the *Cartpt* gene promoter. METH-induced hypomethylation is mediated via a cascade that includes DNA hydroxymethylation. METH was shown to increase DNA hydroxymethylation at the CpG-rich sequences located near the *Crh* TSS and at *Avp* intragenic sites. Because Ten-eleven translocation (TET) enzymes catalyze DNA hydroxymethylation, we conducted chromatin immunoprecipitation (ChIP) assay using TET1, TET2 and TET3 antibodies and found significant METH-induced increase of TET1 binding on the *Crh* promoter sequence and of TET3 binding on an *Avp* intragenic region. There were no changes in TET2 binding on *Crh* and *Avp* DNA sequences. Inhibition of TET activity using 1, 5-isoquinolinediol (ISO) blocked the METH-induced *Crh* and *Avp* mRNA expression. Together, these results show a potential role of TET in mediating METH-induced up-regulation of *Crh* and *Avp* mRNA expression in the nucleus accumbens. These observations hint to the possibility that METH can activate diverse regulatory epigenetic mechanisms to regulate gene expression in the brain.

Title: Choline supplementation to pregnant mice mitigates the neuroinflammatory effects of prenatal diesel exposure to fetal brain

Authors: *S. V. MAURER, J. L. BOLTON, C. E. TYBOUT, S. D. BILBO, C. L. WILLIAMS; Duke Univ., Durham, NC

Abstract: Numerous studies have shown that air pollution causes widespread inflammatory processes in body and brain and is linked to neurocognitive difficulties, increased anxiety and depression, and increased prevalence of neurodegenerative disorders. When exposure to air pollution occurs early in development, children show decreased working memory ability (Sunyer et al., 2015). As well, prenatal exposure to diesel particulate matter increases inflammatory cytokine expression within several brain regions of embryonic day 18 males and leads to long-term negative outcomes for the offspring (Bolton et al., 2012; 2014). In contrast, dietary choline supplementation has been shown to decrease inflammation in adult rats and humans (Rivera et al., 1998; Mehta et al., 2010) and when administered as a supplement to pregnant rats, choline also increases working memory and decreases age-related cognitive decline in the offspring (Meck et al., 2008). The current study sought to determine if dietary choline supplementation protects against the deleterious effects of air pollution on the developing brain. Time-mated C57/Bl6 mice were given a high-choline (SUP – approximately 4.5X choline levels in the CON diet) or control (CON) diet, and a series of diesel particulate (DEP) or vehicle (VEH) exposures throughout pregnancy. Mice were sacrificed and tissues collected on embryonic day 18. The number and activation state of microglia, identified by Iba1+ immunohistochemical staining, in several brain regions were examined to determine the impact choline and/or diesel on microglial development. As expected, we found that the CON/DEP mice had significantly more stout and amoeboid microglia and more total microglia per volume in the dentate gyrus than the CON/VEH and SUP/VEH groups. Remarkably, prenatal choline supplementation to the DEP group completely prevented this increase in microglia number and change in morphology. The effects also appeared to be regionally specific: we found different effects of choline and diesel in fetal hippocampus, fetal hypothalamus, and maternal hippocampus. These findings suggest that prenatal choline supplementation throughout pregnancy may protect the fetal hippocampus against the neuroinflammation associated with air pollution. While we have not yet identified a mechanism of action, choline may be having these effects via an epigenetic mechanism or possibly via direct activation of α7 nicotinic acetylcholine receptors in the developing brain (Wu et al., 2015). Further work is underway to determine how choline supplementation to the pregnant dam leads to alterations in fetal and maternal response to air pollution.

Title: Behavioral effects of whole body hyperthermia and the phenomenon of hormesis

Authors: ***M. DEVDARIANI**;
I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: We do not know how a hyperthermic exposure, that widely is using in cancer clinics, especially in case of whole body hyperthermia (WBH), can affect the brain functions, and what impact it will have on blood rheology. But we do know that the hyperthermia will cause an oxidative stress, the positive or negative consequences of which will be dependent on what we will get - activation or inhibition of hormetic mechanism Proceeding from the above, we decided that the study the WBH effects on the processes of learning and memory, and on rheological properties of blood on the background of selective and nonselective inhibition of various nitric oxide synthases (NOS) will not only allow to identify possible disorders of the brain functions, but also pinpoint the physiological mechanisms of these disorders, as well as some unknown aspects of therapeutic or/and damaging effects of WBH.. The series of experiments were carried out on the groups of white rats placed in a special hyperthermia chamber (400C) for one hour, without any restrictions in freedom of movement. Multi-way maze was used to study the processes of learning and memory (before and after WBH exposure). Rheological properties of blood (aggregability and deformability of RBC, as well as plasma viscosity) has also been analysed. Analysis received data and data presented in literature allow to make the following conclusions, having not only theoretical, but also practical meaning: 1.WBH might be used as one of the most effective triggering factor for launching of hormetic mechanism, especially in the cancer clinic. 2.The critical is to make sure that chosen dose of WBH (temperature and duration) not exceeds the hormetic range. 3.We believe that in case of WBH an upper limit for used temperature must not exceed 40 degree of Celsius, because inhibition of Hormesis mechanism and unavoidable changes in patient's blood rheology might have a significant negative side effects.

Abstract: Physical and psychological injuries frequently drive maladaptive changes in brain neuronal and vascular networks. Interactions between environmental and psychological stressors may leave individuals at a greater risk of adverse neuropathological or behavioral disorders such as PTSD. Using a model of chronic hypobaric-hypoxia in the mouse, we can monitor and identify important contributors to maladaptive neuronal and vascular responses by examining the effects of on the transcriptome and brain anatomy following high altitude exposure. Two strains of commonly investigated mice, C57Bl6 and BALBc, are exposed to a simulated high altitude environment of 5000 meters for up to three months. Throughout this period, mice are subjected to behavioral tests as well as neuropathological assessments at intermediate time points. We demonstrated that mice exposed to high altitude show signs of hippocampal dysfunction in contextual fear conditioning tasks and evidence of microglia activation, particularly in white matter tracts. This enhanced inflammatory signature is also present in the transcriptome of hippocampal and amygdala tissue in both strains of mice. Transcripts related to angiogenesis are also significantly upregulated following chronic hypobaric-hypoxia. *In vivo* imaging of high altitude exposed mice revealed a time-dependent decrease in blood perfusion in the neocortex despite an increase in the vascular density index (VDI). Similarly, MRI derived T2 relaxation times are elevated in the hippocampus and neocortex suggestive of ongoing inflammatory processes consistent with the findings of the transcriptome analysis. We also observe a decrease in apparent radial diffusivity of endogenous tissue water within the corpus callosum suggesting

Deleted: In vivo

inflammation may be driving demyelination under high altitude exposure. In summary, our results suggest that chronic hypobaric-hypoxia causes maladaptive changes resulting in adverse neuropathological and behavioral deficits, accompanied by an abnormal transcriptional signature. These changes may shift the brain to a vulnerable state, which is more susceptible to subsequent stressors, thus leading to a greater risk for adverse outcomes.

Title: Dietary copper reduction and zinc supplementation: An examination of body weight and its mediating effects on fear extinction

Authors: *C. NEELY, S. WILKINS, M. SMITH, J. FLINN;
Dept. of Psychology, George Mason Univ., Fairfax, VA

Abstract: Zinc (Zn) and Copper (Cu) are biometals involved with a variety of behavioral abnormalities and neurological disorders. Zn and Cu actively compete with one another during absorption; thus Zn supplementation can result in an indirect Cu deficiency (Nations et al., 2008; Osredkar & Sustar, 2011). A diet with reduced Cu levels administered starting *in utero* and continuing to four months induced deficits in fear extinction (Neely et al., 2014). An earlier experiment showed that Zn-induced deficits in spatial memory and fear extinction were remediated through Cu supplementation (Railey et al., 2010), suggesting that the effects of excess Zn may be due to a Cu deficiency. In addition, general findings suggest that Cu deficiency has been linked to poor weight gain and ataxia (Everson, Tsai, & Wang, 1967), prompting the need to explore its effects on behavioral measures. The current study utilized a standardized 7012 diet (7012H) formulated with nutritionists at Harlan Laboratories with 23ppm Cu, the 7012H diet with Cu levels reduced to 7-12 ppm (7012Cu), and the 7012H diet with

Deleted: in utero

10ppm Zn administered through drinking water (7012Zn). We included a “copper control” diet with 16ppm Cu (CC) used in past studies (Howell et al., 2014; Lippi et al., 2014) and compared it to the 7012H diet. Sixty-six Sprague-Dawley rats were administered one of four diets for approximately four months and underwent cued fear conditioning and extinction testing. Weight differences could have mediated the relationship between diet and freezing responses as indicated by a significant mean weight difference (omnibus $p<0.01$) at the time of testing with our CC group (464g) weighing significantly more than the other groups (7012H =428.46g; 7012Cu=416.55g; 7012Zn=437.46g). As expected, there were no reported differences among diets in conditioning, $F(3, 62) = 1.22$, $p=0.31$. On extinction, a significant tone*diet interaction ($p=0.02$) demonstrated that the CC animals, who weighed the heaviest, exhibited significantly weaker extinction compared to the 7012Cu- and 7012Zn animals. The 7012H animals exhibited intermediate levels of fear extinction. By extinction recall, the 7012H group exhibited similar freezing percentages as the 7012Cu and 7012Zn groups with no significant differences reported. The CC group, which weighed the heaviest, had elevated freezing responses throughout extinction and recall. Open field results will confirm that our results are not confounded by a motor impairment. Extraneous ingredients such as soy, phytates, and high fat content may have impacted our results. Our data emphasize the necessity to examine extraneous variables, such as weight changes and dietary factors.

Title: Chronic exposure to environmental noise during puberty, improves the execution of a working memory task and the astrocyte proliferation

Authors: ***T. G. MORALES**[1], G. YAÑEZ-DELGADILLO[2], P. HERNANDEZ[2], G. CHIPRES-TINAJERO[2], R. RAMOS-ZUÑIGA[2], J. ESTRADA-GARCÍA[2], S. LUQUÍN[2], Y. RUVALCABA-DELGADILLO[2];

[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: The experiences during development influence brain maturation and might alter the neuroendocrine and cognitive systems. Relevant environmental stimuli may activate the stress response and thus the release of glucocorticoids (GC). This experiences may alter the structure and function of the limbic brain regions that regulate the response to stressful events such as the medial prefrontal cortex (mPFC) and facilitate or impair memory processes. The mPFC participates in cognitive processes such as working memory. Astrocytes are cells that have important functions in the Central Nervous System and they have glucocorticoid receptors. In this study was examined whether exposure to noise stress during development (pre-puberty) could generate effects on working memory and astrocyte population. Male rats Swiss Wistar were exposed to stress environmental noise (EN) during postnatal (PN) 21-36 days. In the present study was evaluated the performance of a working memory task immediately after exposure to EN in T Maze (delay-alternating) and astrocyte numbers in mPFC. Additionally, serum corticosterone levels were measured in these rats. The noise stress significantly increased corticosterone and positively affected the performance of a working memory task particularly at the alternation task with delay. Besides, it was found a difference in the number of astrocytes in the mPFC the group EN. These findings suggest that exposure to environmental noise during development, improves cognitive processes involved in working memory.

Title: The proteomic profile of chronic stress and recovery in the hippocampus and amygdala

Authors: *M. M. KACHEMOV[1,3], P. R. PAODE[2], V. DAVID[3], K. A. TSANTILAS[3], M. ROSENOW[3], J. MOLINARO[1], C. D. CONRAD[2], P. PIRROTTE[3], M. ORCHINIK[1];

Abstract: The stress response facilitates our ability to deal effectively with threatening situations, but exposure to severe or chronic stressors can lead to a number of undesirable neural, physiological, and behavioral outcomes. Chronic stress is associated with structural changes in the rat hippocampus and amygdala, with corresponding changes in behaviors such as enhanced fear responses, depressive-like behaviors, and some deficits in learning and memory. More recent animal studies have uncovered an inherent neuroplasticity that allows certain brain regions to recover from the stress-induced neural changes. Underlying cellular mechanisms likely involve several different cellular and molecular pathways. In order to gain a more comprehensive understanding of the differences in protein expression throughout the timeline of chronic stress and recovery, chronically stressed and recovered rat hippocampus and amygdala proteomes were sequenced using bottom-up proteomics, consisting of high-performance liquid chromatography (HPLC) and tandem mass spectrometry. Male Sprague-Dawley rats were randomly assigned to chronic restraint stress for 6hr/d/10d or 6hr/d/21d (Str-Imms or Str-Imml), stress for 6hr/d/21d followed by a recovery period of no stress for 10 or 21 days (Str-Recs or Str-Recl), or a control group (Con). We hypothesize that the neural recovery process involves a suite of proteins associated with neuronal plasticity, including synaptic and cytoskeletal proteins and neurotrophins. We optimized sample preparation of brain tissue for mass spectrometry to maximize lipid depletion and minimize protein loss. Our methods discovered over 2,300 proteins in non-stressed hippocampal tissue, including small protein markers of 35 kDa or less such as synaptobrevin, calmodulin, and activity-regulated cytoskeleton-associated protein. We are now investigating hippocampal cytosolic, nuclear, and membrane proteins obtained from post-stress recovery rats. Immunoassay techniques will also be performed in order to determine the quantitative and qualitative changes in candidate protein markers identified by mass spectrometry. Collectively, these results will demonstrate the complexity behind the brain's mechanisms for responding to chronic stress along different time points and indicate the overall impact of a recovery period. Our integrative approach will also provide a resource for further investigations into the mechanisms of the brain's recovery from chronic stress.

Title: TrkB mediates the recovery from chronic stress-induced spatial memory deficits and CA3 dendritic retraction

Authors: J. M. ANGLIN, J. B. ORTIZ, P. R. PAODE, S. B. TAYLOR, N. E. MAALOUF, S. KEMMOU, K. NISHIMURA, *C. D. CONRAD;
Psychology, Arizona State Univ., Tempe, AZ

Abstract: Chronic stress leads to hippocampal-mediated spatial learning and memory deficits and hippocampal CA3 dendritic pruning. When chronic stress subsides and a post-stress recovery period ensues, spatial ability and CA3 dendritic complexity recovers to pre-stress levels. Recently, we reported that hippocampal BDNF is necessary for spatial memory improvements during the recovery period after chronic stress ends (Ortiz et al., 2014). However, BDNF was manipulated throughout the chronic stress period and into the post-stress recovery phase. This made it unclear whether hippocampal BDNF was necessary during the recovery period specifically, or whether the outcome reflected delayed effects from the chronic stress period. Since then, a new drug has become available (ANA-12) that can penetrate the blood brain barrier and antagonize the TrkB BDNF receptor. Consequently, we investigated BDNF's role during the post-stress recovery phase specifically and determined whether the TrkB receptor is necessary for spatial memory improvement during the post-stress recovery period. Male Sprague-Dawley rats were chronically stressed by restraint (6hr/d/21d) and then tested in a cognitive battery soon after restraint ended (Str-Imm) or after a three week post-stress recovery period (Str-Rec). Rats were injected daily with ANA-12 (.5 mg/kg or veh, i.p.) during the post-stress recovery period. Spatial ability was assessed with a radial arm water maze (RAWM) and object placement (OP), and then brains were removed and processed for Golgi staining to assess hippocampal CA3 dendritic complexity. As reported in our other studies, all groups learned the RAWM task similarly, by making fewer errors as trials progressed. Differences manifested on the memory retention trials for both RAWM and the OP paradigm. ANA-12 treatment impaired memory retention of the Str-Rec condition in both the RAWM and OP: Str-Rec-ANA showed poor performance that was similar to Str-Imm-Veh, whereas Str-Rec-Veh performed as well as Con-Veh on both tasks. Moreover, hippocampal CA3 dendritic complexity mirrored the behavioral outcomes: ANA-12 blocked the enhanced dendritic arborization that occurs in the post-stress recovery period (Str-Rec-ANA vs Str-Rec-Veh). These results indicate that during the

post-stress recovery period, TrkB signaling is necessary for hippocampal plasticity, as it pertains to spatial ability and CA3 dendritic complexity.

Title: Downregulating hippocampal BDNF expression blocks recovery from chronic stress-induced hippocampal CA3 dendritic retraction

Authors: ***J. B. ORTIZ**[1], E. J. DAAS[1], A. N. HOFFMAN[1], E. FONSECA-TRUJILLO[1], P. R. PAODE[1], S. KEMMOU[1], N. E. MAALOUF[1], E. F. TERWILLIGER[2], C. D. CONRAD[1]; [1]Dept. of Psychology, Arizona State Univ., Tempe, AZ; [2]Dept. of Med., Beth Israel Deaconess Med. Center, Harvard Med. Sch., Boston, MA

Abstract: Chronic stress-induced hippocampal CA3 dendritic retraction and deficits in hippocampal-mediated behaviors return to levels of non-stressed controls, i.e. recover, following a post-stress recovery period. We previously demonstrated that hippocampal BDNF is necessary for recovery from spatial memory deficits in the weeks following the end of chronic stress (Ortiz et al., 2014). Here, we investigated whether downregulated hippocampal BDNF blocks the reversal of chronic stress-induced dendritic retraction of hippocampal CA3 neurons following a similar post-stress recovery period. We used RNA interference to downregulate BDNF expression within the dorsal hippocampus. Specifically, viral vectors containing the coding information for an shRNA directed against BDNF (shRNA) or a scrambled sequence (Scr) were infused into the dorsal hippocampus targeting the CA3 region. Young male Sprague-Dawley rats received bilateral hippocampal infusions of shRNA or Scr (3 infusions per hemisphere, 0.2 µl per

infusion). Rats were then assigned to chronic stress (6h restraint/d/21d) or unstressed controls (Con). Brains were extracted following a 21-day post-stress recovery period (Str-Rec) or immediately following the end of chronic stress (Str-Imm). Brains were hemisected and one hemisphere was flash frozen for BDNF protein quantification and infusion accuracy assessment, while the other hemisphere was processed for Golgi Stain (FD Rapid GolgiStain Kit). The different hippocampal CA3 neuronal types (short shaft and long shaft) show inherent differences in dendritic complexity; therefore, both neuronal types were equally represented within each rat. The neurons were then traced using a light microscope and a camera lucida drawing tube, with at least eight neurons traced per rat. Dendritic complexity was determined by quantifying the total number of bifurcations and dendritic length. The data show that chronic stress led to a reduction in dendritic complexity: Str-Imm-Scr rats showed fewer dendritic branches compared to Con-Scr. Rats that were allowed a post-stress recovery period and infused with the Scr virus (Str-Rec-Scr) displayed a dendritic profile similar to that of control rats. Importantly, BDNF knockdown appeared to hinder the recovery of CA3 dendritic architecture: rats in the Str-Rec-shRNA group had decreased CA3 dendritic complexity compared to their Str-Rec-Scr counterparts. Together with our previous report, these data suggest that BDNF mediates two forms of recovery in the hippocampus following termination of chronic stress: enhancement of CA3 dendritic arborization and improvement in hippocampal-dependent spatial cognition.

Title: Repetitive oxytocin treatment following traumatic stress blocks stress-induced reinstatement of methamphetamine-seeking and neuroadaptations in the prefrontal cortex and hypothalamus

Authors: *C. L. FERLAND, E. L. HERZIG, J. F. MCGINTY;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous research has shown a strong link between neuropsychiatric disorders such as posttraumatic stress disorder (PTSD) and substance use disorders (SUD). Stimulants, such as methamphetamine (Meth), are among the most highly abused by those with comorbid PTSD who exhibit a longer history of Meth use and poorer overall treatment outcomes than individuals with Meth SUD alone. Moreover, traumatic stress exposure independent of PTSD development can precipitate relapse to abuse in recovering SUD individuals. Negative regulation of the endogenous oxytocin system is thought to increase vulnerability to SUD following traumatic stress exposure. We previously showed that in rats with a history of exposure to the predator odor, 2,4,5-trimethylthiazolin (TMT), a single dose of oxytocin (OXT) when injected systemically 30 mins before a conditioned cue or TMT –induced reinstatement test, was able to suppress reinstatement of Meth seeking to both stimuli in rats with a Meth self-administration (SA) history (Ferland et al submitted). The goal of the present study was to examine whether chronic stimulation of the endogenous oxytocin system following traumatic stress exposure would attenuate Meth-seeking.. In rats exposed to TMT or saline for 5 days followed by 10 days of 1.0 mg/kg, i.p. oxytocin (OXT) or saline, we examined (1) TMT (stress)-induced reinstatement of Meth-seeking in rats with a Meth SA history and (2) neuroendocrine alterations and mRNA expression in the dorsomedial prefrontal cortex (dmPFC) and the paraventricular nucleus of the hypothalamus (PVN). TMT pre-exposed (PE) rats injected with saline for 10 days prior to meth SA acquisition exhibited significantly more stress-induced reinstatement of meth-seeking than saline-PE rats injected with either saline. In contrast, repetitive OXT treatment for 10 days suppressed TMT-induced Meth-seeking in TMT-PE and Salne-PE rats.. *Oxt* mRNA in the PVN and *OxtR* mRNA in both the PVN and dmPFC were significantly less in TMT-PE rats injected with saline than in saline-PE controls. Ten days of OXT prior to acquisition of Meth SA prevented the decrease in *Oxt* and *OxtR* mRNA in TMT-PE rats. In addition, TMT-PE rats treated with saline showed a significant reduction in the epigenetic mark *Hdac5* and a corresponding increase in *Bdnf*IV mRNA in dmPFC compared to saline PE animals. Repetitive OXT attenuated the *Hdac5* decrease and normalized *Bdnf*IV mRNA in the dmPFC of TMT PE rats. The results from these studies support oxytocin as a novel therapeutic strategy for SUD with concurrent PTSD. Supported by T32 DA07288 and DoD W81XWH-11-1-1245 Subaward 803-237

Title: The effects of the TrkB agonist, 7,8-dihydroxyflavone, on rats' stress response to predator odor

Authors: *J. KOERBER, C. L. FERLAND, T. S. DENNIS, S. M. BARRY, E. L. HERZIG, J. F. MCGINTY;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Brain derived neurotrophic factor (BDNF) promotes neuronal survival and modulates the rodent stress response through activation of its high affinity tyrosine receptor kinase, TrkB. Although BDNF has tremendous preclinical value, it is hindered by its limited ability to cross the blood-brain barrier. In contrast, the selective TrkB agonist 7,8-dihydroxyflavone (7,8- DHF), readily crosses the blood-brain barrier and has therapeutic effects in several rodent studies modeling stress and learning. Furthermore, our lab has previously demonstrated that rodents repeatedly exposed to 2,4,5-trimethylthiazoline (TMT), a fox fecal extract, have an increased level of peripheral corticosterone, exhibit anxiety-like behavior in behavioral tests, and show augmented reinstatement of methamphetamine-seeking that persists weeks after the initial predator odor exposure. These findings suggest that TMT exposure is an efficacious animal model of posttraumatic stress disorder (PTSD). Based on these findings and others suggesting BDNF is a modulator of stress, we decided to investigate 7,8-DHF's effect on the rodent stress response. We exposed rats to a filter paper soaked in TMT (10 ul, 1% solution, 15 min. sessions) or saline (10 ul, 15 min. sessions) once daily for five days in open field boxes, after three days of pre-exposure habituation. Two hours before the trials, we administered either 7,8-DHF (5 mg/kg, i.p. dissolved in 17% DMSO) or vehicle (17% DMSO) to investigate whether 7,8-DHF would attenuate any component of the stress response induced by exposure to the predator odor. Immediately following the fifth day of TMT exposure, rats were rapidly decapitated without anesthesia, their brains were extracted, and tissue collected from the dorsomedial prefrontal cortex (dmPFC), amygdala (AMY), paraventricular nucleus (PVN), and hippocampus (HIP). Additionally, adrenal glands were weighed and trunk blood was collected for corticosterone analysis. Preliminary results indicate no difference in adrenal weights between groups but the rats exposed to TMT all gained significantly less weight during the five days of exposure and exhibited elevated corticosterone levels, indicating a deleterious response to traumatic stress. However, 7,8-DHF did not affect these measurements. Protein and mRNA levels will be analyzed using the WES system (Protein Simple) and qPCR, respectively. It is expected that the TMT-exposed rats will have reduced levels of *bdnf* mRNA and reduced levels of activated TrkB,

which will be prevented by 7,8-DHF. Acknowledgements: Supported by DA033479 and GAANN

Abstract: Unique methods that effectively reduce, prevent, and even temporarily provide relief from stress are of utmost importance to translational neuroscience research. Not only can these methods have immediate application to those suffering, but they can provide insights into cognitive behaviors that lead to unhealthy levels of stress. We investigated the efficacy of Guided Subtraction Meditation (GSM), a new meditation practice from South Korea that claims to have a method that quickly allows practitioners to dissociate from past traumatic experiences, eliminate stressful patterns of thinking and reduce the occurrence of negative affective and physiologically hyperaroused states. GSM's method involves detaching from life experiences stored in the mind as thoughts and images of the past, present, and future by bringing them up systematically and "letting them go." In a relatively short period (100-150 hrs of practice), this method claims to be able to lead practitioners into a state of stress free, present, and non-judgemental awareness. To determine if this practice actually has the beneficial impacts related to stress and cognition that it claims, we longitudinally tracked practitioners of this meditation (n=15) alongside non-meditating control subjects (n=20) from their first hour of meditation practice to their 300-350th hour of meditation practice. At three timepoints (start, 100-150 hrs and 300-350 hrs of practice or every 8-14 weeks for non-meditator group), we administered Cohen's Perceived Stress Scale and neurophenomenological questions pertaining to stress linked cognitive activity. We also recorded brain EEG activity under three conditions: an eyes closed baseline, a session of GSM, and a "stillness" task, during which time subjects were asked to refrain from thinking. Between start and mid- treatment timepoints, we found trending decreases

in trait cognitive stress, which co-occurred with changes in EEG activity consistent with past findings. We found that across all conditions, there were increases in both anterior right-lateralized 10Hz Alpha and in Frontal Midline 7Hz Theta(FMΘ) EEG power. Lateralized Alpha changes indicate there was an increase in differential PFC activity, implicated in the processing of positive and negative affective states. The FMΘ increases indicate decreased DMN activity associated with stress related mental function. These results suggest that GSM produces significant stress reduction in a normal healthy population, which has implications for use in treating stress related illnesses such as anxiety, depression, and cardiovascular diseases.

Title: Modeling cognitive therapy in the rat: plasticity associated with fear extinction may underly reversal of chronic stress-induced behavioral deficits

Authors: *E. A. FUCICH[1,2], D. A. MORILAK[1,2];
[1]Pharmacol., [2]Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Stress-related psychiatric disorders, like depression or post-traumatic stress disorder (PTSD), are prevalent yet poorly treated. These disorders share cognitive flexibility deficits associated with medial prefrontal cortex (mPFC) dysfunction. Psychotherapies invoking cognitive flexibility can be efficacious even in pharmacotherapy-resistant patients, although, as with pharmacotherapies, response to psychotherapy can be incomplete, some patients do not respond, and relapse remains an issue. Thus, understanding the neurobiological mechanisms underlying its efficacy could inform more rapid, efficacious, or long-lasting behavioral therapies, or could inform the development of adjunct treatment strategies designed to improve its effect. Pre-clinically, we have shown that chronic unpredictable stress (CUS) causes deficits in mPFC-

mediated cognitive flexibility in the attentional set-shifting test (AST), and induces maladaptive coping behavior in the shock-probe defensive burying (SPDB) test in rats. We have shown that fear extinction learning, which engages mPFC cognitive flexibility and conceptually resembles prolonged exposure therapy for PTSD in humans, can model cognitive therapy in rats by improving performance in the AST and SPDB tests that have been compromised by chronic stress (SfN Abstract 468.07, 2014). This study tested whether extinction induced protein translation and phosphorylation of plasticity-related synaptic proteins in the mPFC of stressed rats whose cognitive and behavioral coping deficits are reversed by extinction therapy. Western blot analyses of mPFC tissue showed elevated phosphorylation of ribosomal subunit S6 (pS6) in stressed rats after extinction compared to baseline. Similar results were found in the lateral septum, a sub-cortical target of mPFC that mediates defensive behavior on the SPDB test. Chronic stress increased phosphorylation of AMPA receptor subunit GluR1 at site S831 in the mPFC, and extinction treatment normalized pGluR1(S831) to non-stress baseline levels 24 hr after treatment. These results suggest that fear extinction induces protein translation and changes in the phosphorylation of plasticity-related proteins in the mPFC and at least one of its downstream targets. Such processes may be important to the beneficial effects on cognition and coping behaviors that have been compromised by chronic stress, and may suggest targets for the development of adjunct pharmacological tools to enhance the efficacy of behavioral therapy.

Title: Do new neurons in the hippocampus buffer long-lasting effects of traumatic stress on anxiety-like behavior and learning?

Authors: ***T. J. SCHOENFELD**, H. A. CAMERON;
NIMH/NIH, Bethesda, MD

Abstract: New neurons in the hippocampus are functionally important for normal regulation of the hypothalamic-pituitary-adrenal (HPA) axis response to acute stress, and animals without adult neurogenesis are more susceptible to behavioral abnormalities following mild acute stress. The hippocampus has been implicated in post-traumatic stress disorder (PTSD), with hippocampal volume loss often found with patients suffering from PTSD. The hippocampus is known to be highly plastic in response to stress, and adult neurogenesis in the dentate gyrus is highly regulated by stressful experiences. We tested whether new neurons in the hippocampus were functionally important for behavioral changes associated with traumatic stress. We used valganciclovir to inhibit adult neurogenesis in GFAP-TK (TK) transgenic rats for 8 weeks. Both TK rats and wild type (WT) littermate controls underwent a single-prolonged stress (SPS) procedure, which has been shown to have delayed and long-lasting effects on learning, memory, and affect, and is thought of as an animal model for PTSD. 1-3 weeks following SPS, WT and TK rats were tested on a variety of behavioral paradigms reflecting anxiety-like behavior (novelty-suppressed feeding), spatial memory (object location test), and fear learning (contextual fear conditioning and extinction). SPS reduced proliferation and adult neurogenesis 1 week following stress in WT rats. SPS was anxiogenic in WTs but had a stronger anxiogenic effect in TKs. SPS altered the behavior of WTs in an object location task; SPS had no effect on behavior in TKs, but both control and stressed TKs behaved differently than WT controls. SPS increased contextual fear conditioning in TKs but had no effect on WTs. The results suggest that rats without new neurons in the hippocampus may be more susceptible to the effects of traumatic stress on behavior.

Title: Daily amount of spontaneous running volume influences stress responses and corticotrophin- releasing hormone levels

Authors: *S. YANAGITA, N. KUBOTA, Y. TAKANO, K. TAKEDA;
Tokyo Univ. of Sci., Chiba, Japan

Abstract: Regular physical exercise can relief stress response and increase stress tolerance. In animal studies, it has revealed that spontaneous running using running wheels is particularly effective to enhance anti-stress action. Daily amount of physical exercise volume is an important factor to obtain beneficial effects of physical exercise, although our previous study showed that there are considerable individual differences on the daily amount of spontaneous running distance in rats. It is thus possible that daily exercise volume may influence stress relieving effects. In this study, we focused on the effects of daily amount of spontaneous running on neuroendocrinal response to several kinds of stress in rats. Male Wistar rats were housed individually in cages with or without an attached running wheel. Physically active rats were allowed voluntary access to their wheels for 4 weeks. The rats were screened into high runner or low runner based on the calculated daily running distance. Following to 4 weeks running sessions, the rats in both high and low runners were received severe (foot shock) or mild (psychological) stress conditions. We assessed the levels of brain corticotrophin releasing hormone (CRH), and plasma ACTH and corticosterone using ELISA following to stress stimulations. We also calculated the body and adrenal weights as an index of chronic stress response. The results showed that CRH levels in the several brain regions following to severe stress stimulation were not different between high and low runner although CRH levels in both high and low runners received stress were lower than that in control rats. Plasma ACTH levels after receiving stress in runners was higher than controls. These results suggest that daily physical exercise indeed induces anti-stress action, but these reactions are independent of amount of physical exercise in the case of severe stress conditions. On the other hands, mild psychological stress via contextual fear conditioning test induced different reactions between high and low runners on changing levels of brain CRH following to stress stimulation. This result leads to the hypothesis that severe stress stimulation could buffer the anti-stress action of daily physical exercise, suggesting that daily amount of physical exercise volume may influence stress tolerance via physical exercise to a certain degree. These results of present study suggest that it is require investigating the detail of relationship between exercise conditions and anti-stress action.

Title: Exercise modifies orexin receptor, BDNF, and TrKB receptor gene expression during social stress: Ventral versus dorsal hippocampal regions

Authors: *T. R. SUMMERS[1,2], J. K. ACHUA[1,2], J. P. SMITH[1,2,3,4], M. A. PRINCE[1,2], J. M. ROBERTSON[1,2], C. H. SUMMERS[1,2];
[1]Dept. of Biol., Univ. of South Dakota, Vermillion, SD; [2]Neurosci. Group, BBS, Sanford Sch. of Medicine, USD, Vermillion, SD; [3]Inst. of Possibility, Sioux Falls, SD; [4]Sanford Hlth., Sioux Falls, SD

Abstract: Hippocampal roles in anxiety, stress, emotion, fear conditioning, and depression may be regionally distinctive. The dorsal hippocampus is thought to be primarily responsible for spatial memory and learning, while ventral hippocampus is associated with anxiety, emotion, fear conditioning, and stress. We hypothesized that repeated social defeat using the Stress Alternatives Model (SAM) would identify differences in gene expression for Orx_1 and Orx_2 receptors as well as BDNF and its TrK_B receptor in the dorsal and ventral hippocampus. We further hypothesized that changes in gene expression, measured in dentate gyrus (DG) and CA_1, would correlate regionally with anxious behavior. The SAM arena is an oval open field with portals only large enough for smaller C57BL6/N mice, allowing for escape when mice are subject to attacks by a larger novel aggressive CD1 mouse over four daily (5 min) trials. In the SAM, social interactions result in an even split of escape or submission, with stable behavioral phenotypes established by the second day of interaction. To test for the potential anxiolytic properties of exercise, some mice had access to a running wheel for the duration of the experiment. Stress-induced changes in gene expression for orexin receptors were more prevalent in ventral hippocampus. In the absence of exercise, anxiogenic activity (aggressive social interaction in SAM) diminished Orx_1 and Orx_2 gene expression in the ventral CA_1 of submissive mice, but also decreased Orx_1 mRNA in escaping animals. Decreased ventral CA_1 Orx_1 and Orx_2 gene expression was similar in exercising mice for both escaping and submissive mice. Additionally, both escaping and submissive mice with running wheel access had decreased Orx_2 mRNA in the ventral DG. The only effect found in dorsal hippocampus was in exercising mice, where Orx_2 mRNA in the DG increased in both escaping and submissive mice. In dorsal CA_1, social submission stress reduced BDNF mRNA, which was reversed and increased by voluntary exercise. Social submission also decreased BDNF gene expression in ventral DG, which was alleviated by exercise. Social stress increased TrK_B gene expression in ventral DG for both escaping and submissive animals, which was also reversed and diminished by exercise. The results suggest that social stress-induced changes in gene expression of orexin receptors, BDNF,

and TrK_B receptors are more prevalent in the ventral hippocampus, but both dorsal and ventral regions appear to be involved. We suggest that Orx_1, but especially Orx_2 receptors of the ventral hippocampus are involved in mediation of anxious and depressive behaviors related to social stress.

Title: Exploring the effects of curcumin on morphological changes in the lateral amygdala following chronic corticosterone exposure in rats

Authors: *H. KHANDAKER[1], M. A. BRIONES[1], M. SELIGSOHN[2], T. WINER[2], S. CHIN[2], K. LOPEZ[2], G. SCHAFE[1,2];
[1]The Grad. Center, Behavioral and Cognitive Neur, New York, NY; [2]Psychology, Hunter Col., New York, NY

Abstract: Chronic stress has been strongly implicated in the development of a number of psychiatric disorders, including post-traumatic stress disorder (PTSD). The release of glucocorticoid stress hormones in response to chronic stress has been found to have contrasting effects on both morphology and physiology within different regions of the brain enriched with glucocorticoid receptors such as the amygdala, hippocampus, and prefrontal cortex. Recent findings in our lab have shown that chronic oral exposure to corticosterone (CORT), a stress-associated adrenal steroid, persistently enhances the expression of the synaptically-localized proteins GluR1 and synaptophysin within the lateral nucleus of the amygdala (LA; Monsey et al, 2014), an effect which is consistent with studies that have observed long-lasting dendritic hypertrophy and increased spine density in LA neurons in chronically stressed rats (Vyas et al, 2004; Mitra et al, 2005). Further, we have observed that these CORT-induced synaptic effects in

the LA are prevented if rats are fed a diet enriched with the polyphenol compound curcumin (derived from the rhizome of Curcuma longa) during the CORT exposure period. In the present study, we directly examine whether chronic CORT exposure is associated with spine changes in the LA, and whether a diet enriched with curcumin may prevent these morphological changes. Male Sprague Dawley rats received chronic exposure to either water or CORT (50μg/ml) in their drinking water for 14 days during the 2-week CORT exposure period, half of the rats received a diet of standard rodent chow, while the other half received chow that was fortified with 1.5% curcumin to comprise 4 groups: 1) Water-regular chow, 2) Water-curcumin chow, 3) CORT-regular chow, 4) CORT-curcumin chow. At the end of the 14-day period, brains were collected and processed using a rapid Golgi staining procedure for spine analysis. Our preliminary findings suggest that 2 weeks of oral CORT exposure increases spine density in the LA, and that a diet enriched with curcumin may prevent this effect. Our findings add further support to the hypothesis that a diet enriched with curcumin may mitigate stress-related changes in the brain.

Title: Dietary curcumin enhances extinction of a pavlovian fear memory

Authors: *M. A. BRIONES[1], H. KHANDAKER[1], M. SELIGSOHN[2], A. SEENAUTH[2], M. HUSSAIN[2], G. SCHAFE[1,2];
[1]Psychology, The Grad. Ctr. CUNY, New York, NY; [2]Psychology, Hunter College, CUNY, New York, NY

Abstract: Curcumin, a yellow-pigment compound found in the popular Indian spice turmeric (Curcuma longa), has been extensively investigated for its anti-inflammatory, neuroprotective, and chemopreventative properties. Recently, we have shown that a dietary source of curcumin significantly impairs the consolidation and reconsolidation of Pavlovian fear conditioning, a widely studied animal model of traumatic memory formation in post-traumatic stress disorder (PTSD). Here, we examined the effect of dietary curcumin on the extinction of a Pavlovian fear

memory. Rats were first trained with 3 pairings of a 5 kHz, 75 dB, 30 sec tone conditioned stimulus (CS) that co-terminated with a 1 sec, 0.75 mA footshock (unconditioned stimulus; US). Rats were then fed a diet consisting of either control chow or a 1.5% curcumin-enriched chow for 5 days prior to extinction training consisting of 40 tone-alone CS presentations. Rats fed a diet enriched with curcumin exhibited a significantly faster rate of extinction during training relative to the regular chow control group. Further, when tested for retention of the extinction memory 24 hours later, rats fed the curcumin-enriched diet exhibited significantly enhanced extinction retention relative to controls. Collectively, our findings indicate that dietary curcumin is capable of facilitating extinction learning and enhancing extinction retention. Our findings add further support to the hypothesis that curcumin may be useful as an adjunct in the treatment of psychological disorders such as PTSD that are characterized by fearful memories.

Title: Coping strategies influence emotional resilience and neurobiological markers of depressive symptoms in male and female rats

Authors: M. KENT[1], M. BARDI[1], A. HAZELGROVE[1], K. SEWELL[1], E. KIRK[1], B. THOMPSON[1], K. TREXLER[1], B. TERHUNE-COTTER[1], S. SCOTT[1], *K. G. LAMBERT[2,1]; [1]Psychology and Behavioral Neurosci., [2]Psychology, Randolph Macon Col., Ashland, VA

Abstract: Using a rodent model, our laboratory has identified specific coping strategies associated with enhanced resilience against the emergence of depressive symptoms. Rats with a flexible coping phenotype, for example, exhibit increased neurobiological markers of emotional regulation compared to active and passive copers (Bardi et al., 2012; Lambert et al., 2014). In the current study, responses of male and female rats to prediction errors in a spatial foraging task (dry land maze; DLM) were examined after animals were exposed to a depressogenic chronic unpredictable stress protocol for two weeks. Brains were processed following the DLM training/assessment for fos-activation patterns and several measures of neuroplasticity (e.g.,

BDNF; GFAP, ki-67, doublecortin) in the hippocampus and relevant areas. Results indicated that males exhibited more active exploration in the DLM probe test whereas flexible and active females exhibited more strategic rear responses (targeted to interior of maze) in the absence of the predicted reward than their male counterparts. Regardless of sex, a trend for flexible copers to spend more time in proximity to the previously baited well was observed. In a conditioned fear stimulus test, males exhibited more general exploration in response to the fear-stimulus whereas females exhibited increased rear responses and interrupted grooming sequences. Fecal samples collected during baseline and following forced swim exposure revealed higher corticosterone (CORT) in active copers, whereas flexible copers had higher dehydroepiandrosterone (DHEA) and DHEA/CORT ratios, both indications of enhanced emotional regulation. In the DLM probe test assessing the rats response to uncertainty, flexible copers exhibited fewer fos-immunoreactive cells in the basolateral amygdala and a trend toward lower activation in the insula, with no differences observed in the hippocampus and pyriform cortex. Following DLM assessment, coping profiles differentially influenced markers of neuroplasticity (e.g., GFAP and BDNF); additional analyses are currently ongoing as more neuroplasticity markers are being quantified. In sum, despite increased rates of depression reported in human females, sex effects weren't as pervasive as coping strategies in the neurobiological markers of depressive symptoms and emotional regulation/resilience investigated in the current study. This work was supported by NIMH award 1R15H101698-01A1 to KGL.

Title: Chronic Ouabain counteracted the effects of CUS in the HPA axis and CREB signaling

Authors: *J. A. LEITE[1], A. ORELLANA[2], P. KINOSHITA[3], L. DE SÁ LIMA[3], D. ANDREOTI[3], E. KAWAMOTO[3], C. MUNHOZ[3], C. SCAVONE[3];
[1]Dept. of Pharmacol. - Inst. of Biomed. Sci., USP, São Paulo, Brazil; [2]Dept. of Pharmacol., [3]Univ. of São Paulo, São Paulo, Brazil

Abstract: Ouabain (OUA), a potent inhibitor of the Na,K-ATPase pump, was identified as an endogenous hormone produced in hypothalamus and adrenal gland. This cardiac glycoside binds to Na,K-ATPase and it can activate signaling pathways in concentrations that is not linked to the common effect of the pump inhibition. It has been demonstrated the involvement of the OUA in the acute stress response, where physical exercise is capable of increasing OUA levels in rats, dogs and humans minutes after the onset of physical activity. The central effectors of the stress response are the corticotrophin releasing hormone (CRH), which stimulates the secretion of adrenocorticotropic hormone (ACTH), and this one acts on the adrenal cortex release glucocorticoid (GC) hormones. GCs in turn act back on the hypothalamus and pituitary in a negative feedback cycle to suppress CRH and ACTH production. Chronic unpredictable stress (CUS) activation has been shown to affect health, making the individual more susceptible to infections, tumors, hypertension, heart attack, stroke, autoimmunity and psychopathology. Furthermore, animal models of CUS memory impairment associated with atrophy of neuron in hippocampus and frontal cortex showed down-regulation BDNF expression. The present work investigated the effects of OUA on CUS induced changes in HPA axis and cyclic AMP response element-binding protein (CREB) expression in the hippocampus, frontal cortex and hypothalamus. Adult male rats were subjected to CUS protocol for 14 days and pre-treated intraperitoneally (i.p.) with Ouabain (1.8 mg/kg) (every other day). Serum CORT (corticosterone, the principal form of GCs in rodents) and ACTH were measured using ELISA kit. Electrophoretic mobility shift assay (EMSA) was used to evaluate CREB activity in brain tissues. Our results showed that CUS induced an increase in serum CORT and ACTH levels and chronic treatment with OUA (1.8mg/kg) counteracted the CUS effect by reducing both CORT (39%) and ACTH (53%). In addition, we found that CUS reduced CREB activity and OUA reverted it only in the pre-frontal cortex. Taken together our results indicate that OUA modulates HPA axis and CREB activities in the pre-frontal cortex. Further studies are necessary for elucidation a putative physiological role of this hormone in chronic stress response.

Title: Attenuating epigenetic alterations following exposure to caregiver maltreatment: A role for HDAC inhibition?

Authors: *T. S. DOHERTY, A. K. OHARA, T. L. ROTH;
Univ. of Delaware, Newark, DE

Abstract: Quality of maternal care plays a major role in developmental processes and, when disrupted, in the occurrence of aberrant behavioral trajectories. The underlying mechanisms of this relationship remain elusive, though epigenetic processes such as DNA methylation are promising candidates. Previously we assessed alterations in DNA methylation in adolescent rats that had been exposed to our caregiver maltreatment paradigm and discovered that females exhibited gene-specific (bdnf) changes in response to maltreatment whereas maltreated males exhibited changes on a global level, including global alterations in a recently identified epigenetic modification that plays a role in learning and memory: hydroxymethylcytosine. The aim of the current study was to assess behavioral trajectories (specifically recall of fear memories) resulting from these alterations as well as the effects of an HDAC inhibitor (sodium butyrate, administered concurrently with maltreatment) on preventing these alterations. Infant male and female Long Evans rats were subjected to either nurturing care (from their biological mother or foster dam) or maltreatment from a foster dam for 30 minutes daily from postnatal day (PN) 1 to PN7. Preliminary results indicate that maltreated males exhibit fear extinction retention deficits when compared to controls. Results will be discussed in the framework of consequences, mechanisms, and interventions in early-life stress.

Title: Prior injection of ketamine produces an enduring blockade of the effects of an uncontrollable stress

Authors: S. TILDEN[1], K. BARTHOLOMAY[1], K. SPERR[1], N. CIANCIO[1], J. AMAT[1], *S. F. MAIER[2], L. WATKINS[1];
[1]Univ. of Colorado, Boulder, CO; [2]Univ. Colorado, BOULDER, CO

Abstract: Inescapable, uncontrollable tail shocks (IS) produce neurochemicals ("learned helplessness") that include increased anxiety that is dependent on activation of 5-HT DRN neurons that project to the basolateral amygdala (BLA). There is recent interest in antidepressant and anti-stress effects of sub anesthetic doses of ketamine, an NMDA receptor antagonist. We have previously found that ketamine administered ip 2 hrs before inescapable/uncontrollable tail shocks (IS) blunts the increased anxiety and BLA 5-HT typically produced by IS. We also showed that this effect of ketamine appears to depend on the prelimbic region of the medial prefrontal cortex (SFN 2014). Here we report that the blunting of the IS effects by ip ketamine can last up to 2 weeks. A group of Sprague Dawley rats were implanted with a microdialysis cannula guide directed to the basolateral amygdala. They received an ip injection of ketamine (10 mg/Kg) or saline, a week after surgery. 2 weeks after the ip injection they received a session of IS (100 tail shocks) and BLA microdialysis. Another group of rats were injected ip with ketamine (10 mg/Kg) or saline and 2 weeks later received a similar IS session. A juvenile social exploration test occurred 24 hrs later to evaluate the level of anxiety. Ketamine given 2 weeks before IS appears to blunt the serotonergic increase and heightened anxiety produced by IS. Supported by MH050479,

Title: Protective effect of s-allyil cysteine in a chronic restraint model in rats

Authors: ***A. L. COLÍN GONZÁLEZ**, H. BECERRIL-CHAVÉZ, A. SANTAMARIA;
Inst. Nacional De Neurologia Y Neurocirugia, Mexico, D.F., Mexico

Abstract: How the Central Nervous System responds to chronic stress remains unknown, albeit some studies demonstrate that these responses include neurochemical and morphological and behavioral alterations. An often seen component of chronic stress is oxidative damage, a deleterious event produced by an imbalance between reactive oxygen species (ROS) formation and endogenous antioxidant systems. S-allylcysteine (SAC), a garlic-derived compound, a well-characterized antioxidant, has been shown to scavenge ROS, augment the levels of endogenous antioxidants, and increase the activation of Nrf2. Therefore, SAC is a promising tool for experimental protocols involving oxidative stress. In this work, we tested the effects of SAC on the behavioral, morphological and biochemical alterations in the brain of rats submitted to chronic restraint stress. Rats were immobilized for 6 h per day during 21 days, whereas SAC (50 mg/kg, i.p.) was administered daily as a pretreatment 30 min before the restraint session. At the end of the restraint protocol, different markers of toxicity were estimated: 1) brain morphology, 2) cell death ratio, 3) behavioral tasks (forced swimming test, motor alterations and elevated plus maze), 4) body weight, 5) antioxidant enzymes activity (glutathione peroxidase (Gpx) and glutathione S-transferase (GST)), and 6) lipid peroxidation. SAC reduced the morphological alterations (cell death) in CA3 (hippocampus), striatum and cortex. In addition, the enhanced number of visits that rats under stress made to closed arms in the elevated plus maze -a current index of anxiety- was significantly reduced by SAC. Enzyme activities and lipid peroxidation were both increased in stressed rats in cortex, and subsequently reduced by SAC. These results support a protective role of SAC in the noxious events produced by chronic restrain stress probably exerted by its antioxidant properties.

Title: Stress, mindfulness meditation and theta/beta ratio: a study on EEG oscillation

Authors: *S. YUAN, R. M. ATCHLEY, S. D. GARRETT-RUFFIN, H. C. CROMWELL; Psychology Dept., Bowling Green, OH

Abstract: Stress has been found to alter neural oscillations including theta and beta rhythms. Stress effects upon neural oscillations can be significant and have been found to be related to alteration in emotional regulation and cognition. Examining the ratio between faster (beta) and slower (theta) oscillations could provide more insights into these effects. Our goal of the present study was to explore how stress could alter theta/beta ratios and how this could compare to effects on the individual rhythms. Another goal of the study was to explore how mindfulness meditation practice could impact these stress effects. Mindfulness is a useful tool in clinical work and has been found to reduce stress effects. Mindfulness also has significant effects on brain signals including electroencephalographic recordings, neuroimaging and neurochemical activity. In order to explore the impact of mindfulness meditation in buffering stress and reducing the impact stress has on theta/beta ratio alterations, we trained individuals on mindful meditation prior to stress exposure. The cold-pressor task was used to induce stress. A control group practiced relaxation techniques instead of mindful meditation training. Our results revealed an impact of stress on theta/beta ratio. Stress led to a significantly higher theta/beta ratio compared to pre-stress. The effects of stress on T/B ratio changed for each group. For the most part, mindfulness did not significantly buffer the effects of stress. T/B ratios did seem to be sensitive to each treatment but also changed in the control group over time. This result suggests that T/B ratio may not a stable trait measure. The results also support the view that T/B ratio could be a sensitive marker for the effects of stress and adaptation to stress over time. One avenue for future work is to explore how theta/beta ratio could be used to predict stress effects and the effectiveness of treatment for emotional dysregulation.

Title: Effect of Aged Garlic Extract on mRNA levels of GLUT1, GLUT3 and GLUT4 in brain of diabetic rats

Authors: J. MENDOZA-BELLO[1], *P. AGUILERA[2], M. BARRAGAN-BONILLA[1], B. DE LA CRUZ[1], P. BARRERA-NAVARRETE[1], M. ESPINOZA-ROJO[1];

Abstract: Glucose is the main source of energy for mammalian brain, glucose is internalized by glucose transporter proteins (GLUT) in cells. In brain are abundantly expressed GLUT1, GLUT3, (insulin not dependent) and less proportion GLUT4 (insulin dependent). During diabetes increases the blood glucose levels and brain. This increase causes a high production of reactive oxygen species (ROS), resulting in oxidative stress state, which is an important factor for diabetic complications. ROS are involved in pathways that regulate the expression of the GLUTs, since they are able to activate and inactivate transcription factors involved in gene expression of GLUTs. In recent years it has studied the effect of exogenous antioxidants which regulate oxidative stress, disturbed blood glucose levels and improve diabetic complications. Aged Garlic Extract (AGE) is an exogenous antioxidant that lowers ROS and glucose levels in animal models, but it has not been studied the effect of AGE on the regulation of the GLUTs in the brain. To investigate it, we use Wistar rats, diabetes was induced with streptozotocin (60 mg/kg). AGE treatment (360 mg/kg) was administered daily for 42 days, at the end of treatment, the glucose was measured and animals were sacrificed, brains were dissected and total RNA extraction, RT-PCR and Real Time PCR was realized. In this model, the glucose levels increased in diabetic group. Treatment with AGE had anti-hyperglycemic effect. In diabetic group, the GLUT1 and GLUT4 level mRNA tends to decrease without significance changes, whereas GLUT3 have small increase no significant ($p>0.05$). Administration of AGE caused decreases not significant of GLUT1 ($p >0.05$), GLUT3 showed slight increase not significant ($p>0.05$) in the other hand we did find an increased statistically significant of GLUT4 mRNA ($p<0.05$). It have been showed that oxidative stress could affect DNA binding of transcription regulating factors in hyperglycemia, as the hypoxia inducible factor (HIF) and nuclear factor 1 (NF1). The treatment with AGE, neutralize ROS and HIF could be regulated, this factor active the expression of GLUT1. The expression of GLUT4 is increased by NF1, but during oxidative stress this factor is oxidized, therefore levels decrease GLUT4, the AGE probably induced the increase of NF1, by neutralized ROS. The treatment with AGE is not affect expression of GLUT3 mRNA, we propose that more studies are necessary to elucidate the role of AGE on transcription factors that regulate the expression of GLUT3

Title: Effects of early cortisol exposure on the developing GnRH neuron system in zebrafish

Authors: D. SKINNER[1], *S. RAMAKRISHNAN[2];
[1]Dept of Biology, Neurosci. Program, [2]Neurosci. Program, Univ. of Puget Sound, Tacoma, WA

Abstract: We investigate the effects of chronic stress on the development of GnRH neurons in the early zebrafish (Danio rerio) embryo. Embryonic exposure to stress has been shown to cause problems in the development of GnRH neurons in other fish species most notably salmon and carp. Exposure to stress in zebrafish had been shown to cause problems in reproductive behavior and development. Prior research has also linked abnormal development of the GnRH system in zebrafish to problems in reproduction and reproductive behavior. However, little research has been done on GnRH neuron development under stress in zebrafish. We primarily focused on the extrahypothalamic GnRH1 neurons located in the terminal nerve (TN), with a putative role in neruomodulation and social regulation of reproduction. This study investigates effects of early, chronic cortisol exposure on the TN-GnRH1 neurons of embryonic zebrafish at 2 and 3 days post fertilization (dpf). Transgenic zebrafish embryos with GnRH1 neurons tagged with green fluorescent protein (GFP) were used to easily visualize embryonic changes to the developing reproductive neuroendocrine system. Embryos were exposed to a chronic dose of the stress hormone cortisol (hydrocortisone 10μM) by way of waterborne exposure in their embryo medium from 2 hours post fertilization (hpf) through 72 hpf. Embryos were fixed at 48 and 72 hpf, mounted in agar and their TN-GnRH1 neurons were examined using an upright epifluorescent microscope. The perimeters of individual neurons were marked in ImageJ and neuron area (in μm2) and the short-diameter of the fitted ellipse (in μm) were calculated blind. Blind analysis of the images showed that embryos exposed to cortisol through 48 hpf (n=37 from 6 fish) showed a significant 23.50% reduction in the area of the individual neurons and a significant 13.54% reduction in the radius of the TN-GnRH1neurons as compared to the control embryos (n=22 from 5 fish). Embryos exposed to cortisol through 3 dpf (n=36 from 7 fish) also showed a significant reduction, but to a lesser degree, of 10.80% in the area and 8.58% in the radius of individual GnRH1 neurons as compared to the control embryos (n=27 from 5 fish). Our study suggests that chronic exposure to stress in the early embryo delays or disrupts the

development of TN-GnRH1 neurons in zebrafish (Supported by NSF CAREER Award 1253126 to SR and Univ Puget Sound UEC Grant SR1563 to DS).

Title: Effects of voluntary nicotine self-administration on fear conditioning in rats

Authors: E. RIDENER[1], C. WEBBER[1], C. W. ADAM[2], K. STOLL[2], E. MELONI[1], S. B. CAINE[2], *W. A. CARLEZON, Jr[1];

Abstract: Nicotine can facilitate learning and cognitive performance while also relieving feelings of stress. These two actions may have opposing effects on vulnerability to stress-related illness such as post-traumatic stress disorder (PTSD). The present experiments examined the effect of nicotine self-administration (SA) on the development and expression of PTSD-like symptoms in rats using the fear-potentiated startle (FPS) paradigm. FPS has elements that model an index trauma and enables quantification of exaggerated startle response and extinction deficits, two characteristics observed in humans with PTSD. Long-Evans rats were allowed to self-administer nicotine (0.03 mg/inj) or saline in 12hr (overnight) extended access sessions in standard operant conditioning chambers for a minimum of 14 sessions. Criteria for nicotine dependence was determined by SA of >0.7 mg/session for 4 out of 5 sessions and observable signs of spontaneous withdrawal 11.5 hrs post SA session. After criteria were met, rats were fear conditioned at one of two time points: either immediately after or 11.5 hrs after their last SA session. Fear conditioning consisted of 10 pairings of a 4-sec light (conditioned stimulus; CS) co-terminating with a 0.5-sec 0.6 mA footshock. Two different patterns of post-training nicotine intake were examined: for some rats, nicotine exposure was discontinued between fear conditioning and testing, whereas for others nicotine SA continued. At 10-12 days after fear conditioning, rats were tested immediately after SA three times, each test 48 hrs apart. Two metrics were examined in each of the test sessions: Context-potentiated startle (CPS) and Fear-

potentiated startle (FPS). %CPS was expressed as the percent change in startle after exposure to the conditioning context relative to a pre-training baseline. %FPS was expressed as the percent change in startle elicited in the presence of the light CS relative to trials without the CS. Rats that received fear conditioning immediately after SA sessions plus no further nicotine exposure showed reduced %CPS and normal %FPS, whereas those that continued nicotine SA showed normal %CPS but reduced %FPS. In contrast, rats that were fear conditioned during nicotine withdrawal plus no further nicotine showed elevated %CPS and normal %FPS. Rats that received fear conditioning during nicotine withdrawal plus continued nicotine SA also showed enhanced CPS, but reduced %FPS as well as enhanced extinction. Our data suggest that, under certain conditions, nicotine can reduce behavioral responsiveness to cues associated with a stressful (trauma-like) event, whereas nicotine withdrawal can enhance these same metrics.

Authors: ***A. PAVIN**[1], D. SITARAMAN[2];
[1]Dpt. of Psychological Sci., Univ. of San Diego, San Diego, CA; [2]Psychological Sci., Univ. Of San Diego, San Diego, CA

Abstract: Neuromodulators such as dopamine (DA) and serotonin have long been implicated in innate and learned behaviors. Widespread dopaminergic system manipulations depleting DA levels result in sleep regulation deficits in *Drosophila* Melanogaster (the fruit fly). Further evidence suggests that regulation of feeding is also adversely affected when DA levels are diminished. It remains unclear whether sleep deficits are a cause of dopaminergic regulation of arousal, or of motivational behavior like feeding. Using *Drosophila* as an experimental system, we analyzed specific subsets of dopamine neurons to elucidate dopamine's role in the regulation feeding and motivational behaviors. These data will be presented to establish a clear link

Title: Central mechanism of rosiglitazone induced food intake

Authors: ***J. MATIAS**, E. R. GILBERT, M. A. CLINE;
Virginia Tech., Blacksburg, VA

Abstract: Rosiglitazone, a thiazolidinedione, is a peroxisome proliferator-activated receptor gamma (PPARγ) synthetic activator that increases insulin sensitivity. A documented side effect of this diabetes drug is increased appetite, although the mechanism mediating this response is unknown. To better understand effects on food intake regulation, we evaluated the appetite-associated effects of rosiglitazone in an alternative vertebrate and agriculturally-relevant model, the domesticated chick. Four day-old chicks received intracerebroventricular (ICV) injections of 0, 5, 10 or 20 nmol rosiglitazone and food and water intake were measured. Only chicks that received 20 nmol rosiglitazone increased food intake during the 2 hour observation period, with no effect on water intake. In the next experiment, chicks were ICV-injected with 20 nmol rosiglitazone and hypothalamus was collected at 1 hour post-injection for RNA isolation. Real-time PCR was performed to measure mRNA abundance of appetite associated factors. Neuropeptide Y (NPY) and proopiomelanocortin (POMC) mRNA decreased while NPY receptor 1 mRNA increased in rosiglitazone-injected chicks compared to the controls. Results show that central effects of rosiglitazone on appetite are conserved between birds and mammals, and that increases in food intake might be mediated through NPY and POMC neurons in the hypothalamus.

Title: The interaction of binge-eating and stress-responsivity in mice

Authors: *T. A. CZYZYK[1,2], T. M. TANG[2], N. K. BARKER[2], A. N. POLITO[2], P. A. SMITH[2], J. KRANTZ[2], Y. E. GEDA[2], P. TELENSKY[2];
[1]Anesthesiol., Penn State Univ. Col. of Med., Hershey, PA; [2]Metabolic Hlth. Program, Mayo Clin. Arizona, Scottsdale, AZ

Abstract: Prolonged stress in childhood is associated with binge-eating disorder (BED) in humans, and it is thought that stress can precipitate binge-like eating episodes. We used a novel mouse model of binge-like eating behavior to better understand how glucocorticoids may be involved in the initiation and maintenance of binge-eating. C57BL/6 mice were randomized to three groups: low-fat chow diet only (chow group), unrestricted access to both energy dense, high fat diet (HED, 40% fat) and chow (HED group), or unrestricted access to chow plus access to HED during one 24h period/week (binge group) (Czyzyk, et al. 2010, Obesity, 18: 1710). Serum corticosterone levels (CORT) were measured before, during and after the initiation of binge-eating. CORT was similar across all groups 2h prior to, and 1h after the binge group had access to HED. Compared to controls, CORT was significantly elevated (double) in the binge group 6h after access to HED, but returned to baseline by 20h post-binge. Next, male and female mice with a 52 wk history of bingeing were subjected to 5 min of acute restraint stress prior to sacrifice and measurement of CORT. Basal CORT was significantly elevated in female, but not male mice of the binge group. Acute restraint stress increased CORT 4-8 times in mice of the chow and HED groups; however, neither males nor females of the binge group had elevated CORT in response to this stress. This blunted CORT response to acute stress was not observed after only 14 wk of bingeing. In a behavioral model of stress-responsivity, male mice in the binge and HED groups had significantly increased locomotor activity after a 2h restraint period compared to the chow group. However, female mice did not show this diet-dependent stress-induced hyperlocomotion after 6 wk of binge-eating. Lastly, mice were exposed to maternal separation stress followed by regular exposure to non-littermates (adolescent stress), and then 12 wk of binge-eating. Early-life stress did not overtly change the pattern of HED intake. However,

the combination of early-life stress and a history of bingeing significantly increased basal CORT in females, but not in males. Collectively, our data suggest that 1) elevated CORT after bingeing might drive subsequent overeating by decreasing the compensatory reductions in night-time food intake which has been observed in other rodent models of binge-eating, 2) the hormonal response to an acute stressor is blunted with prolonged binge eating, 3) there is an interaction between binge-eating and early life stress exposure, and 4) there are sex-specific differences in these responses which are consistent with the difference in prevalence of BED between human males and females.

Title: Effect of strawberry extracts on GABA concentration and oxidative stress in the frontal cortex of rats high fat diet fed

Authors: *C. SANDOVAL SALAZAR[1], C. OVIEDO-SOLÍS[2], S. SOLÍS-ORTÍZ[3], H. AGUILAR-ZAVALA[4], V. BELTRAN-CAMPOS[4], J. RAMIREZ-EMILIANO[3];
[1]Univ. De Guanajuato, Celaya, Mexico; [2]Medicina y Nutricion, [3]Ciencias Médicas, Univ. De Guanajuato, Leon, Mexico; [4]Ciencias de la Salud e Ingenierias, Univ. De Guanajuato, Celaya, Mexico

Abstract: Obesity is associated with psychological factors, genetic predisposition and food habits. The inhibitor neurotransmitter γ-aminobutíric acid (GABA) and the frontal cortex have a role in food intake. Some studies reported that chronic intake of a high-fat diet produce changes in GABA concentration and oxidative stress which accompanied by accelerate lipid peroxidation. Natural products, such as flavonoids found in fruits like strawberry have potential therapeutic agents recognized for their antioxidant activity. The aim of this study was to explore the effect of antioxidant strawberry no irradiated (NR) and irradiated (R) extract on the GABA

concentration, lipids damage oxidative in the frontal cortex of rats high-fat diet fed. A total of 40 healthy male rats were divided equally into four groups, the first group was fed with standar diet (SD) and the others groups was fed with high-fat diet (HF) during three months. Subsequently HF groups were separated in three groups (HF, HF-NR and HF-R) which were fed for eight weeks and received strawberry extracts. Food intake was recordly daily. Biochemical parameters was acquired using enzimatic methods. The GABA level was quantified using high-performance liquid chromatography (HPLC). Lipid peroxidation levels were analyzed by measuring thiobarbituric acid reactive substances. The SD-fed rat intake was approximately 30.4% more than the HF, HF-NR and HF-R. The glucose levels of the SD-fed rats were significantly different from the HFD-groups. The strawberry extracts NR and R decreased the cholesterol levels as the SD group. The lipid peroxidation in the frontal cortex were high in HF and HF-NR with significant difference compared with SD group. The strawberry extract R treatment decreased TBARS levels in frontal cortex. The GABA levels in the HF-fed rats demonstrated a significant decrease compared with the SD group in the frontal cortex. The GABA levels in the HF-NR group treated with strawberry NSE extract appeared to be more elevated without reaching to SD group. This results indicate that exposure to hypercaloric diet decrease the GABA concentration and increase oxidative stress in the frontal cortex, suggesting a disturbance in inhibitory process of food intake.

Title: NMDA antagonism and acquisition and expression of fat-conditioned flavor preferences in BALB/c and SWR mice

Authors: *T. T. KRAFT[1,2], D. HUANG[2], S. LAMAGNA[2], D. WARSHAW[2], E. NATANOVA[2], A. SCLAFANI[3], R. J. BODNAR[2];
[1]Home, Englewood, NJ; [2]Psychology, Queens College, CUNY, Flushing, NY; [3]Psychology, Brooklyn College, CUNY, Brooklyn, NY

Abstract: Many forms of appetitive learning are modulated by glutamatergic systems. Both sugar (e.g., sucrose, fructose) and fats (e.g., corn oil, Intralipid can condition flavor preferences (CFP) in rats and mice with previously-observed N-methyl-D-aspartate (NMDA) receptor mediation. The acquisition, but not expression, of fructose-CFP is eliminated by systemic NMDA receptor antagonism (MK-801) in rats. BALB/c mice are more sensitive to MK-801 than SWR mice in eliminating acquisition of both sucrose- and fructose-CFP. Expression of fructose-, but not sucrose-CFP was significantly, but marginally reduced by MK-801 in SWR, but not BALB/c mice. Fat-CFP can also be elicited by pairing distinctive flavors (e.g., grape, cherry Kool-Aid) with two concentrations of corn oil in rats and emulsified Intralipid in mice in training and testing for preferences. Like sugar-CFP, acquisition of fat-CFP is eliminated by NMDA receptor antagonism in rats, whereas expression is marginally affected at high doses. The present study examined whether NMDA receptor antagonism of the acquisition and expression of fat-CFP is subject to genetic variance in BALB/c and SWR mice. Food-restricted BALB/c and SWR mice drank flavored 5% (CS+, e.g., cherry Kool Aid) and 0.5% (CS−, e.g., grape Kool Aid) Intralipid solutions in ten alternating (1 h/day) training sessions followed by two-bottle choice tests with both CS+ and CS- flavors presented in 0.5% Intralipid. In expression, vehicle (Veh) and MK-801 doses of 100 and 200 ug/kg) were administered prior to two-bottle testing. Expression of fat-CFP was significantly reduced by both MK-801 doses in BALB/c (48-50%) and SWR (48-62%) mice relative to Veh preferences (71-72%), indicating the elimination of fat-CFP in both strains. In acquisition, separate groups of BALB/c and SWR mice received Veh or MK-801 (100 ug/kg) injections prior to the daily one-bottle CS+ and CS− training sessions. Six two-bottle CS+ vs. CS− choice tests were then conducted. Fat-CFP acquisition was eliminated by MK-801 in both BALB/c and SWR mice across the three pairs of tests. These data demonstrate that both murine strains require the full integrity of NMDA receptors for the acquisition (learning) and expression (maintenance) of flavor preferences elicited by fat.

Title: The role of lateral septum opioid receptors in feeding behavior

Authors: *M. CALDERWOOD, B. STANLEY;
Dept. of Psychology, Univ. of California Riverside, Riverside, CA

Abstract: Opioid peptides and receptor systems are known to be involved in the modulation and control of feeding behavior (Bodnar, 2004). Morphine, a μ opioid receptor agonist, elicits eating in rats when injected into the multiple brain regions related to feeding and reward including the nucleus accumbens shell (AcbSh) and multiple regions of the hypothalamus (Castro & Berridge, 2014; Stanley et al. 1988). Interestingly morphine produces a particularly large feeding effect when injected into the lateral septum (LS). The mechanisms underlying this septal effect are unknown and the purpose of this study was to address that deficiency. Our replication of Stanley et al., (1988) and found that feeding is elicited by morphine in lateral septum at a range of doses including 5, 8, 17 and 34 μg/.3μl. We investigated the site specificity of this effect by injecting morphine into multiple brain sites bracketing the LS and found significant and robust effects in the LS and ventral LS. Subsequently, we used the immediate early gene cFos in order to identify the pathways involved. We hypothesized that there would be significantly more cFos seen in the AcbSh and ventral tegmental area (VTA). We also hypothesized that there would be increased cFos in the lateral hypothalamus, a brain region known to be involved in feeding and which has direct connections to and from the LS (Risold & Swanson, 1997). We found no significant differences in cFos between morphine and control animals in the AbSh or the VTA. However we did find significantly increased cFos activation in the lateral hypothalamus as well as the septohypothalamic nucleus at 120 and 180 minutes post injection but not 90 minutes post injection for morphine animals compared to control animals. This suggests an important role for the lateral hypothalamus in this feeding effect and potentially a more complex role for opioids in the lateral septum in modulating feeding.

Title: Endocannabinoids and nitric oxide interactions in stress-induced feeding

Authors: ***K. M. CROSBY**[1], J. THEBEAU[1], N. COCHKANOFF[1], A. SMITHERS[2], T. BROOKS[1];
[1]Biol., [2]Chem. and Biochem., Mount Allison Univ., Sackville, NB, Canada

Abstract: Stressful stimuli trigger rapid and requisite changes that allow organisms to cope with stress and restore homeostasis. While this response can be beneficial in the short term, prolonged exposure to stress can result in long-lasting pathophysiological consequences including obesity. The mechanisms underlying the link between stress and obesity; however, are poorly understood. Numerous feeding circuits in the brain play an important role in regulating appetite and body weight, but no region is as fundamentally linked to stress and appetite as the dorsomedial nucleus of the hypothalamus (DMH). Within the DMH, communication between putative satiety neurons is modulated by two signaling molecules: endocannabinoids (eCBs) and nitric oxide (NO). Recent electrophysiological studies have revealed that eCBs and NO interact to influence synaptic activity in the DMH. It remains unknown, however, whether these *in vitro* interactions translate into *in vivo* effects on food intake and how stress alters these signals to promote obesity. Thus, the purpose of this study was to examine if eCBs and NO interact to regulate food intake, and whether this interaction is disrupted by prolonged exposure to stress. Male Sprague Dawley rats received various combinations of drugs to activate or inhibit eCB and NO signaling either into the periphery or directly into the DMH. Following drug administration, food intake and body weight were measured and brains collected to assess neuronal activity through immunohistochemistry studies. To examine the effect of stress, separate groups of animals were subjected to restraint stress, and the experiments repeated as outlined above following the final episode of stress. Overall, we show that eCBs and NO interact in the DMH to modulate food intake, and this effect is influenced by stress. These findings may provide important insight into the mechanisms that underlie stress-induced feeding.

Title: The endocannabinoid system into the Prelimbic Cortex modulates food intake in rats

Authors: *A. A. SCOPINHO[1], L. B. M. RESSTEL[2], F. M. A. CORRÊA[2];
[1]FMRP-USP, Ribeirao Preto, Brazil; [2]Pharmacol., Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Introduction: The endocannabinoid system is involved in the central regulation of feeding behavior. Systemic administration of exogenous cannabinoids or endocannabinoids stimulates eating, and systemic administration of CB1 antagonist attenuates agonists' stimulatory effects on food intake, suggesting the involvement of these receptors in food intake modulation. Although CB1 receptors are present principally in the central nervous system (CNS), little is known about which areas are involved in this modulation and the role of endocannabinoids system. Therefore, the aim of the present study is to investigate the effects evoked by CB1 receptors antagonist (AM251) and fatty acid amide hydrolase (FAAH) inhibitor URB597 microinjected in the prelimbic cortex (PL) on the food intake regulation. **Methods:** CB1 antagonist AM251 (10, 50, 100pmol/100nl), FAAH inhibitor (URB597) or aCSF- artificial cerebrospinal fluid were microinjected into the PL of fed or fasted Wistar rats and 10 min later, the food intake test was performed during one hour for food intake determination. **Results:** The amount of food ingested by fasted animals was significantly higher than fed animals ($F_{(1, 48)}$ = 482,2; P<0.001). Significant effects of treatment with doses of AM251 ($F_{(3, 48)}$ = 74,41; P<0.001) and interaction between the two factors $F_{(3, 48)}$ = 78.26; P<0.001) for total food intake (n=6-8 each group) were observed only in fasted rats. Moreover, significant effects of treatment with doses of URB597 ($F_{(3, 40)}$ = 23.56; P<0.001) and interaction between the two factors ($F_{(3, 40)}$ = 7.075; P=0.0006) for total food intake (n=6-8 each group) were observed only in fed rats. **Conclusion:** The blockade of PL CB1 receptors inhibited food intake in fasted animals, and inhibition of FAAH into the PL increased the amount of food ingested in fed rats, suggesting that PL endocannabinoid system modulated food intake behavior and satiation with involvement of anandamide and CB1 receptors.

Abstract: Obesity is defined as excess body fat and it represents a public health problem in adults and children around the world. This disease is the result of several factors, including consumption of food that has little nutritional value known as “junk food”. Current evidence has shown that feeding animals with junky food induces behavior, neurochemical and molecular changes. In this regard, we have reported previously that rats under cafeteria diet protocol displayed chocolate preference as well as an enhancement in mitogen-activated protein kinase expression in hypothalamus. To test whether intrahypothalamic microinjection of 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT), a serotonin (5-HT1A) receptor agonist, would block chocolate feeding, rats were fed with respective item during 30 days. Next, animals were implanted with a cannulae aimed to the lateral hypothalamus as well as a microdialysis guide-cannula placed into the nucleus accumbens core. After 7 days of recovery from surgical procedures, pharmacological challenges were carried out. Microdialysis samples were analyzed to determine the levels of serotonin (5-HT) by HPLC means. All rats received either a microinjection of saline (control group) or 8-OH-DPAT (10µg/1µL) into the lateral hypothalamus and microdialysis samples were collected hourly. We found that administration of 8-OH-DPAT increased chocolate-intake. Moreover, injection of 8-OH-DPAT in rats fed with chocolate did not modify the contents of 5-HT. The current results suggest that consumption of chocolate involve serotoninergic receptors presumably placed in hypothalamus. However, it seems that 5-HT is not involved in chocolate-intake. Further studies are needed to elucidate the molecular mechanisms of craving junky food.

Title: Long chain fatty acids regulate electrical activity of NPY and POMC neurons in the arcuate nucleus

Authors: **N. J. MICHAEL**[1], M. VAN DEN TOP[2], F.-Y. ZHAO[2], V. R. HAYNES[1], M. WATT[1], *D. SPANSWICK[2];

Abstract: The brain primarily utilises glucose as a source of energy, however, free fatty acids and ketones can serve as an alternate energy source under certain conditions. In addition to acting as an alternate source of energy for the brain, fatty acids have been shown to act centrally to modulate food intake, body weight, and glucose production. Previous studies suggest fatty acids, including long chain fatty acids, act as signalling molecules to some hypothalamic neurons, which may explain the changes in feeding and bodyweight observed with fatty acid administration. We sought to investigate whether the long chain fatty acids, oleic acid and palmitic acid, could regulate the electrical activity of Neuropeptide Y (NPY) and Proopiomelanocortin (POMC) neurons within the arcuate nucleus of the hypothalamus; key neuronal populations known to control energy homeostasis. Whole-cell patch clamp electrophysiology was performed on hypothalamic slices that contained the arcuate nucleus from mice expressing green fluorescent protein in NPY or POMC neurons. Bath application of oleic acid (5μM) was found to excite 36% (9/25) and inhibit 20% (5/25) of NPY neurons. In POMC neurons, oleic acid primarily induced an inhibitory response (50%, 18/36), however, 11% (4/36) of these cells were excited. Palmitic acid (40μM) also displayed both excitatory (22%, 5/23) and inhibitory (26%, 6/23) effects on NPY neurons. The effects of palmitic acid on POMC neurons mirrored those of oleic acid. The majority of the POMC neurons were inhibited by palmitic acid

(43%, 9/21), and a small proportion of these cells were excited (9%, 2/21). These results suggest that long chain fatty acids may exert their effects on energy homeostasis through direct regulation of NPY and POMC neuronal activity.

Title: Muscarinic and nicotinic cholinergic receptor antagonists differentially mediate rat acquisition of fructose-conditioned flavor preference and quinine-conditioned flavor avoidance

Authors: ***F. M. ROTELLA**, K. OLSSON, V. VIG, J. PAGIRSKY, I. YENKO, I. KOHEN, A. AMINOV, T. DINDYAL, R. J. BODNAR;
Psychology, Queens College, CUNY, Flushing, NY

Abstract: Rats display both conditioned flavor preference (CFP) to fructose, and conditioned flavor avoidance (CFA) following sweet adulteration with quinine. Previous studies indicate that whereas acquisition of fructose-CFP was significantly reduced by dopamine (DA) D1, DA D2 or NMDA, but not opioid antagonists, acquisition of quinine-CFA was significantly enhanced and prolonged by DA D1, NMDA or opioid, but not DA D2 antagonists. Both muscarinic and nicotinic cholinergic receptor signaling have been implicated in sweet intake and development of food-related preferences. Moreover, muscarinic (scopolamine: SCOP) or nicotinic (mecamylamine: MEC) cholinergic receptor antagonists decreased expression of fructose-CFP. The present study examined the effects of SCOP and MEC on fructose-CFP acquisition and quinine-CFA acquisition. In fructose-CFP, six groups of rats received vehicle, SCOP (1 or 2.5 mg/kg), MEC (4 or 6 mg/kg) or a limited intake control 0.5 h prior to 10 CS+ (8% fructose and

0.2% saccharin) and CS- (0.2% saccharin) training sessions followed by six 2-bottle CS+ and CS- choice tests in 0.2% saccharin. For quinine-CFA acquisition, five groups of rats received vehicle, SCOP (1 or 2.5 mg/kg) or MEC (4 or 6 mg/kg) 0.5 h prior to 8 one-bottle CS- (8% fructose + 0.2% saccharin: FS) and CS+ (fructose + saccharin + quinine (0.030%: FSQ) training sessions followed by six 2-bottle CS- and CS+ choice tests in fructose-saccharin solutions. Fructose-CFP acquisition was eliminated by SCOP at doses of 1 (40-54%) and 2.5 (45-58%) mg/kg accompanied by a failure to observe CS+ and CS- intake differences during testing relative to vehicle (85-92%) and limited control (74-88%) conditions. In contrast, MEC failed to alter fructose-CFP acquisition. Quinine-CFA acquisition was significantly enhanced and prolonged by MEC at 4 (18-24%) and 6 (11-13%) mg/kg relative to vehicle (34-48%). In contrast, SCOP failed to alter quinine-CFA acquisition. These data implicate the cholinergic receptor system in mediating acquisition (learning) of sugar-induced preferences and quinine-induced aversions with muscarinic receptor signaling controlling the former and nicotinic receptor signaling controlling the latter.

Title: Rapamycin increases cognition and protects against the depressive symptoms associated with chronic food restriction

Authors: *T. KENNY, M. HEBERT, P. MACCALLUM, J. WHITEMAN, G. MARTIN, J. BLUNDELL;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Anorexia nervosa (AN) is characterized by insufficient food intake leading to persistently lowered body weight and is frequently comorbid with anxiety, depression and cognitive deficits. Currently, research into the etiology of anorexia nervosa (AN) is limited by the inability of animal models to produce both its core symptoms and comorbidities. Recent data suggests that a single systemic injection of the mTOR inhibitor rapamycin (RAP) decreases food

intake for several days and lowers body weight for at least 10 weeks, mimicking the core symptoms of AN. Furthermore, preliminary data from our lab suggests that the meal patterning induced by RAP resembles that seen in AN. Thus, the goal of our study was to examine whether RAP could also produce the comorbidities of AN yielding a more comprehensive animal model of AN. We assessed anxious, depressive and cognitive behaviours during the period of decreased food intake following a single injection of RAP (1-7 days post injection), as well as 6 weeks later when food intake was normalized yet body weight remained lowered relative to vehicle-injected control animals. Anxiety-like behaviour was measured in the elevated plus maze, depressive-like behaviours were measured in the forced swim test, and cognition was measured in the novel object recognition task. To ensure that any differences in behaviour were not the result of decreased food intake or body weight alone, we included a vehicle-injected yoked control group who had their food intake matched to that consumed by their RAP-treated counterparts. Consistent with past research, a single injection of RAP decreased food intake for six days and lowered body weight for at least 57 days in rats. Interestingly, RAP improved cognition and reduced caloric restriction-induced depressive-like behaviors in the first week following injection, without altering anxiety-like behaviour or locomotor activity. Our data suggest that RAP does not produce an animal model of AN, rather it may protect against the cognitive and depressive symptoms associated with chronic food restriction. Follow-up studies are underway to examine the influence of RAP on calorie restriction-induced depressive-like behaviours and cognitive impairments. Given the pattern of decreased food intake, increased cognition and decreased depression we propose that RAP acts by upregulating serotonin via the inhibition of interleukin-2. Although our hypothesis that a single injection of RAP may act as an animal model of AN was not supported, the findings suggest that RAP may instead represent a viable option in obesity treatment.

Title: Nitric oxide produces excitation and inhibition of feeding in satiated rats via different mechanisms

Authors: N. HAZUT[1], A. WELLER[2], *A. J. SUSSWEIN[3];
[1]Life Sci., [2]Psychology, [3]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: Previous data by others has shown that nitric oxide (NO) mediates some of the orexic effects of ghrelin and PYY, and therefore it is "known" that NO excites feeding. However, we have recently found that NO is an inhibitor of feeding when rats are satiated, but nonetheless occasionally snack on chow. In this condition, treatment with a competitive inhibitor of L-arginine, the precursor from which NO is synthesized, caused increased snacking, and treatment with an NO donor caused decreased snacking. Treatment with L-arginine also inhibited snacking on chow. However, when satiated animals were offered a high-fat attractive food, rather than chow, the competitive inhibitor caused inhibition of snacking, rather than exciting it. Thus, NO has both excitatory and inhibitory effects in satiated animals, based on the palatability of the snack. NO inhibiting snacking is likely released as a result of satiating signals, whereas NO exciting snacking is released in response to attractive food. A fine-grained examination of the individual bouts of snacking showed that excitatory and inhibitory effects of NO are qualitatively different. NO inhibition regulates the number of bouts, with the NO donor and L-arginine decreasing the number of bouts, and the NO inhibitor increasing them. There were no effects on bout length or bout efficacy. By contrast, with high-fat food the NO inhibitor reduced the efficacy of bouts, without affecting their length or frequency. These data suggest that NO excitation and inhibition of feeding are via different mechanisms, probably localized to different neural sites. Excitation is via effects on bout efficacy, whereas inhibition is via bout number. The effects of an NO donor and of L-arginine in satiated animals challenged with a high fat food were not mirror images of the effect of the NO inhibitor. The NO blocker and exogenous NO and L-arginine all had primarily inhibitory effects on snacking on the high fat diet, the former by reducing bout efficacy, and the latter by reducing number of bouts. These results emphasize the dual effects of NO on snacking.

Title: Influence of glycine in food and water intake, body weigth, transaminases levels and sleep architecture in rats

Authors: F. ALBERTO-PATRICIO[1], S. A. ZAVALA-RIVAS[1], A. K. LEON-OLGUIN[1], I. JASSO-VILLAGOMEZ[2], G. BLANCAS-FLORES[2], J. VELAZQUEZ-MOCTEZUMA[1], *A. JIMENEZ-ANGUIANO[3];
[1]Area de Neurociencias, Depto. Biologia de la Reproduccion, [2]Area de Investigacion Medica, Depto. de Ciencias de la Salud, [3]Univ. Autonoma Metropolitana-Iztapalapa, MEXICO City, Mexico

Abstract: Glycine (Gly) is an amino acid involved as an anti-inflammatory that protects against disease states in animal models of ischemia-reperfusion and injury; attenuates the increase in free fatty acids and in treatment and prevention of type 2 diabetes mellitus. Gly also acts as an inhibitory neurotransmitter of the motor neurons and mediates the post-synaptic inhibition responsible for REM sleep atonia. The administration of Gly improves the quality of sleep and reduces daytime sleepiness. However, the temporary effect of the administration of Gly on metabolism and sleep is unknown. We used 16 male rats (200-250 g), under the following conditions: Control, normal water consumed (n=8) and water with Gly (10 g/1 L) for 60 days (n=8). In the first part of this study, we evaluated the effect of chronic administration of Gly quantified every third day: body weigth, food and water intake of the animals. At the beginning and at the end of treatment of Gly, we measured in samples of blood: Transaminases leves, triglycerides and glucose. In the second part, we evaluated the effect of chronic administration of Gly on sleep pattern. Electrodes were implanted for conventional sleep recordings. Once a week for one month, we realized polysomnographic recordings. Results showed that chronic administration of Gly decrease transaminases levels, food intake and body weight in relation with the control group. In sleep, Gly promoted in the first three weeks an increase in slow-wave-sleep II (SWS II) decreasing REM sleep, in relation to the control group. In the fourth week, Gly caused a gradual decrease in SWS II, with an increase in SWS I. From the gotten results we can suggest a benefical effect of Gly in the metabolism and a dual effect on sleep dependent of the time administration.

Title: Energy balance regulation by GABA neurons of the lateral hypothalamus

Authors: ***C. KOSSE**, P. IORDANIDOU, D. BURDAKOV;
The Francis Crick Inst., London, United Kingdom

Abstract: The brain's ability to control body weight is under intense investigation, and requires the lateral hypothalamus (LH). This ability of the LH has been historically attributed to weight-gain promoting LH neurons containing melanin-concentrating hormone and weight-loss-promoting neurons containing orexin/hypocretin. However, recent investigations revealed a novel subpopulation of LH neurons that are orexin- and MCH-negative, but contain GABA. We have investigated the function of these GABAergic LH neurons using pharmacogenetic tools. We found that modulating LH GABAergic neurons *in vivo* regulates body weight to the same extent as previously reported for MCH neurons. Surprisingly, food intake was not affected by activation of LH GABAergic neurons, suggesting a mechanism of weight control independent of diet. Furthermore, we used optogenetic-assisted circuit mapping to probe connections between LH GABAergic neurons and body-weight-increasing NPY cells in the hypothalamic arcuate nucleus. However, we did not find any evidence for inhibitory control of arcuate NPY cells by LH GABA neurons. Our data elucidate the function of a new controller of diet-independent hypothalamic control of energy balance, opening further avenues for dissecting neurophysiological mechanisms of weight loss.

Title: Treating obesity and related metabolic disorders through a sympathetic approach

Authors: ***C. YANG**, L. SIPE, J. HIRSH, C. DEPPMANN;
Univ. of Virginia, Charlottesville, VA

Abstract: Obesity, along with its many associated health disorders, is one of the foremost healthcare issues facing the modern world. In attempts to stave the ongoing increases in obesity rates, a number therapies for this affliction have been developed, many of which work have produced limited results in reducing obesity rates. Here, we suggest a new avenue for treating obesity by targeting the sympathetic nervous system. We report that wild-type mice placed on weight loss-inducing ketogenic diets exhibit fluctuations in the release of norepinephrine by sympathetic neurons to both white and brown adipose tissue. These fluctuations in norepinephrine appear to correspond to periods of weight loss and stoppage of weight loss across a 12 day time period. Moreover, we show that application of β3-adrenergic receptor agonists enhance weight loss in response to the ketogenic diet while the respective antagonists or complete ablation of the sympathetic nervous system can reduce weight loss responses. These data provide a foundational framework for developing novel therapies to treat obesity.

Title: Feeding effect of 5-HT1A receptor stimulation on PVN with and without inhibition of HPA axis

Authors: *M. RITO, V. LÓPEZ ALONSO, K. REYES SANTOS, G. AMBROSIO SEGUNDO, K. CRUZ GARCÍA, J. MANCILLA DÍAZ;
Univ. Nacional Autonoma De México, México, Mexico

Abstract: Paraventricular nucleus of the hypothalamus (PVN) expressed 5-HT1A receptor in parvocellular area where is located neurons that synthetize and release corticotropin release hormone (CRH). It has been described that stimulation of 5-HT1A receptor on PVN produce an increase of CRH, adrenocorticotropical hormone and corticosterone in rats due stimulation of hypothalamic pituitary adrenal axis (HPA).The aim of the present study was characterize the effect of 5-HT1A receptor stimulation on PVN with or without inhibition of HPA axis. Male Wistar rats of 250-300 g were accustomed to a diet of separate sources of protein, carbohydrate and fat, then a cannula were implanted on right PVN and a second surgery to remove the adrenal glands bilaterally (ADX) or sham surgery (sham). After the post-surgery recovery period of 5 days, the rats were assigned to a group and a treatment, sham (salt solution), sham+8-OH-DPAT, sham+WAY100635, sham+WAY100635+8-OH-DPAT, ADX (salt solution), ADX+8-OH-DPAT, ADX+WAY 100635, ADX+WAY 100635+8-OH-DPAT. 60 min record with continuous duration was made for behavioral satiety sequence (BSS) analysis. The results showed that adrenalectomy decrease food intake. Administration of 8-OH-DPAT decrease total food intake and carbohydrates in sham groups. Pretreatment with WAY 100635 prevent hypophagic effect induce by 8-OH-DPAT. BSS reveal that 8-OH-DPAT delay the natural development pattern of satiety at the beginning of dark phase. Administration 8-OH-DPAT increases Glucose serum concentration. Agonist 8-OH-DPAT decrease food intake of carbohydrates in ADX groups. Adrenalectomized rats interrupt the natural pattern of BSS. Finally is possible to conclude that HPA axis must be intact for integration of serotoninergic and CRH signals to regulate food intake and BSS.

Title: Baclofen, a GABA-B receptor agonist differentially mediates rat acquisition of fructose-conditioned flavor preference and quinine-conditioned flavor avoidance

Authors: K. OLSSON[1], F. M. ROTELLA[2], V. VIG[1], I. YENKO[1], J. PAGIRSKY[1], A. AMINOV[1], I. KOHEN[1], S. EHRENBERG[1], *R. J. BODNAR[2];
[1]Psychology, Queens College, CUNY, Flushing, NY; [2]Psychology- Neuropsychology, Queens Col. & Grad Ctr, CUNY, Flushing, NY

Abstract: Rats display both conditioned flavor preference (CFP) to fructose, and conditioned flavor avoidance (CFA) following sweet adulteration with quinine. Previous studies indicate that whereas acquisition of fructose-CFP was significantly reduced by dopamine (DA) D1, DA D2 or NMDA, but not opioid antagonists, acquisition of quinine-CFA was significantly enhanced and prolonged by DA D1, NMDA or opioid, but not DA D2 antagonists. Activation of GABA-B receptors has been implicated in both the stimulation and inhibition of food intake, depending on the paradigm, route of administration and site of action. Recently, the GABA-B receptor agonist, baclofen (BAC) decreased expression of fructose-CFP. The present study examined the effects of BAC on fructose-CFP acquisition and quinine-CFA acquisition. In fructose-CFP, three groups of rats received vehicle or BAC at doses of 3 or 5 mg/kg 0.5 h prior to 10 CS+ (8% fructose and 0.2% saccharin) and CS- (0.2% saccharin) training sessions followed by six 2-bottle CS+ and CS- choice tests in 0.2% saccharin. For quinine-CFA acquisition, three groups of rats received vehicle or BAC at doses of 3 or 5 mg/kg 0.5 h prior to 8 one-bottle CS- (8% fructose + 0.2% saccharin: FS) and CS+ (fructose + saccharin + quinine (0.030%: FSQ) training sessions followed by six 2-bottle CS- and CS+ choice tests in fructose-saccharin solutions. The magnitude of fructose-CFP acquisition was reduced across the three pairs of choice tests by BAC at doses of 5 (71-76%), but not 3 (89-93%) mg/kg relative to vehicle (85-92%). Quinine-CFA acquisition transiently occurred in vehicle-trained rats after the first (34%), but not the subsequent two tests (47-48%). Whereas rats trained with the 3 mg/kg BAC dose showed stable quinine-CFA across all three tests (33-34%), rats trained with the 5 mg/kg BAC dose displayed significantly enhanced and prolonged quinine-CFA (15-25%). These data implicate the GABA-B receptor system in reducing acquisition (learning) of sugar-induced preferences and in enhancing quinine-induced aversions.

Title: Effects of chronicle central insulin infusion on food intake, glucose metabolism, and adiposity of male and female Wistar rats

Authors: *A. C. KISS[1], M. C. D. DE MACEDO[2], D. W. DA SILVA[2], G. C. DE SOUZA[2], M. O. KLEIN[3,4], L. F. FELÍCIO[3], B. C. WOODSIDE[5];

Inst., São Paulo, Brazil; [5]Psychology Dept., Concordia University, Ctr. for Studies in Behavioral Neurobio., Montreal, QC, Canada

Abstract: High levels of insulin act on the brain decreasing the drive to eat. Research in animals showed that intracerebroventricular (ICV) administration of insulin decreases food intake, body weight, and adiposity. However most of these studies were conducted on males and it is well established that food intake on females varies according to estrous cycle phase and their reproductive state. There is evidence that male and female brains respond differently to ICV acute injection of insulin, with males being more sensitive to insulin catabolic effects. In a previous short experiment in our lab, the effect of chronicle insulin ICV infusion on female rats was studied and although the dose used is known to decrease food intake in males, in females there was no difference. Therefore, the present study aimed to investigate the effects of chronicle central insulin infusion on food intake, glucose metabolism, and adiposity of male and female Wistar rats. Female and male Wistar rats were randomly assigned to the following experimental groups: female saline (FS, n=10), female insulin (FI, n=10), male saline (MS, n=10), and male insulin (MI, n=10). Female rats from FS and FI groups were ovariectomized on postnatal day (PND) 75, 15 days before cannula placement surgery. All rats underwent surgery for cannula placement in the lateral ventricle around PND 90. Osmotic pumps delivered either saline or 10mU of insulin per day at a rate of 1µl/hour for 7 consecutive days. Body weight and food intake were recorded daily. Rats were submitted to glucose tolerance test. Body fat percentage was calculated. Unlike males, females did not present reduced food intake, body weight, or adiposity in response to ICV chronicle insulin infusion. Our results reinforce the importance of

studying sex difference response to the same treatment and add up to the demand to balance the use of males and females in research.

Abstract: The CB1 receptors (RCB1) of the nucleus accumbens shell act as neuromodulators in coding reinforcing stimuli of food, especially when this is high-calorie, high consumption of this food is the major cause of obesity. That is why the aim of the study, is to evaluate the activation of CB1 receptors in rats fed for two months with a standard diet after being exposed to a high-calorie diet for five months. To a group of male rats of the strain Sprague Dawley, exposed for five months to a high-calorie diet (45% of lipid content, n = 4) and then expose them for two months with a standard diet (10% of lipid content). After spontaneous standard food consumption at the beginning of the dark phase was evaluated for two hours. Evaluations were made in subjects who were implanted with a cannula guide in the nucleus accumbens shell, was four treatments in a Latin square, with two days off between treatment. As agonist RCB1 the ACEA (0.5µg/µl) was used, as the antagonist AM281 (0.5µg/µl) was used. The results show that subjects previously exposed to five months of the calorie diet after two months of standard diet are more sensitive than controls.

Abstract: The etiology of obesity involves different factors,including the consumption of food with poor nutriotional content. It is known that feeding animals with junk food promotes significant behavioral and molecular changes. In this regard, we have studied that rats under cafeteria diet protocol displayed chocolate preference as well as an enhacement in the expression of molecular marker, mitogen-activated protein kinase in hypothalamus. If chocolate preference is established,it is likely that neurochemical disruption could be linked with choosing this food item. Then,it is plausible to test the hypothesis that chocolate preference involve hedonic brain areas such as nucleus accumbens (AcbC) as well as endogenous molecules, including dopamine (DA).The aim of the present study was to describe whether D1 receptor antagonist drug (SCH23390) reduces chocolate-intake. To test the hypothesis, rats were fed with chocolate during 30 days. Next, animals were implanted with a cannulae aimed to the lateral hypothalamus as well as a microdialysis guide-cannula placed into the AcbC. After 7 days of recovery from surgical procedures, pharmacological challenges were carried out. Microdialysis samples were collected and analyzed to determine the levels of DA by HPLC means. All rats received either a microinjection of saline (control group) or SCH23390 (10μg/1μL) into the lateral hypothalamus and microdialysis samples were collected during 4h. It was found that microinjection of D1 receptor antagonist increased chocolate-intake. Despite this result, we found that endogenous levels of DA did not show statistical differences after the administration of SCH23390. Although it may be premature to suggest that blocking the activity of D1 receptor presumably placed into lateral hypothalamus, promotes chocolate-intake, preliminary data provides new insight regarding the potential mechanism of action of craving of junky food. This study was supported by Research Grant Program at Escuela de Medicina, Universidad Anáhuac Mayab given to E.M.-R.

Title: Free access to running wheels normalizes hyperphagia and obesity in human growth hormone transgenic rats

Authors: ***M. KOMATSUDA**, K. YAMANOUCHI, T. MATSUWAKI, M. NISHIHARA; Vet. Physiology, The Univ. of Tokyo, Tokyo, Japan

Abstract: Obesity is a major health problem especially in developed countries. Increased food intake and decreased physical activity are considered as two major factors causing obesity. We previously produced human growth hormone transgenic (TG) rats, which are characterized by severe hyperphagia and obesity. Some previous studies show that voluntary exercise in a running wheel affect body weight not only by increasing energy consumption but also by decreasing food intake. Therefore, we examined whether voluntary running wheel exercise causes inhibition of hyperphagia and any alteration of body weight in TG rats. Male TG rats and their wild type littermates were maintained in cages with or without running wheels from 4 (immature) or 8 (mature) to 16 week of age. Food and water were provided ad libtim. Free access to running wheels completely abolished hyperphagia and obesity in TG rats, and this effect persisted until the end of the experiment as far as the running wheel was accessible. This effect was independent from ages that rats started voluntary running. Once those running wheels were locked and immobilized, hyperphagia of TG rats recurred immediately. Unexpectedly, though the running distances of TG rats were significantly less than those of wild type rats, it was sufficient to normalize their food consumption. Next, we conducted c-fos immunohistochemistry in brains of these rats to determine the neurons that are involved in normalizing hyperphagia by running wheels. C-fos positive neurons in the raphe nucleus and medial amygdaloid nucleus increased when rats were kept in running wheel accessible environment. However, activation of these neurons was canceled if running wheels were immobilized three hours before the sampling.

Our findings raises the possibility that rearing environment, which enables rats to access to a running wheel anytime they want, rather than the amounts or intensity of physical exercises, is more important for the maintenance of proper food intake and body weight. Furthermore, neurons in the raphe nucleus and medial amygdaloid nucleus could be relevant to normalizing hyperphagia in TG rats.

Title: Effect of frequent intake of steviol glycosides on the JAK2/STAT3 signaling pathway in the central nervous system of mice

Authors: *A. A. BARRIOS, J. A. ESTRADA, I. CONTRERAS;
Lab. de Neuroquímica, Univ. Autónoma Del Estado De México, Toluca, Mexico

Abstract: Sweeteners are food additives that are commonly used worldwide. There are discrepancies in epidemiological studies evaluating their effect on body weight and appetite; this generates the need to further study the mechanism by which sweeteners could affect satiety and energy balance. This study´s main objective was to evaluate whether frequent intake of the steviol glycosides found in Stevia rebaudiana leaves could cause alterations in the JAK2/STAT3 signaling pathway, mediated by leptin, in the central nervous system of mice. For this purpose, two study groups composed of 14-week-old female BALB/C mice were established: a control group supplied with pure water, and a steviol glycosides group, which was supplemented with this sweetener in their daily water for 6 weeks. Mice were fed ad libitum and weight was measured weekly. The amount of food and drink intake was measured daily. After 6 weeks, body composition of mice was determined using bioelectrical impedance and total brain proteins were obtained, to determine the expression of total and phosphorylated JAK2 and STAT3 by Western Blot. Our preliminary results show that there was a higher consumption of food and water in the control group and also increased body weight, but mice supplemented with steviol glycosides had more adiposity. Regarding JAK2/STAT3, expression of pJAK2 was found to be diminished in the group supplemented with this sweetener, whereas we did not observe changes in the STAT3 proteins. Our results suggest that frequent intake of the steviol glycosides may cause

alterations in energy balance and appetite by altering the phosphorylation of JAK2. The alterations observed in adiposity in supplemented mice could be related to modifications in the activity of the thyrotropin-releasing hormone, which indirectly regulates adiposity in the organism and is controlled by the JAK2 signaling pathway.

Title: Pharmacological treatment as part of inward psychiatric treatment of anorexia nervosa patients; a clinical retrospective study

Authors: ***A. H. LECKLIN**;
Sch. of Pharm., Univ. of Eastern Finland, Kuopio, Finland

Abstract: Anorexia Nervosa (AN) is a serious psychiatric illness. Even though psychotropic drugs are not officially approved for adolescent AN, their use in recent years has increased and many clinicians prescribe these drugs for treatment of comorbid conditions of AN. This study examines the use of medications in adolescent AN inpatients treated in Kuopio University Hospital. A retrospective study of anorexia nervosa patients (n=82, 96 % females) admitted to Department of Adolescent Psychiatry of the Kuopio University Hospital during January 1st 2002 and December 31st 2012 was conducted. Data from medical files were collected. The age of the patients at first admission was 15,6 years (range 11-17). On admission, mean body mass index (BMI) of the patients was 15,6 kg/m^2 (range 12,3-24,4 kg/m^2). Every fifth patient had been vomiting, 62 % were over-exercising, 9 % had abused laxatives or other drugs for weight control. In every third of patients nutritional support was initiated with temporary nasogastric feeding. Psychiatric comorbidity was common: 65 % had depression and every second (51 %) anxiety. Approximately 15 % of the patients showed obsessive-compulsive behavior and 15 % were psychotic. One third of the patients (36 %) had self-destructive behaviour. The average length of hospital stay was 88 days (range 1-612 days). Length of stay correlated with the decrease in the BMI. Psychopharmacological medications were prescribed to 84 % of the patients. SSRIs and mirtazapine were the most common antidepressants while quetiapine and olanzapine were the most often used antipsychotics. Anxiolytic and sedative drugs had been prescribed to half of the patients. Psychopharmacological drugs were rather well tolerated except

for the antipsychotics that caused side effects in every second patient. At discharge, the psychosocial functioning of the patients had improved, their nutritional status was better and there were reductions in symptoms associated with eating disorders.

Title: Decreased dopamine levels in overweight young women

Authors: ***M. SOLIS-ORTIZ**[1], C. SANDOVAL-SALAZAR[2], J. RAMIREZ-EMILIANO[3], A. P. ROMERO-LÓPEZ[3];
[1]Inst. Invest Med, Univ. Guanajuato, Leon, Mexico; [2]Enfermería y Obstetricia, Univ. de Guanajuato, Celaya, Mexico; [3]Ciencias Medicas, Univ. de Guanajuato, Leon, Mexico

Abstract: Dopamine, a very powerful neurotransmitter, control feeding of well-being. The consumption of carbohydrate binging stimulates the brain's production of and utilization of dopamine and regulate Body Mass Index (BMI). Thus, in obese subjects dopamine deficiency may promote compensatory pathological eating to activate reward circuits. However, this relationship is remains unclear. The aim of this study was to evaluate the dopamine levels and consumption of kilocalories in overweight women. Twenty young women with a mean age of 31 years, with a BMI $\geq$ 25 Kg/m^2 and 20 young women with a mean age of 31 years, with a BMI $\leq$ 24.9 Kg/m^2 were evaluated. Dopamine levels in serum, consumption of kilocalories, micronutrients intake and percent body fat were measured and compared between groups. The overweight women compared with the normal weight group, showed decreased dopamine levels ($p= 0.003$), higher BMI ($p= 0.001$), higher percent body fat ($p= 0.001$), increased kilocalories, carbohydrates and lipids intake. This results suggesting that the low level of dopamine in serum may reflect the reward deficiency syndrome caused by a brain reward cascade dysfunction and resulting in abnormal craving behavior.

Title: Intracranial EEG of hippocampal-amygdala dynamics during emotional memory discrimination

Authors: J. J. LIN[1], R. F. STEVENSON[2], S. L. LEAL[2], J. ZHENG[1], J. ROBERTS[2], J. RILEY[1], *M. A. YASSA[2];
[1]Neurol., Univ. of California, Irvine Sch. of Med., Irvine, CA; [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Emotional arousal, mediated by the amygdala, is known to modulate episodic memories stored by the hippocampus, a region involved in pattern separation (the process by which similar experiences are stored using non-overlapping representations). Using high-resolution fMRI, we have previously shown that the DG/CA3 region of the hippocampus is engaged during accurate discrimination of highly similar items during performance on an emotional discrimination task. Furthermore, this effect was specific to negative compared to neutral items. However, the amygdala was modulated by emotion, regardless of memory performance (Leal et al., Hippocampus 2014). We suggested a potential mechanistic account for how emotional information is processed by the amygdala-hippocampal network. While high-resolution fMRI afforded us excellent spatial resolution, a higher temporal resolution is needed to characterize the dynamics of hippocampal-amygdala interactions. In the current study, we tested pre-surgical patients with epilepsy that had hippocampal and amygdala depth electrodes implanted to determine the locus of seizures. Using a high-resolution MRI anatomical template (.55mm isotropic), coupled with post-implantation individual subject MRI scans, we were able to determine the location of the depth electrodes within hippocampal and amygdala subregions. We analyzed power, coherence, and phase-amplitude coupling in the theta (4-8 Hz) and gamma (30-250 Hz) ranges during discrimination of similar emotional and neutral scenes. We found coordinated activity across the hippocampus and amygdala modulated by memory and emotion. Together with our high-resolution imaging findings, we are able to gain a better understanding of how the amygdala-hippocampal network subserves emotional episodic memory.

Title: High-resolution fMRI of hippocampal-amygdala dynamics during emotional memory discrimination in healthy aging and late-life depression

Authors: ***S. L. LEAL**[1,2], J. A. NOCHE[2], E. A. MURRAY[2], M. A. YASSA[2];
[1]Psychological & Brain Sci., Johns Hopkins Univ., Irvine, CA; [2]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Episodic memory loss is a common facet of age-related cognitive decline as well as depression. Medial temporal lobe (MTL) structure and function are altered in both aging and depression, which includes loss of hippocampal volume due to subtle synaptic changes and a susceptibility to interference among similar experiences. Understanding the common and distinct neurobiological bases of age-related cognitive decline and late-life depression will allow us to more appropriately target interventions. We have developed an emotional discrimination task that is sensitive to subtle behavioral effects of emotional memory processing. This task explicitly manipulates stimulus interference (by varying scene similarity) as well as emotional content. Using high-resolution fMRI, we are able to ascribe the behavioral effects to interactions among hippocampal subfields and amygdala nuclei. Previously, we found that young adults with depressive symptoms showed a shift in hippocampal-amygdala activity, with increased amygdala activity and reduced DG/CA3 activity during discrimination of negative scenes (Leal et al., Hippocampus 2014). In the current study, we investigated activity within the hippocampal subfields and amygdala nuclei in older adults with and without depressive symptoms (age 60-90) as they performed the emotional discrimination task in the MRI scanner. We examined activity within hippocampal subfields and amygdala nuclei during accurate emotional discrimination. We find that depressive symptoms are associated with shifts in hippocampal-amygdala processing in

older adults. These findings suggest that the MTL network is altered in aging and depression and that these two conditions may interact to confer added vulnerability in this network.

Title: Sequential priming interferes with mnemonic discrimination of similar objects

Authors: ***J. M. ROBERTS**, K. A. KERNODLE, J. A. NOCHE, E. A. MURRAY, M. A. YASSA;
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Computational models describing sequence memory such as the associative chaining model, the temporal context model, and many others predict that activation of a memory also activates temporally proximate memories. Prior work by our lab has been guided by a model of the hippocampal DG/CA3 network as multi-domain pattern separation/completion network. We applied this model to an investigation of the temporal aspects of memory encoding and retrieval using a variation of a well-established mnemonic discrimination task. During the basic task, participants undergo an incidental encoding phase in which they are shown everyday objects and are asked to indicate for each object whether it is indoor or outdoor. Following encoding, they undergo a recognition memory test, where they are shown repetitions (targets), novel foils, and similar lures (to tax pattern separation). In order to test the effect of sequential priming, we examined discrimination performance during test on similar lure items that were presented following three different types of target cues. The first was the same target that immediately preceded the similar object that they saw during encoding (FORWARD). The second was the target that immediately followed the similar object that they saw during encoding (REVERSE). The third was a completely out of sequence target (RANDOM). We predicted that sequential priming would result in a network bias towards pattern completion due to increased interference resulting from activation of the similar object's neural representation. Thus, we expected lure

discrimination to be reduced in the FORWARD priming condition. Consistent with our prediction, we found that compared to the RANDOM condition, participants were more likely to false alarm to a similar lure object in the FORWARD priming condition, but not in the REVERSE condition. We discuss this result in the context of computational models of sequence memory as well as models of the DG/CA3 network as a multi-domain pattern separation/completion network.

Title: Network mechanism of amygdala and ventromedial prefrontal cortex during labeling of negative emotion

Authors: J. ZHENG[1], H. ERKOL[1], J. RILEY[2], G. GULSEN[1], K. ANDERSON[5,6], S. VADERA[3], M. YASSA[4], R. KNIGHT[5,6], *J. LIN[2];

Abstract: The ability to regulate negative emotions is an important adaptive skill that enables individuals to respond effectively to stress. The network controlling stress involves the amygdala and anatomical connections to ventromedial prefrontal cortex (VMPFC), anterior cingulate, and insula. During regulation of negative emotion, an inverse correlation between the amygdala and VMPFC has been observed in fMRI studies, leading to the hypothesis that VMPFC suppresses activation in the amygdala, in an effort to reduce emotional distress. To explore the electrophysiological mechanism regulating negative emotions, we recorded simultaneously from amygdala, hippocampus, VMPFC, anterior cingulate and insula using intracranial depth electrodes in 3 human subjects. During the task, each subject was asked to 1) label the emotion

by choosing one of two words on the right and left of the screen (angry, sad, afraid, happy, neutral) to describe the emotional face presented in the center; 2) match emotion by choosing one of the two emotional faces presented on the right and left side of the screen to match the emotional expression of a face presented in the center. The analysis focused on comparisons of spectral power and inter-trial phase coherence (ITC) between negative emotions (angry + sad + afraid) and neutral/happy emotions. Specifically, the extent of multimodal phase locking distribution across trials was quantified by phase bifurcation index (Busch,et al., Journal of Neuroscience 2009) wherein a value of -1 denotes absence of synchronization across trials between the EEG signal and time locked stimulus, while a value of 1 indicates perfect phase locking in both conditions. The time frequency spectral analysis showed valence-selective increases in high-gamma activity (HG; 80-100Hz) for negative emotional trials relative to neural/happy trials in the amygdala, hippocampus, VMPFC, and insula. In addition, phase bifurcation index value revealed that in the amygdala and insula, significant phase locking in the 4-8 Hz frequency band was present for both conditions (negative emption and neutral/happy emotion). In contrast, the VMPFC showed selective phase locking in the low gamma range (50-60Hz) only for the negative emotional condition. These results provide evidence that the VMPFC employs gamma phase coherence as an oscillatory mechanism to discriminate negative emotions from neutral/happy emotion, whereas the amygdala and insula play a valence independent role in emotional processing.

Title: Changes in temporal context memory precision along the hippocampal longitudinal axis

Authors: ***M. MONTCHAL**, M. A. YASSA;
UC Irvine, Irvine, CA

Abstract: Specificity is an important aspect of memory that may be differentially supported along the longitudinal (anterior to posterior) axis of the hippocampus. Rodent work has shown that the scale of place fields increases linearly from dorsal to ventral hippocampus (analogous to posterior to anterior in humans). Evidence from fMRI studies in humans has also suggested a

precision scale along the anterior-posterior axis of the hippocampus. This body of work, however, has focused almost exclusively on spatial precision. Computational models of hippocampal function as well as empirical evidence from animal studies have suggested that the mechanisms underlying spatial and temporal memory processing are largely the same. We aimed to examine whether the precision of temporal memory is also represented differentially along the longitudinal axis. We developed a novel, naturalistic task to test the hypothesis that the anterior hippocampus supports memory for less precise temporal context, while the posterior hippocampus supports memory for more precise temporal context. During encoding, participants viewed a 30-minute video (sitcom), to which the participants had no prior exposure. During retrieval they were asked to place still frames from the video on a timeline (0 to 30 minutes). We assessed the precision of their judgments by calculating the temporal distance between the actual time at which the still frame occurred in the video and their indicated time. Based on this measure, we classified trials as low, medium, and high precision and we report activity within hippocampal subregions along the hippocampal axis. These results inform our understanding of the hippocampal division of labor and how the hippocampus represents temporal information.

Title: Repeated study engages neocortex but disengages the hippocampus: Evidence for rapid systems consolidation?

Authors: *Z. REAGH[1,2], H. D. HO[2], E. A. MURRAY[2], M. A. YASSA[2];
[1]Dept. of Neurobio. and Behavior, [2]The Univ. of California, Irvine, Irvine, CA

Abstract: It is widely assumed that repeated study improves memory for all studied information. We recently proposed a theory that challenges this assumption on the basis of competing hippocampal memory traces (Yassa & Reagh, Frontiers in Behavioral Neuroscience 2013). One hypothesis arising from our theory is that repetition of an identical stimulus can induce highly similar but not perfectly overlapping memory traces, which can induce competitive memory interference and lead to a loss of detailed information during retrieval. We previously demonstrated behavioral evidence consistent with this phenomenon, where repeated study was found to boost target recognition but was detrimental to discrimination of similar lure items from those originally studied (Reagh & Yassa, Learning & Memory 2014). The present study replicated this behavioral outcome, and investigated the neural mechanisms underlying this tradeoff. Using whole-brain high-resolution fMRI (1.8mm isotropic), we found that repeated study induced a downward modulation of hippocampal activity, and an upward modulation of neocortical activity. Specifically, we report a repetition-mediated dynamic between the CA1 subfield of the hippocampus and anterior cingulate/medial prefrontal cortices, a relationship implicated in systems consolidation in animal models. We take these findings as evidence for competitive interference among overlapping memory traces, leading to more stable semantic memories at the expense of episodic details. We furthermore suggest that repetitions of a stimulus within a brief time frame may induce a rapid form of systems consolidation.

Title: Remembering emotional gist and detail information: individual differences in age-related memory loss

Authors: *J. A. NOCHE[1], S. L. LEAL[2,1], E. A. MURRAY[1], M. A. YASSA[1];
[1]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Changes in memory performance are one hallmark of cognitive dysfunction in aging. However, it is unclear whether there are modulatory systems that may allow older adults to

compensate for these changes. Previously, we reported that older adults remembered both emotional gist and detail information, compared to young adults who only remembered more emotional gist information (Leal & Yassa, Behav Neurosci 2014, Leal et al., Neurobio of Learning & Memory 2014). It is unclear as to whether this general emotional memory enhancement in aging is compensatory or dysfunctional. A modified version of The Wechsler Memory Scale Logical Memory Subset was developed to assess and control emotional content and to examine gist and detail memory. Adults aged 60-85 were tested on their memory for the gist and detail information for three short stories (negative, neutral, and positive) after an immediate, 20-minute, and 1-week delay. A neuropsychological battery was administered, and subjects were split into aged impaired (AI) and aged unimpaired (AU) groups based on the Rey Auditory Verbal Learning Test (Rey, 1941). Overall, we found a bias for remembering negative gist and detail information, where the effect was largest after one week. The difference between immediate and 1-week delay performance was calculated (forgetting rate), where AI subjects showed a preservation of emotional gist and detail information and a selective forgetting of neutral information, while AU individuals did not exhibit this pattern of forgetting. However, AI subjects remembered positive gist and detail information much better than AU subjects, suggesting that the positivity bias in aging might be driven by individuals who show some memory loss. This may be a mechanism to compensate for a general memory deficit, where emotional information is prioritized at the expense of remembering neutral information.

Title: High-resolution fMRI of source memory and mnemonic discrimination

Authors: ***R. STEVENSON**, Z. M. REAGH, A. P. CHUN, E. A. MURRAY, M. A. YASSA; UC Irvine, Irvine, CA

Abstract: Numerous studies have shown that the hippocampus and neocortex differentially contribute to item recognition and contextual source memory. However, the relationship between source memory and mnemonic discrimination of similar items is poorly understood. General item recognition is thought to be supported by the neocortex, whereas mnemonic discrimination is thought to be supported by the hippocampus, much like source memory. Using a well-validated object discrimination task modified to include a source memory component, previous work in our lab has shown that correct source memory judgements can occur in the absence of mnemonic discrimination (i.e. false alarms), indicating that these processes are behaviorally dissociable (Kim & Yassa, Hippocampus 2013). The present study used high-resolution fMRI to simultaneously assess hippocampal and cortical activity during mnemonic discrimination of similar items and source memory judgments for these items. We found that hippocampal and neocortical activity are differentially modulated by source memory and mnemonic discrimination, supporting the idea that these processes are indeed dissociable at a neural level. As source memory and mnemonic discrimination are thought to reflect recollection and pattern separation respectively, our data suggest distinct neural mechanisms for these computations.

Title: Hippocampus and medial prefrontal cortex show activity and functional connectivity during memory for sequences of events

Authors: *V. K. BOUCQUEY, T. A. ALLEN, D. J. HUFFMAN, N. J. FORTIN, C. E. L. STARK;
Neurobio. and Behavior, Univ. of California, Irvine, CA

Abstract: Memory for the sequence of events is a critical component of episodic memory. However, the neurobiological substrates of this type of memory are not well understood, especially in humans. To address this, we acquired BOLD fMRI data in humans while preforming our cross-species sequence memory task. The task tests memory for non-spatial sequences of events and shows cognitive parallels in rats and humans (Allen et al., 2014), allowing for multidisciplinary research. Subjects were presented with four different sequences of six distinct kaleidoscopic images in succession (e.g., Sequence "ABCDEF"). Subsequently, BOLD fMRI was acquired while subjects were presented images with all items in sequence (e.g., "ABCDEF"), or with one item out of sequence (e.g., "ABC**F**EF"). Subjects initiated image presentations by pressing down a button. Images disappeared when the button was released, or after the decision threshold (1sec) was reached. If an image was "in sequence" the subjects were instructed to hold down the button until the decision threshold was reached (i.e. the image disappeared), if the image was "out of sequence" they were instructed to release the button before the decision threshold was reached. Successful sequence memory was demonstrated if subjects responded accurately to both "in sequence" and "out of sequence" items. Each subject accurately indicated items as "in sequence" and "out of sequence" at levels significantly greater than chance. We then completed a whole-brain analysis contrasting "in sequence" with "out of sequence" presentations. We found that the sequence task showed activation of the hippocampus (HC) and the medial prefrontal cortex (mPFC). In addition, we completed a functional connectivity analysis correlating the BOLD time-series within each of these regions (HC and mPFC) to the rest of the brain. Using the HC as the seed region, we found a reliable correlation of activity with the mPFC over the course of the task, and vice versa. Therefore, hippocampus and mPFC are active as well as likely interacting during memory for sequences of events. The results are consistent with previous research in rats that used a temporary inactivation approach to show the cross-species sequence task relies on the hippocampus and medial prefrontal cortex. Further, single-unit recordings in rats from the CA1 region of the hippocampus and prelimbic region of the medial prefrontal cortex show a dynamic and complementary series of changing representations that can solve the sequence task. The current results extend this work to humans and strongly suggest homologous underlying neural substrates in memory for sequences of events.

Title: Acute moderate exercise improves pattern separation in young adults

Authors: ***K. SUWABE**[1], K. HYODO[1], K. BYUN[1], G. OCHI[1], M. YASSA[2], H. SOYA[1];
[1]Univ. of Tsukuba, Tsukuba City, Japan; [2]Univ. of California-Irvine, Irvine, CA

Abstract: Many studies have revealed that exercise enhances hippocampal functions such as neurogenesis and spatial memory in animals, but there is less evidence for the critical component of episodic memory, pattern separation, associated with the dentate gyrus (DG) of the hippocampus. A recent study has suggested the beneficial effects of exercise on pattern separation in animals (Creer et al., PNAS, 2010), which should be possible considering the facilitatory role of acute exercise for the neuronal activities of the DG, as shown in our animal studies using a treadmill exercise model (Soya et al., BBRC, 2007). Also, considering that increased peripheral adrenalin levels modulate norepinephrine release in the hippocampus through the locus coeruleus (Miyashita et al., 2004), it is conceivable that increased sympathetic nerve activity (SNA) with exercise has an immediate impact on the DG and improves pattern separation ability. We thus postulated that this should be the case in humans. In the present study, twenty-one healthy young adults (mean age 20.9 ± 1.5 years, 8 females) participated in both of two experimental conditions: exercise and resting control. A mnemonic similarity task (MST) was performed after 10 minutes of moderate intensity exercise (50%Vo2peak) or rest (control). Salivary alpha-amylase (sAA) levels and the two-dimensional mood scale (TDMS) were measured at three time points (baseline, just after exercise, and just after encoding). Exercise enhanced discrimination of similar items (participants responded with ‘similar’ or ‘new’ for lure items) compared to rest (exercise: 62.0% vs. control: 58.5%). Analysis by item similarity showed significant main effects of both similarity and exercise. Traditional recognition memory performance (responses of ‘old’ for target items minus responses of ‘old’ for foil items) was unchanged with exercise. sAA and arousal levels measured with the TDMS increased after exercise (time point 2 minus baseline) compared to control. No correlations between sAA changes and MST performance changes or arousal changes and MST performance changes were found. These results support the hypothesis that acute moderate intensity exercise involving increased SNA may improve pattern separation in memory encoding, which may shed light on how exercise impacts memory functions associated with the hippocampus and its neuronal networks.

Title: Cross-linguistic activation in hippocampal neurons of Spanish-English bilinguals

Authors: *E. K. HUSSEY[1], K. CHRISTIANSON[1], P. N. STEINMETZ[2];
[1]Univ. of Illinois At Urbana-Champaign, Champaign, IL; [2]Nakamoto Brain Res. Inst., Tempe, AZ

Abstract: The hippocampus declarative memory system (HDMS) supports the formation of long-term memory, including the acqusition, storage, and retrieval of explicit information (Squire, Stark, & Clark, 2004). These representations can be updated or consolidated over long periods of time to incorporate new sources of information (Eichenbaum & Cohen, 2001; Squire, Cohen & Nadel, 1984). To this end, the HDMS supports real-time language processing, especially during incremental sentence comprehension (Rubin et al., 2011) and referential communication (Duff & Brown-Schmidt, 2012). A strong test of the role of the HDMS in language involves bilingual processing; specifically, bilinguals dynamically activate both languages and flexibly switch between lexical entries while they process linguistic input (Bartolotti & Marian, 2012). To examine the neural mechanisms of this switch, we tested whether the firing of hippocampal neurons change in Spanish-English bilinguals under task conditions requiring flexible switching between their languages relative to within-language (non-switch) cases. We recorded single-unit activity in the hippocampus of Spanish-English epileptic patients as they completed a continuous recognition memory task containing words in both languages. Participants were instructed to judge semantic repetitions over the course of the experimental session; half of the targets repeated in the same language (non-switch trials; e.g., dog appearing after dog) and half repeated in the opposite language (switch trials; e.g., perro appearing after dog). Behaviorally, participants were less accurate and slower to respond to switch relative to non-switch trials (Accuracy: $t=4.54$, $p<0.001$; Correct Frequency-Adjusted Response Time: $t=2.09$, $p=0.04$). Neurally, we observed increased average hippocampal firing for correct targets compared to correct non-targets, replicating Wixed et al., 2014 ($t=-3.64$, $p<0.001$). Of the targets, switch trials elicited greater firing relative to non-switch items in the

right hippocampus (t=-3.61, p=0.003). Interestingly, this effect reversed in left hippocampus (t=2.88, p=0.02), such that switch trials were associated with less firing compared to non-switch cases. This pattern provides support for lateralized repetition-suppression, perhaps due to a left hemispheric bias for semantic processing (Martin, 1999). Finally, we provide the first evidence that flexible cross-linguistic lexical access constitutes another case of HDMS involvement in the language domain.

Title: Hippocampal contributions to configural probabilistic learning

Authors: ***K. D. DUNCAN**[1], B. B. DOLL[2,4], N. D. DAW[3,2], D. SHOHAMY[6,5];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Ctr. for Neural Sci., [3]Dept. of Psychology, New York Univ., New York, NY; [4]Dept. of Psychology, [5]Kavli Inst. for Brain Sci., Columbia Univ., New York, NY; [6]Dept. of Psychology, Columbia Unversity, New York, NY

Abstract: Extensive research has characterized the mechanisms by which the striatum supports stimulus-response learning. A crucial, yet overlooked, component of this learning is identifying the relevant ‘stimulus’ amongst the array of features that comprise an experience. This is challenging, in part, because it is not always clear what makes a “stimulus”: a stimulus can be a singular individual *element*, or, it can be a full *configuration* of features that comprise an experience. We hypothesized that the neural mechanisms that support learning will depend on how the stimulus is defined. Specifically, that the hippocampus, well known for its role in encoding stimulus-stimulus associations, will be involved in stimulus-response learning when the stimulus itself is a configuration of cues. To test this hypothesis, we had participants perform a probabilistic classification task (a variant of the "weather prediction" task) while undergoing fMRI scanning (n=26). Importantly, in our task, abstract cues were independently associated with weather outcomes but were never presented alone and were combined into a small number

of combinations. This design allowed participants to learn either by associating individual cues with outcomes (elemental learning), or by associating the configuration of cues with outcomes (configural learning). We used a reinforcement-learning model to quantify the influence that recent experiences with individual cues and cue-combinations held over participants' choices. This model allowed us to identify (1) individual differences in elemental vs. configural learning and (2) the extent to which each choice reflected elemental vs. configural learning. We found that hippocampal BOLD activity was stronger when people made choices that reflected recent history with cue-combinations, as opposed to individual cues, and that this relationship was most evident in participants whose choices reflected configural learning. Additionally, participants who engaged in more configural learning showed greater functional connectivity between the hippocampus and nucleus accumbens during learning. Furthermore, feedback-related responses in the nucleus accumbens were more correlated with hippocampal activations during choice in participants who engaged in configural as compared to elemental learning. By contrast, people who engaged in elemental learning showed greater functional connectivity between the nucleus accumbens and dorsal striatum than those who engaged in configural learning. Together, these results suggest that the hippocampus may contribute to probabilistic learning by forming configural representations of task states.

Title: First-episode schizophrenia is associated with disrupted network connectivity across separable hippocampal subsystems

Authors: ***V. P. MURTY**[1], A. TOMPARY[2], B. ZENG[4], J. WANG[4], D. GOFF[5], L. DAVACHI[3]; [1]NYU, New York, NY; [2]New York Univ., New York City, NY; [3]New York Univ., New York City, NY; [4]Shanghai Mental Hlth. Ctr., Shanghai, China; [5]Nathan Kline Inst., New York City, NY

Abstract: Hippocampal neurophysiology and network connectivity have been critically implicated in the etiology and symptomology of schizophrenia. The hippocampus is a complex structure consisting of many subsystems, which may differentially interact with discrete cortical targets to contribute to cognition. While few studies have investigated hippocampal networks in schizophrenia, relatively little is known as to how different subsystems of the hippocampus are implicated in this disorder. In the current study, we compared network connectivity of hippocampal subsystems across 29 first-episode schizophrenic patients and 29 matched controls. Data were collected as part of a larger cohort collected at the Shanghai Mental Health Center investigating biomarkers of anti-psychotic treatment in first-episodic schizophrenia. Network connectivity analysis was implemented using a dual-regression approach on resting state fMRI. The hippocampus was functionally segmented into 8 sub-regions using a data-driven approach, i.e. independent spatiotemporal profiles. We found that only four of the eight subsystems showed significant differences in network connectivity across groups: two separable but overlapping regions in right anterior hippocampus, a region of left anterior hippocampus, and a region of left posterior hippocampus ($p<0.05$ whole-brain corrected, bonferonni corrected across subsystems). In general, connectivity profiles of these regions showed greater connectivity with lateral prefrontal regions in controls versus patients, and greater connectivity with thalamic, posterior midline, and ventral visual regions in the patients versus controls. Critically, all schizophrenia patients were naïve to antipsychotic drugs suggesting that these connectivity differences reflect etiology rather than medication. In general, these findings support a model by which connectivity between cortical targets and only particular subset of hippocampal regions are implicated in schizophrenia.

Title: Category specific modulation of resting state networks predicts memory performance

Authors: *J. A. COLLINS, B. C. DICKERSON;
Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Memory consolidation theories predict that coordinated activity between the hippocampus and cerebral cortex is responsible for the storage of a long-term memory trace and that this process is mediated by the re-activation of regions during rest that were active during encoding (reviewed in Tambini, Ketz, & Davachi, 2010). Reactivation mediated memory consolidation occurs during periods of wakeful rest and the associated increase in hippocampal-cortical connectivity has been related to individual differences in associative memory performance (Tambini et al., 2010). A long history of research has supported the existence of specialized cortical regions in the fusiform gyrus and perirhinal cortex that are engaged during the perception and recognition of faces but not other visual stimuli (reviewed in Collins & Olson, 2014). Similar category specificity has been observed in a region of the parahippocampal gyrus for the visual encoding of places (Epstein & Kanwisher, 1998). Reactivation theories predict that face- and place- memory encoding should modulate connectivity within these category selective regions and that this modulation should predict behavior. The goal of the current study was to test this hypothesis. Participants completed a baseline resting-state scan followed by two encoding tasks in which they responded to images of faces or places. Each encoding task was followed by an additional resting state scan and recognition memory for the learned stimuli was assessed outside of the scanner. Face-selective regions of interest (ROIs) were defined in the fusiform gyrus (FFA) and perirhinal cortex (PRC), and a place-selective ROI was defined in the parahippocampal gyrus (PPA). Additional ROIs were defined in the left and right hippocampi that maximally responded to stimuli that were later remembered regardless of category. A significant increase in connectivity was observed between the PPA and left hippocampus following the place but not face-encoding task. After the face-encoding task connectivity was significantly decreased between the PPA and face processing regions (PRC and FFA) as well as the right hippocampus. A whole brain linear regression revealed that the modulation of connectivity between the PPA and the posterior parietal cortex after place encoding predicted individual differences in the recognition of places (but not faces). Individual differences in the recognition of faces (but not places) were predicted by modulated connectivity between the FFA and PRC ROIs after face encoding. Our results thus provide novel evidence for category specificity in the neural mechanisms supporting memory consolidation.

Title: Proactive brain network dynamics predicts episodic memory in children

Authors: *S. QIN[1], S. PRATHAP[2], J. KOCHALKA[2], S. RYALI[2], V. MENON[2];
[1]Dept. of Psychiatry and Behavioral Sci., Stanford Univ., Palo Alto, CA; [2]Stanford Unversity, Palo Alto, CA

Abstract: It is proposed that the human brain is proactive in that it modulates subsequent information processing (Bar, 2007). But whether and how the brain's intrinsic functional organization can proactively impact the efficiency of subsequent learning and memory is not known. Previous studies have only focused on the neurobiological processes of learning and memory in adults at the acquisition and retrieval stages, our understanding of these processes in children is poor. Even in adults, it is unknown how intrinsic brain activity and network configuration contributes to the formation of new memories. To address these questions we combined resting-state and task-related fMRI prior to and during memory encoding in 24 young children (aged 8-14). Brain imaging data was acquired on a 3T GE Signa scanner using a T2*-weighted spiral in-out sequence to gain signal sensitivity and mitigate signal drop-outs. Using a standard subsequent memory paradigm we first identified brain regions (nodes) involved in successful episodic memory formation. We then used a novel Bayesian hidden Markov models (HMM) (Ji & Carin, 2006) to identify dynamic functional networks (DFNs) between these nodes, during rest prior to memory encoding, and its links to subsequent memory performance. Three findings are noteworthy. First, we observed a distributed network of 20 regions (nodes) in the temporal, medial temporal, parietal, and frontal lobes involved in successful episodic memory formation in children, with the left anterior hippocampal activation predictive of individual differences in children's memory performance. Next, we found three major communities of DFNs of these 20 nodes in the resting state prior to memory encoding. Critically, one of the more frequently occurring DFN that comprising the d medial temporal lobe, prefrontal and temporal-parietal cortices negatively predicted subsequent memory performance. These results suggest that proactive brain network dynamics can impact subsequent memory performance. By characterizing proactive brain network dynamics and their links to subsequent episodic memory, our findings provide new insights into how intrinsic brain network organization can influence the formation of new memories. More broadly, our study highlights the importance of proactive brain dynamics in support of children's learning and memory.

Title: Deactivation of brain regions associated with subsequent forgetting predicts effects of value on recognition memory in both young and older adults

Authors: *M. S. COHEN[1,2], B. J. KNOWLTON[2], A. D. CASTEL[2], J. RISSMAN[2];
[1]Dept. of Psychology, Northwestern Univ., Chicago, IL; [2]Psychology, UCLA, Los Angeles, CA

Abstract: There has been growing interest in the phenomenon of "negative subsequent memory" (NSM) effects. These effects, characterized by greater fMRI activity during the encoding of items that are subsequently forgotten relative to those that are subsequently remembered, are thought to reflect changes in internally directed cognition detrimental to learning. Notably, NSM effects tend to be reduced or eliminated in older adults. Presently, we were interested in whether an item's value (i.e., how many points could be earned by recalling that item later) would impact activity in NSM regions during encoding, and whether such value-related changes in activity would affect memory independently from changes in positive subsequent memory (PSM) regions. We were also interested in whether young and older adults would differ for either type of effect. 19 young and 21 older adult participants studied a series of word lists in an fMRI scanner, one word at a time. Each word was preceded by a point value indicating how important the word would be to remember. Memory was initially assessed using a free recall test, but shortly after the scan session, participants were tested again using a recognition test with a 1-6 confidence scale. To better characterize subsequent memory effects in our data, we defined two networks of interest based on a meta-analysis (Kim, 2011) of PSM and NSM effects,

respectively. We found reduced activity in the NSM network during encoding of high- relative to low-value items (significant in young; marginal in old). In addition, in both age groups, adding value-related differences in brain activity in NSM regions to a regression analysis explains significantly more of the value-related difference in recognition confidence than value effects in PSM regions alone. Although the value-related difference in activity in NSM and PSM networks tends to be positively correlated, the beta coefficients are significant in opposite directions. Value-related differences in NSM regions, but not PSM regions, still have significantly negative beta weights when recognition performance scores are re-computed using only those items that were not recalled during the initial free recall test. Together, these results demonstrate that activity in NSM regions is affected by one's motivation to learn individual items. Moreover, these effects appear to be dissociable from value effects observed in PSM regions, suggesting that activity within these networks may be independently regulated. Thus, both young and older adults appear to down-regulate neural activity that is detrimental to encoding in order to enhance memory for valuable items.

Title: Combined physical exercise and cognitive training enhances hippocampal-dependent memory in young adults

Authors: ***J. J. HEISZ**, I. B. CLARK, M. FAHNESTOCK;
McMaster Univ., Hamilton, ON, Canada

Abstract: There is an established link between exercise, neurogenesis, and cognition. Most of this research has focused on non-human animal models, with little known about the effects of exercise on cognition in younger adults. Both physical exercise and cognitive training independently induce hippocampal neurogenesis in animals, suggesting that these different forms of training may work through synergistic neural pathways to benefit memory in younger adults. The present study examined the effects of physical exercise and cognitive training on

hippocampal-mediated memory processes in younger adults, to determine whether combined training yields synergistic benefits. Sixty-six sedentary young adults (age range 18-30 years) were randomly assigned to one of four groups: 1) exercise training group, 2) cognitive training group, 3) combined exercise and cognitive training group, or 4) control group. Memory performance was assessed before and after the six-week intervention on the Pattern Separation task, which targets the dentate gyrus and is associated with hippocampal neurogenesis. Serum brain-derived neurotrophic factor (BDNF) and insulin-like growth factor 1 (IGF-1), factors that support neurogenesis, neuronal survival and function, were also assessed. Combining exercise and cognitive training led to the greatest increase in memory performance requiring pattern separation, but this was accompanied by a corresponding decrease in memory performance requiring pattern completion. BDNF and IGF-1 were not associated with this change in memory performance but were associated with the individual's response to the exercise training, such that high responders to exercise had greater BDNF and IGF-1 than low responders to exercise. The results suggest that exercise and cognitive training may work through synergistic pathways to bias hippocampal function towards pattern separation. However, BDNF and IGF-1 may not be mediating this change in memory function.

Title: Hippocampal contributions to the large-scale episodic memory network predict vivid visual memories

Authors: ***M. STANLEY**, B. GEIB, E. WING, R. CABEZA;
Duke Univ., Durham, NC

Abstract: Multivariate functional connectivity analyses of neuroimaging data using graph theory have revealed the importance of complex, distributed interactions between disparate yet interdependent brain regions for successful cognitive functioning. For the vivid, detailed retrieval of recently experienced events, the hippocampus in particular is thought to play an integral role in facilitating the flow of information throughout the network and integrating specific

information derived from different brain regions. After constructing functional brain networks derived from the beta series of a slow event-related fMRI investigation of visual memory retrieval, we examined differences hippocampal topological properties identified between vivid and dim memories of previously encoded items. Vivid memories for retrieved items were associated with more efficient communication for the hippocampus throughout the entire brain network, as well as with a more central, influential role for the hippocampus in network integration. More specifically, vivid memory for retrieved items were associated with the hippocampus (1) participating in more efficient communication with the rest of the network, (2) exhibiting an increase in connectivity strength with diverse brain regions, (3) displaying stronger connectivity with more central, influential nodes in the network, and (4) massively reorganizing its set of direct connections with the rest of the network. These results underscore the potential of multivariate brain connectivity research for providing valuable new insights into the neural bases of memory processes that extend prior work focused on localizing memory processes to particular cortical areas using univariate methodologies.

Title: Motor responses modulate episodic memory encoding in humans

Authors: ***M. YEBRA**[1], A. GALARZA[1], V. SOTO-LEÓN[2], J. GONZALEZ-ROSA[1], A. OLIVIERO[2], M. C. W. KROES[3], B. A. STRANGE[1];

Abstract: Although cognitive function is typically assessed via actions, little is known about how actions influence cognition. Physical movements are hypothesized to enhance memory1. We therefore tested whether “Go” button-press responses modulate memory encoding by crossing incidental memory encoding with a Go-NoGo task. In a series of experiments (Exps),

healthy subjects were shown 190 b&w objects presented with a blue or yellow frame indicating requirement of a Go button press or NoGo response (with equal number of Go and NoGo trials to avoid "oddball" effects on memory encoding). A recognition test was conducted 1hr later. All encoded images (without frame) were presented plus 190 new images, with subjects indicating whether they remembered (R), were familiar with (K) or did not remember (forgotten, F) the image from the encoding phase. In Exp 1, image presentation time was 1s in both phases, with variable ISI. Exp 2 was identical except that subjects were financially rewarded for responding as fast as they could, and financially penalised for commission errors. Exp 3 was identical to Exp 1 except that stimuli were presented for 250ms. Exp 4 was a replication of Exp 3 in the context of functional MRI scanning. Following pre-processing, using SPM8, memory encoding-related activity was analysed in a GLM comprising regressors modeling encoding responses for subsequent R, K and F trials separately for Go and NoGo. Ensuing contrast images for main effects of Go vs NoGo and R vs F, and the interaction were entered into one-sample t-tests across all subjects. Our behavioral studies consistently reveal better remember accuracy for stimuli paired with Go responses. An interaction between motor response and subsequent memory is observed in an area of dorsal pons consistent with the locus coeruleus (LC). Electrophysiological recordings in non-human primates show phasic LC activity during motor acts2 . Given that LC activity leads to the release of noradrenaline throughout the brain, and that noradrenaline enhances memory3, we suggest that motor modulation of memory is mediated by the noradrenergic system.

Title: The effect of sedation on reconsolidation of emotional episodic memory in humans

Authors: *A. I. GALARZA VALLEJO[1], M. C. W. KROES[2], E. REY DÍAZ-RUBIO[3], M. ACEDO[3], G. FERNANDEZ[4], B. STRANGE[1];

Abstract: There is increasing evidence that memories are not stable but reflect a dynamic process. Following reactivation, memories can become labile and must undergo reconsolidation in order to persist1-3. Disrupting memory reconsolidation may be a promising tool for treating psychiatric diseases. We recently showed4 that an electroconvulsive therapy (ECT) procedure impairs reconsolidation in unipolar depression patients. Specifically, reactivating memory for an emotional story immediately before ECT impaired subsequent recognition, relative to a non-reactivated story, when tested after 24h but not if tested immediately after ECT. One limitation of this study, however, is that it could not determine which component of the ECT - the general anesthetic (GA), the electric current applied to the cranium, or the subsequent seizure - produced reconsolidation impairment. In the current study, we therefore tested the effect of propofol (a short-acting hypnotic used for GA induction and maintenance) on reconsolidation in psychiatric/neurologically normal individuals undergoing brief GA for a routine procedure (endoscopy). Our emotional memory paradigm included two groups. Both groups encoded two emotional stories (identical to those used previously4) one week prior to endoscopy. Each emotional story comprises 3 phases, 1 and 3 being neutral and phase 2 emotionally aversive. For both groups, reactivation of one of the stories (by presenting the first slide of one story only) was conducted in the endoscopy room 1-2 min before receiving propofol. Following endoscopy, both groups underwent a multiple choice memory test, but at different delays: group A after 24 hours and group B after ~90 minutes. Propofol impaired reconsolidation of memory for the emotional phase of the story (Phase 2) in Group A only. A Group (A, B) by Reactivated (yes, no) by Phase (1,2,3) rmANOVA reveals a significant 3-way interaction for the quadratic contrast $F_{1,16}=4.73$, $P=0.045$. Our data therefore demonstrate that a routine anesthetic procedure can impair reconsolidation selectively for emotional episodic memories.

Title: Hippocampal theta during memory guided virtual navigation in human intracranial EEG

Authors: ***D. BUSH**[1], J. A. BISBY[1], C. M. BIRD[2], S. GOLLWITZER[3], R. RODINOV[4], C. SCOTT[5], B. DIEHL[4], A. W. MCEVOY[4], M. C. WALKER[4], N. BURGESS[1];

Abstract: Theta frequency oscillations are prominent in the rodent hippocampal local field potential (LFP) during movement, and are typically in the range of 6-10Hz. Theta oscillations are also associated with human spatial memory function, typically in the range of 3-7Hz. However, the exact relationship between human theta oscillations, movement and spatial memory function is currently unclear. We examined intracranial EEG recordings from depth electrodes located in the hippocampi of twelve pre-surgical epilepsy patients performing a self-paced virtual reality navigation and spatial memory task. In this task, participants were asked to navigate towards, and encode the location of, various visible objects within a single environment. Participants were subsequently cued with the image of a single object, then placed back in the environment and

asked to navigate to the remembered location of that object. We found that power in the higher frequency (6-10Hz) theta band increased significantly during a 1s period around virtual movement onset compared to 1s stationary periods, consistent with MEG findings in a similar task (Kaplan et al., 2012). Moreover, 6-10Hz theta power during this 1s movement onset period correlated with subsequent memory performance. An increase in lower frequency (3-6Hz) theta power was also observed around movement onset, but did not correlate with subsequent memory performance. Next, we identified a more sustained increase in broadband ~3-16Hz oscillatory power during the 3s cue period, but only 6-10Hz theta power during this 3s period correlated with subsequent memory performance. These findings suggest that human hippocampal theta oscillations in the higher (6-10Hz) band are associated with both virtual movement and the accuracy of spatial memory function. Title: Reactivation and anterograde disruption of recently encoded memories: A variant of reconsolidation

Authors: ***R. B. BAUDO**, B. A. WRIGHT;
Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: During learning, memories are transformed from a fragile to a stable state through a process of consolidation. There is growing evidence that when consolidated memories are accessed they re-enter a state of instability, during which they can be modified, and then must be consolidated again. This cycle of reactivation and reconsolidation is revealed by reports that

consolidated memories are susceptible to retrograde interference following a reminder of the memory, even when the reminder occurs weeks to months after the initial training. Here we show behavioral evidence in humans of a mechanism similar to reconsolidation, but in which reactivated memories are susceptible to anterograde interference only within 24 hours of the initial training. Using a perceptual-learning paradigm, we first identified a case in which learning on a target task was disrupted in the anterograde, but not retrograde, direction. Learning across days on interaural-level-difference discrimination (L) (the target task) was disrupted by practicing interaural-time-difference discrimination (T) (the non-target task) before (TL; n=11), but not after (LT; n=10), daily practice on the target task. We then used a paradigm akin to that used to test for reconsolidation. Listeners practiced a bout of the target task in isolation (L) and 30 minutes later practiced the task order that elicited anterograde interference (TL) (L30minTL; n=14). This regimen yielded no improvement on the target task the day after training, suggesting that the initial bout of the target task was reactivated by the reminder and that both bouts were disrupted by the anterograde interferer. Learning returned when the reminder was removed (L30minT, n=10), confirming that the lack of learning in the L30minTL case was not due to retrograde interference of the non-target task (T) on the initial bout of the target task (L), and that the disruption of learning required the target-task reminder. Increasing the time between the initial and reminder bouts from 30 minutes to 24 hours (L24hrTL; n=14) yielded improvement on the target task from the initial bout to the test 48 hours later, but this learning occurred between the initial bout and the reminder, and not between the reminder and the test. Thus, after 24 hours, while the initial bout was no longer susceptible to anterograde interference, new bouts of training on the target task were. These data suggest that during an early stage of memory formation, recently acquired memories can be reactivated, but are susceptible to anterograde interference, while older memories are protected from such disruption.

Title: The effects of anticipatory stress on the neural correlates of associative memory retrieval

Authors: *S. A. GAGNON, A. D. WAGNER;
Psychology, Stanford, Stanford, CA

Abstract: As we go through the world, we continually retrieve information about prior experiences to guide decisions and actions in the present. The process of recollecting specific, associative details about past events involves mechanisms supported by the medial temporal lobe (MTL) and frontoparietal cortical areas. Stress is known to alter MTL processing, and acute stress may also impair function in frontoparietal networks critical for controlled processing. Here, we investigated whether acute anticipatory stress influences memory retrieval processes. Stress was operationalized as the threat of an unpredictable shock. We hypothesized that associative retrieval performance is vulnerable to interference under conditions of stress relative to safety, and that this occurs in part through altering the engagement of the MTL and frontoparietal controlled processes. During encoding, words were paired with either an indoor or outdoor scene while subjects were in a neutral state. At retrieval 24 hours later, subjects were placed into a stress group or control group, and viewed old and new word cues while we recorded physiological measures (electrodermal activity, heart rate, salivary cortisol) and neural activity (via fMRI). If subjects recognized the word as old, they were further asked to recollect the associated scene. Critically, stress subjects were tasked with retrieving information under conditions of stress (threat of shock) or safety. Results revealed that stress during retrieval modulated physiological activity, affected behavioral performance, and influenced retrieval-related neural activity.

Title: Structural and functional contributions to context-dependent relational memory

Authors: *H. SCHWARB[1], C. L. JOHNSON[2], J. L. HOLTROP[2], J. X. WANG[3], P. D. WATSON[2], J. L. VOSS[3], N. J. COHEN[2];

Abstract: Separate contributions of the medial temporal lobe (MTL) and prefrontal cortex (PFC) have been frequently implicated in support of memory function. Research suggests that the MTL is critically involved in forming relational memory representations and the PFC is involved in extracting and using more abstract associative rules. We present data from a novel relational memory task in which participants learn that individuals belong in a single room in each of two buildings. Room assignment is consistent with an underlying contextual-rule structure in which male and females are assigned to opposite sides of a building and the side-assignment switches between buildings. The buildings are dissociable by color and each building serves as a separate context. Diffusion Tensor Imaging (DTI) data was collected from 20 healthy young adults and behavioral performance was correlated with two tracts involved in memory processing: the fornix/fimbria and the uncinate fasciculus. The fornix/fimbria is a white matter tract primarily within the MTL that connects the hippocampus to the thalamus through the mammillary bodies and has previously been associated memory recall. The uncinate fasciculus is a white matter tract that connects the anterior temporal lobe to the inferior frontal gyrus through the MTL and has been implicated in episodic memory. Our data reveal that fractional anisotropy (FA) of the fornix/fimbria is related to successful learning of specific room associations, while uncinate fasciculus FA is related to successful contextual-rule abstraction and use. These data suggest that the fornix and uncinate fasciculus play distinct roles that contribute to successful memory performance on this novel relational memory task. Functional magnetic resonance imaging (fMRI) data in a separate group of 20 healthy young adults are consistent with the DTI data. Successfully learning of specific room associations activated the hippocampus while successful contextual-rule abstraction and use was associated with activity in the anterior frontal lobe. Together these data suggest that MTL and PFC structures exert separable contributions to accurate relational memory performance in this task.

Title: Evidence for the representation of context in human parahippocampal cortex and retrosplenial cortex

Authors: *D. J. HUFFMAN, C. E. L. STARK;
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Decades of research have established that the structures in the medial temporal lobe play an essential role in the representation of contextual information, particularly the representation of spatial information. A recent rodent study extended these findings by providing evidence that the hippocampus contains hierarchically-organized conjunctive representations of items bound to positions within particular contexts (McKenzie et al., Neuron, 2014). We sought to apply a similar approach in humans using functional magnetic resonance imaging (fMRI). Similar to the rodent task, our task contained 8 events which consisted of two contexts and two sets of object pairs. Participants learned event-location associations through trial-and-error learning. The correct location was unique based on: 1) the context, 2) the object pair, 3) the order in which the objects were presented. Thus, participants were required to distinguish between overlapping associative memories. Participants learned the associations the day prior to completing a fMRI scan session. Several lines of evidence suggest that parahippocampal cortex (PHC), retrosplenial cortex (RSC), and posterior cingulate cortex (PCC) are part of a network of cortical regions involved in the representation of contextual information (cf. Ranganath and Ritchey, Nat Rev Neurosci, 2012). Using multivariate pattern analysis of fMRI data, we have previously shown that PHC and RSC/PCC contained similar category information (faces vs scenes) on a trial-by-trial basis (Huffman and Stark, Hippocampus, 2014). In the current study, multivariate pattern analysis revealed that both PHC and RSC/PCC contain context-specific information. Specifically, patterns of activity elicited in response to events that shared the same context were more similar to each other than to events that took place in the other context. Additionally, PHC and RSC/PCC contained similar representations of context on a trial-by-trial basis, supporting the theory that PHC and RSC/PCC are part of a network of regions involved in the representation of contextual information. Further, we found that patterns of activity in RSC/PCC were more similar in response to events that shared the same context and the same items than in response to events that shared the same context but not the same items, thus providing evidence for conjunctive representations within RSC/PCC. The current results extend previous findings, which have largely been based on category-level differences, to the realm of the representation of individual contexts.

Title: Impairments in associative inference following damage to the ventromedial prefrontal cortex

Authors: ***K. SPALDING**[1], M. L. SCHLICHTING[2], D. ZEITHAMOVA[3], A. R. PRESTON[2], M. C. DUFF[1], D. TRANEL[1], D. E. WARREN[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Texas at Austin, Austin, TX; [3]Univ. of Oregon, Eugene, OR

Abstract: Learning in one situation and later applying that knowledge during new experiences is a critical cognitive ability that helps organisms adapt to changing environments, but the neural bases of this adaptive inferential behavior are not fully understood. Laboratory tests of associative inference in humans have examined memory performance for overlapping pairs of items (e.g., AB, BC) and for non-studied inference pairs that shared a common associate (i.e., AC). Using this paradigm, functional neuroimaging studies have shown that increased activation and functional connectivity of ventromedial prefrontal cortex (vmPFC) and hippocampus during encoding of overlapping pairs are associated with superior performance during subsequent inference (Zeithamova, Dominick, & Preston, 2012). In the current study, we used a neuropsychological approach to test the necessity of vmPFC for normal associative inference. Specifically, we tested participants with focal brain damage including vmPFC (N=6; non-amnesic) and demographically-matched healthy normal comparison (NC) participants (N=12) using the paradigm described in Zeithamova et al. 2012. Based on the earlier neuroimaging

findings and also on neuropsychological data suggesting a special role for vmPFC in associative or schematic memory (Warren, Jones, Duff, & Tranel, 2014), we predicted that the vmPFC group would show impairments in the ability to draw associative inferences based on memory despite intact memory for studied items. Participants studied overlapping pairs of items (AB and BC). Participants then completed a three-alternative forced-choice recognition task for studied (AB and BC) and corresponding inferential relationships (AC). Interestingly, despite normal memory on standard neuropsychological tests, the vmPFC group showed a significant impairment for studied pairs. Moreover, as predicted, the vmPFC group was significantly impaired when tested with items requiring associative inference based on memory for studied pairs, even when controlling for the memory impairment for studied pairs. These findings suggest that vmPFC is necessary for memory processes that support learning of overlapping events and novel associative inference. More broadly, these results provide insight into the neural bases of our adaptive ability to integrate existing knowledge with novel circumstances and reinforce a role for the vmPFC in such memory integration.

Title: The core recollection network dissociates as a function of phenomenal and objective recollection

Authors: *P. P. THAKRAL, S. S. YU, M. D. RUGG;
Ctr. for Vital Longevity and Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX

Abstract: It has been reported that hippocampal recollection effects are sensitive not to whether a test item elicits a phenomenal sense of recollection, but to the amount or fidelity of the contextual information retrieved about the study episode. In a previous study (Yu, S.S., Johnson, J.D., & Rugg, M.D. (2012). Hippocampal activity during recognition memory co-varies with the accuracy and confidence of source memory judgments. Hippocampus, 22, 1429-1437),

participants studied pictures presented to the left or right of central fixation. In a later test phase, participants underwent functional magnetic resonance imaging (fMRI) where studied and new pictures were presented in central vision. For each picture, participants first made a remember, know, or new response. For each picture judged remember or know, they then signaled the item's study location using a 6-point confidence scale (ranging from 'definitely-left' to definitely-right'). Hippocampal activity was graded as a function of the accuracy and confidence of source judgments associated with a remember response. Hippocampal activity, however, did not differ between remember responses associated with the lowest level of source confidence and know responses. Here, we assessed whether activity in the hippocampus or other members of the 'core recollection network' dissociated according to whether test items elicited a phenomenal sense of recollection (a remember judgment) or an accurate source judgment. We reanalyzed the previous dataset to create four response categories which dissociated 'phenomenal' and 'objective' recollection: remember-accurate source, remember-inaccurate source, know-accurate source, and know-inaccurate source. A main effect across the parameter estimates associated with each of the response categories revealed differential activity within the hippocampus, angular gyrus, precuneus, and striatum. A follow-up ANOVA with factors of region and response category revealed a significant region by response category interaction. In the hippocampus, remember-accurate and know-accurate responses elicited greater activity than remember-inaccurate and know-inaccurate responses. In all other regions, the general pattern was of greater activity for remember-accurate and remember-inaccurate responses relative to know-accurate and know-inaccurate responses. These results indicate that whereas the hippocampus is solely sensitive to the amount of contextual information retrieved, other regions are more sensitive to whether a test item elicits a phenomenal sense of recollection.

Title: Latent variable modeling of temporal profiles of neural activity during the processing of continuous natural stimuli

Authors: ***M. CHOW**[1], J. CHEN[1,2], U. HASSON[1,2];
[1]Dept. of Psychology, Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., Princeton, NJ

Abstract: In everyday life, information arrives continuously from the environment, and a multitude of mnemonic processes contribute to comprehension moment by moment. However, the complex nature of continuous natural stimuli (e.g., visual or auditory narratives) makes modeling the underlying neural dynamics especially challenging. While much research in fMRI has made use of the general linear model, which requires explicit predictions of BOLD activity across time, in natural stimuli the exact form that neural activity will take across time is difficult to predict. We used latent variable models to characterize neural activity across time during continuous natural stimuli (auditory/visual narratives) by measuring relationships between subjects, within and across conditions. In these models, observed neural timecourses were expressed as a noisy representation of an underlying, group-specific timecourse. We applied this approach to two datasets in which episodic memory was manipulated. Latent variable models enabled us to explicitly describe cortical and hippocampal dynamics during audio/visual narratives where: 1) subjects needed to retrieve episodic details from one day earlier; 2) subjects needed to retrieve episodic details from one minute earlier. In both datasets we were able to differentiate the memory-demanding conditions from control conditions that were perfectly matched for stimulus input. Thus, our latent variable model approach provides a powerful tool for exploring temporal profiles of neural dynamics that support episodic memory and comprehension during real-life continuous stimuli.

Title: Distributed cortical representations of visual features in perception and memory

Authors: ***S. E. FAVILA**[1], R. SAMIDE[1], B. A. KUHL[1,2];
[1]Dept. of Psychology, [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neural activity patterns that reflect stimulus features during perception are reactivated when that stimulus is retrieved from memory. Reactivation of high-level visual category information (e.g., face vs. scene) has frequently been observed in inferior temporal cortex, but there is also evidence for reactivation of lower-level stimulus information in early visual cortex (Bosch et al., 2014). Recent evidence also indicates that reactivation of event-specific information occurs in lateral inferior parietal cortex (Kuhl and Chun, 2014). At present, however, there remains ambiguity regarding the nature of reactivated representations in lateral parietal cortex and how these representations relate to those in high- and low-level visual cortex. Here, we compared activity patterns in occipital, inferior temporal, and lateral parietal areas across perception and retrieval. We asked human participants to learn 32 unique word-image pairs, where images were exemplars from eight object categories (backpacks, cups, fish, flowers, fruits, hats, insects, shoes) and four color categories (blue, green, red, yellow). After learning the word-image pairs, subjects performed two different tasks while undergoing fMRI scanning: perception and cued retrieval. During perception runs, subjects viewed the images (without word cues) while performing an orthogonal target detection task. During retrieval runs, subjects were presented with word cues and recalled the corresponding images. Multivariate pattern analysis showed that, in visual regions, feature sensitivity during perception was reinstated at retrieval. In both tasks, neural activity patterns in early visual cortex discriminated object colors while activity patterns in inferior temporal cortex and lateral occipital cortex discriminated object categories. In lateral inferior parietal cortex, activity patterns during retrieval carried information about both color and object categories. Additionally, comparison of neural activity patterns during perception and retrieval revealed that lateral inferior parietal cortex exhibited exemplar-level reinstatement. These findings suggest a role for parietal cortex in combining event features reinstated in distinct visual cortical areas into an integrated memory.

Title: Visual memories are stored on a Weber-Fechner timeline

Authors: *I. SINGH[1], A. OLIVA[3], M. HOWARD[2];
[1]Psychology, [2]Boston Univ., Boston, MA; [3]MIT, Cambridge, MA

Abstract: It is well-known that memory degrades over time. In continuous recognition the recency effect manifests as a decrease in accuracy and an increase in response time (RT) with the lag of a repeated stimulus. We used visual recognition with highly-memorable pictures to mitigate changes in accuracy and enable a detailed examination of the effect of the passage of time on retrieval dynamics. The recency at which pictures were repeated ranged over more than two orders of magnitude from about 4 s up to about 500 s. Analysis of the RT distributions showed that the time at which memories became accessible changed with the recency of the probe item. These results suggest that visual memories were stored on a timeline that was sequentially scanned. Because the time to access the memory depended on the logarithm of the recency this suggests a timeline with Weber-Fechner spacing.

Title: Identifying the core recollection network based on single-trial measures of neural pattern reactivation

Authors: *E. K. LEIKER, J. D. JOHNSON;
Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Episodic memory retrieval engages a network of brain regions including the hippocampus, posterior parietal cortex, medial prefrontal cortex, and retrosplenial/posterior cingulate cortex. To date, this “core” network has predominantly been identified either by contrasting the neural correlates of behavioral indices of recollection or through resting-state functional-connectivity (FC) analyses. One potential limitation of the behavioral approach is that the contrasts typically involve only a few memory conditions (e.g., remember vs. know, source correct vs. incorrect), leaving open the possibility that the identified regions largely reflect broad differences as opposed to graded changes in recollection. Here, we employed neural measures of reactivating episodic memories, in combination with a pattern-based FC approach (Coutanche & Thompson-Schill, 2013), to facilitate the identification of brain regions that are sensitive to

recollection in a graded manner. Subjects viewed a series of words in the context of different encoding tasks and then completed a source-memory test. Single-trial measures of reactivating the task-related information at the time of retrieval were determined with multivariate pattern analysis (MVPA) and then correlated with voxel-wise activity throughout the brain. On the basis of the pattern-reactivation measure alone, we identified the regions of the core recollection network that have consistently been identified with behavioral analyses. In addition, a number of regions not typically associated with recollection - including lateral occipital cortex and lateral and anterior prefrontal cortex - were also revealed. These findings demonstrate that retrieval-related reactivation is useful in identifying a more expansive core recollection network than previously established, and they suggest that the enhanced sensitivity and continuous (i.e. single-trial) nature of neural patterns may prove effective, more generally, in improving the characterization of functional brain networks.

Title: Memory reactivation during sleep promotes better consolidation of event episodes linked by overlapping memories

Authors: *J. P. OYARZÚN[1,2], J. MORÍS[1,2], D. LUQUE[3,4], R. DE DIEGO-BALAGUER[5,2,1], L. FUENTEMILLA[2,1];

Abstract: Targeted memory reactivation has proven to be an effective approach to strengthen individual memory episodes with high specificity. However, life experiences are overlapped in content. In our study, participants encoded two consecutive sets of different memories sharing a common element, where the second set of memories was sound cued during encoding. In a follow up nap, half of the sounds were presented during Non-REM sleep to promote the reactivation of a selected set of encoded episodes. We found higher recollection for those

memories that overlapped with those whose sounds were presented during sleep. Furthermore, sleep-specific neurophysiological response modulations, such as slow waves and neural oscillations at the delta and theta range (2-8Hz), were associated to the presentation of sounds related to the memory content. These findings support the idea that sleep promotes the emergence of interrelated memory networks by reactivating multiple event episodes that are linked by overlapping elements.

Title: Quantitative analysis of sleep and learning; insights into cortical development and retention abilities in infants

Authors: ***K. C. NEWMAN-SMITH**[1], D. WERCHAN[2], M. GOLDSTEIN[1], L. SWEENEY[1], L. NADEL[1], R. BOOTZIN[1], R. GOMEZ[1];
[1]Univ. of Arizona, Tucson, AZ; [2]Brown Univ., Providence, RI

Abstract: Sleep in the first year of life is characterized by rapid behavioral and physiological changes. Neonatal stages of active, quiet, and indeterminate sleep are replaced by two stages: rapid-eye movement (REM) and non-rapid eye movement (NREM) sleep (Ednick et al., 2009; Jenni et al., 2004). A growing body of literature suggests that maturation of sleep reflects underlying cortical development (Colrain & Baker, 2011; Kurth et al., 2010). We also know that sleep aids retention of new information in older children (Gomez et al., 2006; Hupbach et al., 2009; Friedrich et al., 2015). Here we investigate if sleep supports retention of newly learned information in 6.5-month-old infants. We further investigate if sleep maturation relates to infant's learning abilities. Thirty-six 6.5 month old infants were exposed to an artificial, statistical, language (Thiessan & Saffran, 2003) made up of 4 bisyllabic words, repeated in random order with no pauses. Infants were randomly assigned to a sleep or wake condition. Twenty-one infants slept while monitored polysomnographically (electrode placements at F3, F4, C3, C4, O1, O2), while fifteen remained awake as yoked controls for the sleep infants. After

approximately an hour and a half, all infants' retention of the language was tested across two testing blocks. Previous literature shows that listening longer to ungrammatical strings demonstrates more advanced learning (Hunt, 1971). There was a significant interaction of learning block and grammaticality ($F(1,28)=6.733$, $p<.02$), such that infants had significantly longer listening times to ungrammatical than grammatical in the first block ($t(29)=-2.209$, $p<.05$), than the second ($t(29)=1.112$, p< n.s.). This demonstrates that infants can acquire and retain the linguistic information for at least a short period of time. Infants did not show a significant difference based on sleep condition ($F(1,28)=.21$, n.s.). Quantitative analysis of the polysomnogram data from infants in the sleep group showed a relationship between language learning in Block 1 and NREM EEG activity in the theta range (4.5-8Hz) at all electrode sites (p's<.01), but only at F3, F4, and C4 with SWA (p's<.05). Existing literature highlights a posterior to anterior shift of slow-wave activity (SWA) (Jenni et al., 2004; Kurth et al., 2010). While all infants show greater posterior SWA activity, those with more anterior activity show greater learning ability. Our results are the first to demonstrate a relationship between cortical maturation and learning ability, using sleep as a proxy for neural maturation.

Title: The effect of inhibitory brain stimulation on recognition-induced forgetting

Authors: *A. M. MAXCEY[1], J. BOSTIC[2], H. GLENN[3], C. LEGGETT[3], R. M. G. REINHART[4];
[1]Dept. of Psychology, Tennessee State Univ., Nashville, TN; [2]Ball State Univ., Muncie, IN; [3]Manchester Univ., North Manchester, IN; [4]Vanderbilt Univ., Nashville, TN

Abstract: What are the consequences of accessing a visual long-term memory representation? Previous work has shown that accessing a long-term memory via retrieval improves memory for the targeted item and hurts memory for related items (Anderson et al., 1994). Recently we (Maxcey & Woodman, 2014) found a similar forgetting phenomenon with recognition of visual objects, a surprising finding because the typical assumption is that access to a memory representation during recognition is direct and uncomplicated. The popular inhibition account of

retrieval-induced forgetting posits that inhibition is required to overcome inhibition of competing items during practice, accounting for forgetting of related items (Anderson, 2003). Current theories of recognition memory assume that access occurs in recognition tasks without competition from related memory representations. If this is the case, what is the source of forgetting in our recognition-induced forgetting paradigm? In the present study we ask whether inhibition, the mechanism widely believed to be responsible for retrieval-induced forgetting, plays a role in recognition-induced forgetting. To examine the role of inhibition in our paradigm, we applied cathodal (hyperpolarizing) stimulation to the right dorso-lateral prefrontal cortex (site F4), believed to be engaged in inhibitory processing (Penolazzi et al., 2014). If inhibitory mechanisms are driving this forgetting effect, down-regulating dorso-lateral prefrontal cortex, and thus suppressing inhibitory mechanisms, should eliminate the forgetting effect in our paradigm. We found that cathodal transcranial direct-current stimulation of right dorso-lateral prefrontal cortex eliminated recognition-induced forgetting. These findings indicate that inhibitory mechanisms contribute to forgetting in recognition.

Title: Increased response competition does not affect implicit memory in schizophrenic patients

Authors: *C. M. ROSSI-ARNAUD[1], V. REZENDE SILVA MARQUES[1], P. SPATARO[1], A. SCIARRETTA[2], V. CESTARI[1,3];

Abstract: Schizophrenia is associated with severe deficits in explicit memory and working memory (Aleman et al., 1999; Forbes et al., 2009). In contrast, the extent to which schizophrenia affects implicit memory is less well known. Implicit memory refers to the unintentional retrieval of information encoded during the study phase and is often investigated through repetition priming tasks. An important distinction in the field is that between implicit tasks based on

identification (non-competitive) or production (competitive) processes (Gabrieli et al., 1999). Neuroimaging studies suggest that identification tasks require search processes dependent on the right cerebellum, whereas production tasks require selection processes dependent on the left frontal lobe (Desmond et al., 1998). Previous evidence indicate that schizophrenic patients exhibit reduced priming in production tasks (such as word stem completion and category exemplar generation), but not in identification tasks (like lexical decision and word-fragment completion) (see Marques et al., 2014). However, no study to date has directly tested the effects of response competition in the same implicit tasks in schizophrenic patients and healthy controls. The present study examines this issue in two experiments, with 46 schizophrenic patients and 58 controls. Experiment 1 assessed repetition priming in two versions of the word-stem completion task having few solutions (the low response competition condition) or many solutions (the high response competition condition). Similarly, Experiment 2 employed two versions of the verb generation task having one dominant verb response (the low response competition condition) or no dominant verb response (the high response competition condition). The results showed that repetition priming facilitated the performance of schizophrenic patients and healthy controls to the same extent in both tasks. Furthermore, schizophrenic patients were not disproportionally impaired by increases in response competition. These findings have relevant implications for understanding the functional integrity of the neural underpinnings of identification and production implicit processes in schizophrenia. Title: Alpha oscillations track the content of representations retrieved from long term memory

Authors: ***D. W. SUTTERER**[1], J. J. FOSTER[1], J. T. SERENCES[2], E. K. VOGEL[1], E. AWH[1]; [1]Dept. of Psychology, Univ. of Oregon, Eugene, OR; [2]Dept. of Psychology and Neurosci. Grad. Program, UCSD, San Diego, CA

Abstract: Recent work has demonstrated that it is possible to reconstruct spatially-specific channel tuning functions (CTFs) during the encoding and delay period of a working memory (WM) task using a forward encoding model and electroencephalography. Specifically these CTFs can be derived from the distribution of alpha-band (8-12hz) activity across the scalp, providing a temporally resolved measure of the stored location. Here, we show that a similar decoding approach can be used to track the content and timecourse of representations retrieved from long term memory (LTM). Subjects learned randomly assigned positions for a collection of 120 unique shapes, with the position selected from a continuous 360 degree space around a circle. 24 hours after the initial learning session, subjects were presented with shape cues and asked to retrieve the associated position while EEG was recorded. We found robust spatially-selective CTFs could be obtained from the distribution of alpha-band (8-12hz) power ~600ms after the onset of the retrieval cue. These results suggest that holding representations retrieved from long term memory in mind relies upon a similar neural mechanism to that used to maintain information in spatial WM. Furthermore, these findings reveal a powerful approach for obtaining neural measures of LTM retrieval latency.

Title: Oscillatory theta entrainment enhances source memory retrieval: Neural and behavioural consequences

Authors: *A. CLARKE, B. M. ROBERTS, J. CRIVELLI-DECKER, C. RANGANATH; Univ. of California Davis, Davis, CA

Abstract: Theta oscillations play a critical role in memory processes. During episodic retrieval, theta activity is increased for correctly remembered events and the context they were studied in (source memory) (Burgess & Gruzelier, 1997; Grubber et al., 2008). Moreover, recent evidence

shows that frontal theta power before a retrieval cue predicts subsequent source memory performance (Addante et al., 2011). This suggests that enhanced theta oscillations are not just a consequence of stimulus-evoked memory retrieval processes, but that the cognitive state prior to the retrieval cue also has an influence on memory performance (Rugg & Wilding, 2000). However, the current evidence linking theta oscillations and memory performance remains correlational. Here we sought obtain causal evidence that theta oscillations are critical for episodic memory retrieval, by manipulating the endogenous theta oscillations using an audio-visual entrainment paradigm. Scalp EEG was recorded while participants first encoded a series of words by making a pleasantness or animacy judgment. This was followed by 30 minutes of audio-visual entrainment where LEDs oscillated and tones pulsed at 5.5 Hz (theta group) or a control frequency (14 Hz). During the retrieval test, participants were presented with a mixture of previously encoded or new words and asked to indicate if the word was old or new (item memory) and in what context the item was previously studied. Resting EEG was recorded both before and after entrainment. We found that oscillatory entrainment influenced theta power in the post-entrainment resting EEG data for the theta group, with no changes for the control group. Critically, the theta group showed significantly better source memory performance than the control group. In the EEG, correct source memory judgements were found to have enhanced theta power over frontal electrodes which was greater for the theta entrainment group compared to controls. Our findings show that neural oscillations can be enhanced using sensory entrainment that has frequency specific effects. Entrainment causally altered theta activity, resulting in increased episodic memory performance, and demonstrates the importance of oscillatory theta activity for human memory processes.

Title: Theta-alpha oscillations bind the hippocampus, prefrontal cortex and striatum during recollection: Evidence from simultaneous EEG-fMRI

Authors: *N. A. HERWEG[1], T. APITZ[1], G. LEICHT[2], C. MULERT[2], L. FUENTEMILLA[3,4], N. BUNZECK[1,5];

Res. of Bellvitge, Barcelona, Spain; [4]Dept. of Basic Psychology, Univ. of Barcelona, Barcelona, Spain; [5]Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: The recognition of previously encountered stimuli rests upon an assessment of stimulus familiarity. Some items, however, additionally trigger the recollection of qualitative information associated with the context of encoding. This process of recollective retrieval has primarily been linked with theta (4-8 Hz) power changes in electrophysiological activity (M/EEG) as well as BOLD effects in a network including the hippocampus and frontal cortex, raising the question how these phenomena are related. Although the notion of the hippocampus coordinating neocortical activity by synchronization in the theta range is common among theoretical models of recollection, direct evidence supporting this hypothesis is scarce. By combining EEG and fMRI during a remember/know recognition task, we can show in healthy human subjects that recollection-specific theta-alpha (4-13 Hz) effects at the scalp level are correlated with increases in functional connectivity (PPI) between the hippocampus and prefrontal cortex for recollected compared to familiar items. Interestingly, we observed the same relationship between theta-alpha power and hippocampal connectivity in the striatum, an area that has repeatedly been linked to retrieval success. Taken together, our results provide compelling evidence that theta-alpha oscillations functionally bind the hippocampus, prefrontal cortex and striatum during memory recollection.

Title: The BDNF val66met polymorphism affects the Level of Processing effect of memory: a deep and shallow behavioral and rTMS study

Authors: *A. SHPEKTOR[1], E. F. PAVONE[2], N. VUKOVIC[1], A. LEBEDEVA[1], M. FEURRA[1];
[1]Sch. of Psychology, Ctr. for Cognition and Decision Making, Natl. Res. Univ. Higher Sch. of Econ, Moscow, Russian Federation; [2]Applied Neurosci., Braintrends ltd, Rome, Italy

Abstract: A polymorphism in the BDNF (BDNF val66met; rs6265) gene causing a valine (val)-to-methionine (met) substitution at codon 66 results in altered intracellular trafficking and packaging of BDNF, and in a reduction of its regulated secretion. BDNF-val/val carriers usually showed a better cognitive performance in terms of motor, attention and memory task with respect to those who are met-carriers. Not so far it has been shown that BDNFval66met genotype predicts variation in hippocampal anatomy as well as in human episodic memory function. So far it is still unclear if Val/Val subjects are susceptible to better plasticity and if their cognitive performance is a matter of better connectivity. Here we investigated how the BDNF val66met polymorphism affects cognitive memory performance in healthy young individuals. To do this we used a deep and shallow episodic memory task which is a classical paradigm to test the level of processing effect (LoP). Since val/val might be more susceptible to more stable plasticity change respect to Val/Met carriers, we used Repetitive Transcranial Magnetic Stimulation (rTMS) as interference approach to causally address the role of the left and right DLPFC during episodic memory retrieval with respect to the BDNF val66met polymorphism. To do this, we recruited two groups of healthy subjects (Val/Val and Val/Met carriers). Left and right DLPFC as well as a control site (Vertex) was targeted by time-locked rTMS at stimulus presentation during retrieval. Our findings indicated the causal involvement of the DLPFC in episodic memory by showing for the first time how rTMS at retrieval modulate the behavioral performance accordingly to the BDNF val66met.

Title: Directional coding during imagination

Authors: ***J. BELLMUND**, L. DEUKER, T. NAVARRO SCHROEDER, C. F. DOELLER; Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Successful navigation requires information about both the organism's current and target location as well as about the directional relationship between them. Electrophysiological recordings in rodents suggest that positional information is provided by place and grid cells, while head direction cells code for the animal's allocentric facing direction. Recent neuroimaging studies in humans provide evidence for directional representations in the human brain on a coarse scale by discriminating the four cardinal directions. Here, we use fMRI and representational similarity analysis to examine more fine-grained representations of directions in a novel, virtual-reality direction-imagination task. Participants imagined directions between buildings in a realistic large-scale virtual-reality city. A parametric measure of directional memory was closely related to navigation performance during training and a post-scan map test. Pattern similarity analysis of fMRI data revealed fine-grained directional representations in medial temporal lobe regions associated with navigation. These findings shed light on how the human brain represents directional information, which is crucial for understanding navigational processes.

Title: Representational clustering of associative memories

Authors: ***A. R. BACKUS**[1], L. S. SCHURMANN[1], L. HIMMER[1,2], C. F. DOELLER[1]; [1]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: During everyday life, we continuously acquire new knowledge through associative learning, shaping our network of interconnected memories. However, interrogating such mnemonic network representations in the brain using noninvasive neuroimaging techniques is challenging. Recent functional magnetic resonance imaging studies on implicit temporal regularity and inference learning have shown group-level shifts in mnemonic networks, by comparing neural activity patterns before and after learning. Here, we present a litmus test for this method, using a basic explicit paired-associate learning paradigm with fractal-like visual stimuli. We observe increased pattern similarity between associated stimuli compared to non-associated stimuli as a consequence of learning in the medial temporal lobe and medial prefrontal cortex. Moreover, we reconstruct the mnemonic networks of individual subjects to visualize representational clustering of paired associates. By demonstrating the ability to probe mnemonic networks and learning-mediated reconfigurations in the brain, we validate an important tool for memory research. In addition, this approach can potentially be leveraged to track learning in educational settings.

Title: Narrative remapping in the hippocampus

Authors: B. MILIVOJEVIC, M. VARADINOV, A. VICENTE GRABOVETSKY, *C. F. DOELLER;
Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Essential components of episodic memories are the spatial and temporal context in which events took place. In our daily lives, we often revisit the same environments, and temporally proximal events are not necessarily related. Therefore, a more general context is necessary to organise our memories into networks of related events. Personal narratives may

provide such a general context unrestricted by space and time. But how does the brain enable the formation of such narrative-based contextual representations? One possibility is that hippocampal mechanisms which enable remapping of spatial contexts and their gradual divergence over time also support the formation of narrative contexts. To test this hypothesis, we let our participants watch Sliding Doors, a movie which consists of two interleaved narratives, while monitoring their brain activity using fMRI. We then leveraged representational similarity analysis, using correlations between across-voxel activity patterns as a proxy of neural similarity, to track the emergence of narrative-specific hippocampal representations over the course of the movie. The movie was segmented into TR-length time bins, and each segment was tagged for the following information: narratives, characters and locations. Results of a post-scanning narrative-discrimination task indicated that participants formed reliable narrative representations in memory. In our imaging analysis, we first determined if we can differentiate between the narratives in the hippocampus. We found that this was indeed the case for the right hippocampus and that these narrative-context representations diverged gradually over time, with stable representations emerging only about an hour into the movie. Next, we identified the brain regions which can distinguish between exemplars of specific visual categories: people and locations. Unsurprisingly, regions in the ventral visual stream were sensitive to the within-category exemplar identity. Surprisingly, however, similar differentiation was also observed between exemplars in the hippocampus. These results suggest that the hippocampus not only differentiates between contextual narrative representations, but also between representations of separate items within narratives. These item-specific representations may reflect abstracted nodal representations, which emerge as a consequence of repeated exposure to characters and locations through multiple events. In conclusion, we provide first evidence for the gradual emergence of narrative context representations in the human hippocampus, akin to remapping-induced spatial context representations of rodent place cells.

Abstract: Accurate memory retrieval from partial or degraded input - i.e. when trying to find our way across a park with all the trees having lost their leaves - requires the reactivation of memory traces, a hippocampal mechanism termed pattern completion. Given its extensive excitatory recurrent connections, region CA3 within the hippocampus has been identified as a likely candidate to execute the auto-associative processing essential for pattern completion (Marr, 1971). However, age-related changes in hippocampal integrity have been hypothesized to shift the balance of memory processes in favour of the retrieval of already stored information (pattern completion), to the detriment of encoding new events (pattern separation; Wilson et al., 2006). In this study, we investigated the underlying neural basis of age-related pattern completion differences with 7T-fMRI, using a scene recognition paradigm we have recently established as a behavioral marker for hippocampal pattern completion (Vieweg et al., 2015). Healthy younger and older adults were asked to identify complete or partially masked scenes in the scanner, half of which they had learned previously. For both groups, recognition accuracy was reduced with decreasing stimulus completeness. This effect, however, was more pronounced in older adults, suggesting that pattern completion is adversely affected by aging. Intriguingly, despite this substantial age-related performance decline, older adults also showed a bias toward pattern completion when only partial information was available. Moreover, following the segmentation of hippocampal subfields on T2-weighted images, we performed multivariate pattern analysis to quantify the representational similarity for different levels of stimulus completeness and stimulus type (learned or novel). The results showed that the hippocampal subfields were differentially susceptible to our completeness manipulation, and their involvement differed between age groups. Taken together, our findings provide important insights into the neural representations that underlie pattern completion in the hippocampus elicited by partial information. Moreover, they can pave the way for developing a mechanistic understanding of memory impairments frequently observed in old age and in neurodegenerative diseases that affect hippocampal integrity.

Title: Consolidating and expanding mnemonic networks

Authors: ***S. H. COLLIN**, B. MILIVOJEVIC, C. F. DOELLER;
Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: One of the key features of episodic-memory formation is the integration of multiple events and experiences into coherent mnemonic representations. Over time, these mnemonic networks are often extended with new information. To simulate episodic-memory formation, we have previously used The Sims 3 to make videos of life-like animated events that could either be integrated into narratives or not. We showed increased neural similarity in the hippocampus and medial prefrontal cortex (mPFC) as a result of linking events into a narrative, which suggests the formation of a shared representation coding for linked events [1]. However, it remains unclear whether these ensuing mnemonic networks are also consolidated as unified narrative representations c.f. Ref. [2], and what are the neural mechanisms for expanding such narrative representations after consolidation. To study these outstanding questions, we re-invited the participants from Ref. [1] for a second fMRI session on the subsequent day. On this day, they were presented with the same events as before, with the addition of a new event which was introduced and extended the initial narratives. Results of representational similarity analysis, a multivariate analysis method that uses across-voxel activation patterns as a proxy of neural similarity, showed that Day 1 narrative representations in mPFC were still present on Day 2. However, narrative representations in posterior MTL disappeared on Day 2. Interestingly, a new integrated representation emerged in anterior MTL on Day 2. To examine the neural mechanisms underlying integration of novel information into the consolidated narrative representations, we correlated the across-voxel activation pattern of the novel events with the initial narrative events, showing increased neural similarity in mPFC. These findings suggest that episodic memories are consolidated as unified representations and can be extended with newly available information in mPFC, even after consolidation. This is in accordance with rapid schema formation known to occur in this brain region [3, 4]. However, anterior MTL seems to serve a complementary role in consolidating this expanded narrative, potentially by maintaining a large-scale narrative representation (Collin et al., SfN 2014, 2014-S-3754-SfN) until it is sufficiently strengthened in mPFC. Title: Time is memory: dissociating temporal and sequence coding

Authors: ***L. DEUKER**, N. MONTIJN, L. SCHURMANN, C. F. DOELLER;
Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Episodic memory, which is critically dependent on the hippocampus, has been defined as remembering what happened where and when. While there is a large body of evidence for the role of hippocampus in spatial memory (remembering what happened where), less research has been conducted to elucidate the role of hippocampus in temporal memory (what happened when). Recently, cells have been discovered in the rodent hippocampus, which specifically encode the temporal aspect of an episode. In humans, neuroimaging studies have shown that stimuli, which were temporally linked or that were shown close to each other in a predictable order exhibit higher neural pattern similarity. However, these studies did not investigate temporal memory per se, but used sequential order or presence within the same event boundaries as a proxy for temporal relatedness. In this study, we investigate the role of the hippocampus in representing temporal distance between events over and above the impact of the mere order in which events are shown. To this end, we developed a novel task using complex visual scenes depicting every-day events in the life of a virtual family, created with the life-simulation game 'The Sims 3'. Events were presented as happening during four different virtual days, each event at a specific time. Events were spaced differently in these days, with some events only one virtual hour apart, while other events were separated by four hours. This allows us to dissociate order memory from temporal memory. Crucially, we scanned participants with functional magnetic resonance imaging while they were viewing the events in random order, both before

("pre-phase") and after ("post-phase") they learned which day and time the scenes belonged to. We then compared the change in pattern similarity with representational similarity analysis from the pre-phase to the post-phase. Behaviorally, participants were well able to learn the timing of the scenes. Preliminary fMRI results show that pattern similarity in the hippocampus covaries with the temporal distance between events. These findings may shed new light on the role of the human hippocampus in remembering temporal event structures.

Title: Navigating memories: how episodes and space combine in the hippocampal formation

Authors: ***N. DE HAAS**, L. DEUKER, B. MILIVOJEVIC, C. F. DOELLER;
Donders Institute, Radboud Univ., Nijmegen, Netherlands

Abstract: Two core memory systems are spatial and episodic memory. Both memory systems rely on the same brain structure: the hippocampal formation. So far, it remains unclear what the exact relationship between spatial and episodic memory is and how the hippocampal formation supports these seemingly different functions. We test two prevalent but opposing hypotheses that either the hippocampal formation supports these two systems via a common coding mechanism or via parallel processing. To this end, we combined high-resolution fMRI with behavioural tasks leveraging virtual reality and a life-simulation game. In the current experiment, participants had to learn associations between objects and two spatial contexts (spatial task) as well as two episodic contexts (episodic task), respectively. The distribution of objects over spatial and episodic contexts resulted in four different types of object pairings in a 2x2 factorial design: pairs which share 1) a spatial context only, 2) an episodic context only, 3) both a spatial and episodic context and 4) no context. Before and after each task, we presented all objects in randomized order and recorded brain data. This allows us to detect changes of across-voxel pattern similarity for the different types of object pairs as a function of preceding task manipulation. We are then

able to test different predictions of the opposing theories concerning when and where changes in similarity occur for each type of pair in the hippocampal formation. Preliminary results of multivariate pattern analysis (n= 14) show an increase in neural similarity in the hippocampus for object pairs which either share a spatial context or an episodic context. This suggests that our experimental manipulation is powerful enough to induce changes in neural similarity between object pairs in the hippocampal formation and therefore suited to test predictions of the opposing hypotheses.

Title: Structural connections of the medial prefrontal cortex: Dividing motor, semantic and default mode networks

Authors: ***R. JACKSON**, C. J. BAJADA, M. A. LAMBON RALPH, L. L. CLOUTMAN; Neurosci. and Aphasia Res. Unit, Sch. of Psychological Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: The medial prefrontal cortex (mPFC) is implicated in multiple domains, including the default mode network (DMN) and semantic processing. However, whether sub-regions are variably related to different domains, is unknown. This is the first exploration of the structural connectivity across the entire mPFC as a way to inform function. Structural connectivity analyses were performed on diffusion-weighted MR images from 24 participants. Unconstrained probabilistic tractography was seeded from ROIs of Brodmann areas 6, 8, 9, 10 and 11 using the PICo algorithm. As a follow up, tractography was computed for each voxel in ventromedial PFC (vmPFC). This allowed tractographic parcellation of the vmPFC using the PARCEllation of Neural Images using Pico method. Differential connectivity was identified. BA6 connected to primary motor cortex and the corticospinal tract. BA11 connected to anterior temporal lobe (via the uncinate) and primary visual and auditory regions (via IFOF). BA9, positioned between these

extremes, showed local connectivity (frontal cortex and insula). BA8 and 10 had similar but reduced connectivity to BA6 and 11, respectively. In moving from BA6 to 11, a gradient of connectivity was demonstrated from motor through local to high-order cognition areas. However, mPFC subregions were not differentially connected to networks associated with distinct higher order functions (e.g., semantics vs. DMN). Therefore, a secondary analysis was conducted to parcellate the vmPFC (BA10 and 11) based on structural connectivity without user-defined ROIs. vmPFC voxels formed 2 clusters, with differential connectivity from basal BA11 (orbitofrontal cortex) and dorsal BA11 and BA10. The orbitofrontal cortex connected to temporal and occipital regions related to semantic and sensory processing, whereas more dorsal areas connected to DMN regions. Distinct areas of the mPFC are connected to regions involved in motor, semantic and default mode networks. The novel tractographic parcellation technique allowed an emergent division of regions with distinct functional roles.

Title: Multivariate structure-function relationships in human brain networks

Authors: ***B. MISIC**[1], R. BETZEL[2], M. DE REUS[3], M. VAN DEN HEUVEL[3], M. BERMAN[4], O. SPORNS[2];

Abstract: The emergence of spontaneous fluctuations in brain networks is shaped by the underlying anatomical connectivity patterns. Although the edge-wise correspondence between structural and functional connections has been convincingly demonstrated in multiple reports, little is known about how coherent functional network patterns emerge from structural networks. In the present study we move beyond the correspondence between individual structural and functional edges, and investigate the association between structural networks and functional networks. Data were derived from the Human Connectome Project (HCP), with n = 215 participants. Structural and functional data were parceled into 66 regions using the FreeSurfer atlas, and then further subdivided into 114 approximately equally sized parcels. Structural connectivity was estimated by applying computational tractography to diffusion tensor imaging (DTI) data, while functional connectivity was estimated as a Pearson correlation coefficient between functional magnetic resonance imaging (fMRI) time series, recorded in the absence of any overt task. Structure-function relationships were assessed using multivariate partial least squares (PLS) analysis. A structure-function covariance matrix was constructed by computing the covariance between all possible pairs of structural and functional connections across participants. The matrix was subjected to singular value decomposition, yielding a set of latent variables – weighted combinations of structural and functional connections that optimally covary with each other. The statistical significance of latent variables was calculated using permutation tests, while the statistical reliability with which individual connections contribute to latent variables was estimated using bootstrap resampling. We find five statistically significant patterns

($p < 0.001$), reflecting robust combinations of structural and functional subnetworks that are optimally associated with one another. Importantly, the patterns generally do not show a one-to-one correspondence between structural and functional edges, but are rather rich and heterogeneous, with many functional relationships arising from seemingly unrelated, upstream anatomical connections. We also find that structural connections between high-degree hubs are disproportionately represented, suggesting that these connections are particularly important in establishing coherent functional networks. Altogether, these results suggest that the emergence of spontaneous fluctuations in neural activity occurs due to a complex combination of interactions on the structural connectome.

Title: Hippocampal connectivity with the visual and motor systems reflects the cognitive requirements of the task

Authors: ***D. D. BURMAN**[1], T. D. HOPKINS[2];
[1]Northshore Univ. Healthsystem, Evanston, IL; [2]NorthShore Univ. HealthSystem, Evanston, IL

Abstract: By synchronizing cortical activity, the hippocampus can influence widespread regions of cortex, including regions not implicated in its known roles of memory, spatial perception, and sensorimotor integration. Whether the hippocampus influences sensory and motor cortical areas, independent of its known roles in memory and perception, is unknown. In a group of twelve subjects, cortical activation was identified in two finger-tapping tasks (repetitive, remembered sequence) and two visual tasks (checkerboard , simple fixation). To identify task-specific patterns of hippocampal connectivity, psychophysical interactions (PPI) were computed between task conditions for each hippocampal voxel, and the magnitude of correlated activity was mapped in activated areas (sensorimotor cortex for motor tasks, occipital cortex for visual tasks). Sensorimotor connectivity was observed for both motor tasks, with peak connectivity during repetitive movements coinciding with each finger's topographic representation. Although visual

activation extended into the periphery during the checkerboard task, hippocampal connectivity during visual tasks was limited to central vision. For all tasks, peak hippocampal connectivity among individuals (> 80% of maximum) typically mirrored the region of peak activation (> 80% of maximum), and peak connectivity from the left and right hippocampus overlapped. Unexpected based upon its known properties, these results suggest a role for the hippocampus in the cognitive control of intentional processes.

Title: Multivariate pattern analysis of resting state activity reveals spontaneously organized brain state dynamics

Authors: *R. H. CHEN[1], P. SHAFTO[3,2], M. W. COLE[1];
[1]Ctr. for Mol. and Behavioral Neurosci., [2]Psychology, Rutgers University, Newark, Newark, NJ;
[3]Psychology and Computer Sci., Univ. of Louisville, Louisville, KY

Abstract: Resting state functional connectivity MRI is increasingly used to characterize functional networks in the human brain. We recently found that the resting state network architecture is present across a wide variety of tasks (Cole et al., 2014), suggesting the general functional relevance of resting state networks. This illustrates the importance of better understanding the processes underlying the organization of resting state neural activity. Recent literature has focused on resting state dynamics - variability in the structure of resting state activity across time. However, current methods use arbitrary temporal window lengths to characterize network configurations, despite rapid and variable transitions in spontaneous activity. Furthermore, we hypothesized that spontaneous dynamics are not restricted to functional connectivity changes - that they likely extend to distributed multivariate activation pattern changes as well. We therefore applied multivariate pattern analysis (MVPA), a popular method for task neuroimaging, to characterize global brain state transitions during resting state with fMRI (functional MRI). Similar to a form of MVPA called representational similarity analysis (Kriegeskorte, 2008), we assessed the similarity of brain activity patterns through time.

Unlike previous approaches, however, we applied this across all pairwise time points. When observing contiguous time points this revealed rapid transitions across multiple distinct but stable brain states. When observing non-contiguous time points we found that many of these multivariate patterns repeated across time (and across subjects), suggesting some brain states are spontaneously "revisited". In addition to increasing our understanding of resting state dynamics and brain state transitions, this approach may open possibilities for future research by bringing a powerful class of methods developed for task neuroimaging to investigate resting state neuroimaging data. Title: Segregated and integrated brain dynamics underlying higher cognitive reasoning in humans

Authors: ***L. HEARNE**[1], L. COCCHI[1], J. B. MATTINGLEY[1,2];
[1]Queensland Brain Inst., St Lucia, Australia; [2]Sch. of Psychology, Univ. of Queensland, St Lucia, Australia

Abstract: Human intelligence is defined as the ability to understand complex ideas, adapt effectively to the environment, engage in complex reasoning and overcome obstacles by taking thought. Early neuropsychological and lesion-mapping studies implicated frontal brain regions as

key to the processes underlying intelligence. More recently, the application of network-sensitive analysis techniques to neuroimaging data has extended this view by highlighting the importance of whole-brain patterns of neural activity and connectivity. In the current study we collected 7T fMRI data with high temporal and spatial resolution in a cohort of adult participants who also underwent intelligence testing. Participants' brain responses were measured both at rest and during a novel non-verbal reasoning task akin to Sudoku. We examined the neural underpinnings of intelligence-related task performance using a combination of approaches sensitive to segregated changes in neural activity and integration between discrete brain regions. We found that reasoning evoked both increased and decreased neural activity and connectivity between widespread brain regions comprising several endogenous neural networks. Additionally, our results suggest a link between endogenous functional connectivity related to intelligence and changes in brain dynamics that arise due to increased cognitive reasoning demands. Taken together the findings suggest that reasoning processes required for high-level intelligence reflect widespread changes in neural dynamics across multiple brain networks.

Title: Hub-centric prefrontal network predicts lesion-effective site for contextual memory in macaques

Authors: *T. OSADA[1,2], Y. ADACHI[1], K. MIYAMOTO[1], K. JIMURA[3], R. SETSUIE[1], T. WATANABE[1], Y. MIYASHITA[1];

[1]Dept Physiol, Univ. Tokyo Sch. Med., Tokyo, Japan; [2]Dept Physiol, Juntendo Univ. Sch. Med., Tokyo, Japan; [3]Prec Intel Lab, Tokyo Inst. of Tech., Yokohama, Japan

Abstract: Neuroimaging and neurophysiological studies have revealed that multiple areas in the prefrontal cortex (PFC) are activated in a specific memory task, but severity of impairment after PFC lesions is largely different depending on which activated area is damaged. No approach has been established to localize the lesion-effective site among the activated areas. We hypothesized that task-activated PFC areas form an ordered network centered at a task-specific "functional hub", and the lesion-effective site corresponds to the "functional hub", but not to a task-invariant "anatomical hub" in a static anatomical network. Here, we conducted fMRI experiments in two macaque monkeys performing temporal-order judgment with a list of visual stimuli in a 4.7-T MRI scanner (Osada et al., 2015). After serial presentation of a stimulus list, the monkeys were simultaneously presented with two of the listed stimuli and were required to select which stimulus had appeared more recently. Behaviorally, significant differences in correct response rates and reaction times due to the inclusion of end stimuli were observed ($p < 10^{-4}$, paired t-test), indicating that the cognitive demands varied depending on whether the end stimuli were included or not. We compared cortical activity during high and low demand judgment, and identified significant activations, including multiple bilateral PFC areas ($p < 0.05$ FWE corrected). Based on task-evoked connectivity among the activated areas calculated by psychophysiological interaction, we found that the activated areas formed a hub-centric network. The task-specific functional hub assessed by betweenness centrality (area 9/46d) corresponded to the well-documented lesion-effective site, avoiding the neighboring non-lesion-effective site. We also evaluated the anatomical network among the activated areas with the aid of CoCoMac database, and found that the anatomical hub (area 8Ad) did not correspond to the lesion-effective site. Quantitatively, with a novel simulated-lesion method based on support vector machine, the predicted severity of impairment was proportional to the hubness of the lesioned area in the functional network, rather than in the anatomical network. These results support our functional hub hypothesis and suggest that PFC areas dynamically shape a hub-centric network to reallocate the lesion-effective site depending on the cognitive processes, apart from anatomical hubs.

Abstract: A critical challenge in neuroscience relates to the identification of the essential cognitive processes that shape perception, learning, memory, and behavior. Such cognitive processes are often dynamic, evolving through time or over the course of an experiment, and are typically inaccessible to direct measurement. Often, experiments are designed to allow investigators to infer features of a cognitive state by measuring various behavioral responses to stimuli. For example, in a learning task, researchers might use reaction time and response accuracy to infer how well a subject has learned an association. State space methods have been used successfully to model dynamic features of the neural and behavioral signals for a variety of cognitive tasks. Typically, such methods either make strong assumptions about the data structure, for example that the data are normally distributed and the cognitive process evolves linearly, or else are narrowly designed for a particular experimental paradigm. However, many classes of experiments include similar behavioral responses that are known to have distributions that are not well modeled as normal and dynamics that are not linear. For example, reaction times for simple tasks are non-negative and typically have asymmetric distributions. Many behavioral signals are either discrete, e.g. a binary response or multinomial decision, or a mixture of continuous and discrete signals. In this research, we propose a general mathematical framework to estimate cognitive state processes using common behavioral signals that include a range of distributions. Under this framework, the cognitive process is modeled as a time-dependent state variable, and the conditional distributions of the behavioral signals are modeled as a function of the cognitive process and experimental factors. We propose an adaptive filtering solution to simultaneously infer the model parameters and estimate the cognitive state process through the course of an experiment. The adaptive filter consists of a signal-smoother and an EM algorithm, which sequentially estimates model free parameters and the cognitive state variable to maximize the likelihood of the observed behavioral signals. The algorithm has been applied in two behavioral datasets; using the algorithm, the moment-to-moment variation in the subject behavior and its underlying cognitive process are captured. We derived the prediction algorithm

for observations with gamma, Bernoulli, and mixture of gamma and Bernoulli distributions; the proposed methodology can be extended to other behavioral signals with log-normal, Poisson, or multinomial distributions, or mixture of these distributions.

Title: Feature-based attention during sequential tasks

Authors: ***T. M. DESROCHERS**[1], A. G. COLLINS[1], D. BADRE[1,2];
[1]Dept. of Cognitive, Linguistic, and Psychological Sci., [2]Brown Inst. for Brain Sci., Brown Univ., Providence, RI

Abstract: We complete many sequential tasks in the course of every-day life that require the selective allocation of attention as one progresses through sub-goals towards a common end goal. For example, when making a sandwich, attention could be directed towards color as a feature when selecting a tomato or towards shape as a feature when slicing the bread. Previous studies have shown that cuing the to-be-attended feature modulates the activity in the corresponding extrastriate cortex. However, there is debate as to whether these effects are the result of top-down or bottom up processes, given that most of the previous work used experimental designs where the feature to be attended was predictably blocked. We designed an experiment to examine these attentional processes in the context of simple sequences of tasks. Human participants were asked to sequentially repeat four judgments (e.g. color, shape, shape, color) in a block. Importantly, the dimension to be attended to was provided only by the internal sequence

representation, and the specific feature (e.g. red or blue) was random for each stimulus. Additionally, we simultaneously manipulated the stimulus features available and provided participants “clues” as to the currently relevant task/dimension on approximately one third of the trials by presenting a feature that was not an option for selection in the irrelevant dimension (e.g. green on a “shape” trial). Preliminary results indicate that a large network of frontal, parietal, and extrastriate cortical areas are activated on trials which participants received a clue versus no clue, despite no overall effect of clue trials on reaction times. We will also discuss follow up analyses that seek to dissociate patterns of activation related to bottom-up attentional capture mechanisms versus putative top-down feature based selection.

Title: Cortical patterns of alpha power in auditory sensory memory

Authors: ***A. WILSCH**[1], M. J. HENRY[1], B. HERRMANN[1], J. OBLESER[1,2];
[1]Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: The neural and behavioral dynamics of decay in working memory and sensory memory are not well understood. Increased memory load, for instance, is accompanied by increased alpha power (8–13 Hz) during memory retention. However, it is not known how alpha power across brain areas is modulated during memory decay, and whether a priori factors such as temporal expectation for to-be-remembered auditory information can counteract this memory decay. We here present data from two samples, using magnetoencephalography (N=20) and behavioral data modeling (N=19) in order to asses memory decay in auditory sensory memory. First, in an auditory delayed matching-to-sample task, we manipulated temporal expectations (fixed vs. jittered cue–stimulus time interval) for a pair of pure-tone sequences (S1-S2; discriminability individually adjusted) embedded in white noise and varied the duration of the delay between S1 and S2 (1, 2, 4 s). Longer delays impaired memory performance (analyzed using signal detection theory and area under the ROC-curve; A_z), but this impairment was less strong for fixed than for jittered S1 onset-time. Longer delays also modulated alpha power (analyzed using Fast Fourier transform and an adaptive spatial beamformer for source analysis):

Alpha power declined parametrically with longer delays in visual cortex, inferior parietal lobe, and precuneus. However, alpha power decreased relatively less after temporally expected S1 onsets compared to unexpected S1 onsets in left supramarginal gyrus. Across conditions, individual modulation of alpha power predominantly emerging from these areas predicted individual performance modulation. Second, to study the impact of temporal expectations on memory decay more precisely, we behaviorally tested six different delay phases (0.6–7.0 s) in a second sample. An exponential decay function with independent growth and decay terms was fitted to the performance measure A_z, separately for fixed and jittered trials. Fixed-foreperiod trials were associated with a significantly larger estimated growth term indicating enhanced maintenance of the representation after temporally expected compared to unexpected S1 onsets. To summarize, temporal expectations counteract decay in auditory sensory memory. Specifically, temporal expectations improve memory performance, while attenuating the alpha power decline as memory decays. Moreover, cortical patterns of the alpha power effects revealed by source analyses encourage a more nuanced perspective of the inhibitory role of alpha power.

Title: Probing functional connectivity between default and salience networks using single pulse electrical brain stimulation

Authors: ***J.-C. HSIANG**[1,2], B. L. FOSTER[2], S. GATTAS[2], V. RANGARAJAN[2], J. PARVIZI[2];

Abstract: A direct functional relationship between the default mode network (DMN) and salience network (SN) has been proposed based on slow fluctuations of hemodynamic response.

However, given the limitation of this method, the direction of such connectivity remains poorly understood. Our current study utilized cortico-cortical evoked potentials (CCEP) to fill this gap of knowledge. In 4 human participants with focal epilepsy implanted with depth electrodes, we applied single pulse electrical stimulation to selected electrode pairs in DMN and SN regions. These sites were selected in each participating subject based on network identity information from rs-fMRI and electrocorticography data obtained from the same subject. The DMN sites included the retrosplenial cortex (RSC) and medial prefrontal cortex (MPFC) while the SN nodes contained the dorsal anterior cingulate cortex (dACC) and insula. Our findings suggest a robust connectivity within networks, but an intriguing pattern of connectivity between nodes of different networks. For instance, when the dACC was stimulated, evoked responses were consistently recorded in the RSC but not vice versa. Our findings provide another layer of information about the pattern of connections between different networks of the brain and raise questions and hypotheses that can be addressed with targeted studies in the future.

Title: Spatiotemporal motifs of correlated interactions across resting state networks

Authors: M. KAFASHAN[1], S. CHING[1], *B. A. PALANCA[2];
[1]Electrical and Systems Engin., Washington Univ. in St. Louis, St. Louis, MO; [2]Anesthesiol., Washington Univ. Sch. Med., Saint Louis, MO

Abstract: INTRODUCTION: Conventional correlation analysis of blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) signals allow the brain to be segmented into multiple modules of functional-linked regions, referred to as resting state networks (RSNs). These RSNs mirror activation patterns evoked by behavioral tasks and represent statistically correlated neural activity spatially distributed over salient epochs of time. This approach obscures incompletely characterized temporal dynamics of interaction within and across RSNs during different arousal states. **METHODS:** Healthy human volunteers underwent BOLD fMRI during quiet wakefulness and while rendered unresponsive by 1.2 vol% sevoflurane. Stringent frame censoring of motion artifact and regression of whole brain global signal were applied to the BOLD signals. A winner-take-all algorithm was employed to select 1076 regions with > 90% probability of assignment to seven RSNs. Repeated pseudorandom resampling of these 6 x 6 x 6 mm regions was performed with 15 representing each RSN. BOLD time series were concatenated across subjects and both arousal states. Correlation trajectories for each region pair were calculated using a bounded Kalman filtering approach (11 second window). Using a *K*-means algorithm, we defined 8 orthogonal clusters with region pair membership defined by the strength of covarying correlation trajectories. **RESULTS:** Clusters of correlation trajectories (Figure 1) are maintained to varying degrees across arousal state over time. The clusters can be described as the following: (1) covarying high correlation trajectories of intra-RSN regions pairs (Cluster 1), (2) intermediate correlation trajectories within and between RSNs (Cluster 2 and 3), (3) weak correlation interactions between RSNs (Cluster 4 and 5), and (4) very weak correlation interactions between RSNs (Cluster 6, 7 and 8). **CONCLUSIONS:** Clustering based on covarying correlation trajectories yields structural motifs that may represent higher order patterns of interaction between RSNs.

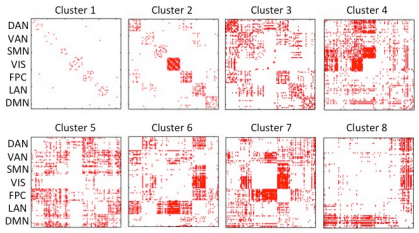

Figure 1: Clusters defined by covarying correlation trajectories. DAN: Dorsal attention, VAN: ventral attention, SMN: somatomotor, FPC: frontoparietal control, VIS: visual, LAN: language, DMN: default mode networks.

Title: Facilitating spatial working memory in patients with diabetic polyneuropathy by transcranial direct current stimulation

Authors: *Y.-J. WU[1,2,3], P. TSENG[4], H.-W. HUANG[1], J.-F. HU[5], C.-H. JUAN[6], K.-S. HSU[7], C.-C. LIN[1];

Abstract: Diabetes mellitus may lead to multiple complications, including diabetic polyneuropathy (DPN) and spatial working memory (SWM) deficits. Since DPN and SWM impairment can be two neurological entities, manifesting peripheral and central neuropathy respectively in diabetic patients, we investigated the SWM deficit of the DPN patients and intended to improve it by anodal transcranial direct current stimulation (tDCS) over right dorsolateral prefrontal cortex. This age- and education-matched intervention study enrolled patients with DPN (n=16) and control subjects (n=16). A forward- and backward-recall computerized Corsi Block Tapping task (CBT), both with and without a concurrent motor interference task was used to measure SWM capacity. Each participant underwent tDCS-CBT (2mA/35cm2, 15 minutes) and sham-CBT (2mA/35cm2, 30 seconds) sessions on two separate days in a pseudorandom counterbalanced order. The results showed that DPN patients had lower score of Montreal Cognitive Assessment (MOCA) and lower working memory span on Wechsler Adult Intelligence Scale-Fourth Edition (WAIS-IV) compared with control subjects, whereas there was no significant between-group difference on the general intelligence (WAIS-IV). The working memory span of backward recall CBT with concurrent motor interference was positively correlated with the nerve conduction velocity (NCV) value in DPN patients before tDCS treatment. However, this correlation diminished after tDCS treatment associated with the improvement in memory span of the low performers with worse NCV. The trends that DPN

patients presented lower memory span compared with the control subjects were consistent across all four conditions of CBT. Anodal tDCS improved the spans of backward recall and backward recall with interference among all subjects. Particularly, the spans of backward recall with interference were significantly improved after tDCS in DPN patients. This is the first study delineating the positive correlation between diabetic peripheral neuropathy severity and spatial working memory capacity, and the beneficial effect of tDCS on spatial working memory for DPN patients as well as the control subjects, that will be implicated and applicable to the clinical practice.

Title: Integration of Ebbinghaus Functions, Signal Detection Theory, and the Weber-Fechner Law for understanding component processes of working memory

Authors: *J. L. REILLY[1], V. VISWANATHAN[2], T. KARPOUZIAN[1], D. STERN[1], B. KIM[1], F. ZHANG[3], H. BREITER[1];
[1]Northwestern Univ. Feinberg Sch. of Medicin, Chicago, IL; [2]Dept. of Marketing, Kellogg Sch. of Management, Northwestern Univ., Evanston, IL; [3]Dept. of Psychology, Drexel Univ., Philadelphia, PA

Abstract: Objective: Working memory (WM) requires generation of a mental representation with a particular information load (i.e., amount) that is maintained over a temporal delay period, placing constraints on WM capacity. Component processes underlying WM performance as load and delay demands increase include i) the change in correct responses and errors as defined by Ebbinghaus functions; ii) the trade-off regarding information maintenance and segregation of signal and noise distributions characterized by signal detection theory; iii) the ease of distinction between a probe and encoded array, akin to a just noticeable difference (JND) as characterized by the Weber Fechner Law; and iv) the efficiency of response selection as indexed by reaction time (RT). In 2 independent experiments (Exp_1, Exp_2) we used a modified Sternberg Recognition paradigm with variable load and delay demands and conducted iterative modeling to map relationships among component processes of WM. Methods: Two cohorts of healthy young

adults (Exp_1 n=56, Exp_2 n=50) completed a computerized visuospatial recognition task in which information load (Exp_1 1,3,5, 7 items, Exp_2 3,5,7 items) and delay length over which information was held (Exp_1 2.25 - 5.75s, Exp_2 1.50 - 9.50s) varied. After briefly viewing an encoding array and following a variable delay interval, subjects responded whether a probe item matched the spatial location of any item in the encoding array. Hits/misses (signal trials), false alarms (FAs)/correct rejections (noise trials), and response time (RT) were recorded. d' and B were calculated (from hits and FAs) for signal detection measures as was a JND metric which reflected the spatial distance between a probe item and the nearest item in the encoding array. Separate statistical models evaluated i) the effects of load, delay, JND, d' and B on RT, and ii) the effects of load, delay, JND, and response time on hits and FAs. Results: For signal trials, RT was predicted by load, JND, d' and B but not delay, while RT on noise trials were predicted by load, JND, and d' but not B. In turn, hits were predicted on signal trials by load, delay, JND, and RT, whereas FAs on noise trials were predicted by these same terms except for delay. Discussion: Findings from these experiments provide a novel approach for unpacking and integrating component processes of WM and suggest: i) load and JND predict RT, ii) load, delay, JND, and RT predict hits, iii) load, JND, RT predict FA, and iv) d' and B generally predict RT. These observations argue there are quantifiable relationships (i.e., a function space with feedback) among these processes that underlie the variation in capacity of this core cognitive ability.

Title: Electrophysiological correlates of attentional capture by to-be-remembered and to-be-forgotten visual stimuli

Authors: *E. SASIN[1], M. NIEUWENSTEIN[2];
[2]Dept. Of Exptl. Psychology, [1]Univ. of Groningen, Groningen, Netherlands

Abstract: Previous research has shown that visual attention is biased towards items that match the content of working memory (WM). These behavioral findings were further supported by event-related potential (ERP) studies that showed that WM-matching distractors elicited an N2pc

component that reflects the deployment of attention (Kumar, Soto, & Humphreys, 2009). In the present study, we first used behavioral measures to investigate whether attention is still guided towards WM-matching items after an instruction to forget them. Participants memorized a colored shape, which was followed by a cue that indicated whether it should be remembered or forgotten. Subsequently, participants searched for a tilted line among vertical distractor lines, each embedded within a colored shape. The interval between the cue and the visual search task (ISI) was 200, 600, 1000 or 1400 ms and on some trials, one of the distractors in the search task matched the earlier-memorized object. The results showed that the matching distractor captured attention regardless of whether it had to be remembered or forgotten, but the capture effect by to-be-forgotten distractors was smaller. In addition, the capture effects were independent on the interval separating the cue and the search array. Taken together, these results suggest that an instruction to forget an earlier-memorized object attenuates but does not fully abolish memory-driven capture. In a subsequent EEG study we modified experimental procedure in order to directly measure the maintenance of the to-be-remembered and to-be-forgotten distractors in WM. Previous studies provided evidence that contralateral-delay activity (CDA) is a component that indexes active maintenance of object representations in WM (Carlisle, Arita, Pardo, & Woodman, 2011). Therefore, the experimental procedure in the ERP study was identical to the behavioral experiment except that a word cue was presented at the beginning of a trial, indicating whether the colored shape to the left (LEFT) or to the right (RIGHT) of the fixation cross had to be memorized. The ISI between the cue and the visual search task was 200 or 1000 ms. Electrophysiological correlates of the WM-matching distractors that had to be remembered or forgotten will be explored with ERP analysis, focusing on N2pc component that is measured during the visual search task and CDA component that is measured after the presentation of the word cue.

Title: Investigating the role of attention in the time course of visual working memory

Authors: *J. JACOB[1], C. JACOBS[1], B. G. BREITMEYER[2], J. SILVANTO[1];
[1]Psychology, Univ. of Westminster, London, United Kingdom; [2]Psychology, Univ. of Houston, Houston, TX

Abstract: We compared scanning of working memory for simple geometric shapes in cued (location, neutral) and non-cued (control) conditions to investigate the role of attention in the time course of visual working memory. A memory array of 4 items preceded a probe item at varying inter-stimulus intervals (ISIs), ranging from 520 to 5000ms, in the control condition, and in the cued conditions the array preceded a cue at varying ISIs, followed by the probe after 300ms. The location cue pointed to one of the 4 array items, either matching or mismatching the probe. The neutral cue pointed toward all four locations of the memory array. Observers reported whether the probe matched or mismatched the memory array. Response reaction times were collected, and comparison effects (CE) were computed by subtracting average reactions times for matched from mismatched memory array-probe pairings. Similar to previous findings (Jacob, Breitmeyer & Treviño, 2013), CEs in the control condition varied systematically across ISIs, likely reflecting fluctuations in attention and working memory content. The CEs in the location-cued condition followed the same temporal pattern as the control condition, but with dampened fluctuations, terminated by 4000ms. As expected, the location cue utilizes spatial attention to compare the cued item and the probe, reducing memory load. This is likely to reflect spatial attention overriding the effects of attention to WM content. In contrast, the CEs in the neutral-cued condition showed CE fluctuations with higher amplitude for later ISIs. The neutral cue enhances processing of the content of working memory, amplifying CEs as ISIs increase. Our results suggest that attention plays a role in in determining stages of information processing in working memory.

Title: Dietary saturated fat versus monounsaturated fat has reversible effects on brain function and the secretion of pro-inflammatory cytokines in young women

Authors: ***J. A. DUMAS**[1], J. BUNN[2], J. NICKERSON[3], K. CRAIN[4], D. EBENSTEIN[4], E. TARLETON[5], J. MAKAREWICZ[1], M. E. POYNTER[4], C. L. KIEN[4];
[1]Psychiatry, [2]Med. Biostatistics, [3]Radiology, [4]Med., [5]Clin. Res. Ctr., Univ. of Vermont Col. of Med., Burlington, VT

Abstract: Our previous studies indicated that lowering the typically high intake of palmitic acid (PA) in the Western-patterned diet was reversibly associated with increased physical activity and decreased inflammatory stress. Physical activity can be mediated by executive functioning, and inflammatory signaling may impair cognition. Therefore, we hypothesized that dietary PA and oleic acid (OA) might differentially alter activation of brain regions associated with regulation of executive functioning as well as innate immunity. Thus, in 12 female subjects participating in a randomized, cross-over trial comparing 3-week high PA (HPA) and low PA/high OA diets, we evaluated functional magnetic resonance imaging (fMRI) using an N-back test of working memory, cytokine secretion by lipopolysaccharide-stimulated peripheral blood mononuclear cells (PBMC), and plasma cytokine concentrations. During the HPA diet compared to the HOA diet, activation in the caudate and putamen ($p < 0.005$) was relatively increased, PBMC secretion of interleukin (IL)-18 was higher ($p = 0.015$) and IL-1β trended higher ($p = 0.066$), and plasma concentrations of both IL-1β and IL-6 were higher ($p < 0.05$). Thus, effects of the HPA diet included less efficient brain functioning, the production of pro-inflammatory cytokines *in vivo*, and enhanced secretion of inflammasome-regulated cytokines from LPS-stimulated leukocytes *ex vivo*. This novel human study shows an inter-relationship between dietary fatty acid-induced changes in brain activation and pro-inflammatory cytokine production from circulating leukocytes.

Title: Load-dependent versus training-induced power changes within the working memory network - An EEG study

Authors: ***H. GUDI**[1], J. M. RIMMELE[2], P. BRUNS[1], A. K. ENGEL[2], B. ROEDER[1]; [1]Biol. Psychology and Neuropsychology, Univ. of Hamburg, Hamburg, Germany; [2]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Since the brain comprises highly interconnected networks, neuroplasticity as a consequence of training must be investigated at a network level rather than by focusing on local changes. In the present study we investigated neuroplasticity as a following of an extensive working memory (WM) training. An adaptive n-back paradigm was applied in two groups of healthy participants trained with either voice stimuli (group 1) or tactile stimuli (group 2). A control group performed a 1-back task (group 3). The EEG was recorded prior to and after a four sessions lasting training while participants performed an auditory 2-back-task (i.e., with the voice stimuli used during the training sessions in group 1). In the post-training session, participants additionally performed an adaptive n-back task to assess neural network activity while performing at their limits. A pre-post sessions comparison of neural oscillations elicited in the 2-back task revealed an increase in theta-band power at fronto-parietal channels after training in both groups 1 and 2, as compared to the control group 3. Additionally, to address load effects, oscillatory activity was compared between the low load (2-back task at post-training session) and high load (individually adapted n-back task at post-training session) conditions. A main effect of load was observed across all groups (1, 2, 3) indicating a decreased posterior-temporal but increased frontal theta-band power in the high load condition as compared to the low-load condition. Our findings are in accord with previous work relating enhanced executive demands to increased frontal theta band power and a higher familiarity with the stimulus material to a reduction in the posterior theta activity. Interestingly, the neural correlates of group-specific training effects differed from those of group-independent load effects suggesting partially different neural mechanisms. Conflict of interest and funding The authors declare no competing financial interests. This study was supported by the DFG (SFB936/A3/B2) and the EU (ERC-2009-AdG-249425; ERC-2010-AdG-269716).

Title: Response speed and contextual congruency affect visual short term memory introspection

Authors: *C. JACOBS, J. JACOB, J. SILVANTO;
Univ. of Westminster, London, United Kingdom

Abstract: Metacognition is a form of introspection in which one reflects upon one's own cognitive processes. Multiple factors modulating metacognition in long-term memory (LTM) have been identified (Koriat, 2007), but less is known about what influences metacognition of working memory. Here, we investigated the effects of two factors known to modulate LTM metacognition and/or LTM task performance on metacognitive performance (i.e. the difference between introspective ratings for accurate - inaccurate trials) in a visual short-term memory (VSTM) task. In experiment 1, we investigated the effect of reaction times (RTs), because, in LTM, trials with shorter RTs tend to be endorsed with higher confidence ratings (Kelley & Lindsay, 2003). Participants were tested on their memory for the orientation of Gabor patches over a 5 second delay period. Response speed was manipulated by artificially speeding up participants' RTs or by slowing them down. After their initial response, participants rated on a 4-point scale either vividness of their memory, or confidence in their response. In both the confidence and vividness groups, metacognitive sensitivity decreased for each experimental condition compared to baseline, possibly due to the additional working memory load of having to remember an additional task rule. In experiment 2, we investigated the effect of context, because we hypothesized that this would differentially affect the vividness and confidence groups. The task was identical to experiment 1, but this time cue and test stimulus were surrounded by coloured rings, either of the same (i.e. congruent context) or different (i.e. incongruent context) colour. Confidence ratings, but not vividness, showed increased metacognitive sensitivity when the context changed compared to when the context at encoding and retrieval remained identical, possibly due to the alerting effect of the contextual change. However, accuracies were unaffected. These results are in accordance with earlier studies that also indicate that introspection and metacognitive assessment of visual working memory are more than just a read-out of the original memory trace (Bona et al., 2013; Bona & Silvanto, 2014).

Title: Contralateral delay activity tracks fluctuations in working memory success

Authors: *K. C. ADAM, E. K. VOGEL;
Psychology, Univ. of Chicago, Chicago, IL

Abstract: Neural measures of working memory (WM) storage such as the Contralateral Delay Activity (CDA) are powerful tools in working memory research. CDA amplitude is sensitive to WM load, reaches an asymptote at known behavioral limits (3 items) and predicts individual differences in capacity. An open question, however, is whether neural measures of load also track trial-by-trial fluctuations in performance. Change detection tasks require estimation of performance across an average of many trials, but newer whole-report tasks allow measurement of performance for individual trials. Here, we took advantage of the single-trial nature of a whole-report task to test the relationship between CDA amplitude and working memory performance. If WM failures are due to decision-based errors and retrieval failures, CDA amplitude should not differentiate good and poor trials within a single set-size. On the other hand, CDA amplitude should clearly track performance if WM failures are due to storage failures. Experiment 1 (N = 25) validated the whole-report working-memory measure with a bilateral CDA design. As expected, CDA amplitude tracked set-size, reaching an asymptote at 3 items. Additionally, load-dependent N2PC selection effects were observed. In Experiment 2 (N = 37), we tracked fluctuations in performance by using only a single challenging set-size (6 items). The amplitudes of the N2PC as well as the CDA were higher (more negative) for high-performance trials compared to low-performance trials, suggesting that fluctuations in performance were related to the successful selection and storage of items.

[1]Inserm-CEA Cognitive Neuroimaging Unit, CEA Saclay, Gif Sur Yvette, France; [2]Univ. Pierre et Marie Curie, Paris, France; [3]Ecole des Neurosciences de Paris, Paris, France; [4]Univ. Paris-Sud, Gif Sur Yvette, France; [5]Collège de France, Paris, France

Abstract: Working memory (WM) refers to the temporary maintenance and manipulation of internal representations. Historically, it has been regarded as inextricably linked to consciousness (Baars & Franklin, 2003; Baddeley, 2003; James, 1890), with subjective awareness and WM sharing similar neural networks and the ability to report their contents. Recent evidence questions this view: Consciousness may neither be compulsory for WM, nor may all of the contents of WM be reportable (Soto, Mäntylä, & Silvanto, 2011; Dutta et al., 2014; Soto & Silvanto, 2014). Instead, an "unconscious" WM (unWM) system might exist, which - outside the realms of subjective awareness - receives, maintains, and operates on information. We here sought to exploit behavioral and neural data to clarify the relationship between conscious perception and WM, test the existence of, and characterize the features of unWM operations. Specifically, we conducted an MEG/EEG study (N Exp1 = 23) in conjunction with two behavioral experiments (N Exp2 = 28, N Exp3 = 30) in healthy human subjects who performed a paradigm in which, after a delay (0 - 4.1s), the position (20 or 24 possible circular locations) and visibility (1 [unseen] - 4 [clearly seen]) of a masked target square had to be indicated. Preliminary analyses of MEG recordings revealed a de-synchronization in the alpha and beta bands over frontal sensors observed only in conscious but not in unconscious trials, showing that these types of trials relied on distinct brain mechanisms. Still, participants reported the correct target position better than chance, even when not having seen the target. This blindsight effect resisted the presentation of visible distractors (Experiment 1), suggesting that unconscious information may be maintained for several seconds and shielded against distraction. In addition, a simultaneous demand on conscious WM (Experiment 2) modulated (but did not extinguish) participants' ability to indicate the correct target position. Unconscious WM may thus share the same resources as conscious WM. Crucially, blindsight persisted even when participants had to report a rotated target position (Experiment 3), indicating that, as expected of WM, unconscious information may be maintained and manipulated. These results support the notion that WM may not exclusively operate on conscious inputs and challenge current beliefs of the relationship

between WM and consciousness. An unWM system may exist, allowing for the maintenance and manipulation of unconscious internal representations. Ongoing MEG analyses should reveal the neural mechanisms enabling the maintenance of sensory information under conscious and unconscious conditions.

Title: Attenuation of the p300 in patients with psychosis using a novel serial order oddball paradigm

Authors: *J. AXELROD[1], W. C. HOCHBERGER[1], T. A. CARRATHERS[1], S. K. KEEDY[2], S. K. HILL[1];
[1]Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]Clin. Neuropsychology and Psychopharmacological Res. Unit, Univ. of Chicago, Chicago, IL

Abstract: Against a background of generalized cognitive impairments, individuals on the psychosis spectrum also show a unique deficit in serial order recall. The P300 presents as a viable marker for the updating and maintenance of information in working memory. We previously validated this novel serial order recall ERP paradigm in healthy individuals showing differential attenuation in P300 amplitude across oddball and non-oddball trials. This is the first study to assess this P300 paradigm in psychosis patients. Findings indicate that this novel task successfully elicited a P300 response, albeit attenuated, in patients. Thus, this novel task can be used to evaluate the integrity of neural circuits underlying P300 generation and related working memory and attentional processes in psychotic disorders. Future studies can focus on the impact of cognitive demand with varying delayed and response output conditions on P300 amplitude in this novel task, as well as the relationship between serial order position and signal degradation in psychotic disorders.

Title: Cognitive interference effects during manual force production in adults with Type II Diabetes

Authors: *S. L. GORNIAK[1], B.-C. LEE[2], J. WANG[3];
[1]Dept. of Hlth. & Human Performance, [2]Univ. of Houston, Houston, TX; [3]Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: The overall aim of this project was to evaluate the relationship between cognitive decline and outcomes in manual sensorimotor behavior in adults with Type II Diabetes (T2D). Recent studies show that adults with T2D experience significant declines in cognitive function compared to healthy controls. As cognitive function is a major component of many daily motor activities, there is a critical need to investigate the impact of T2D on cognitive-motor actions. Ten (10) community-dwelling T2D patients and ten (10) age- and sex-matched healthy controls were recruited and evaluated in this cross-sectional study (6 females and 4 males per group; age = 60 ± 7 years). Cognitive, sensory, and motor performance was evaluated in one testing session. Health state and metabolic data (eg. glycated hemoglobin values, A1c) were also collected. Mild cognitive impairment, particularly in the domain of working memory was found in the T2D group versus controls. Control participants did not show any evidence of cognitive deficits. A relationship between working memory performance and A1c was found. Decrements in both sensory and motor performance in the T2D group were also found, compared to controls. When T2D patients were asked to perform manual activities in conjunction with working memory tasks (dual-tasking), both manual and cognitive performance declined significantly versus control performance. These data are the first to suggest simultaneous cognitive-motor losses in community-dwelling patients living with T2D. Cognitive-motor losses likely play a significant role in T2D patients experiencing difficulty in performing basic activities of daily living, such as bathing, grooming, and feeding.

Title: Revealing hidden states in working memory using EEG

Authors: ***M. WOLFF**[1,2], J. DING[3], N. MYERS[2], M. G. STOKES[2];
[1]Univ. of Groningen, Groningen, Netherlands; [2]Oxford Ctr. for Human Brain Activity, Oxford, United Kingdom; [3]Univ. of Oxford, Oxford, United Kingdom

Abstract: It is often assumed that information in working memory (WM) is maintained via persistent activity states. However, recent evidence indicates that information in WM could be maintained in an effectively 'activity-silent' neural state (Sreenivasan, Curtis, & D'Esposito, 2014). Silent WM is consistent with recent cognitive and neural models (Mongillo, Barak, & Tsodyks, 2008), but poses an important experimental problem: how can we study these silent states using conventional measures of brain activity? Here, we propose a novel approach that is analogous to echolocation: using a high-contrast visual stimulus, it may be possible to drive brain activity during WM maintenance and measure the WM-dependent impulse response. Specifically, we recorded electroencephalography (EEG) while participants performed a simple visual working memory task in which a single, randomly oriented grating was remembered. Crucially, a fixed, task-irrelevant 'impulse' stimulus was shown in the maintenance period in half of the trials. The electrophysiological response from occipital channels was used to decode the orientations of the presented gratings. While stimuli could be reliably decoded during and shortly after stimulus presentation, decoding accuracy dropped back close to baseline in the delay period. However, the visual evoked response from the task-irrelevant stimulus resulted in a clear re-emergence in decoding accuracy. Interestingly, although the impulse response pattern differentiated the WM-stimulus, the discriminative pattern did not match the patterns during memory encoding. Our experiment provides important proof-of-concept for a promising and simple approach to decode 'activity-silent' WM content using non-invasive EEG. Mongillo, G., Barak, O., & Tsodyks, M. (2008). Title: Working memory during pregnancy: prefrontal and parietal eeg correlation

Authors: *M. L. ALMANZA, M. GUEVARA, M. HERNANDEZ-GONZALEZ;
Inst. De Neurociencias, Guadalajara, Mexico

Abstract: Pregnancy is a dynamic process in which significant behavioral changes take place. A substantial proportion of pregnant women perceive that their memory is impaired during this period. Similar results have been obtained in laboratory studies and they suggest that working memory may be altered during pregnancy. So far, these studies have only used neuropsychological tests. We need to go deeper in the neural substrates of the underlying working memory in pregnant women; particularly the dorsolateral prefrontal cortex and posterior parietal cortex, as these brain structures are critical components within the neural circuitry underlying working memory. This is why the goal of the current work is to examine the relationship between working memory during the three trimesters of pregnancy and its association with characteristic changes in inter and intrahemispheric frontal-parietal EEG correlations. Forty women were divided into 4 groups: three included women in different trimesters of pregnancy (E1, E2 and E3) and a control group of nonpregnant women (CO). Prefrontal EEG derivations (F1, F2, F3, F4) and parietal (P3, P4) was recorded during a visuospatial (Corsi block-tapping task) and verbal (verbal digit span) working memory. It was found that the degree of coupling EEG prefronto-parietal during the working memory tasks is characteristic for each trimester of pregnancy. It suggests that while behaviorally in the three periods the participants presented an efficient execution for the tasks, they showed a different EEG correlation pattern. Especially in participants of groups E1 and E3, the performing of both tasks of working memory (verbal or visuospatial) was associated with a higher correlation of slow EEG bands in non-specialized hemisphere, while in the participants of groups E1 and E2 the prefronto-parietal EEG correlation of gamma band in the hemisphere specialized for each task (verbal-left hemisphere and visuospatial-right hemisphere) was presented. These changes in the degree of cortical coupling of slow and fast EEG bands could be associated with the inhibition of irrelevant tasks for the activity and the temporal organization of working memory and the maintenance and manipulation of information. These EEG correlation data give objective evidence of participation prefronto-parietal circuit and gamma band oscillation in modulating working memory in pregnant women.

Title: Task related functional connectivity within varieties of complex skill learning

Authors: M. A. O'CONNELL[1], *C. BASAK[2];
[1]Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX; [2]The Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX

Abstract: Two cognitively demanding fMRI tasks acted as a platform to examine game learning-related interactions in task-positive and task-negative brain networks. The hybrid block design tasks were a memory updating task (random N-back; Basak & Verhaeghen, 2011) and a task-switching paradigm with blocks for single and dual tasks (Basak et al., 2008). These paradigms allowed us to look at four task conditions - switching and updating information in working memory (WM), switching between two tasks (Dual Task), no switching requirements (Single Task) and Rest. We investigated functional connectivity using seed-to-voxel based analysis, for three specific brain networks: fronto-executive (FE), fronto-parietal (FP) and default mode network (DMN). Right Anterior Prefrontal Cortex, right Inferior Parietal Lobe and Posterior Cingulate Cortex were chosen as the seeds for the FE, FP and DMN networks, respectively (Voss et al., 2010, 2012). Thirty-one younger and 32 older adults played two types of computer games, one strategy and one shooter. Each game, irrespective of the type, needed about 5.5 min to play; thus yielding an average of 12 strategy and 12 shooter games in 1.5 hours. Game learning for each game was estimated by calculating composite z-scores of the game outputs, viz. levels reached, number of games played, final level won. Functional connectivity results for 63 participants, after controlling for age differences, indicated that the FE and FP networks differ substantially across the 4 conditions. The Dual and Single Task conditions, compared to the WM, resulted in a broader connectivity to regions of cognitive control, e.g., DLPFC and Supramarginal Gyrus. Importantly, individual differences in game learning predicted different connectivity for strategy vs. shooter. Strategy learning predicted broader connectivity in the FE and DMN in WM condition; shooter learning predicted broader connectivity in all 3 networks in both the Single and Dual conditions. Subsequently, separate regression analyses were conducted for each age group. For the younger adults, in WM condition, the FE connectivity (but not FP) was differentially predicted by strategy (Cingulate

Gyrus) vs. shooter (Superior Frontal Gyrus) learning. No significant relationships were observed in the older adults. In the Dual Task condition, older, not younger, adults showed broad connectivity in both the FE and FP networks predicted by both types of learning. These results suggest that the demands of cognitive control in a task may vary across the two age groups; this in turn may lead to differential connectivity for the two cognitive control networks (FE and FP) in relation to the two types of game learning.

Title: Motion-related noise in structural brain images may be revealed with independent estimates of in-scanner head motion

Authors: N. K. SAVALIA[1], P. F. AGRES[1], M. Y. CHAN[1], K. M. KENNEDY[1], D. C. PARK[1,2], *G. S. WIG[1,2];
[1]Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX; [2]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Accurate measures of brain structure are essential to neuroimaging for anatomical localization, image registration, and the general study of functional brain organization across populations. However, recent evidence suggests that motion-contaminated T1-weighted magnetic resonance imaging (MRI) results in misestimates of brain structure (Reuter et al., 2015). Particularly alarming, many cross-cohort studies contrast individuals who differ in their degree of motion during MRI (e.g., children with ADHD vs. healthy controls, older vs. younger adults). Accordingly, this motion confound could systematically bias analyses of between group differences. Since conventional datasets collect T1 images without catchall prospective motion correction methods and limited direct measures of head motion, a practical alternative is needed to account for the potential motion-induced noise in measures of brain anatomy. We analyzed the head movements during functional MRI (fMRI) scanning of 266 healthy adults (20-89 years,

169F) to identify stable features of in-scanner head motion. The sample comprised a subset of participants from the Dallas Lifespan Brain Study (DLBS) who completed the full DLBS neuroimaging protocol. The protocol allowed extensive quantification of head motion across a variety of scans with differing task demands while also acquiring a T1 structural image in the same session. We found magnitude of head motion increased with age and exhibited high within-subject stability across scan types. Comparing motion estimates to quality control (QC) ratings of T1 structural images revealed a strong relationship between the two, indicating one might be used to inform the other. Both QC ratings and measures of head motion predicted independent variance in general estimates of brain structure (e.g., FreeSurfer-derived cortical and volume-based morphometrics; Fischl, 2012), independent of the effects of age. Images believed to be susceptible to motion-related noise showed reduced structural estimates versus age- and gender-matched samples, leading to inflated effect sizes in the relationships between multiple anatomical measures and age. Of additional relevance, examining motion-contaminated anatomical scans revealed that the regions most prone to potential movement-related effects included many reported to undergo prominent atrophy with age. The findings suggest that problematic motion-related noise in structural brain scans may be retrospectively flagged and removed, in part, via a combination of techniques relying on rater-defined QC and estimates of motion obtained from independent scans collected during the same session.

Title: The interaction rating scale advanced brief (IRSA-Brief) as an index of social competence development

Authors: *T. ANME[1], E. TANAKA[1], S. OKAZAKI[2], N. SADATO[2];
[1]Univ. of Tsukuba, Tsukuba, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Objective: It is essential to develop a behavior scale easy to implement comparative and practical usage for neurosciences. This study evaluated the validity and reliability of the short form of the Interaction Rating Scale Advanced (IRSA-Brief) as a practical index of social competence development. Methods: Fifty adults completed a five-minute interaction session and were assessed with the IRSA-Brief and IRSA. Health social professionals evaluated their social competence based on regular practical assessments. IRSA-Brief is a shortened form of the IRSA. In this version, the six IRSA sub-scales are summarized by the three most common subscales of social competence: “coordination,” “self-regulation,” and “assertion.” The IRSA-Brief was developed by examining each of the original scale’s 92 items, and choosing the most feasible items to represent each IRSA-Brief subscale in terms of content validity and psychometric acceptability. Two different sets of variables were scored for each sub-scale: behavior items and impression items. Each subscale assessed the presence of behavior (0 = no, 1 = yes) and the sum of all items in the subscale provided the overall behavior score. The total score range was from 0 to 39. Scores for the impression items and the overall impression item were on a five-point scale: 1 = not evident at all, 2 = not clearly evident, 3 = neutral, 4 = evident, 5 = evident at high level. The evaluator completed the 39-item checklist focusing on each behavior (e.g., expresses his/her own feeling to the partner). Inter-observer reliability was found to be 90%. The IRSA-Brief’s objective is to evaluate interactions in a short period of time in daily situations. Results: The results indicated that the IRSA-Brief scores had a moderately high correlation with the IRSA scores (r = 0.41) and the professionals’ practical evaluations (r = 0.72). Cronbach’s alpha was 0.84. Discussion: As the IRSA-Brief can measure social competence with high validity and reliability, providing evidence of social competence development. Conclusion: IRSA-Brief would be useful in practical settings to further assist with social competence development, support, and treatment in neurosciences.

Title: Testosterone administration modulates neural responses to morally-laden scenarios in females

Authors: *C. CHEN;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Several neuromodulators, including testosterone, influence moral cognition. However, the neural mechanism by which testosterone modulates moral reasoning remains to be determined. Using a placebo-controlled within-subject design, the current study examined the neuromodulatory effect of testosterone administration in young females by combining moral dilemmas, second-to-fourth (2D: 4D) digit ratio (a proxy of fetal testosterone), functional magnetic resonance imaging (fMRI), and subjective ratings on morally-laden scenarios. Results showed that acute testosterone administrations elicited more utilitarian response to evitable dilemmas, in which 2D: 4D predicted 22% of the variance. The activity in the amygdala, anterior insula, ventromedial, and dorsolateral prefrontal cortex (DlPFC) was increased to perceived agency in spite of comparable subjective ratings. The effective connectivity between amygdala and dlPFC was reduced. The activity in the temporoparietal junction predicted utilitarian responses to evitable dilemmas. The findings demonstrate acute effect of testosterone on neural responses associated with moral judgments. Administering a single dose of testosterone can modulate the capacity of emotional regulation and perspective taking, which, in turn, heightens reactivity to social provocation and to make utilitarian judgments. **Keywords:** moral evaluation; testosterone; utilitarian judgment; fMRI; agency 1

Title: Actor-observer bias in moral evaluation: an fmri

Authors: *Y.-J. CHEN;
Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Morality is a fundamental component of human cultures and has been defined as prescriptive norms regarding how people should treat one another, including concepts such as

justice, fairness, and rights. Actor-observer bias explains the errors that one makes when forming attributions about the behavior of others. When people judge their own behavior, and they are the actor, they are more likely to attribute their actions to the particular situation than to a generalization about their personality. Yet when an observer is explaining the behavior of another person, they are more likely to attribute this behavior to the actors' overall disposition rather than to situational factors. Many studies have explored the influence of moral evaluations on judgments about the intentionality of actions. Using fMRI, the current study examined the extent to which actor-observer bias affect behavioral ratings of praise and blame and how they modulate the online neural response when participants evaluate morally laden (good and bad) everyday actions. The activity in the amygdala, anterior insula, ventromedial, and dorsolateral prefrontal cortex (DlPFC) was increased to perceived agency in spite of comparable subjective ratings. The effective connectivity between amygdala and dlPFC was reduced. The activity in the temporoparietal junction predicted utilitarian responses to evitable dilemmas. The findings demonstrate acute effect of testosterone on neural responses associated with moral judgments. Administering a single dose of testosterone can modulate the capacity of emotional regulation and perspective taking, which, in turn, heightens reactivity to social provocation and to make utilitarian judgments.

Title: Oxytocin differentially affects moral judgment of permissibility and punishment

Authors: *M. LEE[1], S. SUL[2], E. KIM[3], K. LIM[4], N. SHIN[4], S. KIM[6], J. KWON[5], H. KIM[7]; [1]Psychology, Korea Univ., Seoul-City, Korea, Republic of; [2]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [3]Dept. of Psychology, Yonsei Univ., Seoul, Korea, Republic of; [4]Dept. of Psychiatry, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [5]Seoul Natl. Univ. Col. of Med., Seould, Korea, Republic of; [6]Seoul Natl. Univ. Med. Res. Ctr., Seoul, Korea, Republic of; [7]Psychology Dept., Korea Universiy, Seoul, Korea, Republic of

Abstract: People consider both intention and outcome of an actor's behavior when making moral judgment. A growing body of evidence suggests that these two types of information are processed by separate neural systems (Treadway et al., 2014; Yu, Li & Zhou, 2015) and the extent to which the judgment is affected by each type of information depends on the specific type of moral decision being made (Cushman, 2008). The present study aims to investigate the effect of intra-nasally administered oxytocin (OXT), the evolutionarily preserved neuropeptide that is known to influence a wide range of prosocial behaviors (Hurlmann et al., 2010), on the way that intention and outcome affect moral judgments of permissibility and punishment. In a between subject, double blind, and placebo-controlled design experiment, 38 male participants were randomly divided into two groups and self-adminstered 40 IU/ml of oxytocin (N=22) or placebo (N=16) using intranasal sprays. The main task design and stimuli were adopted from Young and Saxe (2008): Participants were required to read a series of short scenarios presented through computer screen and indicated whether the action of the protagonist depicted in the scenario was 1) morally permissible and 2) punishable on the 7-point likert scale. The valences of intention and outcome are independently manipulated so that 4 unique combinations of a protagonist's intention (neutral vs. negative) and outcome (neutral vs. negative) were created for each scenario. In order to investigate the effect of OXT on two types of moral judgments, two separate 2(Group) x 2(Intention) x 2(Outcome) mixed ANOVA were performed on the behavioral ratings and reaction times(RT) for each combination of intention and outcome in both tasks. The analysis showed no significant OXT-related effects in overall rating patterns in both tasks. However, OXT does seems to influence RT and have a mitigating effect in the punishment judgment task: Participants with OXT administration than those in the placebo group were generally slower to respond, and tended to give more lenient punishment ratings to the sets of intention-outcome combinations that fall in the intermediate level of emotional impact or perceived "severity," as opposed to those with low or high severity. This pattern of effect in behavioral rating is only present in punishment judgment. These results are consistent with the previous findings that OXT effect could be regulated by various contextual factors (Bartz et al., 2011), and suggest that social approach tendency induced by OXT administration may run counter to the decision mechanism involved in punishment judgment.

Title: The role of individual differences on the effect of intranasal oxytocin on perceived social and non-social stimuli

Authors: *E. E. HECHT[1], D. L. ROBINS[2], T. Z. KING[1];
[1]Dept. of Psychology, Ctr. for Behavioral Neurosci., Georgia State Univ., Atlanta, GA; [2]A.J. Drexel Autism Inst., Drexel Univ., Philadelphia, PA

Abstract: Oxytocin (OT) plays a role in social cognition, but the specific nature of this role in the human brain, and the extent to which individual differences may contribute to variation in the response to intranasal OT, are still under investigation. The current double-blind, placebo-controlled study involved 30 female subjects. At visit 1, all subjects received intranasal placebo. At visit 2, half of the subjects were randomly assigned to receive intranasal OT, while the other half received placebo again. All subjects were not on hormonal birth control and experienced natural regular menstrual cycles, and both visits occurred approximately 30 days apart during the luteal phase of the menstrual cycle. Measures included a battery of psychological and behavioral tests as well as a neuroimaging session. In an fMRI task, subjects viewed cartoons of moving shapes, some of which could be interpreted as positive- or negative-valence social interactions, and some of which simply depicted random movement. Subjects responded with button presses to answer questions about the shapes' social relationships or physical characteristics. After scanning, subjects re-watched the videos and provided free-response descriptions. fMRI results indicate that intranasal OT increased activation in regions of the brain associated with social and affective processing during trials in which the shapes' movements were perceived as social interactions. These regions included ventromedial and orbitofrontal cortex, the superior temporal sulcus and lateral temporal regions, amygdala, inferior frontal gyrus, and inferior parietal cortex. Interestingly, many of these regions, particularly visual sensory regions, also showed some degree of OT-induced increased activation during trials where shapes merely moved randomly around the screen. We also examined the relationship between individual psychological variation, variation in brain organization, and response to OT. Together, these results expand our understanding of the effects of intranasal OT, provide information about the extent to which individual differences may mediate OT's effects, and raise new questions about the role of endogenous OT in social and non-social cognition.

Abstract: Human social behavior is largely based on the interpretation of actions of others during social interaction. Cooperative interaction promotes and strengthens social bonding with prosocial behavior, associated with feelings such as friendship and liking, whereas non-cooperative interaction leads to rejection or even punishment associated with feelings of disliking and hate. Distinguishing between cooperators and non-cooperators involves theory of mind: the ability to infer the mental states of others. Here we examined the similarities and differences of the neural responses while inferring mental states of cooperators and non-cooperators. Thirty-four volunteers participated in a social interaction (a modified version of the Dictator game) with two confederates: one used a cooperation strategy (Coop), and the other a non-cooperation strategy (NoCoop). As a result of experiencing the confederate's strategies, the participants increased the amount of money offered to the Coop and decrease it to the NoCoop. In a subsequent fMRI session participants were asked to think about the confederates feelings in situations with negative or positive emotional valence. Results revealed that all conditions activated the theory of mind network (i.e. temporoparietal junction, precuneus, medial prefrontal cortex). However, the response to the Coop and NoCoop situations resulted in distinct activations; negative situations lead to increased activity in the left prefrontal cortex for Coop, and bilateral prefrontal cortex as well as the right middle temporal gyrus for NoCoop. A final analysis showed that confederate liking ratings correlated with activity in social and emotional areas for Coop in positive situations (left temporoparietal junction, right temporal pole, and bilateral amygdala). While for NoCoop in negative situations correlated with incentive-based learning areas (right caudate and putamen, and left accumbens). Both conditions could indicate positive affect in the participants. These results suggest that thinking about non-cooperators mental states demand more cognitive control and semantic processing. The results also suggest that the degree of affection developed to the cooperators involve mechanisms for sharing mental and emotional states. In contrast, when dealing with non-cooperators, mechanisms related to the learning of social-reward signals are used instead.

Title: Advisors adapt their confidence reports strategy to increase their future influence

Authors: *U. HERTZ[1,2], B. BAHRAMI[2];
[2]Inst. of Cognitive Neurosci., [1]Univ. Col. London, London, United Kingdom

Abstract: The exchange, announcement, of private information and opinions, which finally inspire action, is at the heart of human social interaction. Flow of information from the most informed party to the least informed one is not as straightforward as it seems. The transmission of information is strictly linked with reputation, influence, and personal traits and inclinations that could impact it. Recent studies have focused on the client or advisee point of view, developing computational models for tracking the reliability and expertise of advisers (Behrens et al, 2008; Boorman et al, 2013). From an adviser point of view, influence has a fundamental role on the amount and type of information that will be conveyed (Bayarri and DeGroot, 1989). In fact, the communication choices have strong effects on reputation, trust and credibility. The wrong choices could lead to an instant invalidation of all the previous efforts and achievements. We developed a novel task to evaluate the strategies that an adviser utilizes when transmitting Information. On a trial by trial basis the participant has access to a probability of reward being in one of two locations. He is then asked to advise a client about the location of the reward using a confidence scale. Another adviser also provides confidence report to the client, available to the participant. The client makes a decision, and according to its outcome and the adviser's confidence reports updates the influence weights assigned to each adviser. The task was published online in Amazon Mechanical Turk. 58 participants completed the task, 31 males (age range 21-56) and 27 females (age range 23-55). Our results show that participants tend to change their confidence report policy according to their influence on the client. When the client preferred the other adviser participants reported confidence was higher compared to when the client was following them. When their influence was high and the client was following their advice participants' reports tended to be better calibrated with evidence, rendering them more reliable. However, when the client preferred the other adviser their reports became more extreme and less reliable. The changes in report policy with social influence were observed even when individual differences in perceptual accuracy and confidence reports bias were accounted for.

Confirming the predictions of the theoretical model (Bayarri and DeGroot, 1989), these results show that people communicate in a way that takes into account their current social status and the effect of their reports on their future influence.

Title: Extrapolation of social information to physically similar individuals contributes to stereotyping

Authors: ***B. A. LEVY**[1], C. I. BAKER[2];
[1]Natl. Inst. of Mental Hlth., Chevy Chase, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Previous evidence demonstrates that social evaluations of a face can transfer to morphed versions of the same face even when the transformed face is perceived as a new identity (Todorov et al., 2010). The current study investigated whether this similarity-driven generalization of social information functions at a group level to induce stereotyping. Morphing software was used to create three different groups of nine faces with high degrees of within-group similarity. In the first study, a subset of individuals from each group appeared in a learning task that took the form of an investment game. The individuals acted as trustees that returned or kept money invested with them by the participant. Individuals from one group returned the investment on 80% of trials while those from the other two groups did so on 50% and 20% of trials, respectively. Participants were not made aware that the faces belonged to different groups. Participants then completed a test phase in which they replayed the game, this time choosing whether to invest with novel individuals from each group while receiving no feedback as to whether each individual returned or kept the investment. Paired t-tests showed that the behavior of the individuals seen during the learning phase substantially influenced the frequency with which participants chose to invest with physically similar individuals in the test phase, as well as explicit trustworthiness ratings of those individuals. Notably, this effect occurred despite a complete lack of feedback that could be used to judge the trustworthiness of the novel individuals seen in the test phase, suggesting that information about a subset of individuals is

readily utilized to create group-level stereotypes that bias evaluations of perceptually similar individuals. In the second study, participants completed an alternate version of the paradigm in which the learning phase consisted of a guessing game where individuals from each of the three groups were paired with monetary reward 80%, 50%, or 20% of the time, respectively. This change eliminated the relationship between the behavior of the individuals seen in the learning phase and the frequency with which participants chose to invest with physically similar individuals during the test phase, suggesting that the results of the first study occurred due to generalization of a trustworthiness stereotype rather than simply a learned association between certain faces and reward.

Title: Visual preference for images of primate faces in non-human primates

Authors: D. DZIOBEK[1], S. ZHANG[2], J. ASHE[3,5], *X. LU[6,4];
[1]Grad. Program in Neurosci., [2]Dept. of Biomed. Engin., [3]Dept. of Neurosci., [4]Neurol., Univ. of Minnesota, Minneapolis, MN; [5]Neurol. Service, Veterans Affaris Med. Ctr., Minneapolis, MN; [6]Brain Sci. Ctr., VA Med. Center, Minneapolis, Minneapolis, MN

Abstract: Autism is a devastating neurological disorder of unknown cause, unclear pathogenesis and without an effective treatment. The defining feature of autism is a profound deficit in social behavior including a lack of interest in social bonding, particularly, reduced eye contact. Rodent models of autism may not accurately recapitulate the social deficits in primate behavior characteristic of the disease. Non-human primates, however, have a highly developed sense of social cognition, and ethological studies of these animals have shown that they have more interest in information about social interactions than environmental cues that are critical for survival. We tested the extent to which social cognition determined behavioral choices in non-human primates. Specifically, we examined the preference of monkeys for images of faces relative to images of other familiar and unfamiliar inanimate objects. In an effort to characterize the strength of natural social behaviors in non-human primates, we studied their preferences for different classes of images including: (i) familiar and unfamiliar non-food inanimate objects, (ii) familiar food, (iii) and familiar and unfamiliar human and monkey faces. In the behavioral task,

two animal subjects were required to indicate their preference for one of two simultaneously presented visual images by making a saccade to that image after which they received a liquid reward. In the majority of trails, the images were from different classes. When presented with two neutral inanimate images, the monkeys showed no preference ($p<0.0001$, binomial distribution fit). However, when images of a face were paired with a neutral object or a familiar food, the monkeys preferred the face in more than 80% of trials ($p<0.0001$, binomial distribution fit). There was no difference in preference for familiar or unfamiliar faces. In addition to their preference, the animals had shorter performance times toward faces ($p<0.01$, Wilcoxon rank sum). Our data suggest the preference of non-human primates for faces is driven by considerations of social cognition that are so prominent in all primates. The overwhelming preference for images of faces was maintained even when paired with images of preferred foods. We believe that this natural tendency to prefer images of other primates could be used as an assay to probe autistic behavior in monkey models of autism. Eliciting changes in this preference for faces, inactivating or stimulating specific brain regions in non-human primates using pharmacological or electrical methods would provide much needed insights into which neural circuits and processes may be perturbed in human cases of autism.

Title: The role of oxytocin in altruism and emotional responses to inequality

Authors: *R. B. RUTLEDGE, A. O. DE BERKER, S. ESPENHAHN, R. J. DOLAN; Univ. Col. London, London, United Kingdom

Abstract: Social comparison is an important factor in subjective well-being and many studies suggest that relative wealth is a major determinant of life satisfaction. We developed a social decision-making task which allowed us to quantify the impact of inequality aversion on momentary subjective well-being or happiness. We found that well-being reflected not only

rewards received by the participant, but also rewards received by their partner. Unequal outcomes, whether advantageous or disadvantageous ('guilt' or 'envy', respectively), reduced average well-being. As the neuropeptide oxytocin plays a role in a range of social behaviors, including altruism, we conjectured that this might partly depend on inequality aversion. Thus we repeated this experiment in a double-blind placebo-controlled design in which participants received intranasal oxytocin in one session and placebo in the other session. Although well-being was affected by both advantageous and disadvantageous inequality, oxytocin selectively reduced the negative impact of disadvantageous inequality, leaving unaltered the effect of advantageous inequality on well-being. Oxytocin administration in the same subjects increased generosity in a separate social value orientation task. We discuss these findings in light of oxytocin's role in prosocial behaviors.

Title: Dopamine mediates human maternal bonding. A behavioral PET-fMRI study

Authors: *S. ATZIL[1], C. CATANA[1], B. C. DICKERSON[1], R. FELDMAN[2], J. HOOKER[1], L. F. BARRETT[1,3];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Bar-Ilan Univ., Ramat-Gan, Israel; [3]Northeastern Univ., Boston, MA

Abstract: Introduction- In rodents, the dopaminergic circuit is involved in social affiliation, specifically in the context of maternal bonding. Additionally, individual differences in bonding behaviors in rats are related to differential mesolimbic dopaminergic activity (Champagne et al. 2004). In humans, a dopaminergic mechanism for social affiliation has yet to be evaluated. We hypothesized that human maternal bonding involves dopaminergic reward circuitry. We further hypothesized that individual differences in human maternal bonding depends on this dopaminergic reward circuitry. To test our hypotheses, we applied for the first time simultaneous fMRI-PET imaging to mothers while watching videos of their infants. Additionally, we tested

whether bonding behavior predicted the social reward response. Methods and Results- To evaluate whether mothers secret dopamine in response to their infants, we assessed the binding potential of raclopride, a D2 receptor antagonist radiotracer, while mothers are viewing their own compared to an unfamiliar infant films. We predict that mothers will respond to their own infants with increased dopamine release. In line with our hypothesis, mothers had a significantly higher dopamine release during the own infant film in the left pallidum (t= -5.283, p=0.001), left hippocampus (t= -2.468, p= 0.036) and left amygdala (t= -2.784, p= 0.024). Individual differences in bonding was assessed by behavioral mother-infant synchrony, and used as a predictor for the maternal dopaminergic response. Mothers who are more synchronous with their infants had higher dopamine secretion to their infant in the right pallidum (Rpearson=-0.79, p=0.02). The sensitivity to social reward (assessed by questionnaire) robustly predicted higher selective dopamine secretion to the own infant in the left and right putamen (Rpearson=-0.856, -0.837, p=0.007, 0.009). Discussion- This study demonstrates for the first time that human mothers respond to their infants with dopaminergic secretion, which is consistent with the rodent literature. Moreover, individual differences in bonding are related to distinct dopaminergic pattern, as synchronous mothers have higher dopaminergic reward response to their infant. These preliminary results provide initial proof of concept for the use of PET and specifically D2 radiotracers to study social- affiliation in humans.

Title: Early attention orienting effect and implicit liking effect during an eye gaze cueing task: a magnetoencephalography study

Authors: ***N. GEORGE**[1,2,3,4,5], S. DUBAL[6], J. ULLOA[5];
[1]Inst. du Cerveau et de la Moelle Epiniere (ICM), Paris, France; [2]Umr 7225, CNRS, Paris, France; [3]U1127, Inserm, Paris, France; [4]Umr_s 1127, Sorbonne Universités - UPMC Univ. Paris 6, Paris, France; [5]Ctr. MEG-EEG, ICM/CNRS/Inserm/UPMC/ENS, Paris, France; [6]ICM, CNRS / Inserm / UPMC, Paris, France

Abstract: Social cues can greatly impact our perception of surrounding objects. For instance, eye gaze signals others' current object of attention and potential preferences, and in doing so, it has the power to influence our attentional state and affective evaluation of seen objects. While social influences have been long ago acknowledged, their neural underpinnings have only recently started to be investigated and are still to be fully clarified Here, we aimed at investigating the modulations of brain activity related to attention orienting and to implicit affective value attributed to visual targets during an eye gaze cueing task. Twenty-six participants participated in this magnetoencephalography (MEG) study. We recorded the neuromagnetic activities evoked by seen targets when participants were engaged in a Posner-like paradigm of attention orienting by gaze. A liking rating task was then used to assess the hedonic value attributed to the targets. Using source localization based on weighted Minimum-Norm Estimate (wMNE), we analyzed the brain responses during the target display period as a function of attention orienting and hedonic evaluation. Our results were twofold. First, we observed faster response times for valid (looked-at) than invalid (not looked-at) targets, reflecting the typical attention orienting effect induced by eye gaze or eye gaze cueing effect. This effect was accompanied by enhanced responses to invalid relative to valid targets between 90 and 400 ms in occipital and superior parietal regions, with responses lateralized to the hemisphere contralateral to the target presentation side. This demonstrates early neural effects of attention induced by eye gaze. Second, although we did not find a reliable influence of eye gaze on liking, we showed that, at the neural level, high- relative to low-liked targets elicited enhanced activation in a right posterior lateral temporal region between 90 and 380 ms during the gaze cueing task. This suggests that there is an early and sustained encoding of the implicit hedonic value of objects. Altogether these results shed new light on the attentional and affective processing of objects in a social context.

Title: ERP evidence of the implicit evaluation of self-relevance for everyday objects

Authors: *G. TRUONG, T. S. T. HUANG, T. C. HANDY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: When made explicit through cueing or instruction, self-relevance has been found to drive attention and increase cognitive processing (Turk et al., 2011; Cunningham et al., 2008). However, there is evidence that attentional capture by self-related stimuli can also occur automatically (Alexopoulos et al., 2012). Given that previous research (Handy et al., 2010) shows that people make hedonic preference judgments about objects rapidly and implicitly, the current study investigated whether people also make rapid and implicit self-relevance judgments when viewing objects. Participants viewed a series of images of everyday objects (e.g., pineapple, football) during a supposed target identification task while electrical brain responses were recorded via EEG. Following this task, participants reviewed all of the object images and selected the ten most personally relevant and ten least personally relevant stimuli. We then compared event-related potentials (ERPs) elicited by these two categories. Both objects selected as most relevant and least relevant demonstrated greater P300 mean amplitudes, relative to the P300s elicited by the average of all objects. Furthermore, the late positive potential (LPP) was greater for the most self-relevant objects relative to least self-relevant objects and all objects. These results suggest that although highly self-relevant and highly non-self-relevant stimuli elicit initial attentional processing, highly self-relevant stimuli receive uniquely additional evaluation even when such evaluation is not essential to present task demands.

Title: Brain response to overhearing one's own name: an fMRI study

Authors: *T. NAKANE;
Nagoya Univ. Sch. of Med., Nagoya, Japan

Abstract: It is reported that the medial prefrontal cortex (mPFC) is involved in hearing one's own name. However, it is not clear yet if mPFC always respond to one's own name regardless of ongoing task. We hypothesized that one should not show mPFC activation when s/he is engaged to the task in which one's own name is irrelevant. Thirty healthy adults volunteered to the study. Stimuli were vocalized names of participant's own (S), repeated other's (R), and variable others' as control (C). During a trial, two names (either S+C, R+C, or C+C) were presented binaurally and simultaneously. Each of the names was followed by high or low short tone burst. In the Name detection session, participants judged whether the presented names contained S or R (i.e. target names) and pressed a button. In the Tone judgement session, participants judged whether the beep was high or low. If mPFC always responds to one's own name, the contrast S-R should activate mPFC in both Name detection and Tone judgement sessions. The results showed that S-R during Name detection session activated mPFC (Figure 1), but that during Tone judgment session did not (Figure 2), even though the identical sound stimuli were presented. We conclude that association of hearing one's own name and mPFC activation is contingent.

Title: Know thyself; aberrant neural activity during self-reflective processing of depressed youth with trauma history

Authors: ***R. NG**[1], H. SCOTT[2], G. SMYDA[4], S. MALONE[3], K. QUEVEDO[2];
[1]Inst. of Child Develop., Univ. of Minnesota, Twin Cities, Minneapolis, MN; [2]Dept. of Psychiatry, [3]Univ. of Minnesota, Minneapolis, MN; [4]Grad. Sch. of Publ. Hlth., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Negative self-reflective processing is central to depressogenic cognitions, and a potent predictor of severity/recurrence of depressive disorders. In a similar vein, dysfunction in neural networks that support self-reflective processing (midline cortical structures: MCS) and emotion processing (limbic region) has been observed among those with depressive disorders. Importantly, youth with a history of trauma are at significantly greater risk for treatment-resistant depression relative to depressed non-traumatized peers, perhaps partially due to ancillary abnormal corticolimbic functioning underlying self-processing that is resistant to current treatment approaches. To date, however, there is no research that has explored neurobiological correlates of self-processing in youth with depression and trauma. This investigation is important

to our understanding of self-organization in adolescence, a sensitive window for identity formation, particularly when permeated by trauma exposure. This study examined neural activity during the processing of positive/negative self-descriptors from the self and the mother's point of view (p.o.v.) in 37 healthy (HC) and 86 depressed adolescents. We applied a mixed block and event-related paradigm to investigate neural activity during processing of positive/negative self descriptors as a function of p.o.vs. Among depressed youth, 41 experienced significant trauma (DT) and 45 reported no history of trauma (DC). We hypothesized: 1. DT youth would show greater MCS activation during processing of negative vs. positive self-descriptors compared to both DC and HC; 2. DT adolescents would exhibit more MCS and limbic activity during processing of negative phrases from the mother's p.o.v than DC and HC youth. Whole-brain and region of interest analyses both supported our predictions. A group x condition interaction indicated that youth with both depression and trauma history showed robust neural activity of MCS and limbic regions during first person p.o.v processing of negative vs. positive self descriptors compared to DC, while HC youth instead showed heightened activation of MCS for positive vs. negative self-descriptors. Results suggest that higher emotional salience for positive self-information that is known to be protective against psychopathology, is severely altered in depressed traumatized youth. These findings offer novel evidence that self-representations of DT youth are more informed by higher salience of negative self-descriptors from both the self and the mother's perspective, which in turn, subserves the cognitive vulnerability for chronic depression.

Title: Neural responses to heartbeats in the default-mode network encode the self-relatedness of spontaneous thoughts

Authors: *M. BABO REBELO, C. RICHTER, C. TALLON-BAUDRY;
Lab. De Neurosciences Cognitives, ENS, Paris, France

Abstract: The brain constantly receives and integrates signals from the internal organs (Critchley & Harrison 2013). By creating a dynamic and unified representation of the organism,

these neural maps of visceral activity could generate a basic form of self (Craig 2003, Damasio 2010). The brain monitoring of the heart can be studied via neural responses to heartbeats which have been recorded in the medial prefrontal cortex (Park et al 2014), a visceral center implicated in self-related processing (Northoff et al 2006). Here, we investigate the link between heartbeat-evoked responses (HERs) and the self. We considered the self in two distinct dimensions (Christoff et al 2011): the self as subject - the subject who acts, perceives or feels; and the self as object - the reflective self, when explicitly thinking about oneself. 20 human participants fixated a screen and mind-wandered until a visual stimulus interrupted their spontaneous thoughts at random intervals. Interrupted thoughts were then evaluated by the subject on four continuous scales: the degree of involvement of the self as subject (low to high), the object of the thought (self/external), the time (past to future) and valence. We recorded magnetoencephalographic and cardiac activity to test whether the amplitude of HERs (evoked-responses locked to the T-wave of the cardiac cycle) before the interrupting stimulus reflected the orientation of the ongoing thought, on each scale. HERs significantly differed depending on the involvement of the subject as the subject, the protagonist, of the ongoing thought ([298 327ms] after the T-peak, Monte-Carlo p=0.0397). This difference was localized in the left ventral precuneus (vPC, Monte-Carlo p=0.037). HERs significantly differed depending on the object of thought ([94 169ms] after the T-peak, p=0.0112), in the left ventromedial prefrontal cortex (vmPFC, Monte-Carlo p=0.030). No differences were found for time and valence. We show here that the brain monitoring of visceral signals encodes the self-relatedness of spontaneous thoughts in the default-mode network (DMN), in line with our hypothesis that neural responses to visceral inputs anchor self-related thoughts to an internal reference frame. The vmPFC is a visceral center of the brain (Vogt & Derbyshire 2009) and would be more related to self evaluation and introspection. The vPC is considered a rich club node (van den Heuvel & Sporns, 2013), contributing to the integration of information across resting state networks. Such a central role in brain dynamics fits well with the idea that the vPC is implicated in the most basic form of self.

Title: NMDA receptors in noradrenergic neurons regulate tonic activity of locus coeruleus and facilitate attentional set shifting in mice

Authors: *P. E. CIESLAK[1], N. LLAMOSAS[2], T. KOS[1], L. UGEDO[2], M. TORRECILLA[2], J. RODRIGUEZ PARKITNA[1];
[1]Inst. of Pharmacol. PAS, Kraków, Poland; [2]Univ. of the Basque Country, Leioa, Spain

Abstract: Noradrenergic (NA) neurons of the locus coeruleus (LC) exhibit tonic and phasic modes of activity, which closely correspond to attentional processing and behavioral performance. Here, by using NR1DbhCre transgenic mouse strain, we tested effects of inactivation of NMDA receptors, on LC activity and behavioral performance in tasks requiring selective responding in a stable environment (the go-no/go discrimination task) or flexible responding in a changing environment (the attentional set shifting task, ASST). We found that mutation caused an increase in spontaneous tonic activity of noradrenergic cells in LC, without appreciably affecting their phasic (bursting) activity. On the behavioral level, both control and mutant mice exhibited high accuracy of responding to „go" signals (hit rate) and limited ability to refrain from responding to "no-go" signals (false alarm rate). Detailed analysis revealed that mutant mice had decreased ability to discriminate between "go" and "no-go" signals, which could indicate increased distractibility. However, mutant mice exhibited also facilitated shifting of attention between different types of stimuli (digging media and odors), in the ASST paradigm. These results show that NMDA receptors located in NA cells regulate tonic activity of LC and that selective loss of NMDA receptors facilitate attentional set shifting, possibly by increasing the propensity for exploration.

Title: Nicotinic α4β2 receptor stimulation strengthens both working memory- and attention-related neuronal activity in prefrontal cortex

Authors: ***M. WANG**[1], Y. YANG[1], Y. SUN[2], S. YANG[1], L. E. JIN[1], V. C. GALVIN[1], A. F. T. ARNSTEN[1];

Abstract: Acetylcholine (Ach) projections to the primate dorsolateral prefrontal cortex (dlPFC) play a critical role in working memory and attention regulation. Electrophysiological studies in awake behaving monkeys performing a spatial working memory task have found that the dlPFC contains many Delay cells and Fixations cells, which are considered as the cellular basis underlying working memory and sustained attention. Delay cells show spatially tuned, persistent firing across the delay period when the spatial position must be held in working memory, while Fixation cells increase firing at trial onset and sustain firing until the saccadic response. Our previous studies showed that Ach acting at nicotinic-α7 receptors (nic-α7R) has an essential influence on the working memory-related firing of Delay neurons in the primate dlPFC, permitting NMDA receptor (NMDAR) actions in glutamate synapses, and rescuing neuronal firing from NMDAR blockade. Here, we report that Ach acting at another nicotinic receptor, the nic-α4β2R, has subtle beneficial effects on Delay cell firing, but far more prominent beneficial influences on dlPFC Fixation cells that relate to sustaining attention across the length of a trial. Furthermore, nic-α4β2R stimulation of Delay cells can rescue the reduction in delay-related firing caused by presenting distractors during the delay period. These data suggest that nic-α4β2R agonists may be useful in the treatment of Attention Deficit Hyperactivity Disorder and related conditions with impaired sustained attention.

Title: Behavioral phenotyping of mice deficient in CHRNA7

Authors: *J. YIN[1,2], C. SCHAAF[2,1];
[1]Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX; [2]Baylor Col. of Med., Houston, TX

Abstract: 15q13.3 microdeletion syndrome is a rare genetic disorder caused by a deletion of a segment of chromosome 15. The deletion is commonly 1.5Mb in length and encompasses 6 genes, but patients with small deletions, which only encompass the CHRNA7 gene, have also been reported. The clinical phenotypes associated with this syndrome are variable, but commonly include developmental delay/intellectual disability and impaired social interaction. Other clinically important features include epilepsy, impulsive behavior, aggression, depression, and schizophrenia. A mouse model deficient of CHRNA7 was generated and reported to be grossly normal in growth, anxiety-like behaviors, learning and memory, as well as sensorimotor gating. However, the presence of repetitive behavior, altered social interaction or depression had not been assessed in this mouse model. We tested heterozygous and homozygous Chrna7 mutant mice and their wildtype littermates for repetitive behaviors in self-grooming, holeboard exploration, and marble burying, for social interaction behaviors in the three-chamber paradigm, partition test, social interaction video scoring, and tube test, and depression in the tail suspension test and forced swimming test. The Chrna7 knockout mice showed increased marble burying and self-grooming behaviors depending on gender. In addition, knockout mice of both genders had significantly more social avoidance behaviors compared to heterozygous and wildtype littermates, suggesting an altered social response, as can be seen in human patients as well. Compared to human clinical manifestations in individuals with homozygous or heterozygous 15q13.3 deletion, the phenotypes present in this Chrna7 knockout mouse model are subtle, which raises questions about the potential contribution of other genes in the 15q13.3 locus, or possibly the presence of compensatory mechanisms in mouse which can not fully compensate for the loss of CHRNA7 in humans.

Title: Optogenetic silencing of locus coeruleus activity in mice impairs cognitive flexibility in an attentional set-shifting task

Authors: K. JANITZKY[1,2], *M. T. LIPPERT[1], A. ENGELHORN[4], J. TEGTMEIER[4], J. GOLDSCHMIDT[1,6], H.-J. HEINZE[2,5,6], F. W. OHL[1,3,6];

Abstract: The locus coeruleus (LC) is the main source of noradrenergic projections in the brain and essential for attention-dependent cognitive processes. Here we used unilateral optogenetic silencing of the LC in an attentional set-shifting task (ASST) to analyze the influence of the LC on prefrontal cortex-dependent functions in mice. In order to reversibly silence the LC, we expressed the halorhodopsin eNpHR3.0 in its noradrenergic cells. We found that yellow-light mediated silencing selectively impaired performance in those phases of the task that most critically rely on orbitofrontal and prefrontal function. Both reversal learning and attentional set-shifting were impaired, suggesting a general effect of LC-silencing on cognitive flexibility. In contrast, silencing did not have a measurable effect on the phases of the task that are less dependent on cognitive flexibility (e.g. compound discrimination and intra-dimensional shifts). These findings suggest a modulatory influence of the LC on cognitive flexibility, likely mediated through both prefrontal and orbitofrontal networks.

Title: The effects of histone deacetylase inhibitors treatment on executive function and prefrontal cortex in adolescent rats

Authors: *J. A. MCGAUGHY[1], G. WELCH[2], F. M. VASSOLER[3], E. M. BYRNES[3];
[1]Dept Psych, Univ. New Hampshire, Durham, NH; [2]Univ. of New Hampshire, Durham, NH; [3]Biomed. Science, Section of Neurosci., Cummings Sch. of Vet. Med. Tufts Univ., North Grafton, MA

Abstract: In preclinical models, histone deacetylase inhibitors (HDACi) have been proposed as a potential class of cognitive enhancers for neurodevelopmental, neuropsychiatric, and neurodegenerative diseases associated with deficits in learning and memory. To date, the effects of these potential cognitive enhancers on executive function, specifically selective attention, during normal neurodevelopment remain unknown. Adolescent rats have poor impulse control and are less cognitively flexible than adults as shown by both a susceptibility to distraction and increased cognitive rigidity in tests that require attentional set shifts. Recent work from our lab supports the hypothesis that high densities of norepinephrine transporters in the prefrontal cortices during adolescence leads to immaturities in attentional set shifting that are mitigated by the administration of selective norepinephrine reuptake inhibitors. HDACi increase transcription of the norepinephrine transport (NET) protein, which is hypothesized to further decrease extracellular norepinephrine and increase cognitive rigidity in adolescent rats. The current study investigated the effects of HDACi on the performance of adolescent rats in an intradimensional/extradimensional attentional set shifting task (ID/ED). Adolescent animals treated with the HDACi , sodium butyrate (0.0, 0.6 or 1.2 g/kg/ml) showed differential effects on performance that varied based on cognitive demands. In a separate cohort, western blotting was used to assess HDAC inhibition in prefrontal subregions critical to executive function as well as the effect of this drug on adolescent cortical NET levels. These data will provide additional information regarding the potential use of HDACi as cognitive enhancers during a key developmental period and will provide additional information on the role of specific subregions of the prefrontal cortices in moderating these effects.

Title: Increased impulsive choice following repeated exposure to methylphenidate during early adolescence but not during adulthood

Authors: *Z. ABBAS[1], A. SWEET[1], E. AFRAND[1], G. HERNANDEZ[2], A. ARVANITOGIANNIS[1];
[1]Psychology, Concordia Univ., Montreal, QC, Canada; [2]Psychology, Univ. de Montréal, Montreal, QC, Canada

Abstract: It is known that the psychostimulant methylphenidate (commonly known as Ritalin) improves measures of self-control and impulsive choice. What is not sufficiently understood is how repeated treatment with methylphenidate affects impulsive choice in the long run and whether exposure to methylphenidate at different periods of life produces similar or different long-term effects on impulsivity. Here we used an animal model for impulsive choice to explore these issues. First, we examined whether giving methylphenidate through early adolescence would affect delay aversion, an operational measure of impulsivity, later in adulthood. We then tested whether equivalent long-term effects would be observed if exposure to the drug occurred during adulthood. Delay aversion refers simply to a high preference for immediate smaller rewards over delayed larger rewards. Starting on postnatal day 25 or postnatal day 60, male rats received one of four doses of methylphenidate (0, 2, 4 or 8 mg/kg; ip) for ten consecutive days. Twenty-five days later, all rats were trained in operant conditioning chambers to choose between a lever that produced a small (one food pellet) immediate reward and a lever that produced a large (four food pellets) delayed reward across a range of delays (from 0.1-s to 63-s). After performance stabilized, all groups showed the expected orderly decrease in preference for the larger reward as the delay to obtain it increased. Importantly, analyses revealed a reduced selection of the delayed larger reward, indicative of increased impulsive choice, in those animals that were treated with lower doses of methylphenidate during early adolescence but not the higher dose. In contrast, no differences were observed in the selection of the delayed larger reward in animals that were treated with various doses of methylphenidate during adulthood. These findings suggest that methylphenidate exposure during different stages of life has disparate effects on impulsive choice. When given during adolescence, treatment with certain doses of methylphenidate can increase impulsive choice long after the end of treatment; however, the same may not be true when methylphenidate treatment is given during adulthood.

Title: Prefrontal cortical Neuregulin-ErbB4 modulation of impulsive behavior in rats

Authors: *T. PATTIJ[1], D. SCHETTERS[1], M. LOOS[2], S. SPIJKER[3], T. J. DE VRIES[1]; [1]VU Univ. Med. Ctr., Amsterdam, Netherlands; [2]Sylics, Amsterdam, Netherlands; [3]VU Univ., Amsterdam, Netherlands

Abstract: Impulse control disturbances are key features of various neuropsychiatric and neurological disorders, such as attention-deficit/hyperactivity disorder, drug addiction, Parkinson's disease and schizophrenia. Whereas over the last years accumulating evidence has highlighted monoaminergic modulation of the processes underlying impulse control, investigating novel mechanisms beyond monoamines may provide new intervention strategies to ameliorate impulse control disturbances. Recent work has associated the Neuregulin (Nrg)-ErbB4 pathway with several neuropsychiatic diseases, as well as indicated its involvement in preclinical murine measures of impulse control [Loos et al (2014) Biol Psychiatry 76]. The aim of the present study was to further investigate the role of this Nrg-ErbB4-dependent mechanism in impulsive action in rats. To this end, a group of rats was trained in the 5-choice serial reaction time task (5-CSRTT), an operant paradigm that provide measures of visuospatial attention and inhibitory control processes. Upon stable baseline performance, during test sessions the ErbB4 tyrosine kinase receptor inhibitor JNJ-28871063 (JNJ) was intracranially infused into the medioprefrontal cortex. Results showed that JNJ dose-dependently improved measures of impulsive action. Importantly, other measures in the 5-CSRTT reflecting visuospatial attention or aspects of motivational behavior were not altered by JNJ. In conclusion, the present data further strengthen a role for the Nrg-ErbB4 pathway in the prefrontal cortex in cognitive functioning, and in particular point towards involvement in the processes underlying impulse control.

Title: Cortico-striatal interactions mediating sustained attention performance: Simultaneous high-temporal resolution/multi-analyte microdialysis in prefrontal cortex and striatum

Authors: ***Y. KIM**[1], O. S. MABROUK[2], M. SARTER[3];
[1]Dept. of Psychology, [2]Dept. of Chem. and Dept. of Pharmacol., [3]Dept. of Psychology and Neurosci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Cholinergic activity in the cortex is necessary for attentional performance. Specifically, prior studies demonstrated that removal of cholinergic input impairs the detection of cues (e.g., McGaughy et al., 1966) and that optogenetic enhancement of cholinergic activity enhances hit rates (Gritton et al., 2015). Moreover, prior studies using conventional microdialysis methods indicated attentional task-associated increases in cholinergic activity during task performance and that the presentation of distractors augmented cholinergic activity even while performance suffered (St. Peters et al., 2011). Conversely, we found that poor attentional control observed as a trait in sign-tracking rats is associated with relatively low levels of cortical cholinergic activity (Paolone et al. 2013). The collective evidence from these studies supports the hypothesis that levels of cholinergic neuromodulation in the cortex mediate the top-down control of attention, and that variation of cholinergic neuromodulation specifically impact the selection of cues for cue-oriented behavior. However, the selection of cues and the sequencing and execution of cue-associated responses have also been attributed to striatal circuits. We therefore implanted microdialysis probes into the medial prefrontal cortex as well as into the dorsomedial striatal projection region of this cortex. We collected dialysates from both regions in rats performing a sustained attention task involving the reporting of the presence and absence of cues. Moreover, we used benzoyl chloride derivatization and HPLC-mass spectrometry (Song et al., 2011, 2012) to simultaneously determine 16 neurotransmitters and metabolites from minute-based dialysis collections (High-Temporal Resolution/Multi-Analyte Microdialysis; HTRMAM). Results indicate complex correlations and de-correlations between analyte levels across the two brain regions, over time and in response to distractor manipulations. Moreover, results from sign-tracking versus goal-tracking rats suggest that in addition to attenuated levels of cholinergic neuromodulation in the cortex, relatively weaker fronto-striatal co-release patterns are associated with their attentional vulnerabilities. The use of HTRMAM coupled with multi-site dialysis allows a relatively fine-grained, comprehensive characterization of coordinated and dissociated activation patterns across multiple neuronal systems mediating complex behaviors.

Title: Leptin and lepRb neurons in the medial prefrontal cortex facilitate cognitive flexibility

Authors: *H. ZHANG, X.-Y. LU;
UTHSCSA, San Antonio, TX

Abstract: Dysfunction of the medial prefrontal cortex (mPFC) is a hallmark of many psychiatric disorders, impairing executive function such as cognitive flexibility and working memory. Leptin, an adipokine, has been demonstrated to regulate mood and cognitive function. The leptin receptor, LepRb, is expressed in the mPFC; however, the involvement of leptin and LepRb neurons in the mPFC in cognitive flexibility has not been investigated. In this study, an attention set shifting test (ASST) was used to assess the effects of leptin and its target neurons in the mPFC on cognitive flexibility. Mice were injected with different doses of leptin (0, 0.1,1.0 mg/kg, i.p.) after being trained to dig for food (training session). The test session included seven discrimination, reversal and shift tasks given in a specific sequence. We found that leptin selectively improved simple discrimination, compound discrimination reversal and extra-dimensional shift. Deletion of LepRb in the mPFC caused no change in cognitive flexibility but abolished the effect of leptin. The extra-dimentional shift was enhanced following acute stimulation of LepRb neurons in the mPFC and impaired after acute inhibition of LepRb neurons in this area using DREADD technology. These results suggest that leptin and LepRb neurons in the mPFC are critical for the regulation of cognitive flexibility.

Title: Alpha-2A noradrenergic activation improves behavioral flexibility during feature-based reversal learning

Authors: ***A. HASSANI**, M. OEMISCH, M. BALCARRAS, S. WESTENDORFF, T. WOMELSDORF;
Dept. of Biol., York Univ., Toronto, ON, Canada

Abstract: The alpha2a-noradrenergic (a2a-NE) agonist Guanfacine is a recently approved drug prescribed for attention-deficit-hyperactivity-disorder amongst others. It targets postsynaptic a2a-NE receptors at pyramidal cell spines where it enhances synaptic efficacy independent of locus coeruleus mediated presynaptic NE modulation. Due to its specificity, it provides a unique opportunity to study the role of cortical noradrenergic stimulation in attentional control. Previously, Guanfacine has been found to improve working memory by enhancing maintenance of task relevant information, and more controversially, to improve attention allocation by reducing distractibility to task irrelevant stimuli. It is unclear if Guanfacine related improvement to attention is solely based on working memory enhancement. In order to elucidate Guanfacine's actions on attentional performance, we trained a rhesus monkey in a feature-based reversal-learning task in which two simultaneously presented stimuli of different color were alternately associated with reward. Stimulus motion direction informed the monkey of the choice direction. Stimulus dimming served as the cue to initiate a choice and occurred either separately or simultaneously, thereby inducing less or more stimulus conflict, respectively. Prior to task performance, 0.075mg/kg Guanfacine were administered intramuscularly. First, we found that Guanfacine led to an increased number of rewarded trials and an increased proportion of rewarded over error trials. Secondly, Guanfacine decreased overall distractibility, defined as less error saccades towards stimuli. This reduction in distractibility was most apparent when stimuli dimmed simultaneously, requiring higher conflict resolution. Lastly, we found a trend for reduced perseverative errors during reversal learning. We applied a reinforcement-learning model to quantify the role of reward feedback, decision noise, and working memory decay to explain performance. The model indicated that Guanfacine mediated performance showed enhanced sensitivity to positive feedback and reduced decision noise, but had no influence on short-term memory decay of color-reward associations. Our results indicate that Guanfacine enhances behavioral flexibility along 3 separable routes: by making behavior more reliable and persistent, by improving resistance to interference, and by enhancing sensitivity to reward which may explain reduced perseverative errors. These findings show that feature-based reversal learning in monkeys can serve as a versatile animal model to understand neuronal origins of attention deficits in neuropsychiatric conditions.

Title: Cortical afferents to rat locus coeruleus and pericoeruleus: Implications for optimal behavioral performance

Authors: ***H. BOWREY**, M. H. JAMES, M. D. REIDY, G. ASTON-JONES;
Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Introduction: According to the Adaptive Gain Theory (AGT; Aston-Jones and Cohen, 2005), the locus coreuleus-norepinephrine (LC-NE) system plays an important role in optimizing behavioral performance. Both tonic and phasic LC-NE neuronal activities vary significantly in relation to task performance. For example, during accurate task performance reflecting focused attentiveness, LC neurons fire tonically at a moderate rate and exhibit selective, phasic responses associated with task-related decisions. In contrast, poor performance reflecting task disengagement is associated with increased tonic activity and an absence of phasic activation in LC-NE neurons. The AGT proposes that descending cortical projections to LC may assist in determining transitions between phasic and tonic modes of LC-NE activity. In particular, the orbitofrontal cortex (OFC) and anterior cingulate cortex (ACC) have been highlighted as potential modulators of LC activity due to their critical roles in evaluating rewards and costs. Although a small number of studies have reported the presence of cortical inputs to LC, the topography of LC innervation from OFC and ACC remains to be extensively characterised. Further, the selectivity of cortical input to the peri-LC dendritic region remains unclear. Methods: Male Sprague-Dawley rats received injections of cholera-toxin B (CTb) retrograde tracer (20nl) unilaterally into either the nuclear core of LC or the peri-LC dendritic area under electrophysiological guidance. At least seven days later, animals were deeply anesthetized and perfused with fixative to visualize the CTb tracer. Brains were sectioned into 25-µm thick sections and stained for both CTb and tyrosine hydroxylase (TH). Retrogradely labelled cells

were then examined and quantified in various cortical areas (Bregma +4.20 to +2.52), including prelimbic cortex (PL) and infralimbic cortex (IL), anterior cingulate cortex (ACC) and orbital frontal cortex (OFC). Results: All injection sites were confined to the LC/peri-LC areas. Consistent with previous reports, retrogradely labelled cortical cells was observed in IL. In all cases, retrogradely labelled cells were also observed in the PL and ACC. Occasional retrogradely labelled cells were also observed in ventral and lateral OFC regions. Conclusions: Consistent with the hypothesis that OFC and ACC may modulate LC activity, neurons in these regions innervate the LC and peri-LC regions. Studies are ongoing utilising anterograde tracing to characterize the topography of these inputs into LC/peri-LC regions.

Title: 5HT2A receptor blockade in the orbitofrontal cortex does not attenuate repetitive behaviors in the BTBR mouse

Authors: *D. A. AMODEO[1], E. RIVERA[2], J. A. SWEENEY[3], M. RAGOZZINO[2]; [1]Psychology, Univ. Illinois, Chicago, Chicago, IL; [2]Univ. of Illinois at Chicago, Chicago, IL; [3]Univ. of Texas South Western, Dallas, TX

Abstract: Previous studies have found that individuals diagnosed with autism spectrum disorder (ASD) display impairments in behavioral flexibility as evidenced by a probabilistic reversal learning deficit. This learning deficit is driven by an inability to maintain a new choice pattern, demonstrated by an increase in regressive type errors. Similarly, the BTBR T+Itpr3tf/J (BTBR) mouse model of ASD shows a similar deficit on probabilistic reversal learning that is also due to a specific increase in regressive errors when compared to B6 mice. Many previous studies have implicated the orbitofrontal cortex (OFC) in behavioral flexibility. We recently demonstrated that acute systemic treatment with M100907, a 5HT2A receptor antagonist, attenuates probabilistic reversal learning in the BTBR mouse. The current experiment investigated whether direct infusion of M100907 into the ventral orbitofrontal cortex attenuates a probabilistic reversal

learning deficit and repetitive grooming in BTBR mice. Mice were tested in a spatial discrimination task using a 80/20 probabilistic reinforcement procedure. In the spatial discrimination, mice were tested on acquisition and reversal learning across two consecutive days. Mice learned to obtain a cereal reinforcement from the “correct” spatial location (reinforced on 80% of trials) compared with the “incorrect” spatial location (reinforced on 20% of trials). The learning criterion in both phases was choosing the ‘correct’ location on 6 consecutive trials. For grooming behavior, mice were individually placed in a clear plastic cage and the cumulative time spent grooming all body regions across 10 min was recorded. Five minutes prior to the reversal learning phase or repetitive grooming test, mice received a bilateral infusion of vehicle, 0.2µg or 0.6µg M100907 into the ventral orbitofrontal cortex. BTBR mice were not impaired on initial learning of the spatial discrimination compared to that of B6 mice, similar to previous findings. Vehicle-treated BTBR mice were impaired on probabilistic reversal learning compared to that of vehicle-treated B6 mice. Neither the 0.2µg or 0.6µg doses of M100907 into the ventral orbitofrontal cortex attenuated the reversal learning deficit in BTBR mice, although both doses led to a significant increase in perseverative errors. In addition, M100907 treatment did not attenuate repetitive grooming in BTBR mice. These findings suggest that altered 5HT2A receptor functioning in the ventral OFC may not be responsible for behavioral inflexibility and other repetitive behaviors in BTBR mice.

Title: Serotonin 5HT1A receptor blockade potentiates impulsive effects of a cannabinoid CB1 receptor inverse agonist, but not a neutral antagonist in rats: Possible relevance for pharmaceutical safety

Authors: J. E. JAGIELO-MILLER[1], E. S. PLYLER[1], T. M. PROPER[1], F. M. MYERS[1], C. M. LUSKIN[1], M. C. NORMANN[1], K. VEMURI[2], A. MAKRIYANNIS[2], *P. J. MCLAUGHLIN[1]; [1]Dept. of Psychology, Edinboro Univ. of Pennsylvania, Edinboro, PA; [2]Ctr. for Drug Discovery, Northeastern Univ., Boston, MA

Abstract: CB1 inverse agonists, such as rimonabant, failed to receive FDA approval due to psychiatric side effects, including suicidal depression and anxiety, in a minority of clinical trial participants. This may be partly due to a lack of valid preclinical models of such effects, as well as identifying features of vulnerable subpopulations that can be modeled in preclinical studies. Impulsivity is often a component of suicidal behavior; moreover, dysregulation of the serotonin 5HT1A receptor may play a role in suicide, depression, and other disorders, and has been shown to produce impulsivity in animals on tasks such as Fixed Consecutive Number (FCN). However, interpretations of impulsivity in tasks based on timing of intervals or counting of responses may be confounded with effects on cognitive processes needed to complete the task. Therefore, in the present study, impulsivity was assessed using a novel Variable Consecutive Number task with a discriminative stimulus (VCN-SD), in which male rats were reinforced for pressing a lever only after a criterion number of responses on another lever, which retracted for 2.6 s after each response. The criterion randomly varied between 12, 15, 18, 21, and 24 responses on a per-trial basis, and was signaled by a tone, eliminating counting- or timing-based strategies. To assess whether interrupted communication at the 5HT1A receptor produces vulnerability to negative effects of CB1 inverse agonism, the CB1 inverse agonist AM 251 was administered systemically, first alone, and then following pretreatment with the 5HT1A antagonist WAY 100,635 (WAY). It was found that AM 251 per se did not decrease accuracy (percentage of chains that reached criterion) at doses up to 8.0 mg/kg. However, following pretreatment with either 0.1 or 0.3 mg/kg WAY, which were also ineffective per se, 4.0 mg/kg AM 251 substantially impaired accuracy. Moreover, dose condition interacted with criterion; that is, effects of the WAY-AM 251 combination were only apparent at longer criterion values, strongly implicating an increase in impulsivity. The neutral CB1 antagonist AM 6527 had no effects on accuracy, alone or in combination with WAY. These results clearly indicate impulsivity, often identified as a component of suicide, can be produced by AM 251, during a state of 5HT1A blockade. Future research is needed to determine whether this finding identifies a 5HT1A-related vulnerability to psychiatric symptoms, and to identify others, in clinical populations. It is also suggested that CB1 neutral antagonists such as AM 6527 may have a safer profile in regard to behavioral impairments than CB1 inverse agonists such as AM 251 or rimonabant.

Title: Double dissociation of octopamine and dopamine on choice behavior in *Drosophila*

Authors: ***E. A. GOROSTIZA**, B. BREMBS;
Univ. Regensburg, Regensburg, Germany

Abstract: In 1918, McEwen demonstrated that wing defects, caused by mutation or damage, profoundly affect phototaxis in walking *Drosophila* fruit flies (McEwen, 1918). We have recently described experiments showing that flies are constantly monitoring their flying capability and adjust their light/dark preference accordingly (Gorostiza & Brembs,. 2014). This discovery revealed that phototaxis, which appears simple and hard-wired, comprises a value-based decision-making stage, negotiating external stimuli with the animal's internal state. We also discovered that neuronal activity in circuits expressing dopamine and octopamine, respectively, is necessary and sufficient for adjusting light/dark choices in flies. Here, we present data to disentangle the neural circuits involved in this value-based decision-making process. The data were collected in a screen comprising different subpopulations of dopaminergic and octopaminergic neurons, as well as other suitable candidates. Gorostiza EA, Brembs B (2014): Behavioral flexibility in *Drosophila* Soc. Neurosci. Abstr., 651.17 McEwen, R. S. R. (1918). The reactions to light and to gravity in *Drosophila* and its mutants. J. Abstract: Impaired regulation of physiological and cognitive reactivity to potential threat is a core feature of affective disorders including mood and anxiety disorders. However, the neural mechanisms underlying this emotion regulation are poorly understood. It has been suggested that the prefrontal cortex (PFC) plays a crucial role in modulating neural activity in subcortical structures that are responsible for the processing and expression of fear and anxiety. Recent studies from our laboratory showed that an anxious phenotype, including enhanced anxiety to a social stimulus, innate fear and conditioned fear (Agustin-Pavon et al, Biol Psychiat. 2012; Shiba et al 2015 Front Sys Neurosci) was induced by excitotoxic lesions of either the anterior orbitofrontal cortex (antOFC) or ventrolateral PFC (vlPFC) independently. These results raise the question as to whether the antOFC and vlPFC act on common or distinct downstream subcortical targets to down-regulate negative emotion. To address this, the present study combined localised excitotoxic lesions in the PFC of a non-human primate and functional neuroimaging (18F-FDG microPET) with a fear-inducing behavioral paradigm. Marmoset monkeys with unilateral lesions of either antOFC (area 11) or vlPFC (area 12) were scanned immediately following exposures to a fearful (rubber snake and darkness) or ‘safe’ context, and the differences in regional ligand uptake were compared. Analysis of three antOFC lesioned animals so far has revealed that, in the intact hemisphere, FDG uptake in the amygdala was significantly increased in response to the fearful context compared to the ‘safe’ context. However, this difference in FDG uptake between the two contexts was not seen in the amygdala of the lesioned hemisphere, being high in both fear and ‘safe’ contexts. These results will be compared with those of the vlPFC, providing important new insight into the top-down control of the subcortical emotion network. It may also progress our understanding of the neurocognitive mechanisms underlying marked symptomatic differences in mood and anxiety disorders, which in turn could lead to the refinement of diagnoses and the individual tailoring of therapeutic strategies.

Title: Astrocytes are involved in cognitive flexibility

Authors: *A. T. BROCKETT, E. A. LAMARCA, B. A. BRIONES, E. GOULD;
Psychology, Princeton Univ., Princeton, NJ

Abstract: Astrocytes are a relatively understudied cell type in the brain despite being numerous and structurally complex. Across evolution, animals with more complex brains capable of more complex behavior also have more numerous and morphologically complex astrocytes (Oberheim et al. 2008). This suggests that astrocytes may be active participants in complex cognition. Recent evidence suggests that running increases astrocyte size and endfeet coverage as well as dendritic complexity in the medial prefrontal cortex (mPFC) and hippocampus. These running-induced changes in both astrocytes and neurons were associated with enhanced cognitive functioning (Brockett et al., 2015). Astrocytes are capable of regulating synaptic plasticity through the release of small molecules such as D-serine (Henneberger et al., 2010); moreover, the collective action of astrocyte Ca2+ signaling has been shown to regulate gamma oscillations in the hippocampus, which can influence object recognition memory (Lee et al., 2014). The mPFC is highly involved in the maintenance of cognitive flexibility, but what a reduction in the number of astrocytes in the mPFC does to such behavior and the surrounding neurons remains relatively unknown. As a first step toward addressing these questions, we reduced the number of astrocytes in the mPFC using a low dose of the astrocyte-specific toxin L-alpha-aminoadipic acid (L-AAA) (Banasr & Duman, 2008) in adult male Sprague Dawley rats before testing them on the attentional set-shifting task (ASST). Astrocyte reduction in the mPFC resulted in impairment on the mPFC-dependent portion of the ASST compared to vehicle-treated controls. L-AAA did not result in any changes in neuron density, neuronal cell body size, dendritic spine density, dendritic spine size or neuronal expression of immediate early genes in the mPFC, suggesting that astrocyte reduction occurred without noticeable negative consequences to surrounding neurons. Future studies will use more directed strategies for disrupting astrocyte signaling to determine the influence of astrocytes on cognitive flexibility.

Title: Prefrontal cortico-thalamic network connectivity for cognitive control

Authors: *J. M. PHILLIPS[1], N. A. KAMBI[1], S. R. KECSKEMETI[2], Y. B. SAALMANN[1]; [1]Psychology, [2]Brain Imaging Core, Waisman Ctr., Univ. of Wisconsin-Madison, Madison, WI

Abstract: The prefrontal cortex (PFC) has an established role in cognitive control, that is, flexibly adapting behavior according to goals, context and rules. Anatomical tracer studies indicate that the lateral PFC has dense, reciprocal connections with the parvocellular compartment of the medio-dorsal thalamic nucleus (MD) (Ray & Price, 1993 J Comp Neurol 337:1). However, the contribution of MD to cognitive control remains relatively unexplored. We hypothesize that PFC and MD interact to support cognitive control, specifically that MD regulates information processing across PFC. In this framework, MD may selectively activate different groups of PFC neurons based on cognitive control demands. To enable our investigation of MD-PFC connectivity, we performed high resolution (1.0 mm isotropic) diffusion weighted imaging on 4 anesthetized macaque monkeys using the GE MR750 3T scanner with a 16-channel receive-only head coil (MRI Instruments). We acquired 60 diffusion directions (b=1000 s/mm2 and NEX=14) and 112 b=0 images. We used FSL for EPI distortion, eddy current and motion correction, prior to Bayesian estimation of diffusion parameters and probabilistic tractography. Our tractography results were broadly consistent with anatomical tracer studies. However, diffusion tractography had the advantage of delineating projection zones within areas specific to each monkey, which cannot be precisely ascribed on the basis of published tracer data. Based on probabilistic cortical connectivity patterns, we subdivided MD into three subdivisions: medial, dorsal and lateral subdivisions predominantly connected with orbitofrontal cortex, medial PFC and lateral PFC, respectively. The lateral subdivision occupied the relatively largest portion of MD and seemingly corresponded to parvocellular MD. Importantly, circumscribed zones of the lateral MD subdivision connected with both PFC areas 46 and 9/46. This suggests that there is an indirect cortico-thalamo-cortical pathway between areas 46 and 9/46 via MD, in addition to the direct cortico-cortical pathway between these PFC areas. Our data implies that the parvocellular MD is well positioned to coordinate information transmission between lateral PFC areas. The diffusion tractography data also allow us to target MRI-compatible linear microelectrode arrays to interconnected sites between the areas 46, 9/46 and parvocellular MD, for simultaneous multi-site recordings of thalamo-cortical dynamics during cognitive control. We propose that a general function of MD, and other higher-order thalamic areas like the pulvinar, is to regulate cortical processing according to behavioral demands.

Title: A bayesian method of categorizing neurons based on functional properties

Authors: ***T. BLANCHARD**, S. T. PIANTADOSI, B. Y. HAYDEN;
Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Historically, it has often been useful to classify neurons as belonging to one of a few discrete functional categories based on the variables they are sensitive to. However, there has been a recent surge in research finding that cortical neurons often have mixed selectivities and lack discrete functional categories. Are neurons best thought of as having a random mix of tuning to variables or as belonging to discrete categories? To investigate this, we developed a Bayesian clustering method of classifying the tuning properties of neurons. This method allows us to test for whether the tuning properties of neurons in a dataset are best characterized as coming from the same distribution or from multiple distributions (categories). Our approach also allows us to determine when the data leaves high uncertainty about the existence of clusters. It also allows us to test for systematic relationships between how neurons encode one variable and another variable. We demonstrate these methods on data from the prefrontal cortex.

Title: Prefrontal information processing during spatial decision making in rats

Authors: *T. JAHANS-PRICE[1], R. BOGACZ[2], M. W. JONES[1];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Cortical activity correlates of binary decision making have been well-described in nonhuman primates (e.g. Roitman, J.D. & Shadlen, M.N., 2002) and more recently in rodents (Jahans-Price et al. 2014; Raposo et al. 2014; Hanks et al. 2015). In both cases cortical neurons display ramping activity, suggesting they could be integrating evidence for choice alternatives. Meanwhile, the rodent hippocampus is implicated in decision making and in planning future actions. For example, during moments of quiescence in decision making tasks, decoded hippocampal spatial representations appear predictive of future behaviour (Foster and Pfeiffer, 2013; Johnson and Redish, 2007). During this phenomenon, the animal's head often orients towards and switches between potential options, as rats appear to consider the alternatives in a process described as vicarious trial and error (VTE). In order to investigate whether hippocampal and prefrontal information processing is coordinated during VTE, we recorded local field potential (LFP) and multiple single neuron action potentials from medial PFC units and hippocampal LFP from five adult rats during a spatial decision making task. PFC units were recorded from three rats using an array of independently moveable tetrodes and from two rats using multi-shank silicon probes. The task, based on Powell and Redish (2014), requires a rat to run left or right at a T-junction in order to gain a reward - one side of the maze is rewarded in each session. The side rewarded is chosen pseudorandomly and in a subset of sessions is switched mid-session. Rule variation is used to discourage automated behaviour and increases instances of VTE. During moments when rats appear to be considering route options at T-junctions, we analyse information processing in the prefrontal cortex, oscillations in the hippocampus and the interactions between both structures. Of the prefrontal units recorded we found a subset of 41% which displayed side-selectivity, firing at higher rates on either the left or right side of the maze. Within VTE events prefrontal neurons selective for a particular maze side displayed higher activity if the rat subsequently entered that side, compared to entering the alternative side. We also saw an increase in theta power during VTE compared to equivalent slow movement. These results demonstrate that PFC represents future outcomes and participates with the hippocampus during the planning that occurs in VTE events.

Title: Synchronous beta oscillations in the fronto-striatal loop for behavioral rule switching in non-human primates

Authors: *F. GERARD-MERCIER, K. TANAKA;
RIKEN BSI, Cognitive Brain Mapping Lab., Saitama, Japan

Abstract: Behavioral flexibility is crucial for survival in a versatile environment. Behavioral rules (sets of stimulus-action contingencies given a certain environmental setting) have to be constantly evaluated for current relevance, and switches between rules have to occur whenever the environmental setting changes. Crucially, in everyday life, which rule to follow in which setting is implicit and uncued, unlike in most experimental studies of behavioral flexibility. We therefore sought to investigate in non-human primates the neural correlates of uncued behavioral rule switching. We trained monkeys to perform a task analog to the Wisconsin Card Sorting Test, in which they had to perform different sets of actions in response to the same stimuli depending on the -frequently changing- current rule. On each trial, a colored shape was presented (sample), then, three test items appeared around the sample, one matching the sample in shape (but not in color), a second in color (but not in shape), and the last in neither shape nor color. Monkeys had to touch the test item that matched the sample in shape, or in color, depending on the current rule. Importantly, which rule (shape or color) had to be followed was not cued, and the sample-action contingencies were fixed, so that errors reflected failure in rule maintenance. The rule switched whenever the monkey had made 6 consecutive correct responses, after a minimum of 12 consecutive trials. While the monkeys performed this task, we carried out simultaneous recordings in three sites of the fronto-striatal loop crucial for executive function: the dorsal bank of anterior cingulate sulcus (part of ACC), dorsolateral PFC (area 46d, within the principal sulcus), and the dorsal part of anterior caudate head, the part of the striatum known to receive the most extensive inputs from ACC and dlPFC. Preliminary analyses showed prominent low beta (~15Hz) LFP oscillations in all three sites both during fixation (just before sample onset) and around feedback. Coherence measures indicated that these oscillations were synchronized across all three sites. Moreover, both power and coherence were modulated by rule (both during fixation and around feedback), and whether the response was correct or wrong (around feedback). These data, consistent with previous reports, support the idea that low beta oscillations provide communication channels for the evaluation and maintenance of the current

behavioral rule, and that dynamical changes in subpopulations of synchronized neurons provide the substrate for behavioral flexibility.

Abstract: Checking compulsions is among the most common behavioral features of obsessive-compulsive disorder (OCD), an anxiety disorders reaching 2-3% of the population. Checking compulsion derives and escalates from once-functional behavior. It is thought to be a behavioral attempt to relieve anxiety caused by high levels of doubt and uncertainty. Numerous studies suggest that alteration of prefrontal cortices would lead to abnormal cognitive control of action (e.g. conflict monitoring or error detection) and could be related to compulsive checking behavior. However the physiology of checking behavior remains poorly understood and no concrete and reliable model of physiological checking has been developed so far. The present behavioral study tends to characterize physiological doubt and checking behavior in non-human primates (NHP). To do so, we designed a novel behavioral task to study electrophysiological correlates of decision making, doubt and checking in NHP. We trained two rhesus monkeys (Macaca mulatta) on the Check-or-Go task while recording their frontal EEG activity. We also collected saliva samples to quantify cortisol concentration along sessions in order to correlate this biological marker of anxiety with checking behavior. Our behavioral paradigm allows the animal to multiple-check and potentially change the availability of the reward before taking the final decision leading to that reward. By manipulating the ambiguity of the visual cue embedding the reward status (reward operational cue), we successfully modulated animal uncertainty and created doubt. Behavioral results showed that the animal uncertainty level influenced not only

performances and reaction times but also checking behavior rate. Fronto-central EEG potentials were also modulated by visual cues' ambiguity level and checking decision. Daily cortisol quantification revealed a positive correlation between monkeys' checking behavior and anxiety level. Taken together, our study demonstrated that the Check-or-Go task is a valid behavioral tool to study the impact of ambiguity on doubt and the subsequent adaptive checking behavior and will thereby help us provide new insights into OCD mechanisms.

Title: The role of prefrontal fast-spiking parvalbumin interneurons in attention

Authors: ***S. K. ÄHRLUND-RICHTER**, H. KIM, M. CARLÉN;
Karolinska Institutet, Stockholm, Sweden

Abstract: Attention allows us to filter out irrelevant sensory information in favor of relevant information. The signatures of attention have been well described in visual cortex but the neural sources and computation responsible for the control of attention has not been established. The medial prefrontal cortex (PFC) oversees a large range of higher cognitive functions and has been demonstrated as central in the control of attention. PFC influence visual processing but the cellular and physiological underpinnings have not been characterized, including the contribution of the local PFC network. Cortical fast-spiking parvalbumin interneurons (FS-PV) are known for their involvement in coordination of the local circuitry and generation of gamma oscillations. More recently, prefrontal FS-PV interneurons have been shown to be recruited by behavior and to even play a direct functional role in expression of behavior. To investigate the role of mPFC FS-PV neurons in the control of attention we conducted extracellular single-unit recordings in PV-Cre mice preforming an attention task, the 3-choice serial reaction time task (3-CSRTT). During the task animals are required to allocate attention in order to detect a brief visual stimulus (cue) in an operant chamber, and to report the cue location by nose poking. We analyzed the population activity of FS-PV neurons and WS putative pyramidal neurons during attentional

processing and found that the activity FS-PV neurons but not WS neurons predict successful attentional processing. In addition, successful attentional processing was correlated to an increased level of gamma oscillation in mPFC. Using optogenetics we could demonstrate a direct functional role of mPFC FS-PV neurons and gamma oscillation in the control of attention. Moreover, optogenetic manipulation of mPFC FS-PV neurons enables enhancement of attentional processing. <!--EndFragment-->

Title: Methylphenidate reduces noise correlations and improves neural ensemble coding in the primate lateral prefrontal cortex

Authors: *S. TREMBLAY[1], F. PIEPER[2], A. SACHS[3], J. MARTINEZ-TRUJILLO[4]; [1]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [4]Western Univ., London, ON, Canada

Abstract: Methylphenidate (MPH), commonly know as Ritalin©, is one of the most widely prescribed drug to treat patients with attention deficit hyperactivity disorder (ADHD). Despite its proven effectiveness in both children and adults, we currently have a limited understanding of the neural mechanisms by which the drug improves cognitive performance in both ADHD patients and normal controls. Using multielectrode arrays implanted in the primate prefrontal cortex, we show that MPH, at low doses that improve cognition, reduces noise correlations within prefrontal neuronal ensembles without substantially modulating the overall level of neuronal activity. This effect improved the neural ensembles performance at encoding the focus of attention during a behavioural task. Our results identify a novel network-level mechanism of action of MPH on information coding by prefrontal neuronal ensembles in the primate brain.

Title: Neural mechanisms of shape discrimination under partial occlusion: a circuit model of V4 and prefrontal cortex

Authors: ***H. CHOI**[1,2], A. FYALL[2], E. SHEA-BROWN[1], A. PASUPATHY[2];
[1]Applied Mathematics, [2]Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: The primate visual system has an exquisite ability to recognize objects in natural scenes even though most objects appear partially occluded. The robustness of shape discrimination in the brain has yet to be matched in computer vision. How the brain recognizes partially occluded shapes, therefore, is an important question. Here we investigate possible underlying neural mechanisms using a computational model of V4 and prefrontal cortex (PFC) based on our recent electrophysiological recordings from the macaque. We propose that feedback signals from PFC to V4 contribute to the representation and discrimination of partially occluded shapes. We studied responses of V4 and PFC neurons while monkeys discriminated pairs of shapes under varying degrees of occlusion. In V4, neurons showed weakened shape selectivity early in their responses as the occlusion increased. Later in time, around 200 ms after the stimulus onset, the responses peaked again, and the amplification of selectivity was more prominent for the stimulus under intermediate level of occlusion. Interestingly, neurons in PFC, which receive signals from V4, responded strongly to occluded stimuli but very weakly to

unoccluded stimuli. Moreover, PFC responses peaked in between the early and the later peaks of V4 responses. These observations are consistent with the hypothesis that PFC provides feedback modulation responsible for the later increase in shape selectivity in V4 under occlusion. Based on these experiments, we constructed a model composed of two layers of neurons corresponding to V4 and PFC. Our model includes two populations of V4 neurons, which respond preferentially to two different test stimuli. Each V4 population gives excitatory feedforward inputs to two different populations of PFC neurons, whose responses are also modulated by an occlusion-dependent gain function. The PFC output is fed back to the V4 neurons with the matched shape preference. The model outcome agrees with the experiments, predicting low V4 shape selectivity under occlusion during the earlier peak, which increases later during the second peak. In addition, our preliminary data indicates that a gain function that merely detects the presence of occlusion promotes shape selectivity as well as a gain that gradually increases as degree of occlusion increases. Our combined modeling and electrophysiology are consistent with the idea that feedback from PFC to V4 plays a significant role in maintaining shape discrimination under partial occlusion. These results suggest a possible role of feedback for object recognition in the ventral visual pathway.

Title: Theta-phase reset and interareal burst synchronization to gamma activity co-occur in a theta-gamma coupled attention network

Authors: ***B. VOLOH**, T. WOMELSDORF;
Biol., York Univ., North York, ON, Canada

Abstract: Selective visual attention relies on mechanisms that integrate goal-relevant events through a distributed network of neurons encoding goal-relevant information. Yet it is unclear

how external events are converted into an endogenous signal driving network formation. Ongoing but unrelated rhythmic activity fluctuations across cortical sites may be phase reset by a relevant external event, thus imposing a common neural context onto which goal-relevant information can be mapped [1]. Alternatively, transient burst firing modulate the effective connectivity of network nodes, whereby the strong post-synaptic activation may drive relevant neurons to an active processing mode [2]. Importantly, both phenomena may not be mutually exclusive: bursts may provide the drive for widespread phase resetting, or a phase reset may bring neurons into burst firing modes. Thus, phase resets and bursts could underlie the updating of goal relevant representation in larger-scale networks. To test for these possible interactions of burst firing and phase reset, we have analyzed the local field potential (LFP) and neuronal burst firing in anterior cingulate and prefrontal cortices (ACC/PFC) in macaques performing a selective attention task. Shifting attention depended on the integration of stimulus feature information with cue information. In previous work, we have shown that during the attentional stimulus selection, neuronal spike bursts in ACC/PFC synchronize to gamma and beta LFP oscillations [2]. At the same time, LFPs in the ACC phase coupled low frequency 5-10Hz theta phases with gamma activity in lateral PFC [3]. Here, we characterize these phenomena and their putative relation. First, we found that theta phase-providing LFPs showed a phase reset during correct but not erroneous attention shifts. Second, these LFPs hosted single-neuron bursts that were coupled to distant gamma in direct relation to the strength of theta-gamma coupling. Finally, burst-LFP synchronization showed the opposite relation with network strength at beta frequencies, illustrating a segregation of theta-gamma interactions from processes in the beta-band. These results show that the recruitment of behaviorally relevant neural ensembles occurs in the presence of both theta-phase resetting and bursts synchronizing with distal gamma. Both phenomena occur in the same cortical site, and are directly correlated with the degree of ensuing theta-gamma coupling, suggesting that they contribute to the formation of goal-relevant networks. Title: Opposite development of short- and long-range anterior cingulate pathways in autism

Authors: *B. ZIKOPOULOS, Y. J. JOHN, J. TEPE, H. BARBAS;
Boston Univ., Boston, MA

Abstract: Autism spectrum disorders (ASD) have been consistently linked with changes in brain connectivity that disrupt neural communication, especially in frontal networks. Our prior work indicated that compared to neurotypical controls, the white matter below anterior cingulate cortex (ACC) area 32 (A32) of adults with ASD has an elevated proportion of thin axons that likely connect ACC with nearby areas, and a reduced proportion of thick axons that likely extend over long distances (Zikopoulos and Barbas, Journal of Neuroscience, 2010; Zikopoulos and Barbas, Frontiers in Human Neuroscience, 2013). These findings are in agreement with reported gross changes in the volume and structural integrity of frontal white matter in ASD. It is not clear however, whether changes in the fine structure of axons below ACC and the pathways they form appear early or late in development. To address this question we used post-mortem brains of children (ages 3-10 years) and adults (ages 30-44 years) with and without ASD, and systematically sampled and imaged the white matter below ACC at very high resolution in the electron microscope. We used unbiased methods to quantitatively study the density and ultrastructure of individual myelinated axons. In the ASD group the mean inner and outer diameters of myelinated axons showed a decrease from childhood to adulthood, whereas in the control group they showed an increase. Further analysis of thin and thick axon populations that form short-range cortical and long-range pathways showed significantly different developmental trajectories. The proportion of thin axons present in childhood and adulthood remained roughly constant in neurotypical controls, whereas it increased in individuals with ASD. In contrast, the relative proportion of thick axons in young and adult individuals increased from childhood to adulthood in the control group, but remained flat in ASD. These findings are consistent with the idea that changes in axonal architecture affect in distinct ways short- and long-range cortical pathways, modifying the interactions of nearby or distant brain structures. Axon diameter affects conduction velocity, which in turn influences physiological processes including neural synchrony and communication, in processes that are disrupted in ASD. Moreover, our preliminary data suggest that changes in the relative size composition of axons in the white matter below ACC appear later in life and may reflect continued disturbances in axon growth and guidance in autism.

Title: The 'Cortical Spectrum': scores of cortical areas, but only a handful of cortical types in the primate brain

Authors: *Y. J. JOHN, B. ZIKOPOULOS, M. GARCIA CABEZAS, H. BARBAS;
Neural Systems Lab., Boston Univ., Boston, MA

Abstract: The structure of the cerebral cortex is generally viewed in two ways: as a mosaic of indistinguishable six-layered columnar circuits, and as a patchwork of discrete architectonic areas. These seemingly distinct views converge on the idea that the basic six-layer structure is identical across the cortex, and that all areas perform similar canonical functions, differing only by their connection patterns. But a growing body of evidence suggests that the organization of the cortex is best understood by systematic variation. The cortex is neither a uniform six-layered structure, nor a collection of dissimilar areas with sharp boundaries -- it is best characterized as a spectrum, in which structural features change smoothly, and discontinuities are rare. To investigate the nature of the cortical spectrum, we studied key structural properties of different cortical areas, representing all systems, including the densities of neurons, glia and myelinated axons, ranging from the pial surface to the underlying white matter tracts. These data allowed us to divide a large number of areas into a much smaller number of robust types of cortices that differ in systematic ways. Overall, laminar density of neurons and myelin were informative and changed gradually from low to high levels in limbic, association, and the most specialized primary cortices. Laminar-specific changes in cell morphology, especially in layer 3, were also useful in discriminating and clustering areas. Categorization of many different cortical areas into a few cortical types within each system allowed us to identify analogies between different systems and processing streams. Our analysis also highlights specializations in cortical structure that reflect specialized processing streams and functions. Rather than being taxonomical, this cortical topology serves as a powerful framework within which to understand brain structure and function. These broad cortical types provide useful insight into patterns of cortico-cortical connectivity, which are often altered in neurologic and psychiatric disorders. The pattern of

connections between two given cortical areas is not simply a function of inter-areal distance, but depends quantitatively and qualitatively on the types to which the areas belong. The cortical spectrum perspective allows for a principled approach to determine functional cortical hierarchies, and leads to testable hypotheses regarding neural development and the evolution of the mammalian cortex.

Title: Fine timescale dopaminergic modulation of prefrontal neuronal circuit activity

Authors: ***K. TAO**, S. FUJISAWA;
RIKEN Brain Sci. Inst., Wako, Saitama, Japan

Abstract: The prefrontal cortex is one of the major projecting targets of dopamine neurons in the ventral tegmental area (VTA). These mesoprefrontal dopamine neurons has been considered to modulate prefrontal network activity tonically through volume transmission as well as phasically in a synaptic fashion. However, the effect of phasic firing of dopamine neurons on prefrontal circuit activity in a sub-second timescale remains elusive. Here we show that, in a classical reward conditioning paradigm under head-restrained apparatus using mice, fast-spiking interneurons (FS INs) in the medial prefrontal cortex (mPFC) respond both to water rewards and reward predicting cues. Both water rewards and optogenetic stimulation of dopaminergic neurons in the VTA elicited firing of FS INs in the mPFC. Conversely, the vast majority of regular-spiking neurons were inhibited by these manipulations. Subcutaneous injection of SCH23390, a dopamine receptor D1 (D1R) antagonist, suppressed firing of FS INs induced by rewards. These results suggest that mesoprefrontal dopaminergic neuronal firing inhibit overall neuronal activity in the mPFC in a D1R-dependent manner, presumably in concert with glutamatergic inputs from lower order cortices or thalamic nuclei.

Title: Inter-areal spiketrain correlations of anterior cingulate and prefrontal cortex during attention shifts: Cell-type, anatomical, and temporal specificity

Authors: *M. OEMISCH[1], S. WESTENDORFF[1], S. EVERLING[2], T. WOMELSDORF[1]; [1]Dept. of Biol., York Univ., Toronto, ON, Canada; [2]Dept. of Physiol. and Pharmacol., Western Univ., London, ON, Canada

Abstract: Anterior cingulate cortex (ACC) and dorsal prefrontal cortex (PFC) are believed to coordinate activity during goal-directed behavior to identify, select and monitor relevant sensory information. The ACC is suggested to monitor and bias attentional selection, while lateral and dorsal prefrontal areas are involved in the actual implementation of attentional control. To this point it is unclear how the distributed brain areas interact to integrate their respective attention information, and studies investigating direct interactions between these areas have been sparse. Here we recorded >2000 pairs of cells and tested whether spiketrain interactions of neurons across macaque ACC and PFC reflect such coordination during stimulus selection in a spatial attention task. For this task monkeys had to attend one of two colored stimulus gratings and discriminate a transient clockwise or counter-clockwise rotation in order to receive liquid reward. The attentional target was indicated by the color of a fixation point. Spiketrain correlations were computed using joint peri-stimulus time histograms (JPSTHs) and confirmed with Pearson correlations. We found that spiketrain correlations emerged shortly after an attention cue and were evident for 50-200ms time windows. Increased firing correlations were strongest for neuron pairs in area 24 (ACC) and areas 8 and 9 (dorsal PFC), they were independent of overall firing rate modulations, and firing events in PFC preceded firing events in ACC. For a subset of cell pairs from ACC and PFC the observed functional spiketrain connectivity carried information about the direction of the attention shift, whereby neurons encoding contralateral attention shifts engaged in increased synchronization, while neurons encoding ipsilateral shifts engaged in decreased synchronization. Reliable firing correlations were evident across area boundaries for neurons with broad spike waveforms (putative excitatory neurons) as well as for pairs of putative excitatory neurons and neurons with narrow spike waveform (putative interneurons). These findings reveal that stimulus selection is accompanied by slow time scale firing correlations across those ACC and PFC subfields implicated to control

and monitor attention. This functional coupling could index the selective routing of goal-relevant information and may reflect the transient coordination of larger, reciprocally interacting brain networks at a characteristic 50-200ms time scale.

Title: The representation of abstract information that guides decision making in PFC of rats

Authors: ***S. TERADA**[1,2], Y. SAKURAI[1], H. NAKAHARA[2], S. FUJISAWA[2];
[1]Kyto Univ., Saitama, Japan; [2]RIKEN BSI, Wako, Japan

Abstract: Decision making is often guided by prediction of outcome such as reward. Both reward prediction and action selection need to be acquired and generated on neuronal representation that reflects sensory inputs or information of the environment. Critically, the representation should not be merely a collection of sensory inputs but instead, should be organized to encode and abstract information required for prediction and selection. So far mostly using a simple sensory cue, the prediction and selection have been studied in the field of value-based decision making, however, surprisingly little is known about the neural representations for the abstraction of the required information during the acquisition and generation. For this purpose, we have newly developed a behavioral task for rats, cue-combination task. Central for this task is that the correct choice of action should be determined by a combination of two cues (sound and odor cues); they cannot be determined by either of cues alone. In each session, sound and odor cues will be presented simultaneously for a couple of seconds to the rat, followed by a choice period, i.e., right or left lever to pull for getting a reward. Large-scale extracellular single

unit recordings in the prefrontal cortex (PFC) during this task revealed that several neurons, referred to here as combination cells, discharge at the time of presentation of only one of the combination patterns of the sound and odor cues. Most of the rest populations of PFC neurons were activated in a choice-dependent (i.e., left or right) manner. We hypothesize that PFC have the different function for this task, and their interaction might form and represent abstract information to solve exacting decision problems.

Title: Markers of plasticity suggest higher vulnerability in prefrontal limbic cortices in primates

Authors: ***M. GARCIA-CABEZAS**, H. BARBAS;
Hlth. Sci. (Neural Systems Lab), Sargent College, Boston Univ., Boston, MA

Abstract: Limbic cortices are at the base of every cortical system and show particular architectonic features, such as absence of layer IV or a poorly developed layer IV, lower neuron density and lower myelin content. They have widespread connections with sensory and other high-order association areas and strong reciprocal connections with the amygdala and the hypothalamus. In contrast, eulaminate cortices have six layers, higher neuron density and higher myelin content than limbic cortices. Eulaminate areas have more restricted cortical connections and receive fewer projections from the amygdala and the hypothalamus, which are not reciprocal. At the cellular level, pyramidal neurons in limbic areas have more branched and more spinous dendritic trees than the eulaminate areas. These architectonic, connectional and cellular features suggest that the limbic cortices are generalists in cortical processing while eulaminate cortices are specialists. These features also suggest that limbic cortices are more plastic than eulaminate cortices. To further investigate features that differentiate limbic and eulaminate areas we studied the distribution of CamKII and the glutamate receptor subunit NR2B, two markers of

synaptic plasticity, and of GFAP, a marker of astrocyte activation, in anterior cingulate (limbic) and dorsolateral prefrontal (eulaminate) areas in rhesus monkeys. Anterior cingulate areas 25 and 32 have higher density of CamKII and NR2B in all their layers. In dorsolateral eulaminate areas 9 and 46 the middle layers show lower expression of these markers. GFAP is denser throughout all layers of limbic cortices, while in eulaminate areas its expression is mostly restricted to layers I-IIIa and VI. Limbic cortices are implicated more frequently in neurological and psychiatric diseases than eulaminate cortices. For instance, in Alzheimer's disease neurons in limbic cortices have more tau inclusions than eulaminate areas and in depression the subgenual cingulate cortex is critically affected. These findings suggest that limbic cortices are more plastic but also may be more vulnerable to insults and disease than eulaminate cortices.

Title: Effects of focal prefrontal ischemic lesions on delay discounting and ultrasonic vocalizations in the rat

Authors: ***R. A. DÉZIEL**, R. A. TASKER;
Univ. of Prince Edward Island, Charlottetown, PE, Canada

Abstract: Stroke is the most common cause of long-term disability in adults worldwide, and it has been estimated that approximately 30% of stroke survivors experience cognitive impairments persisting for at least three months post-stroke. Cognitive deficits post-stroke are characterized by various symptoms including aphasia, attentional deficits, inhibitory control deficits, and social/emotional dysfunction. Many of these cognitive deficits occur because of damage to the prefrontal cortex (PFC), which has been heavily implicated as the seat of higher order cognitive functions in the brain. An improved understanding of the role of the PFC in cognitive functions post stroke requires appropriate preclinical models. Utilizing bilateral microinjections (400

pmol) of the vasoconstricting peptide endothelin-1 (ET-1) into either the medial or orbital PFC in male SD rats (n = 10-12/group) we produced localized ischemic lesions in these areas of the PFC (or sham). The effects of these lesions on cognition were assessed using tests measuring inhibitory control (delay discounting) as well as by recording and analyzing ultrasonic vocalizations produced during behavioural testing both pre- and post-stroke. Post-mortem lesion size and location was determined histologically. The combination of localized damage and behavioural tests of cognition shows potential for developing a model of post-ischemic cognitive dysfunction that will support subsequent studies of cognitive rehabilitation and cortical neuroplasticity.

Title: Downregulation of mediodorsal thalamic activity reduces GABAergic neurotransmission in the medial prefrontal cortex, disrupting the E/I balance, and impairing cognitive function

Authors: *B. R. FERGUSON[1], W.-J. GAO[2];
[1]Neurobio. and Anat., [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The mediodorsal (MD) thalamus plays a critical role in cognition through its extensive innervation of the prefrontal cortex (PFC). The MD's dense glutamatergic afferents synapse directly onto excitatory pyramidal neurons, and inhibitory GABAergic interneurons in the medial PFC (mPFC). GABAergic interneurons are essential in coordinating the activity of neighboring neurons and enhancing information processing within their local circuitry. Given the mPFC's classic implication in cognition and executive function, gaining a richer understanding of the subcortical structure driving GABAergic tone in this region is of fundamental importance. We hypothesize that the MD provides preferential synaptic drive to prefrontal inhibitory neurons, aiding in the regulation of local circuit activity and optimizing behavioral outcomes. To explore this we utilized the pharmacogenetic strategy, DREADDs, to downregulate MD activity and evaluate the consequences for working memory and cognitive flexibility, as well as the underlying alterations in mPFC synaptic transmission. Following MD inhibition, we observed

impairments in both working memory and cognitive flexibility as demonstrated by poorer performance in the T-maze and Cross-maze set-shifting task respectively. Additionally, we see reductions in mPFC GABAergic activity concomitant with elevations in excitatory neurotransmission. This suggests that the MD is crucial in maintaining the E/I balance in the mPFC circuitry, and the resultant cacophony generated when MD afferent drive is decreased may underlie behavioral deficits. Ongoing studies involve seeking to rescue these deficits by restoring GABAergic activity with a GABAA-positive allosteric modulator, indiplon.

Title: Representational transition from behavioral tactics into action by neurons in primate posterior medial prefrontal cortex

Authors: ***Y. MATSUZAKA**, A. SASAGAWA, H. MUSHIAKE;
Tohoku Univ., Sendai, Japan

Abstract: Use of various response tactics (i.e. the protocol to decide action) is an important aspect of adaptive behavior. Previous physiological studies revealed that the posterior medial prefrontal cortex (pmPFC) of primates participates in the selection of voluntary action only when the task required the selection of valid tactics as well. Because the selection of tactics and the selection of action are different levels of decision making, we studied how this area contributes to these processes. Two monkeys were trained to perform a two-choice arm reaching task in which the monkeys chose one of the multiple tactics to select the direction of reaching movements. The selection of the tactics and the selection of the reaching direction were temporally separated. In experiment 1, a color cue directly instructed the tactics (either reach to or away from the subsequent spatial cue) of the forthcoming reaching movement. After a variable length of delay period, a spatial cue (either left or right) appeared, prompting the monkeys to reach either ipsilaterally or contralaterally to its location, depending on the tactics instructed by the preceding color cue. Neurons in the pmPFC exhibited selective activity for the cued tactics during the delay period, but such activity quickly disappeared and was replaced with

action-selective activity once the action was determined. In experiment 2, the monkeys were trained to search the valid tactics using a series of color cues. After the tactics was determined, an additional color cue instructed the monkeys to select the action. We found that numbers of pmPFC neurons which encoded the tactics during its search or selection also encoded the forthcoming action after the target of arm reaching was determined. Further, the appearance of action selective neuronal activity was frequently accompanied by the reduced selectivity for the tactics. The switch of neuronal representation of task-relevant information indicates that the pmPFC contributes to the transformation of the appropriate tactic into action.

Title: Effect of amygdala lesions on local field potentials in the primate prefrontal cortex during a reward-guided task

Authors: *C. P. MOSHER[1], S. TAMANG[1], E. A. MURRAY[2], P. H. RUDEBECK[1]; [1]Friedman Brain Inst. and Dept. of Neurosci., Ichan Sch. of Med. at Mount Sinai, New York City, NY; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Reward-guided behaviors require functional interactions between the amygdala and the prefrontal cortex, specifically the orbital and medial divisions (OFC and MFC, respectively). In monkeys, bilateral excitotoxic lesions of the amygdala attenuate reward- value signals of individual neurons recorded from the OFC, but not the MFC (Rudebeck et al., 2013, Neuron, 80: 1519). The response properties of single neurons, however, only reflect the local processing and output of an area; a more complete understanding of this network might be informed by considering population-level activity and the inputs to an area, which can be studied using local field potentials (LFPs). To better determine the population dynamics of reward-value coding in the amygdala-MFC-OFC network, we performed time-frequency analysis on LFPs recorded from the OFC and MFC of three monkeys engaged in a stimulus-choice task. Recordings were

made both before and after excitotoxic lesions of the amygdala. On each trial of the task, monkeys were free to choose between two sequentially presented visual stimuli that were each associated with different amounts of fluid reward. Because the LFP is thought to represent the population-level input to a structure, we expected to find signatures in the prefrontal LFP that (1) reflect the reward-value associated with a visual stimulus, (2) are altered when value signals from the amygdala are removed, and (3) precede or coincide with local single cell activity. Our analyses suggest that the visual stimuli presented in the task evoke a response in the LFP in both the OFC and the MFC. This evoked response is composed of a low (<2 Hz) and mid-range frequency band (4-20 HZ). The power in these frequency bands scales with the reward-value of the visual stimuli. These value-induced modulations in LFP are stronger and occur earlier in the OFC than in the MFC. Following bilateral, excitotoxic lesions of the amygdala and, consistent with the single neuron data that were previously reported, the magnitude of the evoked LFP response decreases and the latency of the response is delayed. However, in contrast to the effects of amygdala lesions on single neuron encoding, the number of LFP sites that encode reward-value was significantly reduced in both the OFC and MFC. These analyses reveal that following amygdala lesion there is an uncoupling of LFP and single unit activity related to reward-value coding in MFC. Future analysis will further determine the relationship between single unit activity and fluctuations in LFP power.

Title: Contributions of the orbitofrontal cortex (OFC) to cognitive flexibility and associative learning during an attentional set-shifting task

Authors: ***M. D. CASTAGNO**, B. J. SLEEZER, B. Y. HAYDEN;
Univ. of Rochester, Rochester, NY

Abstract: Flexible decision-making often requires a process of trial and error learning to discover newly relevant rules or stimulus-reward associations. Although numerous studies indicate that different regions of the striatum and frontal cortex contribute to different types of flexible decision-making, few have examined how these regions contribute to different phases of rule identification throughout periods of trial and error learning. Recent work from our lab suggests that the ventral and dorsal striatum differentially contribute to early and late phases of trial and error learning during a primate version of the Wisconsin Card Sorting Task (a classic test of attentional set-shifting). To further examine how the brain implements flexible shifts in attention when trial and error processes are required, we recorded the activity of single neurons in the orbitofrontal cortex (OFC) while two monkeys performed a monkey version of the Wisconsin Card Sorting Task. Our version of the task involved a trial-and-error phase before monkeys could identify the correct rule on each block. Our data indicate that neurons in OFC demonstrate changes in firing rate associated with switching rules (i.e., switch signals). We also find that neurons demonstrate changes in firing rate in response to reward predictive stimuli (i.e. associative learning signals). More specifically, we find that associative learning signals peak early in the block and plateau for the remainder of the block. Taken together with our previous studies in the striatum, these results suggest that the OFC and striatum may work in conjunction to facilitate attentional set-shifting when trial and error learning processes are required. Although these results appear to be inconsistent with studies indicating that damage to or inactivation of the OFC does not disrupt this type of cognitive flexibility, we hypothesize that the OFC may be involved, but not essential for this process. Moreover, we hypothesize that attentional deficits in disorders such as ADHD may arise due to combined dysfunction in the OFC and striatum.

Title: Demand for control reduces coding sparseness in dorsal anterior cingulate cortex

Authors: *H. AZAB, B. HAYDEN;
Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Factors that elicit control, such as conflict and surprise, enhance aggregate neural activity in dorsal anterior cingulate cortex (dACC) but do not consistently drive activity of single neurons. We hypothesized that aggregate measures may reflect broader recruitment of neurons that link contexts to strategies rather than responses of specific neurons that abstractly signal the need for control. In other words, aggregate responses to the need for control may be a consequence, not a direct cause, of control. In a new gambling task, we found that conflicting options and surprising outcomes do not measurably increase neuronal activity, but do increase coding density (meaning, they reduce population sparseness). We propose a simple connectionist model in which all individual dACC neurons link contexts to strategies, and in which practice and familiarity (assumed to be greater to low-conflict and unsurprising outcomes) prunes connections. This pruning leads to more efficient responding but reduced recruitment, and thus lower BOLD signal, for default cognition relative to controlled cognition. These findings endorse the novel hypothesis that dACC regulates control emergently, without the need for specific dedicated control neurons.

Title: Large-scale sensory integration in the mouse cortex during a tactile detection task

Authors: ***P. F. LE MERRE**[1,2], P.-A. SALIN[3], C. C. H. PETERSEN[1], S. CROCHET[1,2]; [1]Lab. of Sensory Processing, Brain Mind Inst. Fac. of Life Sci., Ecole Polytechnique Federale De Lausanne (EPFL), Lausanne, Switzerland; [2]WAKING Group, [3]SLEEP Group, CRNL, Lyon, France

Abstract: Sensory perception leading to goal-directed behavior involves multiple, spatially-distributed and inter-connected cortical areas. It has been hypothesized that sensory information flows from primary sensory areas encoding mainly the properties of the stimulus, to higher-order, more frontal areas encoding the valence of the stimulus. To understand further the integration of sensory signals, we have recorded sensory evoked potentials (SEPs) simultaneously from different cortical areas in mice performing a whisker-based sensory detection task (Sachidhanandam et al., 2013). Mice were chronically implanted with 6 high-impedance electrodes and were either trained to lick a spout immediately after a 1 ms single

whisker deflection to obtain a reward (detection task) or were exposed in the same conditions to the whisker stimulus that was not associated with the reward (neutral exposition). In trained mice, we observed SEPs in all recorded areas with latencies increasing from the barrel-field of the primary somatosensory area (wS1) to the secondary somatosensory area (wS2), the whisker motor area (wM1), the parietal area (PtA), the dorsal hippocampus (dCA1) and the medial prefrontal cortex (mPFC). For each area, we investigated whether the sensory evoked responses correlated with task performance by comparing Hit and Miss trials. We found that the early peak of the SEP differed little between Hit and Miss trials in most areas except for mPFC and dCA1, where SEPs in Miss trials were markedly reduced. Interestingly, SEPs recorded in mice after neutral exposition were also particularly reduced in these areas as compared to trained mice, suggesting that training induced plastic changes in the mPFC and hippocampus leading to increased SEPs in response to the conditioning stimulus. Our results support the idea that mPFC and dCA1 could signal the relevance of a sensory stimulus in the context of a well-defined behavior, whereas sensory areas would be more constrained by the nature of the stimulus.

Title: Differential contribution of ventral and dorsal striatum to early and late phases of cognitive set reconfiguration

Authors: *B. J. SLEEZER, B. Y. HAYDEN;
Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Flexible decision-making, a defining feature of human cognition, is typically thought of as a canonical prefrontal cortex (PFC) function. However, recent work suggests a possible role for the striatum as well. We recorded activity of neurons in both the ventral (VS) and dorsal (DS) striatum while rhesus macaques performed a version of the Wisconsin Card Sorting Test, a

classic test of flexibility. Our version of the task involved a trial-and-error phase before monkeys could identify the correct rule on each block. Our data indicate that neurons in both the VS and DS demonstrated changes in firing rate associated with switching (i.e. switch signals). We found that switch-related activity was strongest in VS early in the trial-and-error period of the block, when the rule was unknown, and strongest in DS later, immediately before the rule was fully established and maintained. We also found that neurons in the VS and DS demonstrated changes in firing rate when monkeys viewed reward predictive stimuli (i.e. associative learning signals). Importantly, we found that associative learning signals arose earlier in the block in the VS and later in the DS, consistent with the appearance of switch signals in each region. These results support a functional hand-off from VS to DS during set reconfiguration and suggest that striatal switch signals may play a role in facilitating the acquisition of stimulus-reward associations during flexible decision-making.

Title: Selective inactivation of the nucleus accumbens and the prefrontal cortex during value based decision making in mice

Authors: *H. NAKAYAMA[1], N. HEINTZ[1,2];
[1]The Rockefeller Univ., New York, NY; [2]Howard Hughes Med. Inst., New York, NY

Abstract: Adaptive decisions require multiple cognitive processes. These cognitive processes include initiating actions at appropriate timing, selecting appropriate actions, and evaluating outcomes to adjust subsequent decision. To understand neural mechanisms underlying these processes, we trained mice to perform a two-option choice task with probabilistic reward in which mice need to learn through trial and error. Mice were required to respond to a nose port in the center to initiate each trial. Subsequently, mice were allowed to make either left or right choice followed by reward delivery at predetermined probability. Each trial was divided into three time windows (trial initiation period, choice period and outcome delivery period), and neuronal activity in the prefrontal cortex (PFC) and the nucleus accumbens was optogenetically inactivated during these time periods. Distinct circuit elements in the PFC and the NAc were inactivated using transgenic mouse lines and AAVs expressing Archaerhodopsin (ArchT). We

found differential behavioral changes depending on the target and the timing of inactivation. During the trial initiation period, inactivation of indirect pathway medium spiny neurons (MSNs) in the NAc increased number of premature response, which was defined as left or right choices without initiating trials with center nose-pokes. A similar change in premature response was also observed after inactivation of specific inputs to the NAc or direct inactivation of the PFC while inactivation of direct pathway MSNs had no effect. During the choice period, inactivation of the PFC affected the current choice. Inactivation of direct pathway MSNs during the outcome delivery period affected the subsequent choice in an outcome dependent manner. Inactivation increased the probability of mice making the same choice in the subsequent trial, and this effect was specifically observed after unrewarded trials. These results suggest that distinct circuit elements in the PFC and the NAc work together for successful task execution and value based decision making.

Title: Ensemble coding of goal-directed actions in the mouse premotor cortex

Authors: *M. J. SINISCALCHI[1], V. PHOUMTHIPPHAVONG[2], M. LOZANO[2], A. C. KWAN[2];
[1]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT; [2]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: The ability to adjust rapidly to different situations is a hallmark of cognitive control. However, the cortical network mechanisms that mediate switching between multiple action selection strategies are unclear. Here, we used head-fixed behavior, two-photon calcium imaging, and pharmacological inactivation to dissect the role of ensemble dynamics in the mouse premotor cortex (M2/Cg1) for strategy switching. We found that multiple behavioral strategies were each associated with a distinct subset of population activity patterns. Interestingly,

subsequent presentations of the same task set returned the network to similar dynamics. These stable yet divergent network states altered choice representation by recruiting different subpopulations of neurons, but did not change the choice preference of individual cells. Additionally, muscimol inactivation of M2/Cg1 facilitated repetitive action selection, while disrupting the transition to a goal-directed behavioral strategy. Our results show that the mouse premotor cortex employs multiple functional configurations to match the behavioral demands of a task requiring cognitive flexibility.

Title: Neurons in the primate dorsolateral prefrontal cortex encode summed quantities and choices during an arithmetic task

Authors: ***B. MASSI**, H. SOHN, H. SEO, D. LEE;
Neurobio., Yale Univ., New Haven, CT

Abstract: The ability to perform mental arithmetic on quantities provides a fitness advantage to human and non-human animals. For example, an animal may want to estimate the total number of stored food items across multiple caches, or a banker may want to optimize a number of financial investments. Despite the ubiquity of this cognitive process, the neurophysiological basis of mental arithmetic is seldom studied in isolation. To study the neurophysiological underpinnings of mental arithmetic in the dorsolateral prefrontal cortex (DLPFC), a region involved in both numerical cognition and executive control, we developed a novel arithmetic task that requires monkeys to estimate the sum of two quantities. During each trial, the animal fixated a central target while three clusters of dots appeared sequentially around the fixation target. After a short delay, each cluster entered one of the two peripheral target areas, which was followed by another delay before the presentation of the next cluster of dots. The first cluster of

dots (the augend) remained hidden until the end of the trial after it entered the target area. The second group of dots (the addend) appeared centrally and moved to the same target area containing the augend, but remained visible. Finally, the third group of dots (the singleton) appeared and moved to the other target area and also remained visible. After another delay, the animal was required to shift its gaze to one of the targets and received a juice reward with a magnitude proportional to the number of dots at the chosen target. Importantly, the probability that the sum was greater than the singleton was 0.5 for each value of the sum, so the sum of the augend and addend alone could not inform optimal action selection. Overall performance in the arithmetic task was significantly above chance (~83%), even on trials in which non-arithmetic heuristics are ineffective (~76%) and control trials in which numerosity was dissociated from low-level visual cues (~83%). We found that single neurons in the dorsolateral prefrontal cortex heterogeneously encode task-relevant variables, including the numerosity of the augend and addend, as well as their sum in addition to information about planned actions. These results suggest that the DLPFC contains multiple types of neural signals that are important for arithmetic operations.

Title: Strain specific patterns of the mouse brain functional and structural connectivity

Authors: *L.-A. HARSAN, M. REISERT, A. MECHLING, N. HUEBNER, T. BIENERT, H.-L. LEE, J. HENNIG, D. ELVERFELDT;
Univ. Hosp. Freiburg, Med. Physics, Freiburg, Germany

Abstract: Enormous effort has been focused during the last decade on addressing non-invasively the issue of intrinsic organization of brain functional connectivity (FC). Using resting state fMRI (rsfMRI), the FC architecture of the human brain has been revealed in multiple networks. However, the intrinsic connectional architecture of functional networks (FN) in the mouse brain remains a significantly underexplored research area. The primary goal of our study was to bridge this gap, by systematically and comparatively probing the intrinsic brain FC of two mouse

strains, intensively used in the fundamental and preclinical neuroscience : the C57Bl6/N and the Balbc/J strains. We compared the strain-dependent living mouse brain FC patterns with the structural connectome fingerprints, mapped in-vivo at high resolution diffusion based tractography. We depicted with rsfMRI inter-strain variations in the FC network of the mouse brain. The relevant, influential brain regions were classified for each strain, using the strength and the number of relevant connections. Regions with simultaneous above mean strength and mean number of relevant connections were considered hubs. Some common FC hubs were identified in both strains. This includes, Hippocampus, Cingulate cortex and Retrosplenial (dys)granular cortices as important areas of the limbic system, as well as motor cortex or thalamus which is also known as an important relay for structural connectivity. A first interesting between-strains difference was the inclusion of the somatosensory cortical (SSC) areas as hubs for the C57Bl6/N strain but their exclusion from the group of Balbc/J mice. We further checked if the difference arises from decreased (statistically irrelevant) inter-hemispherical connectivity of the SSC areas or from reduced intra-hemispherical connectivity. Our investigation revealed significantly lower inter-hemispherical correlations between the primary SSC in Balbc/J population when compared with the C57Bl6/N strain. However, a stronger intra-cortical connectivity was assessed in this strain, suggesting a different assembly of the brain networks in the two strains. The modifications into the inter-hemispherical FC were paralleled by the structural networks results in Balbc/J mice, showing important variations in the structural callosal inter-hemispherical pathway. Uncovering the large scale functional and structural connectivity patterns, in a strain specific manner, represents a first step towards a better understanding of modifications in basal, healthy state networks under the impact of various factors, related with genetic, pharmacological or pathological conditions.

Title: Manipulating projection-specific neuronal populations using a dual viral approach to examine the neural bases of Pavlovian-instrumental transfer

Authors: ***B. K. LEUNG**[1], L. S. ZWEIFEL[2], B. W. BALLEINE[1];
[1]The Univ. of Sydney, Brain and Mind Res. Inst., Camperdown, Australia; [2]The Univ. of Washinton, Seattle, WA

Abstract: Stimuli that predict rewards can have both general invigorating properties and selective response-biasing properties on goal-directed actions. The influence predictive learning has on choice between actions can be demonstrated using the outcome-specific Pavlovian-instrumental transfer (PIT) paradigm; specifically, during the presentation of a conditioned stimulus (CS), rats selectively increase the performance of instrumental actions that predict the same outcome as the CS. We previously demonstrated that disconnection of the medial ventral pallidum (VPm) and the mediodorsal thalamus (MD) removes the response-biasing properties of a stimulus such that rats respond indiscriminately on actions during the presentation of the CS. Here, we employed the use of designer receptors mediated by designer drugs (DREADDs) to target projection-specific neuronal populations during specific PIT. It was revealed that inhibiting VPm axonal terminals in the MD produced a similar deficit to the disconnection such that the rats did not show a bias towards the instrumental action that shared a common outcome with the CS. On the other hand, using DREADDs in combination with the retrograde transducing canine adenovirus-2 virus expressing Cre construct (CAV2), we have demonstrated that activating MD-projecting VPm neurons enhanced the response biasing properties of animals during PIT performance compared to controls, suggesting artificial activation of these neurons facilitated PIT. Finally, we examined regions in the prefrontal cortex (PFC) receiving input from the MD during PIT performance. We employed an inter-hemispheric disconnection approach where two projection-specific neuronal populations were manipulated in opposite hemispheres to evaluate serial connections from the VPm to MD and MD to PFC during PIT performance. Together, these results provide the first evidence of direct, monosynaptic pathways in a serial circuit mediating the response-biasing properties of a CS in specific transfer.

Title: Examining the role of the LC in foraging and exploration

Authors: *G. KANE[1], E. M. VAZEY[2], R. C. WILSON[3], A. SHENHAV[1], G. ASTON-JONES[2], J. D. COHEN[1];
[1]Dept. of Psychology, Princeton Univ., Princeton, NJ; [2]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ; [3]Dept. of Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Locus coeruleus-norepinephrine (LC-NE) neurons fire in two modes: phasic, with burst responses to salient stimuli; and tonic, with increased baseline firing and an absence of burst responses. The adaptive gain theory (AGT) proposes that these modes reflect different behavioral strategies - burst responses in the phasic mode orient animals to respond to stimuli that predict rewards, facilitating exploitation of available rewards; but when little reward is available, increased baseline activity in the tonic mode facilitates searching for new sources of rewards (Aston-Jones & Cohen, 2005). However, these predictions have never been directly tested at the neural level. To test these predictions, we used Gq coupled designer receptors exclusively activated by designer drugs (DREADDs; hM3Dq) to stimulate tonic activity in LC neurons in rats performing a patch foraging task and an exploit-explore task. In the foraging task, rats lever press for rewards in a depleting patch, but can choose to incur a time cost to forage to a patch with replenished reward (foraging decision). We found that rats will stay in patches longer when they start with higher rewards, and they will stay in all patches longer when the time to forage to a new patch is increased. AGT predicts that stimulating LC tonic firing will cause rats to leave patches earlier. However, we found that DREADD stimulation of LC-NE neurons increases reaction time to make decisions, increasing the time animals spend in patches. In our exploit-explore task, rats play a series of games in which we examine how they decide between an option with known reward value and one whose value is ambiguous. We found that rats attribute an information bonus, an increase in the perceived value of the ambiguous option for the information gained from selecting that option, which is used to guide future decisions. Additionally, rats exhibit increased decision noise at the beginning of games. Increased decision noise reduces the influence of reward value on decisions, promoting sampling of all options, which also promotes learning the value of the ambiguous option. AGT predicts that stimulating LC tonically should increase decision noise. Tests of this idea are underway. Future studies will more precisely determine how LC influences foraging and exploit-explore decisions. Supported by PHS grants R01-MH092868, K99-MH104716.

Title: Effects of adolescent cannabinoid exposure on risk based decision-making in rats

Authors: *E. JACOBS-BRICHFORD, L. R. AMODEO, M. S. MCMURRAY, J. D. ROITMAN;
Univ. of Illinois At Chicago, Chicago, IL

Abstract: Adolescence is characterized by increases in risk-taking across a range of behaviors, including experimentation with alcohol and illicit drugs. Marijuana is the most widely used illicit drug among adolescents, and increased use coincides with a period of marked brain development, particularly in the prefrontal cortex (PFC). PFC is important for responding flexibly and adaptively to variations in environmental contingencies. Perturbations of PFC maturation can lead to impaired decision-making, resulting in increased impulsivity and excessive risk-taking. Of particular interest is medial prefrontal cortex (mPFC), which is continuing to develop throughout adolescence, and is thought to be crucial is shifting behavior as rewards become uncertain or less valuable. Marijuana use during adolescence may impair mPFC function, leading to increased preference for riskier rewards. In this study, we investigated the long-term effects of chronic adolescent cannabinoid exposure on risk based decision-making. 24 male and female Long Evans rats received i.p. injections of WIN 55, 212-2, a CB1 agonist, from postnatal day 30-60. Once animals reached adulthood, their risk-preference was measuring using a gambling task. Rats chose between two levers, one of which paid a small, certain reward, and the other paid a larger, probabilistic reward. The probability of receiving the large reward was varied randomly on each session, ranging from 12.5% to 67%. As rats performed this task, we used *in vivo* electrophysiology to record mPFC activity. Neural responses to cues and outcomes are compared across the range of risk-preferences between WIN-treated animals and controls.

Title: Comparison of neural representations between rat anterior insular and orbitofrontal cortex in risky decision making

Authors: ***H. ISHII**[1], Y. KAIZU[1], S. TAKAHASHI[1], S. OHARA[1], P. N. TOBLER[2], K.-I. TSUTSUI[1], T. IIJIMA[1];
[1]Div. of Sys. Neurosci., Tohoku Univ., Miyagi-Ken Sendai-Si, Japan; [2]Univ. of Zurich, Zurich, Switzerland

Abstract: We often puzzle over the choice of taking a risk for a higher gain or playing it safe and thereby avoiding a loss. Excessive risk taking can lead to ruin but, we never win races if we always avoid risks. How does the brain balance risk taking and avoiding? The two brain regions, the anterior insular cortex (AIC) and the orbitofrontal cortex (OFC), have been thought to play key roles in this risky decision making (Tobler et al, 2007; Burke et al, 2013). We previously reported that inactivation of the AIC decreased risk preference of the rats in a gambling task whereas inactivation of the OFC increased it (Ishii et al., 2012). These results suggest that the AIC promotes risk taking whereas the OFC suppresses it. They also imply the possibility that the relative strength of the AIC and the OFC activities are crucial for balancing the opposing motives of whether to take a risk or avoid it. To test this hypothesis, we have recorded neural activities of the AIC and the OFC during the performance of the gambling task which we had used in the previous study. The outline of the task is as follows. Water deprived rats were given two choices to get water. One was a sure option which guaranteed 2 drops of water. The other was a risky option which possibly provided 4 drops of water but in 50% (no water in the other 50%). These two options were associated with left and right levers respectively. Interestingly, the rats normally prefer the risky option in this task (Ishii et al., 2012; Ishii et al., 2014), and the rats used in the present study showed consistent preferences. To date, we have recorded single unit activities from 131 neurons in the AIC and 20 neurons in the OFC. Majority of the neurons (over 80%) showed related activities to any event of the task (lever press, outcome announcement, reward delivery, etc.). Among them, here we focus on the neural activities appeared just before the lever press which might relate to the choice of either the risky option or the sure option. We found that 11 AIC neurons showed larger increase in the firing rate for risky choices than for sure choices. These activities were possibly interpreted as risky choice selective, but before that, the following possibility should be excluded. These activities might reflect just subjective preference rather than purely selectivity for risky choice because behaviorally the rats preferred

the risky option under this choice condition (4/0 drops vs. 2 drops). However, these neurons showed similar selective activities for risky choice under the choice between 4/0 drops vs. 3 drops condition where the rats preferred the sure option. Thus, this type of AIC neuron is thought to be purely “risky choice selective”. A parallel study is going on also on the OFC.

Title: Action-dependent state prediction in mouse posterior parietal cortex during an auditory virtual navigation task

Authors: ***A. FUNAMIZU**, B. KUHN, K. DOYA;
Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Model-based decision making requires representation of predicted states that are updated by action-dependent state transition models. To investigate their neural implementation, mice were trained to do an auditory virtual navigation task and neuronal activity was recorded in the posterior parietal cortex (PPC) and its sensory upstream, the secondary visual cortex (V2), with the genetically encoded calcium indicator GCaMP6f after gene transfer by AAV2/1 and 2-photon microscopy. A mouse was head restrained and maneuvered a spherical treadmill. 12 speakers around the treadmill provided an auditory virtual environment. The direction and amplitude of sound pulses emulated the location of the sound source, which was moved according to the mouse’s locomotion on the treadmill. When the mouse reached the sound source and licked a spout, it got a water reward. The task consisted of two conditions: continuous condition in which the guiding sound was presented continuously and intermittent condition in which the sound was presented intermittently. In both conditions, mice increased lickings as they approached the sound source, indicating that mice recognized the sound-source position and predicted a reward. In intermittent condition, the anticipatory licking was increased even when the sound was omitted (Mann-Whitney U-test, $p = 4.87E-8$), suggesting that mice updated the

predicted sound-source position based on their own actions. We optically recorded calcium transients of up to 500 neurons simultaneously in each of layers 2, 3 and 5 in 8 mice. A subset of neurons increased the activities as mice approached the sound source (i.e., the goal). This increase of activities was observed both with and without sound inputs in all the layers of PPC (two-sided paired t-test, p = 0.0049 - 2.42E-11), while the increase was observed only during sound inputs in V2 (p = 0.679 - 0.0279). To test how the increase of activities in PPC and V2 contributed to the prediction of goal distance, we conducted a decoding analysis. Bayesian decoder predicted the goal distance from the recorded population activities: the decoder was trained with the data in continuous condition. In layers 3 and 5 of PPC, the predicted distance significantly decreased both with and without sound inputs (two-sided paired t-test, p = 2.54E-5 and 1.91E-5) consistently with the actual distance to the goal. In contrast, V2 required the sounds for updating distance predictions (p = 0.0752 and 0.0412). These results suggest that PPC, but not V2, realizes action-dependent state prediction in the absence of sensory input.

Title: Fasudil, a Rho-kinase inhibitor, transiently remodels prelimbic prefrontal cortical dendritic spines and enhances goal-directed decision-making

Authors: ***A. M. SWANSON**[1,2], S. L. GOURLEY[1,2];
[1]Pediatrics, Emory Univ., Atlanta, GA; [2]Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: An essential component of goal-directed decision-making is the ability to maintain flexible responding based on an expected reward. Doing so requires learning about, and consolidating, information regarding the predictive relationship between actions and their outcomes. Effective consolidation may require plasticity of cortical circuits, including the structural remodeling of dendritic spines. We investigated this hypothesis by inhibiting Rho-kinase, a key regulator of the actin cytoskeleton. First, we show that deep-layer prelimbic prefrontal cortical dendritic spine density *predicts decision-making strategies*, such that lower densities are associated with engagement in action-outcome response strategies, while higher densities are instead associated with stimulus-response habits, which are insensitive to action-outcome contingencies. Next, we show that pairing the Rho-kinase inhibitor fasudil with an opportunity to update knowledge regarding action-outcome relationships restores goal-directed decision-making in mice that have otherwise developed stimulus-response habits due to extensive response training. This "paired" fasudil delivery results in a transient pruning of prelimbic cortical dendritic spines, while fasudil delivered 4 hours after the event alters neither decision-making strategies nor prelimbic cortical dendritic spine density. These findings suggest that fasudil promotes the consolidation of action-outcome relationships by enhancing the plasticity of dendritic spines in the prelimbic cortex. We next asked whether dendritic spine plasticity is also associated with the consolidation of action-outcome relationships in typical, drug-naïve mice. We trained mice to develop either goal-directed or habitual response strategies, and brains were collected either during or after an opportunity to consolidate new information regarding action-outcome contingencies. Dendritic spines in deep-layer prelimbic cortex were enumerated. Together, our findings suggest that action-outcome decision-making is associated with dendritic spine plasticity in deep-layer prelimbic cortex and that enhancing this plasticity, *e.g.*, with fasudil, can augment the consolidation of information regarding the predictive relationship between actions and their outcomes.

Title: The role of orbitofrontal cortex in model-based planning in the rat

Authors: *K. J. MILLER[1], A. AKRAMI[2], M. BOTVINICK[2], C. BRODY[2,3];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ; [3]Howard Hughes Med. Inst., Princeton, NJ

Abstract: Imagine you are playing chess. As you think about your next move, you consider the outcome each possibility will have on the board, and the likely responses of your opponent. Your knowledge of the board and the rules constitutes an internal model of the chess game. Guiding your behavior on the basis of model-predicted outcomes of your actions is the very definition of cognitive planning. It has been known for many decades that humans and animals can plan (Tolman, 1948), but the neural mechanisms of planning remain largely unknown. Recently, a powerful new tool for the study of planning has become available: the "two-step" task introduced by Daw et al. (2011). This task allows, for the first time, the collection of multiple trials of planned behavior within a single experimental session, opening the door to many new experimental possibilities. We have adapted the two-step task for use with rodents, and developed a semi-automated pipeline to efficiently train large numbers of animals. Here, we show that the rodent two-step task reliably elicits planning behavior in rats, and we characterize the role of the orbitofrontal cortex (OFC) in this planning behavior. We find that inactivations of OFC substantially impair the ability to plan, and that single units in OFC encode planning-related variables, such as the values associated with actions taken at each step in the two-step task. These data demonstrate the OFC is crucial for planning, and begin to shed light on the computational role that it plays in the planning process.

Title: Nucleus accumbens core lesions decrease reward magnitude sensitivity in steady state impulsive choice

Authors: *S. EDMISTEN[1], J. R. PETERSON[2], M. CAMPA[2], K. KIRKPATRICK[2];
[2]Psychological Sci., [1]Kansas State Univ., Manhattan, KS

Abstract: Impulsive choice behavior involves choosing between a smaller reward that is available after a shorter delay versus a larger reward that is available after a longer delay. Delays or amounts of rewards can be manipulated across conditions to determine general patterns of preference for SS or LL options. A propensity to make impulsive choices has been linked with drug abuse, gambling, and Attention Deficit Hyperactivity Disorder (ADHD). The nucleus accumbens is believed to be critical in determining reward values that guide choice behavior. Research suggests that ADHD may be due to an overly responsive nucleus accumbens core (NAc). Our earlier work with NAc lesions indicated deficits in adjusting to increases in reward magnitude so that when reward magnitude increased, choice behavior did not change significantly. A recent study from our laboratory found that dynamic testing procedures resulted in more random and impulsive behavior. Previous lesion studies employed dynamic procedures which may have shown non-specific deficits in the lesion rats' behavior as a result of dealing with the changing magnitudes and delays. The present study investigated how the NAc influences impulsive choice behavior when using a steady state systematic procedure where opportunities to learn magnitudes and delays is maximized. We hypothesized that rats with NAc lesions should show deficits in adjusting to increases in LL magnitude in comparison to sham control rats if the NAc is critical for reward magnitude valuation. Two groups of rats underwent testing in an impulsive choice task after receiving an NAc neurotoxic lesion or sham surgery. This task exposed rats to a constant short delay (10 s) on the SS lever and a longer (30 s) constant delay on the LL lever. Rats received 1 pellet for choosing the SS in all phases whereas an LL choice resulted in a 1, 2, or 4 pellet reward across the phases. Rats were tested on each magnitude until stable behavior was reached to maximize opportunities for learning of the SS and LL delays and magnitudes. A second test was administered to examine the rats' overall ability to detect differences in reward magnitude using a reward sensitivity task. In this task, both the SS and LL delay utilized a variable interval 30 s schedule (range 1-59 s). An SS choice resulted in a 1 pellet reinforcer and the LL increased across days from 1- 4 pellets. Lesion rats showed reduced sensitivity to reward magnitude changes, failing to adapt choice behavior to increases in reward. These results indicate that lesion effects are general across dynamic and steady state tasks, suggesting that NAc lesions result in broad deficits in reward magnitude processing in impulsive choice.

Title: Short- and long-term effects of dietary manipulations on impulsive choice behavior and motivation in rats

Authors: *C. C. HILL, K. KIRKPATRICK;
Dept. of Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Research in humans suggests that there is a correlation between impulsivity and obesity; specifically, those with higher percent body fat tend to be more impulsive. However, human research is unable to disentangle the cause of greater impulsive choice in people with obesity. For example, obese individuals may make more impulsive decisions as a result of weight gain, impulsive individuals may be at a greater risk for obesity, or some other cause may result in the development of more impulsive behavior. To determine how diet may directly contribute to impulsive choice behavior, the present study manipulated dietary exposure in rats and tested the effects on impulsive choice and incentive motivation. Rats were divided into three groups (high-fat, high-sugar, and control) where diet composition differed, but energy budget remained the same by controlling for the number of calories each group received each day. The high-fat group received chow with a lard supplement, the high-sugar group received chow with a sugar-gelatin supplement, and the control group received all chow. All rats were then tested on a systematic steady state impulsive choice procedure, in which individuals were presented with a choice between a smaller reward available sooner (SS) or a larger reward available later (LL). The LL reward was 2 pellets available after 30 s across all phases. The SS reward was 1 pellet, and it was available after a delay that increased across phases, such that the SS reward was available after 5 s in phase 1, 10 s in phase 2, and 20 s in phase 3. After the impulsive choice task, rats completed a progressive ratio task to evaluate incentive motivation to work for food. Results on the initial impulsive choice task indicated that the high-sugar and high-fat group made significantly more impulsive choices than the control group. After completing the two tasks while on the diet, all rats completed the same tasks again while on an all chow diet. This allowed us to determine if the effects of diet on impulsive choice and motivation were long lasting, or if they reversed after switching to a more balanced diet. The results from this experiment suggest that diet, specifically a diet high in fat or sugar, induces impulsive choice, which may explain the relationship between impulsivity and obesity. These findings present a challenge for promoting healthy food choices, as the food being consumed may make it harder to make the more self-controlled choices that are needed for long-term weight management.

Title: Females in the forefront: the effects of a temporal intervention on impulsive choice in Sprague Dawley rats

Authors: *A. T. MARSHALL, S. L. STUEBING, A. TRIPLETT, K. KIRKPATRICK; Dept. of Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Impulsive choice behavior is widely studied in both psychological sciences and neuroscience to better understand the underlying mechanisms of maladaptive behaviors such as gambling, obesity, and addiction. Such experiments often utilize rat models to identify sources of individual differences in impulsive choice. Recent attempts at elucidating the primary mechanisms governing impulsive choice behavior have revealed that individual differences in temporal precision are a significant predictor of individual differences in impulsive choice. Moreover, time-based interventions significantly improve temporal precision and simultaneously reduce impulsive choices. The predominant use of male rats in this research highlights the wide gap in the literature regarding female decision-making behavior, and, as a result, the understanding of mechanisms of impulsive choice in females is limited. The goal of the present experiment was to assess individual differences in impulsive choice in female rats, and determine whether a time-based intervention would reduce impulsive choice, while also improving temporal precision similar to what has been found in male rats. Impulsive choice behavior was assessed through a smaller-sooner (SS) versus larger-later (LL) choice paradigm, in which SS choices resulted in 1 food pellet after 5, 10, and 20 s in successive phases, while LL choices always resulted in 2 food pellets after 30 s. Timing behavior was assessed through peak-procedure trials that were intermixed with free-choice trials. Impulsive choice and timing behavior were comparable to male Sprague Dawley rats from previous studies with these procedures conducted in our laboratory, with both measures affected by changes in SS delay. Half of the rats were then exposed to a temporal intervention which consisted of fixed interval 10- and 30-s schedules of reinforcement, while half of the rats were exposed to a control fixed ratio task. The rats were then re-exposed to the same impulsive choice task as before the intervention. Post-intervention impulsive choice was differentially affected by exposure to the intervention or control task. Overall, this study of female impulsive choice and exposure to

fixed-interval schedules of reinforcement within a temporal intervention aids in understanding the nature of female decision-making processes and suggests some comparable processes to male rats.

Title: Social dominance increases risky choice but not impulsive choice

Authors: ***J. R. LOTT**, C. DAVIS, J. R. PETERSON, K. KIRKPATRICK;
Kansas State Univ., Manhattan, KS

Abstract: Dominance is a component of social interactions where a dominant individual would have preferred access to an ideal mate, food source, and shelter. Research has shown a dominant/subordinate relationship forms between pair housed rats. Additionally, dominant rats have increased risky decision making, which is the preference for an uncertain larger (UL) reward over a certain smaller (CS) reward in testing. In humans, this translates into a higher incidence of maladaptive behaviors such as drug abuse, gambling, and obesity. However, whether or not impulsive choice is of higher incidence in dominant animals is unclear. Impulsive choice is the preference for a smaller sooner (SS) reward over a larger later (LL) reward. Impulsive choice is also an indicator for similar maladaptive behaviors to risky choice. Another important factor is whether dominance simply enhances the expression of innate behaviors, or if dominance causes those behaviors. The present study therefore sought to assess both risky and impulsive choice as a function of housing and dominance, and examined the effects of current and former housing conditions on choice behavior. The study was conducted in two main parts with different housing conditions. In the first part, half of the rats (n=12) were paired-housed and half (n=12) were singly-housed. All rats then underwent operant response tasks including an impulsive choice task, a risky choice task, and a progressive ratio task (progressively larger

response required for reward). During operant tasks, the rats were measured for dominance via a tube test and pinning behavior in their housing containers. The first part of the study showed no differences between single- and paired-housing conditions in either the impulsive or risky choice tasks. However, dominant rats in the paired housing conditions were significantly more sensitive to probability manipulations in the risky (UL) option and also showed a trend of higher overall risky (UL) choice but no difference in impulsive choice. In part two, the housing conditions were reversed and the same operant tasks and dominance measures were used. Between parts one and two of the study, the behavior of each rat did not change significantly. However, paired rats varied more in their risky and impulsive choice than single housed rats. These results suggest that dominance enhances the expression of innate risky behaviors in paired-housed rats. Variation in behavior caused by paired housing conditions could have potentially important implications for the assessment of individual differences under standard (pair-housed) conditions.

Title: Flexible use of predictive cues beyond the orbitofrontal cortex: role of the submedius thalamic nucleus

Authors: ***M. WOLFF, Dr**[1,2], F. ALCAZAR[2], A. R. MARCHAND[2], E. VIDAL[2], A. FAUGÈRE[2], E. COUTUREAU[2];
[1]CNRS UMR5287, Univ. of Bordeaux, INCIA, Bordeaux Cedex, France; [2]CNRS UMR5287, Univ. of Bordeaux, Bordeaux, France

Abstract: The orbitofrontal cortex (OFC) is known to play a crucial role in learning about specific event consequences. However, the contribution of OFC thalamic inputs to these processes is largely unknown. Using a tract-tracing approach, we first demonstrated that the submedius nucleus (Sub) shares extensive reciprocal connections with the OFC. We then compared the effects of excitotoxic lesions of the Sub or the OFC on the ability of rats to use outcome identity to direct responding. We found that neither OFC nor Sub lesions interfered with the basic differential outcomes effect. However, more specific tests revealed that OFC, but not Sub rats were disproportionally relying on the outcome, rather than on the discriminative

stimulus, to guide actions, which is consistent with the view that the OFC integrates information about predictive cues. In a final experiment using a Pavlovian contingency degradation procedure, we found that both OFC and Sub lesions produced a severe deficit in the ability to update Pavlovian associations. Altogether, the submedius therefore appears as a functionally relevant thalamic component in a circuit dedicated to the integration of predictive cues to guide behavior, previously conceived as essentially dependent on orbitofrontal functions.

Title: Thalamocortical control of goal-directed behaviors in rats

Authors: ***F. ALCARAZ**[1], A. R. MARCHAND[1], E. J. KREMER[2], E. COUTUREAU[1], M. WOLFF[1];
[1]CNRS UMR5287, Univ. of Bordeaux, Bordeaux Cedex, France; [2]CNRS UMR 5535, Univ. of Montpellier, Montpellier, France

Abstract: Survival of living organisms depends on the ability to flexibly select and engage in actions appropriate for their needs or desires. Such adaptive goal-directed behaviors are thought to be supported by distributed circuits encompassing the prefrontal cortex, the striatum, the basolateral amygdala and the limbic thalamus. Recent experimental data consistently indicated that functional interactions between the medial prefrontal cortex (mPFC) and the mediodorsal thalamus (MD) are crucial for these processes. In the present study we detail the anatomical connections between the two regions and provide an explicit functional assessment of this thalamocortical pathway in instrumental tasks. By combining the use of a retrograde viral vector carrying the cre recombinase (CAV-2 Cre) with that of an AAV providing cre-dependent expression of hM4di (inhibitory DREADD) receptor, we were able to reversibly inhibit the activity of MD neurons selected by their specific cortical projections to the mPFC. While this manipulation has no effect in an instrumental devaluation task, rats were unable to update action-outcome relationships during an instrumental degradation task. Altogether, these results suggest a possible differential involvement of thalamocortical and corticothalamic pathways: the former

appears to be necessary for the flexible use of action-outcome relationships while the later may control outcome value updating.

Title: Double dissociation in the role of the basolateral amygdala and the insular cortex in the acquisition and performance of goal-directed actions

Authors: *S. L. PARKES[1,2,3], G. FERREIRA[1,3], E. COUTUREAU[2,3];
[1]INRA, UMR 1286, Bordeaux, France; [2]CNRS, UMR 5287, Bordeaux, France; [3]Univ. de Bordeaux, Bordeaux, France

Abstract: Choice between goal-directed actions requires both knowledge of the relationship between actions and their consequences and the ability to compare those consequences on the basis of their current value. Recent evidence indicates that the basolateral amygdala (BLA) and the insular cortex (IC) play a critical role in goal-directed behavior, however the precise role of these regions in the acquisition versus performance of goal-directed actions remains unknown. Here, we used a pharmacogenetic approach, the DREADD (designer receptors exclusively activated by a designer drug), to inhibit neuronal activity in the BLA or the IC selectively during the acquisition or the performance of goal-directed actions. Rats first received stereotaxic injection of an adeno-associated virus expression system carrying the inhibitory hM4Di designer receptor (AAV8-CaMKIIa-hM4Di-mcherry) into either the BLA or the IC. Following recovery, rats were trained to press two levers for two distinct outcomes after which one of the outcomes was devalued by sensory specific satiety immediately prior to a choice extinction test. Rats were injected with either the hM4Di specific agonist clozapine-N-oxide (CNO; 1 mg/kg) or saline either before training or before the choice test. BLA inhibition prior to training, but not prior to test, abolished selective devaluation. In contrast, IC inhibition before test, but not prior to

training, disrupted outcome devaluation. These results suggest a double dissociation in the role of the BLA and the IC in the acquisition and performance of goal-directed actions. Specifically, the BLA, but not the IC, is required for learning specific action-outcome associations whereas the IC, but not the BLA, is necessary for the performance of goal-directed actions based on the current incentive value of their outcomes.

Title: Prefrontal dopamine D1 and D2 receptors regulate dissociable aspects of risk/reward decision-making via distinct ventral striatal and amygdalar circuits

Authors: *N. L. JENNI[1], J. D. LARKIN[1], S. B. FLORESCO[2];
[1]Psychology, [2]Psychology and Brain Res. Ctr., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: We routinely face decisions that require weighing the relative costs and benefits associated with different rewards in order to select better courses of action. Nodes within the mesocorticolimbic dopamine system interact in situations of reward uncertainty to guide risk/reward decisions. Work from our group has shown that D1/D2 receptor modulation within the medial prefrontal cortex (mPFC) increases or reduces preference for large/risky options in opposing ways. Recent work suggests that there are different populations of prefrontal neurons that exclusively express either the D1 or the D2 receptor subtype. Here, we investigated whether these distinct prefrontal D1 or D2 expressing neurons may differentially modulate risk/reward decisions, via distinct subcortical output pathways. Decision-making was assessed using a probabilistic discounting task. Rats were well-trained to choose between levers that delivered small/certain or large/uncertain rewards_the odds of which decreased systematically across 4 blocks of discrete-choice trials (100% -12.5%). We used asymmetrical unilateral infusions of a D1 or D2 antagonist the mPFC, in combination with a contralateral inactivation of the nucleus

accumbens (NAc) or basolateral amygdala (BLA) to selectively disrupt D1 or D2 modulation of PFC output to these regions. Selectively disrupting D1 modulation of PFC-NAc circuits (but not PFC-BLA projections) reduced preference for the large/risky option, that was driven primarily by a reduction in reward sensitivity, in that rats were less likely to follow receipt of a risky win with another risky choice. In contrast disrupting D2 modulation of PFC projections to the BLA (but not the NAc), increased preference for the large/risky option, driven by a reduction in negative feedback sensitivity, (i.e.; rats were less likely to shift to the small/certain lever following a non-rewarded risky choice). These findings suggest that PFC DA D1 and D2 receptors may modulate dissociable aspects of risk/reward decision-making via actions on separate populations of neurons that have distinct subcortical projection targets. mPFC D1 receptor activity modulates on ensembles projecting to the NAc that promote seeking for larger/uncertain rewards Activation of PFC D2 receptors modulates a separate ensemble projecting to the BLA that are sensitive to non-rewarded actions in order to mitigate biases for the large reward and facilitate flexible patterns of choice. These findings provide novel insight into the dopaminergic microcircuits within the mPFC that facilitate reward seeking and efficient decision making.

Title: Dissociable effects of nucleus accumbens and medial orbitofrontal cortex inactivation and dopaminergic manipulations on risk/reward decision making assessed with a novel “Blackjack” task

Authors: *D. R. MONTES[1], M. T. L. TSE[1], S. B. FLORESCO[2];
[1]Psychology, [2]Psychology and Brain Res. Ctr., Universtity of British Columbia, Vancouver, BC, Canada

Abstract: Studies with humans and animals have revealed different aspects of risk/reward decision making are mediated by distributed neural circuits that include the pre- and orbitofrontal cortex (OFC), the nucleus accumbens (NAc) and the dopamine system. Previous research from

our group has explored the contribution of these circuits using probabilistic discounting assays. In these tasks, the odds of obtaining a larger reward changes systematically over a session, and rats must keep track of changes in choice/outcome contingencies using internally-generated information to guide efficient decision making. However, real-life choice situations often are associated with external cues that provide some information about the relative likelihood of obtaining reward. For example, an experienced blackjack player knows that the risk of losing a hand is higher when the dealer is showing an “ace” compared to a “6” card. The present study developed a novel operant-based assay we refer to as the “Blackjack” task that models these types of situations. Rats were trained to choose between a small/certain option that always yielded 1 pellet and a large/risky option (4 pellets) delivered with different probabilities. Prior to a choice trial, one of two distinct tones were presented, each of which was associated with either a 12.5% (High Risk) or 50% (Low Risk) chance of obtaining the large/risky reward. An equal number of High and Low Risk trials were randomly interspersed over 40 trials. Under control conditions, well-trained rats selected the risky vs certain option more often (60-70%) on Low Risk trials compared to High Risk trials (30-40%). Reversible inactivation of the NAc shell increased risky choice; an effect that was more prominent on High Risk trials and was driven by a reduction in negative feedback sensitivity (ie- reduced lose-shift behavior). In contrast, preliminary data indicate that NAc core inactivation reduced risky choice on Low Risk trials. Inactivation of the medial OFC increased win-stay and lose shift behavior selectively on Low Risk trials, leading to reduced preference for the risky option on these trials. Systemic administration of the dopamine antagonist flupenthixol impaired decision making, increasing/decreasing risky choice on High and Low Risk trials, respectively, whereas amphetamine selectively increased risky choice on High Risk trials, increasing/decreasing win-stay/lose-shift behavior. Collectively, these data provide novel insight into the mechanism that mediate risk/reward judgements guided by external stimuli and suggest that this “Blackjack” task may be useful for investigating the neural bases of normal and abnormal decision making.

Title: Neural responses observed only in a gambling task in the rat anterior insular cortex

Authors: ***Y. KAIZU**[1], H. ISHII[1], S. TAKAHASHI[1], S. OHARA[1], P. N. TOBLER[2], K.-I. TSUTSUI[1], T. IIJIMA[1];

Abstract: We often puzzle over the choice of taking a risk for a higher gain or playing it safe and thereby avoiding a loss. Excessive risk taking can lead to ruin but we never win races if we always avoid risks. How does the brain regulate risk taking? We are focusing on the anterior insular cortex (AIC) as a key player which influences the risky decision making. We previously investigated the causal role of the AIC in risky decision making by using pharmacological inactivation on the rats (Ishii et al., 2012). In the study, water deprived rats were required to choose either a risky option which possibly provided 4 drops of water but in 50% (no water in the other 50%) or a sure option which guaranteed 2 drops of water. The rats normally prefer the risky option in this task. However, when the AIC was inactivated, the rats decreased their preference for the risky option and came to choose the sure option. From this result, it is concluded that intact AIC promotes risk taking. To reveal the AIC function more clearly we recorded single unit activities from the AIC during the performance of the same gambling task. Here we focus on the neural responses during the outcome delivery. In this task, the rats were noticed whether they got win or lost by presenting different sound before they got reward. We found that a subset of neuron increased the firing rate only when the sound indicating win was presented. Interestingly, these activities disappeared when the risky option was replaced to the sure option. Other subset of neuron responded only to the sound indicating loss. According to the results of the previous studies (Ishii et al., 2012, 2014), the following neuronal activities are expected to be recorded. Some AIC neurons might show the change in the firing rate at the decision period in the risky choice. Some AIC neurons at the waiting period might reflect win expectation/loss anxiety when the risky option was chosen. In the previous studies we found that the current decision is influenced by win/loss-experience in the previous risky choice (outcome history-dependent effect). So, the outcome related activities might influence the choice in the next trial.

Title: Acute and chronic effects of d-amphetamine on decision-making and loss sensitivity

Authors: *S. WONG[1], C. A. BADENHORST[2], A. BRIGGS[2], J. A. SAWADA[2], A. J. GRUBER[2];
[2]Neurosci., [1]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Repeated administration of psychostimulant drugs such as amphetamine reduces the ability of animals to learn from reward omission. In this study we examined the effect of both acute and chronic amphetamine administration on rapid choice adaptation following reward omission in rats during a competitive 2-choice task. Loss-driven choice adaptation is demonstrated by a so-called 'lose-switch' behaviour, in which animals tend to switch actions on trials following reward omission. We found that acute amphetamine injections immediately prior to the task significantly reduced lose-switch responding in a dose-dependent manner, which is consistent with the prevailing theory that brief pauses in dopaminergic tone signal negative reward prediction errors. In contrast, chronic amphetamine administration (3 weeks, escalating dose) followed by 10-day withdraw caused a significant increase in lose-switch responding, suggesting increased sensitivity to reward omission following repeated drug administration. Previous work in our lab (Skelin, 2014) revealed that the dorsolateral striatum (DLS) is critically involved in innate lose-switch behaviour. Other research (Jedynak, 2007) has demonstrated that repeated methamphetamine administration causes increased spine density in the DLS, and decreased spine density in the dorsomedial striatum (DMS). This may result in the DLS exerting greater control over choice behaviour, thereby increasing the expression of lose-switch behaviour. To further investigate the role of dopamine projections to the DLS in mediating lose-switch behaviour, we optogenetically stimulated neurons in the substantia nigra expressing tyrosine hydroxylase, and assayed the effects on lose-switch behaviour and dendritic morphology in the DLS. Together, these experiments demonstrate opposing effects of acute and chronic administration of amphetamine on loss sensitivity, and suggest a role for the dopaminergic innervations of the dorsolateral striatum in this behaviour.

Title: Neurochemical analysis of biogenic amine neurotransmitters and amino acids associated with countermanding task performance in rats

Authors: *J. BEUK[1], G. B. BAKER[4], R. J. BENINGER[2], M. PARÉ[3];
[1]Dept. of Biomed. and Mol. Sci., [2]Psychology & Psychiatry, [3]Biomed. and molecular sciences, Queen's Univ., Kingston, ON, Canada; [4]Psychiatry, Univ. of Alberta, Edmonton, AB, Canada

Abstract: The countermanding task measures inhibitory control by examining the ability to withhold a response to a go stimulus when a stop signal is presented occasionally. Male Wistar rats (N = 12) were trained to respond to a visual stimulus by pressing the lever below an illuminated light for food reward, but to countermand the lever press subsequent to a tone (stop signal) presented in 25% of trials after a variable delay. Modelling of task performance provides an estimate of the length of time needed to countermand responses, the stop signal response time (SSRT). Following countermanding testing, brains were extracted, flash frozen and stored until high performance liquid chromatography (HPLC) with electrochemical detection was conducted to determine levels of the monoamine neurotransmitters dopamine, norepinephrine and serotonin as well as their metabolites in frontal cortex and hippocampus. Levels of bioactive amino acids (alanine, arginine, aspartate, GABA, glutamate, glutamine, glycine, D-serine, L-serine and taurine) were determined using HPLC with fluorescence detection following derivatization. Preliminary observations suggest that some of these neurochemical measures predict inter-individual variability in task performance. In general, the levels of monoamines, as well as GABA, in the hippocampus were positively correlated with SSRT, i.e. the higher their levels, the poorer the inhibitory control. These findings pave the way to identify the contributions of neurotransmitter systems to inhibitory control. Acknowledgements: Supported by NSERC and CIHR.

Title: Ventral striatum is necessary for temporal specificity of expectations in dopaminergic reward prediction error signals

Authors: *A. LANGDON[1], Y. TAKAHASHI[2], G. SCHOENBAUM[2], Y. NIV[1];
[1]Princeton Univ., Princeton, NJ; [2]NIDA/NIH, Baltimore, MD

Abstract: Firing patterns of midbrain dopaminergic neurons are thought to encode errors in reward prediction and, as such, represent a key component in theories of the neural mechanisms of reward-based learning. Among various structures that project to the midbrain, the ventral striatum is often thought to provide the dopamine system with input that represents current reward predictions, and is sometimes conceptualized as a 'critic' that learns expected reward value given the environmental state. A recent study tested the role of the ventral striatum in modulating dopaminergic reward prediction signals by recording activity of putative dopaminergic neurons from the ventral tegmental area while rats with neurotoxic (or sham) lesions of the ipsilateral ventral striatum performed a simple odor-guided choice task [1]. The phasic firing of dopamine neurons in sham-lesioned rats was consistent with signaling a reward prediction error when the timing or size of rewards was altered across blocks of the task. In contrast, dopamine neurons recorded from the lesioned rats did not show the characteristic phasic prediction-error pattern when the timing of reward delivery was changed unexpectedly. Interestingly, the typical prediction-error response to changes in reward size was completely intact, suggesting a functional dissociation between predictions of timing and magnitude of reward. Here we present a model of temporal difference learning that explicitly incorporates temporal expectations in signaling reward predictions, and dissociates these from predictions of magnitude. In this model, temporal relationships between cues and rewards in a given state are learned concurrently with the expected value of that state. Importantly, temporal expectations regarding state duration are used to gate value-based prediction error signals, modulating learning according to the likely time of reward delivery. We model lesions of the ventral striatum as an inability to learn precise temporal expectations regarding reward delivery, and show how this critically changes state value estimation and thus reward prediction-error signals, mimicking the experimental results above. This model makes precise the role of temporal expectations in shaping reward prediction errors and suggests the ventral striatum is critical for forming and exploiting these temporal expectations during reward-based learning. Title: The role of Akt1 in the regulation of behavioral and electrophysiological responses in reward-based decision making in mice

Authors: ***C. CHEN**[1,2], Y.-W. LIU[2], W.-S. LAI[2,3,4];
[1]Psychology, Lab. of Integrated Neurosci. and Ethology, Taipei, Taiwan; [2]Psychology, [3]Grad. Inst. of Brain and Mind Sci., [4]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Accumulating evidence from human genetic studies and animal studies suggests the involvement of AKT1 in the pathogenesis of schizophrenia and reward prediction error. Recent findings from our lab and others also imply the importance of AKT1 in the regulation of dopamine-dependent behaviors, methamphetamine-induced behavioral sensitization, goal-directed behavior, decision making, and striatal neuronal activity, especially in Akt1-deficient mice. To further investigate the role of Akt1 in the regulation of probabilistic reward-based decision making, male Akt1 heterozygous (Het) mutant mice and their wild-type (WT) littermate controls were used in this study. Both Het and WT mice were trained to learn Pavlovian-conditioned pairing and a 2-choice dynamic foraging task with different reward probability. During the Pavlovian-conditioned pairing, our behavioral data revealed that there is no genotypic difference in their sign-tracking or goal-tracking behavior. However, in the 2-choice dynamic foraging task, Het mice took fewer trials to steady choose high reward choice compared with WT controls. Their trial-by-trial choice behaviors were further analyzed to elaborate parameters for

reinforcement learning. Compared with WT controls, our model-fitting data revealed that Het mice have a higher learning rate but a lower choice perseveration. Based upon these findings, *in vivo* local field potential recording from the dorsomedial striatum was conducted in these mice during different stages of decision making process in the dynamic foraging task. Our preliminary data revealed a genotypic difference in the power spectrum density (dB) of local field potential during baseline. Data collection and analyses are still in progress. Findings from this study can enhance our understanding of the role of Akt1 in reward-based decision making and its involvement in the pathogenesis of schizophrenia.

Title: Activity encoding spatial working memory in macaque frontal cortex is highly structured, yet incompatible with current attractor network models

Authors: ***C. D. HOLMES**, C. PAPADIMITRIOU, L. H. SNYDER;
Dept. of Anat. and Neurobio., Washington Univ. In St Louis, Saint Louis, MO

Abstract: Working memory, the ability to maintain and transform information, is critical for cognition. Neuronal activity in dorsolateral prefrontal cortex (dlPFC) and frontal eye fields (FEF) is elevated while monkeys hold a spatial location in memory for 1-3 s (Bruce and Goldberg, 1985; Funahashi et al. 1989). The premier model for spatial memory is the continuous attractor network (Wang, 2009). Memoranda are represented as localized "bumps" of activity in a topographic map of nodes. Due to a balance between local excitatory and global inhibitory recurrent feedback, the bumps are maintained indefinitely, even after the original stimulus is removed. The amplitude and profile of the bump does not change over time, although random drift leads to inaccuracy that tends to increase with time. Other studies have argued for more complex dynamics in memory activity. For example, single cell responses may ramp up or down over the memory period, or turn on for only a limited time within the memory period. These results have inspired alternatives to the attractor model. We recorded 161 neurons in dlPFC and FEF as monkeys held spatial memories for up to 15 s. Single cells were carefully isolated and

optimally driven, using a continuous distribution of targets. Cells with significant memory activity became tuned early (within 1 or 2 s) and most (80%) lost their tuning (turned off) before the end of the 15 s memory period. Across trials and cells, the time at which cells lost their tuning was exponentially distributed. Surprisingly, however, each cell had a relatively fixed turn-off time. Once off, cells did not turn back on. These results are not compatible with most previous models of memory. While our results are quite novel, they nonetheless replicate the main findings of earlier work that tested memory for only a few seconds. Like the earlier studies, we find that many cells are continuously active during the first two seconds of memory, with activity in some cells ramping up and others ramping down. Transient activations, multiple on/off cycles, and other complex dynamics similar to those reported previously also appear in our data, but only when non-optimal stimuli are used. These complex dynamics do not reflect the operation of memory circuits. Instead, they reflect noisy responses from the flanks of the tuning curves. In summary, most memory cells turn on early in the memory period, stay active for a variable but cell-specific amount of time, then shut off and stay off for the remainder of the memory period. These findings challenge the attractor network model of working memory, but also show that memory responses are much more structured than suggested by competing heterogeneous models.

Title: Involvement of medial prefrontal neurons during the decision process in an audiovisual working memory task

Authors: *B. PLAKKE, L. M. ROMANSKI;
Dept. of Neurobio. & Anat., Univ. of Rochester Sch. of Med., Rochester, NY

Abstract: The medial prefrontal cortex (mPFC) is involved in detecting conflict, decision-making, audio-vocal control and motor processing. It also receives input from temporal lobe

auditory and multisensory regions, however few studies have examined its response to naturalistic auditory or audiovisual stimuli. Our previous work has shown that ventrolateral prefrontal cortex (VLPFC) integrates face and vocal information and is necessary for audiovisual working memory. Here, we asked whether mPFC might also play a role in audiovisual processing. We recorded from mPFC in macaques while they performed an audiovisual nonmatch-to-sample task. Subjects attended an audiovisual movie clip of a face-vocalization as the Sample and detected the occurrence of a Nonmatch (when the face or vocalization differed from the Sample movie). Preliminary data showed mPFC cells are active during several task epochs including the sample (55%), the delay (65%), the match (41%) and the nonmatch (32%) period. In contrast to previous findings from VLPFC, a larger percentage of units were responsive during the Match, when the animal correctly withheld a response. Additionally, there was a subset of neurons active during the correct detection of both Nonmatch and Match stimuli, indicative of decision related activity. These decision related units were more commonly found in mPFC compared to previous results from VLPFC. This data suggests that both VLPFC and mPFC are part of a neuronal circuit underlying audiovisual working memory in the primate brain.

Title: Transient synchronizations and cross-frequency interactions between prefrontal cortex and striatum underlie category learning

Authors: *R. LOONIS[1,2], E. G. ANTZOULATOS[3], S. L. BRINCAT[1], E. K. MILLER[1]; [1]The Picower Inst. for Learning and Memory and Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Dept. of Anat. and Neurobio., Boston Univ., Boston, MA; [3]Ctr. for Neuroscience, Dept. of Neurobiology, Physiology, and Behavior, Univ. of California, Davis, CA

Abstract: There is emerging evidence that oscillatory synchrony plays a role in learning. Thus, we examined oscillations in two areas known to be important for category learning, the prefrontal cortex (PFC) and striatum (STR; Antzoulatos and Miller, 2011 and 2014). Two monkeys were trained, on each day, to classify dot patterns into two categories. Brincat and Miller (2015) reported frequency-specific interactions between the PFC and hippocampus (HIPP) during object associative learning. They found an increase in post-decision beta synchrony (12-30 Hz) if the monkey's choice was correct and an increase in theta (3-7 Hz) if the choice was incorrect. Similarly, we found increased synchrony between the PFC and STR during category learning but the opposite pattern from that seen between the PFC and HIPP. Beta band synchrony increased after an incorrect choice and theta band synchrony increased after a correct choice. This could reflect a difference between areas or between types of learning (associative vs category). Furthermore, post-decision PFC-STR synchrony in the beta band waxed and waned periodically and was correlated with theta-band evoked potentials in the PFC and STR. This correlation between the PFC-STR synchrony and theta band evoked potentials dissipated over learning. Moreover, during learning, the phase of PFC theta signals modulated the amplitude of gamma (30-50 Hz) activity in the STR. These data suggest that rhythmic interactions between the PFC and STR play a role in category learning.

Title: Oscillatory synchrony and working memory updating in the monkey cortex

Authors: *C. DEVIA[1,2], J. ROSE[1,2], E. K. MILLER[1,2];
[1]Picower Inst. for Learning and Memory, [2]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Volitional control of what is maintained is a defining characteristic of working memory (WM), but little is known of its neural basis. To study this, we recorded local field potentials (LFPs) from parietal (LIP) and prefrontal cortex (LPFC and OFC) while subjects performed a value-based working memory task. The monkeys were motivated to retain high-value targets at the expense of low-value targets. On each trial, two targets were presented in sequence at two of four possible locations. Each target was followed by a reward cue that signified the value of that target (juice amount). On some (RETAIN) trials a high target value was followed by a low value target, thus motivating monkeys to retain the first target. On other (UPDATE) trials, the low value target appeared before a high value target, thus motivating monkeys to update the working memory with the second, higher-value target. At the trial's end, monkey made a saccade to either target location, for which they received that amount of juice. We compared LFPs power and phase synchrony on RETAIN vs UPDATE trials during the presentation of the second cue. The LIP showed broadband activity, with significantly more power only for UPDATE trials. These episodes of high power spanned from alpha to low gamma band (8-51 Hz). In frontal areas, only low frequencies had significant modulation (2-33 Hz). The LPFC had more power in beta band for UPDATE trials and in delta/theta for RETAIN. We observed the opposite relation for OFC, with significant augmented power in theta range for UPDATE trials and more beta activity for RETAIN. Synchrony between parietal and frontal areas increased, but only for UPDATE trials. The three regions showed increased between-area synchrony in beta and gamma and LIP and frontal areas showed increased lower frequency (2-30 Hz) synchrony for UPDATEs. This suggests that oscillatory activity is involved in both updating and protecting (retaining) WM. The LIP is more involved in updating. The prefrontal cortex is engaged for both updating and retaining WM contents.

Title: Temporal fine-structure of activity in PFC of macaque during in multi-item working memory

Authors: *M. LUNDQVIST[1], J. ROSE[1], P. HERMAN[2], S. L. BRINCAT[1], T. J. BUSCHMAN[1], E. K. MILLER[1];

Abstract: Prefrontal cortex (PFC) neural activity is thought to underlie the maintenance of information in working memory (WM). This activity is often assumed to be more or less continuous, but a sub-class of WM models suggests that the activity occur in discrete bursts. Here, we analyze data from PFC of macaque monkeys performing a multi-item WM task in which items are presented serially to test these assumptions. Neuron spiking as well as LFPs were analyzed. We found stimulus-load related changes in beta (20-37 Hz) and gamma (55-90 Hz) band power in the trial-averaged spectral content. A detailed analysis of the time-frequency spectral content of individual trials suggested a complex dynamic with discrete “bubbles” of elevated gamma or beta power, well defined in frequency and time. These gamma and beta bubbles lasted on the order of 50-300 ms and occurred seemingly at random points during individual trials, but gamma bubbles were predominant during stimulus encoding. By contrast, beta bubbles were more likely during the memory delays. Also, gamma bubbles increased around the time monkeys anticipated having to use the contents of WM and thus may also be important for decoding information from WM. Neuron spiking tended to occur within the gamma bubbles, but the gamma bubbles were not explained by spiking per se because individual bubbles were narrow in frequency range. Thus, spikes seemed to ride on top of gamma bubbles consistent with the view that they reflect brief moments of elevated rhythmic firing in local cell assemblies. These results differ from a standard view of WM in which neurons simply sustain their activity. They support models in which information is stored in WM in discrete bursts of rhythmic firing allowing maintenance of multiple items without interference between them or from sensory processing (Lundqvist et al., 2011). Lundqvist M, Herman P, Lansner A (2011) Theta and gamma power increases and alpha/beta power decreases with memory load in an attractor network model. Title: Prefrontal coding shifts from perception to memory recall during learning

Authors: *S. L. BRINCAT, E. K. MILLER;
The Picower Inst. for Learning and Memory and Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: How do neural networks support both bottom-up processing of perceptual inputs and top-down recall of perceptual memories? We simultaneously sampled spiking and local field potential (LFP) activity from the lateral prefrontal cortex (PFC) and hippocampus of monkeys performing an object paired-associate learning task. On each trial, a sequence of two unrelated objects was shown, separated by a brief delay. The monkeys' task was to learn through trial-and-error which objects were arbitrarily designated as associative pairs. Each day, they learned four novel associations within a few hundred trials. PFC spiking activity conveyed both perceptual information about the objects, as well as mnemonic information reflecting anticipatory recall of the expected paired-associate. This mnemonic information increased in parallel with learning, along with a concomitant decrease in perceptual information. Thus, the PFC shifted from emphasizing bottom-up perception to top-down recall. Task performance was also accompanied by prominent beta-band (~12-25 Hz) LFP oscillations, with distinct components tightly locked to object onsets (evoked potentials) and not phase-locked to trial events. Beta-band evoked potentials--likely reflecting bottom-up input--decreased with learning. In contrast, non-phase-locked beta oscillations--likely reflecting local or top-down processes--increased both in their power and in their strength of synchronization with the hippocampus. These results suggest that prefrontal cortex plays a role in both bottom-up perceptual and top-down mnemonic processes. As associative memories are successfully formed, PFC and associated networks appear to switch from a perception-dominated mode to a memory-dominated one.

Title: Hippocampal neural activity during a delay-based decision-making task

Authors: ***A. MASUDA**, S. FUJISAWA, S. ITOHARA;
RIKEN Brain Sci. Inst. - Wako, Wako-Shi, Saitama, Japan

Abstract: Impulsivity, the tendency to make decisions and/or take action rapidly without long-term foresight, is typically associated with attention-deficit hyperactivity disorder and various forms of drug addiction. Top-down cognitive control mediated by prefrontal cortical interactions with limbic structures, including the hippocampus, is hypothesized to regulate impulsivity. Hippocampal neurons fire during the delay in delayed-non-match-to-sample tests or other working memory tasks in monkeys and rodents. This neuronal activity is interpreted to be a mechanism for working memory to hold information for a certain amount of time. It is not clear, however, if the hippocampal neurons encode information for delay discounting of reward values, involved in impulsivity. Using silicon probes with multichannel electrodes, we recorded neural activity in the CA1 region of mice performing a delay-based decision-making task in a T-maze. Large and small rewards were allocated to each side arm with or without a delay, respectively. The delay duration in the large-reward arm was varied (0 - 40 s) in each session. The choice ratio to the large reward-delayed arm was negatively correlated with the delay duration. Local field potentials during the delay were characterized by strong theta oscillations and a lack of sharp-wave/ripples, unlike local field potentials observed during delays in working memory tasks. Sizable numbers of CA1 neurons exhibited significant increases (30% of the population) and decreases (50%) in their firing rates during long (>20 s) delay periods. Importantly, 40% of the delay-activated neurons exhibited significantly increased firing rates as a function of delay length, indicating that these neurons encode information of the duration the mice must wait during the trial. To investigate the location-selectivity of these delay-activated neurons, we switched the large reward-delayed arm with the small reward-non-delayed arm, and found that 80% of the delay-activated neurons had location selectivity and 20% had no location selectivity, indicating that some population of hippocampal neurons encodes waiting times independent of spatial information. These findings suggest that the hippocampus senses a delay and encodes the information required for delay discounting of reward values.

Title: Computation of reward prediction error by projections from medial striatum to midbrain dopaminergic neurons in domestic chicks

Authors: ***C. WEN**[1], T. MATSUSHIMA[2];
[1]Hokkaido Univ., Sapporo, Hokkaido, Japan; [2]Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Midbrain dopaminergic (DA) neurons have been supposed to represent the reward prediction error (RPE) signal, a critical variable in the paradigm of reward-dependent reinforcement learning (Schultz et al. 1991; Roesch et al. 2007; Cohen et al. 2012), but the neuronal mechanisms underlying its computation are not fully understood. Medial striatum (MSt, homologous to the ventral striatum in mammals) may be critically involved, as (1) it has reciprocal connections with DA neurons (Bálint et al. 2004, 2011), and (2) its lesion impairs both acquisition and extinction in food-reinforced associative learning (Izawa et al. 2001, Ichikawa et al. 2004). The following lines of evidence further support the assumed involvements. First, some MSt neurons code the actual reward, whereas other MSt neurons code the reward prediction even in the reward period. Week-old chicks were trained in color discrimination task reinforced by food reward, in which LED colors were associated with foods of different amount and delay. After chicks had been successfully trained, we compared the single unit activities between two conditions. In control condition, chicks received food as trained (therefore, as predicted). In the following omission block, the food was omitted for one of the reinforced LED colors leading to a negative prediction error. MSt neurons were categorized to 2 groups, one with excitation and the other with inhibition during the reward period. Majority of the former (excitation-type neurons, 9/11) stopped firing immediately after the omission. On the other hand, more than half of the latter (inhibition-type neurons, 3/4) maintained inhibition after the omission. In contrast, as the second line of the evidence, considerable proportion of neurons in the midbrain tegmentum coded the negative RPE in reward extinction. The reward-period activity was lower in the omission block, if compared with the activities in the no-reward-predicting trials. These neurons were located in/near the tegmental regions rich in DA neurons. As the third line, MSt neurons proved to have direct synaptic contacts with DA neurons. Anterograde tracing using biotinylated dextran amine revealed terminal boutons juxtaposed on soma and proximal dendrites of the tyrosine hydroxylase immunopositive neurons in the tegmentum. We can reasonably assume a scenario that (1) parallel descending projections from MSt convey both of the reward prediction and the actual reward signal, and (2) summation of these signals yields RPE in DA neurons through direct synaptic convergence. Further *in vitro* slice studies are needed to characterize how synaptic actions are integrated in DA neurons.

Title: Monkeys (Macaca mulatta) represent magnitude with flexible spatial mappings

Authors: ***R. F. L. DIAMOND**[1,2], R. P. GAZES[3], R. R. HAMPTON[1,2];
[1]Psychology, Emory Univ., Atlanta, GA; [2]Yerkes Natl. Primate Res. Ctr., Atlanta, GA;
[3]Bucknell Univ., Lewisberg, PA

Abstract: Humans often activate a mental representation of a number line when performing quantitative tasks. This is illustrated in the spatial numerical association of response codes (SNARC) paradigm in which people report whether a sample number is odd or even (Dehaene, Bossini, & Giraux, 1993). Western humans respond more quickly on the left when the number is small and on the right when the number is large. This indicates that responding is facilitated when the response is congruent with the mental number line even though no explicit magnitude processing is required. The polarity of the mental number line is determined by experience reading and counting. This is indicated by the fact that Palestinians, who read and count from right to left, show a pattern opposite that seen in most Westerners, responding faster on the right for small quantities and left for large quantities (Shaki, Fischer, & Petrusic, 2009). The capacity to represent both space and quantity is available to many species, so we might expect similar space-magnitude interactions in nonhuman primates (Adachi, 2015; Rugani, 2015). Monkeys and humans share homologous brain regions implicated in both the processing of space and magnitude. Neurons in the nonhuman primate ventral intraparietal area (VIP) of the intraparietal sulcus, respond selectively to presentations of numerosities (Nieder & Miller, 2004). Single cell recordings from the VIP in macaques have also shown that neurons in this area respond to spatial cognition (for a review see Grefkes & Fink, 2005). The intraparietal sulcus has also been implicated in both spatial and numerical cognition in humans (Hubbard et al., 2005). To determine whether spatial representations are involved in quantity processing across species, we tested for SNARC phenomena in monkeys. Monkeys matched the color of sample arrays of 1 to

10 dots to color comparison stimuli on the bottom left and right sides of a computer-controlled touchscreen. After being trained to associate small magnitude stimuli with left side responses and large magnitude stimuli with right side responses, monkeys were more accurate in color matching when responding on the left after seeing a small number of colored dots and when responding on the right after seeing a large number of colored dots. This occurred even though the number of dots was irrelevant to the task. The effect reversed twice after monkeys were trained in the opposite spatial association. These results are consistent with a flexible spatial representation of magnitude in monkeys.

Title: Two types of representations for numerosity ‘zero’ in the Parietal Cortex of the Monkey

Authors: ***S. OKUYAMA**[1], H. MUSHIAKE[2];
[1]Neurosurg., Southern Tohoku Gen. Hosp., Iwanuma, Miyagi, Japan; [2]Dept. of physiology, Tohoku Univ. Sch. of Med., Sendai, Japan

Abstract: Zero is a fundamental concept in mathematics and modern science. Mathematical history suggests that before the development of the notation system of zero, humans seemed to recognize the concept of zero without a symbol. Recent reports showed that preschool children and non-human primates could distinguish empty objects from existing objects. Therefore, the concept of zero seems to be non-verbal as well as non-zero numerosities. How is numerosity zero (the absence of visual items) represented in the primate cortex? To address this question, we trained two monkeys to perform a numerical operation task including numerosity zero. The monkeys were required to convert a preoperational number of visual objects into a target number of visual objects by numerical operations (addition or subtraction). Behavioral results showed that the monkeys’ success rates linearly declined (linear regression, $r2 = 0.97$, $P < 0.01$) as a function of the target numerosity including numerosity zero. We recorded 614 cells in the VIP of a monkey performing the task. In the VIP, cellular activity selective to the target numerosity 0-4 was found in 185 neurons (30%) during the presentation of the target numerosity. Among these,

137 neurons showed differential activities to numerosity zero (‘zero’ neuron) (target period, 99/614, 16%). We found two types of ‘zero’ neurons in the VIP exhibit changes in activity during the presentation of the target numerosity of zero. The first type of ‘zero’ neurons (66/614, 11%) exclusively represented numerosity zero in absence or presence manner. The second type of ‘zero’ neurons (31/614, 5%) encodes numerosity zero and non-zero numerosity continuously (decreased activities as a function of target numerosities). Our findings suggest that numerosity zero could be coded parametrically as an extension of non-zero numerosities on the same numerical continuum (i.e., 0, 1, 2, 3, ...) and exclusively as nothingness of counting objects (i.e., absence or presence).Representations of numerosity zero in the parietal cortex may be a precursor of non-verbal concept of zero in primates.

Title: Medial prefrontal cortex supports reversal learning by facfacilitating shifting amongst competing attractor states in the hippocampus

Authors: *K. G. GUISE[1], M. L. SHAPIRO[2];
[1]Neurosci., Mount Sinai Sch. of Med., New York, NY; [2]Neurosci., Ichan Sch. of Med. at Mount Sinai, New York, NY

Abstract: Episodic memories reflect the past and inform future behavior. Although these representations can be activated by environmental cues, sensory information alone is often not enough to unambiguously retrieve specific memories. We examined how interactions between the medial prefrontal cortex (mPFC) and the hippocampus contribute to selective memory retrieval as rats learned rapid serial spatial reversals on a plus maze. We found that the mPFC is crucial for disambiguating recent memories, but with an unexpected time course: mPFC activity was necessary during current learning to reduce interference with future learning, but not during

current learning to reduce interference from recent memories. Simultaneous recordings from the mPFC and hippocampus during reversal learning revealed that while population activity of both mPFC and CA1 discriminate goal states, the trajectory of the mPFC representation during reversal learning tends to lead and predict the trajectory of the CA1 representation. CA1 unit recordings in ipsilateral mPFC-inactivated animals showed that the goal representation in CA1 was less distinct across initial learning and reversals and that transitions between states were slower. Taken together, the data suggest that rule representations from the mPFC may be convolved with hippocampal representations in order to help discriminate amongst multiple, recently activated memories; when these discriminators are missing across multiple learning epochs, proactive interference builds up and deficits in reversal learning begin to emerge.

Title: Neural activity of monkey prefrontal and posterior parietal cortex during foraging for multiple targe

Authors: ***M. KADOHISA**[1,2], K. WATANABE[1,3], M. KUSUNOKI[1,2], M. J. BUCKLEY[1], J. DUNCAN[1,2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Cognition and Brain Sci. Unit, MRC, Cambridge, United Kingdom; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: The prefrontal cortex (PFC) and posterior parietal cortex (PPC) which are reciprocally connected have been reported to show similar neuronal activity patterns while monkeys perform a memory-guided task. To address roles of the PFC and PPC in working memory for multiple concurrent targets, monkeys were trained with spatial and object foraging tasks in which animals explored a choice array searching for targets and remembered them once found. The target was defined by the location within a 5-choice array in the spatial foraging task, and by the object identity within a 4-choice array in the object foraging task. A choice array was presented on a

touch panel with a central fixation point (FP). Each trial started when the animal held a home key and fixated the FP for 700-1500ms (pre-choice period), then the animal released the home key and touched one of the choice locations /objects when FP changed in color (response period). After 350- 450ms of touch-hold period, the color of the selected choice location/object changed to green or red, revealing that location/object was a target or non-target, respectively (feedback period). When a target was selected, a drop of soft food was given as a reward (reward period). The number of targets was one or two and trials were repeated until the animal had touched all the target locations/objects, then a cycle of foraging trials ended. Cycles with the same targets were repeated four times to form a set of cycles, so that targets searched for targets by trial and error in the first cycle (acquisition phase), then exploited this knowledge in subsequent cycles (retention phase). In the acquisition phase, the animals searched targets efficiently with few repeated touches on the same locations/objects. In the retention phase, the animals' performance improved quickly with almost no error touches in the later cycles. While animals performed the foraging task, we recorded single unit activity in the PFC and PPC. We found many neurons in both PFC and PPC showing selectivity for the chosen location/object in the response period. A smaller number of neurons in both areas showed selectivity in the pre-choice period. In the feedback period, both PPC and PFC also strongly encoded the chosen location/object identity. In addition, the neuronal activity in this period was modulated by the phase, with some neurons more activated in the acquisition phase and others in the retention phase. The results suggest collaboration of PFC and PPC in successive stages of complex, multi-step behavior, including learning from feedback during initial exploration, and use of this knowledge in later exploitation.

Title: Cytoarchitectonic information of rat medial prefrontal “delay” neurons revealed by single-neuron electroporation

Authors: ***K. OYAMA**[1], Y. TATEYAMA[1], C. LO[1], S. OHARA[1], F. KARUBE[2], F. FUJIYAMA[2], T. IIJIMA[1], K.-I. TSUTSUI[1];
[1]Grad. Schl. of Life Sci., Tohoku Univ., Sendai, Japan; [2]Lab. of Neural Circuitry, Doshisha Univ. Grad. Schl. of Brain Sci., Kizugawa, Japan

Abstract: We have recently established a novel technique for labeling single neurons persistently without microscopic guidance by injecting a plasmid encoding a fluorescent protein electroporatively after recording their activity extracellularly with a glass-pipette electrode. This technique enables us to clarify the cytoarchitectonic information of electrophysiologically recorded neurons, such as cell type, laminar distribution, and projection sites. In this study, we investigated the cytoarchitectonic information of rat medial prefrontal cortex (mPFC) neurons which showed the sustained activity during a delay period in a delayed response task, which is thought to be the neural correlate of the working memory, by using this technique. We trained head-fixed rats to perform a visuo-spatial delayed response task. In this task, a visual stimulus (illumination of a LED) was presented at either left or right side of the head of the rat, and the rat was required to lick one of the two spouts at the visually instructed direction after 2 s of a delay period. After they learned the task, we recorded single-unit activity in the rat mPFC during the performance of this task. We found that some mPFC neurons showed sustained activity during the delay period. Immediately after the recording, we switched the connection to the electrode from an amplifier to a stimulation isolator, and injected the plasmid encoding fluorescent protein included within the glass-pipette electrode into the recorded cell by applying a negative voltage pulse train (0.5-ms-long square pulses with an amplitude of −10 V, 50 delivered at 50 Hz). By histological inspection following the recording experiments, we could observe that some neurons were clearly stained with the fluorescent protein, and identify the cytoarchitectonic information of those neurons. We found that stained neurons were mainly pyramidal neurons and that they were distributed both in the superficial and deep layers of the mPFC. We could also trace the axonal projections of some neurons. We found that some neurons in the layer II/III projected to adjacent brain regions (M2 cortex and prelimbic cortex), and some neurons in the layer V projected to the dorsomedial part of the striatum. These results suggest that pyramidal neurons located in various layers in the rat mPFC are involved in the working memory, and support the idea that the delay activity is maintained through the cortico-cortical network and cortico-basal ganglia loop.

Title: New insight on neural substrate at single unit level of behavioral task learning from emerging neural activity patterns

Authors: ***J. SI**, W. MA;
Arizona State Univ., Tempe, AZ

Abstract: The goal of this study is to discover the evolution of dynamic single unit based neural activity patterns as task learning takes place. Toward this goal, 1) we collected frontal cortical single unit firing activity from rat medial agranular (AGm) and lateral agranular (AGl) areas while rats performed a direction-cued lever press learning task; 2) we developed a new, automatic, expectation-maximization (EM)-based analysis tool to let neural activity data self-organize and form automatic clusters according to similarities among neural activity patterns. The algorithm, referred to as the automatic and robust EM or AREM, allowed us to capture latent features within the neural activity data automatically and according to objective measures as task learning proceeded. The learning task required rats to associate a left/right side light cue with a respective side lever press. The rats had 2 seconds to choose between a left or a right side lever after the directional cue presentation. It usually took rats 20-30 sessions (days) to learn the task from chancel level accuracy to about or above 85% accuracy. We used 16-channel single unit extracellular recording systems to acquire rat neural activity. For all 4 rats analyzed in this study, 4-5 channels from each rat (totaling 19 channels for 4 rats) consistently carried single unit neural action potentials throughout the learning process and therefore were used in this analysis. A single neuron was first sorted and labeled. Its activity during an initial sub-interval (0.8 s) of the cue-on period (2 s) was binned (40 ms bin) to form a vector for each trial. Single session based trials were then pooled together to form the “session dataset”, which were automatically placed into 2-3 clusters. We analyzed the compositions of each cluster through learning. We discovered the following. 1) During initial task learning, all 4 rats encoded previous trial outcome (success or failure). 2) As learning progressed, a dominant cluster emerged, which encoded more strongly the error/success factor than the direction cue/press factor ($p<0.05$). The other cluster(s) shrank to reach a steady state not significantly and consistently encoding post error/success factor. Rat A was an exception who actually was not able to solve the learning task. Only recently have some researchers started to address how trial outcomes may be encoded in single neurons in relation to future actions during learning. This study is the first time to directly capture and quantify the emerging single unit neural activity pattern in relation to the important

previous trial outcome factor. This may serve as the first step toward gaining insight on neural mechanism of learning behavior.

Title: CPEB2 regulates hippocampus-related long-term synaptic plasticity and memory

Authors: W.-H. LU[1,2,3], *C.-T. CHIEN[4], Y.-S. HUANG[1,2,3];
[1]Inst. of Biomed. Science, Academia Sinica, Taipei, Taiwan; [2]Inst. of Biochem. and Mol. Biology, Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Taiwan Intl. Grad. Program in Mol. Medicine, Natl. Yang-Ming Univ. and Academia Sinica, Taipei, Taiwan; [4]Academia Sinica, Inst. of Mol. Biol., Taipei, Taiwan

Abstract: Activity-dependent de novo protein synthesis in either axons and/or synapto-dendritic compartments is necessary to sustain long-lasting modification of synapses and consequently support long-term memory. Cytoplasmic polyadenylation element binding protein 2 (CPEB2) is a translational regulator and widely expressed in the central nervous system, so we examine whether CPEB2-controlled translation is important for learning and memory. Because of respiratory distress-associated neonatal lethality in CPEB2 knockout (KO) mice, the conditional CPEB2 wild-type (cWT) and KO (cKO) mice of which cpeb2 gene is ablated in neurons expressing Cre recombinase under the control of CaMKII promoter, were used for behavioral and electrophysiological analyses. Although CPEB2 cKO mice performed normally in anxiety-related tests, including open field and elevated plus maze, they exhibited memory consolidation deficit in hippocampus-associated Morris water maze and contextual fear conditioning tests. Moreover, certain forms of synaptic transmission, including long-term depression (LTD) and long-term potentiation (LTP), were impaired in the Schaffer collateral-CA1 region of cKO hippocampal slices. To identify the molecular and cellular defects underlying aberrant memory performances and electrophysiological responses, we used WT and KO cortical/hippocampal neurons to examine dendritic spine morphology and miniature excitatory postsynaptic current (mEPSC). CPEB2 KO neurons exhibited elongated spines and reduced mEPSC amplitude. Using the RNA-immunoprecipitation approach, we identified a list of CPEB2-bound mRNAs. In combination with literature knowledge regarding of the abnormal responses identified from the

aforementioned experiments, we are examining whether several candidate RNAs are dysregulated in the absence of CPEB2, thereby leading to memory defects in the cKO mice.

Title: An interneuron-dependent decrease in sharp-wave ripple frequency in a mouse model of Dravet Syndrome

Authors: ***C. S. CHEAH**[1], W. A. CATTERALL[1], J. C. OAKLEY[2];
[1]Pharmacol., [2]Neurol., Univ. of Washington, Seattle, WA

Abstract: Dravet syndrome (DS) is an infantile-onset epileptic encephalopathy caused by loss-of-function mutations in SCN1A. Frequent, often prolonged seizures begin at 6-9 months in a previously healthy infant, with progressive cognitive impairment and severe intellectual disability in adulthood. Seizures are pharmacoresistant and no therapy exists for cognitive impairment. Cognitive impairment may result from permanent seizure-related brain injury or, alternatively, intrinsic mutation-related changes in neuronal excitability may underlie both seizures and intellectual disability. Haploinsufficiency of Scn1a in mice (DS mice) results in a selective decrease in sodium current and reduced excitability in GABAergic interneurons, together with seizures, autistic features, and memory impairment. Mice with interneuron-specific deletion of Scn1a recapitulate the core DS phenotype, supporting impaired inhibition as the cause of seizures and co-morbidities in DS. In this work, we examined whether the reduction in interneuron excitability observed in DS mice is sufficient to impair sharp wave ripple (SWR) formation. SWRs are high-frequency hippocampal field potential oscillations (140 - 220 Hz) essential for spatial memory formation and dependent on high frequency, synchronous firing of GABAergic interneurons. We recorded SWRs bilaterally in hippocampal area CA1 with chronically implanted, fine wire electrodes in awake, behaving DS and wild-type (WT) littermates. SWRs are most prominent in non-REM sleep in both DS and WT mice, and SWR in DS mice are 26% slower than WT. Elevated body temperature increases network excitability, and the SWR rate in both WT and DS mice increased by 15% at elevated temperatures. In DS

mice this increase approximates WT SWR frequencies at normal body temperature, demonstrating that DS mice retain the capability to form faster SWRs. Parallel experiments in mice with interneuron-specific Scn1a deletion showed a similar trend, implicating inhibitory neurons as the primary effectors of the DS SWR dysfunction. Decreased SWR frequency mediated by reduced interneuron excitability, due to Scn1a haploinsufficiency, provides a potential physiologic basis for spatial memory impairment in DS mice. Similarly, reducing interneuron sodium current in a conductance-based hippocampal network model decreased SWR frequency which implies that SWR frequency is primarily determined by the intrinsic excitability of interneurons, independent of network connectivity (Unpublished work, BN Lundstrom and JC Oakley). Together, these results suggest that therapies targeted at repairing interneuron excitability may improve memory in DS.

Title: Decreased ripple frequency from low sodium conductances in an interneuron network

Authors: *B. N. LUNDSTROM[1,2], J. OAKLEY[1];
[1]Univ. of Washington, Seattle, WA; [2]Mayo Clin., Rochester, MN

Abstract: Dravet Syndrome is marked by severe febrile seizures, development delays, and impaired memory (1). Mice with mutations in SCN1A, which causes Dravet syndrome, demonstrate reduced sodium currents in GABAergic interneurons (2), seizures and early death (3), and impaired memory (4). Ripples are high frequency oscillations (140-220 Hz) of field potentials generated in the hippocampus and associated with intact memory (5). Unpublished work (JC Oakley et al) has found that hippocampal CA1 ripple frequency is reduced for SCN1A heterozygote mice (mean 123 Hz, SD = 8.6 Hz, n = 4) as compared to wild-type (mean 165.5 Hz, SD 6.0 Hz, n = 4). Here the intent is to examine whether reduced sodium conductances in a network model yield reduced ripple frequencies, and to what extent reciprocal connections are required. We simulated a CA1 hippocampal network using Wang-Buzsaki conductance-based interneurons receiving Gaussian shaped excitatory stimuli. Neurons were connected by fast, strong, and shunting inhibitory synapses. Results show that ripple frequencies are reduced when sodium conductances of the inhibitory interneurons are reduced. Ripple frequency is primarily

determined by the amount of input excitation and the intrinsic excitability of the neurons, rather than by details of network connectivity, reciprocal connections, or the amount of synchrony in the network. The reduction in ripple frequency with reduced sodium conductance is maintained in the absence of reciprocal connections. In the case of Dravet mice, these results imply that the reduced ripple frequency seen in CA1 is primarily the result of reduced interneuron excitability due to the SCN1A mutation. This may provide a physiological explanation for impaired memory in these mice. References: 1. D. Chieffo et al., Neuropsychological development in children with Dravet syndrome. Title: Creatine transporter deficient mice show changes in hippocampal morphology

Authors: *K. MILES, M. SKELTON;
Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Creatine (Cr) is a nitrogenic acid responsible for maintaining ATP homeostasis in eukaryotic cells. The loss of Cr, through deficits in either Cr transport or synthesis, leads to significant intellectual disability, epilepsy and aphasia. The most common cause of Cr deficiency is Creatine Transporter Deficiency (CTD), is an X linked disorder that has been estimated to affectsbe the underlying cause of 1-2 percent of the populationXLID. Patients with this disorder often display intellectual disability, seizures, or deficits in memory formation. The presence of a truncated transporter disrupts creatine metabolism resulting in an overall lack of energy to carry

out cellular function. Tissues and organs with high energy demand, such as the brain and muscle, suffer most from this depletion in creatine. While the role of Cr in the cell is well understood, the mechanisms that underlie the neurologic phenotype observed in CTD patients is still unclear. The purpose of this study was to determine if the lack of Cr caused changes in brain morphology and neuronal architecture. Creatine transporter knockout (CrT-/y) mice, which show significant cognitive deficits similar to human CTD patients, were used for these studies. CrT-/y did not show any gross morphological changes in the brain compared with their CrT+/y counterparts. In order to determine if neuronal changes were present, CrT-/y mice were crossed with mice expressing eYFP driven by the promoter for the surface antigen Thy 1 (Thy1-eYFP). Neuronal density and architecture was evaluated in the hippocampus using confocal microscopy. CrT-/y mice had fewer Thy1+ neurons compared with their WT counter parts, suggesting a loss in neuronal density. Using a creatine transporter knock out (CrT KO) mouse that expresses Thy1 GFP (a cell surface antigen that depicts cellular morphology) our lab was able to image the murine hippocampus using confocal microscopy. Images revealed marked differences in neuronal density and projections between our wild type and knock out mice. Initial examination of neuronal architecture suggests that neurons from CrT-/y mice have aberrant aborization when compared to CrT+/y mice. Understanding the structural changes in these knock out animals will translate to functional anomalies within CTD in an effort to reveal more about this disease. These data suggest that the lack of brain Cr leads to abnormal hippocampal development that could be one of the underlying causes of the cognitive deficits observed in CTD. Future work will determine if the loss of Thy1+ neurons corresponds to neuronal loss and the mechanisms that lead to Cr-mediated changes in neuronal architecture.

Title: Spatial reference memory acquisition in a water maze under light and dark conditions

Authors: *S. PATEL[1], K. KING[2], A. DHURI[2], S. LEE[2], E. J. MARKUS[2];
[2]Dept. of Psychology, Behavioral Neurosci. Div., [1]Univ. of Connecticut, Storrs, CT

Abstract: Spatial navigation requires the use of allocentric information or external distant cues in the environment. While most research has focused on spatial visual information processing, potential distal cues include other, non-visual, modalities as well. The current study compared spatial reference memory acquisition in an open water maze under light and dark conditions. Room conditions in the dark consisted of an infrared LED illuminator (850nm, <2lx), and rats wore custom fitted vests with an infrared LED (940nm) attached. Video-tracking software recorded the animals' swim latency and distance traveled until reaching a hidden platform. We examined the degree to which the light and dark groups learned the spatial reference memory task. Following asymptotic performance for the dark group, both groups were subsequently given probes under the opposite light/dark conditions to examine carry-over effects. Do rats initially trained under light conditions carry over the spatial information to the dark? And do rats trained in the dark carry over their spatial information to the light? A visible platform test was used as a control to determine the extent to which rats could see under dark conditions. In addition, a white noise control probe was used to test rat's dependence on auditory cues in the maze room.

Title: Inactivation of dorsal and ventral hippocampus during a temporal sequence task in a radial arm water maze

Authors: *S. LEE, A. RATHEY, D. LEW, K. KATUGAM, E. J. MARKUS;
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: The hippocampus has been linked with the formation and retrieval of an experience or episodic memories. In rats, the hippocampus is divided into dorsal and ventral regions. It has been proposed that dorsal is important for spatial processing, and ventral related to fear and anxiety. However, the conflicting results from different studies suggest an interaction with task demands, and a change in sensitivity along the dorso-ventral axis. To date, most rodent studies have focused on the "what" and "where" aspects of hippocampal processing. Our study examined the "when" aspect through teaching rats a temporal sequence task in a radial arm water maze. We previously showed rats could learn seven different goal locations in sequence. In the present study, Fisher-344 rats were trained to swim to three different locations in correct sequential order. Each of the three sessions was separated by a 30 min interval, and start arms varied pseudo-randomly for each session. Muscimol, a selective GABA-A agonist, was used to temporarily inactivate hippocampal subregions in a within-animal repeated design. Different combinations of bilateral, unilateral, and contralateral infusions were used to differentiate the relative contributions of dorsal and ventral hippocampus. To what degree will hippocampal inactivation at the start of the sequence vs. mid-sequence disrupt the successful completion of the three sessions?

Title: Comparing dorsal and ventral hippocampus oscillations and oscillatory interaction between hippocampus and prefrontal cortex during place and response learning in rats

Authors: J. YOON[1], X. LI[1], D. KATZ[1], S. VU[1], V. WICKENHEISSER[1], A. RATHEY[1], *E. J. MARKUS[2];
[1]Psychology, Behav. Neurosci. Div., [2]Univ. Connecticut, Storrs Manfld, CT

Abstract: It is postulated that the oscillatory dynamics in the hippocampus support cognitive function in humans and rodents. Theta (4-12 Hz) and gamma (slow: 25-55 fast: 65-90Hz), two main types of oscillation in the hippocampus, has been linked to several key cognitive operations, including spatial navigation, memory encoding and retrieval. In most studies theta and gamma oscillations were recorded from the dorsal hippocampus. However the hippocampus is not a homogenous structure, anatomical and functional dissociations exist along the dorso-ventral axis. In addition, the rodent prefrontal cortex integrates spatial information encoded in the hippocampus with mnemonic information concerning route and task rules in order to direct behavior appropriately during hippocampal dependent task. Local filed potentials (LFP) were recorded from dorsal and ventral hippocampus and from prefrontal cortex in rats while they learn “place” and “response” tasks on a plus maze. For the place task, rats were rewarded for going to the same “place” regardless of the start arm. For the response task rats were rewarded for making a right turn on the maze. These tasks differ in the degree they depend upon hippocampus. For each task, theta and gamma frequency, coherence, power and it’s correlation with running speed were compared during the decision and post reward running epoch. How theta power and coherence were modulated with learning was also analyzed, both within and across the test days. Also, band specific hippocampal-prefrontal interactions were investigated throughout the different learning stages of place and response task.

Photonics, Wuhan Natl. Lab. for Optoelectronics, Huazhong Univ. of Sci. and Technolgy, Wuhan, China

Abstract: The hippocampus (HP) is a medial temporal lobe structure that critically involved in declarative memory formation and spatial navigation. The lateral- and medial-entorhinal cortex (EC) provide major inputs to HP through separated perforant pathways (PP): EC layer II -> dentate gyrus (DG) -> CA3 -> CA1, and EC layer III -> CA1, also known as tri- and di-synaptic pathway respectively. Despite of extensive knowledge about the tri-synaptic pathway, little is known about the fine-scale connectivity and function of the direct EC -> CA1 di-synaptic circuit. Here, we report that a direct circuit of lateral-EC III to distinct group of CA1 calbindin-expressing pyramidal cells (PCs) in the dorsal HP contributes to olfactory associative learning. Using light-activated channelrhopdopsin (ChR2)-assistant circuit mapping, we demonstrate that medial-EC III homogeneously innervate all examined HP CA1 PCs, while lateral-EC III selectively target to the subpopulation of HP CA1 PCs that are morphologically more complex (complex PCs, cPC) and specifically expressing an intracellular Ca2+-binding protein calbindin (Calb, CB). Specific optogenetic inactivation of either Calb-expressing PCs or direct lateral-EC PP pathway in the dorsal HP CA1 region during the training severely impaired the learning process of an olfactory associating go/no-go task. Op-tetrode recording of these identified Calb-positive cPCs showed that they exhibited and developed higher selectivity of neuronal spiking responses to odor cues over the training days compared to those Calb-negative PCs (Simple PCs, sPC). Thus, our study revealed a distinct direct circuit from the lateral-EC III to HP CA1 Calb-expressing PCs is required for the olfactory associative learning.

Title: Hippocampal-thalamo-cortical network connectivity for episodic memory and spatial processing

Authors: *N. A. KAMBI, J. M. PHILLIPS, Y. B. SAALMANN;
Dept. of Psychology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Episodic memory is the explicit remembering of objects, events and the associated contexts experienced in one's personal past. A large body of clinical and experimental work in humans has converged on the hippocampus as a critical brain region supporting episodic memory. However, the role of other regions such as the retrosplenial cortex and anterior thalamus, which have robust anatomical connections with the hippocampus, is not clear. Independently, this network has also been implicated in spatial navigation in rodents. The major aim of this study is to better understand how the hippocampal-thalamo-cortical network supports both episodic memory and spatial processing. Our working hypothesis is that the anterior thalamus plays a key role in regulating information transmission between the hippocampus and retrosplenial cortex. To measure network connectivity, we acquired high-resolution diffusion-weighted images (1 mm isotropic) from the 3T GE MR750 scanner with a 16-channel receive-only head coil in 4 anesthetized monkeys along 60 diffusion directions; (b=1000 s/mm2 and NEX=14). We used FSL for EPI distortion, eddy current and motion correction prior to Bayesian estimation of diffusion parameters, and probabilistic diffusion tractography (PDT). We used PDT to track connections between the anterior thalamus, retrosplenial cortex, and subiculum, a major output of the hippocampus. The fiber paths obtained with PDT broadly conformed to previous anatomical tracer studies. However, PDT allowed identification of projection zones within each network area specific to individual monkeys. The results showed that the subiculum connected with both medial and lateral parts of the anterior thalamus (roughly spanning all subnuclei of the anterior thalamus), whereas the retrosplenial cortex mainly connected to the lateral part of the anterior thalamus (corresponding to the approximate location of the anterior dorsal and anterior ventral subnuclei). Importantly, the retrosplenial cortex and subiculum showed partially overlapping projection zones in the lateral part of the anterior thalamus. This suggests that there is an indirect pathway between the subiculum and retrosplenial cortex via the anterior thalamus, in addition to the direct pathway. Our data suggests that the anterior thalamus is well positioned to regulate information transmission between the subiculum and retrosplenial cortex. The PDT data also enables us to target multi-contact probes to interconnected sites of the subiculum, retrosplenial cortex and anterior thalamus for simultaneous multi-site recordings during episodic-like memory recall and spatial transformations.

Title: Synchronization between Hippocampus and Entorhinal Cortex in behaving rats

Authors: *X. S. GONZALO COGNO[1,2], E. KROPFF CAUSA[3,2], M. MONTEMURRO[4], I. SAMENGO[1,2];

Abstract: Hippocampal place cells and entorhinal grid cells play a crucial role in spatial navigation by encoding the location of the animal in the environment. Here, we explore the degree of synchronization of the two neural populations in awake behaving rats. The animal runs along a linear track inside a bottomless car whose velocity is controlled by a computer. This setup allows us to have complete control and knowledge of all kinematical variables (position, velocity and acceleration), and to produce many repetitions of exactly the same trajectory. In these conditions, the local field potential (LFP) from both the Medial Entorhinal Cortex and the Hippocampus were recorded. We analyzed the degree of coherence between both signals. We found that the trial-to-trial variability of the phase difference between both LFPs depends on the state of motion of the animal, with increased synchronization as the rat runs faster. In this study we describe this effect quantitatively, and we explore the causal and dynamical factors through which velocity is linked to coherence.

Title: The influence of spatial and temporal context on oscillatory interactions between dentate gyrus, CA3, CA1, and subiculum in rats during performance of object recognition memory tasks

Authors: *J. B. TRIMPER[1], C. R. GALLOWAY[2], K. MANDI[2], A. C. JONES[2], J. R. MANNS[2];
[1]Psychology, [2]Emory Univ., Atlanta, GA

Abstract: Previous studies have found that neuronal oscillations in the hippocampus relate to object recognition memory task performance in rats and monkeys. For example, during exploration of novel objects, coherence between hippocampal subregions CA3 and CA1 in rats increased markedly in the low gamma range (30 - 55 Hz) relative to a pre-exploration baseline, an increase that correlated with subsequent memory performance (Trimper et al., 2014, Hippocampus, 24, 341-353). Expanding upon these findings, we report here findings from two separate experiments asking how neuronal oscillations dynamically change throughout four of the hippocampal subregions during performance of two separate object recognition tasks designed to ask about the role of spatial and temporal context on neuronal activity. In the first task, rats responded on average to a swap in two objects' spatial locations by significantly increasing their exploration durations relative to when the two objects were repeated in the same location. In the second task, rats explored novel objects after a repeated temporal context more than after a novel temporal context, replicating previous findings with the same task (Manns et al., in press, Animal Cognition). Initial neural analyses revealed differences in levels of coherence between hippocampal subregions during novel object encoding (exploration relative to pre-exploration baseline), with low gamma coherence increasing significantly between dentate gyrus (DG) and CA3 and between CA3 and CA1, but not between CA1 and subiculum. Significant DG-CA3, CA3-CA1, and CA1-subiculum coherence increases above 90 Hz were also observed, possibly reflecting contributions of spiking activity to the local field potentials. No coherence differences were yet observed in the theta range. Future analyses will ask how oscillatory interactions differ based on task conditions and performance on both tasks.

Title: Medial septal glutamatergic neurons mediate hippocampal theta oscillations and velocity correlated firing of hippocampal neurons during locomotion

Authors: *F. FUHRMANN[1], D. JUSTUS[1], H. KANEKO[1], L. SOSULINA[1], D. FRIEDRICHS[1], T. BEUTEL[1], S. SCHOCH[3], M. SCHWARZ[3], M. FUHRMANN[2], S. REMY[1,3];

Abstract: In the hippocampal formation the firing of principal neurons defines a cognitive map of the environment, which is used for memory-guided navigation. Precise neuronal firing at spatial locations requires the integration of locomotion velocity. It has been shown that synchronized oscillatory activity of brain circuits and neuronal activity rates have long been known to be coupled to locomotion speed. However the mechanism mediating the hippocampal state transition to higher activity levels during the initiation of locomotion remains not fully resolved. The medial septal nucleus and the diagonal band of Broca (MSDB) play a central role in the integration of locomotor programming by relaying ascending input from the pontine-hypothalamo-septal pathway to the hippocampal formation. It is well established that the medial septal nucleus is a primary regulator of theta rhythm that orchestrates the firing of hippocampal interneurons and principal neurons at theta frequencies between 5-12 Hz. We now show that glutamatergic neurons (VGluT2+) of the MSDB mechanistically link locomotion with the entrainment of theta oscillations and the speed-related regulation of hippocampal CA1 pyramidal neuron firing rates. We used cell-type specific monitoring of the Ca2+ activity of MSDB VGluT2 neurons during locomotion and optogenetically stimulated these neurons during single-cell whole-cell patch-clamp and population two-photon imaging of CA1 pyramidal neurons in awake head-fixed mice. We found locomotion-correlated activity of both MSDB VGluT2 neurons and CA1 pyramidal neurons and show that the firing frequencies of MSDB VGluT2 neurons control the initiation and velocity of locomotion as well as the entrainment of correlated theta oscillations. Combining mono-transsynaptic retrograde tracing and brain slice electrophysiology our findings reveal a disinhibitory mechanism that facilitates the synaptic integration of Schaffer collateral (SC) and perforant path (PP) input by CA1 pyramidal neurons

during the brain-state transition from resting to locomotion. Locomotion-related firing of VGluT2 septo-hippocampal projections resulted in alveus/oriens interneuron mediated suppression of SC and PP feed-forward inhibition already before locomotion onset. Through this mechanism the velocity-dependent activity of MSDB VGluT2 neurons is translated into increased axo-somatic depolarization and higher firing rates of hippocampal CA1 pyramidal neurons during locomotion.

Title: Design and use of a head-mount fluorescent miniature microscope to visualize neuronal activity during memory formation

Authors: ***C. YAN**[1,2], Y. SOUDAGAR[1], V. MERCALDO[1], A. J. RASHID[1], P. W. FRANKLAND[1,2,3], S. A. JOSSELYN[1,2,3];

Abstract: How information is encoded and stored in the brain is a long-standing fundamental question in neuroscience. We have previously shown auditory fear memory is more likely to be encoded by lateral amygdala (LA) neurons with elevated level of transcription factor CREB (Han et al., 2007, Han et al., 2009). However how the activity of these neurons with high level of CREB contribute to memory allocation during memory formation is not fully known. We hypothesize that neurons overexpressing CREB have a higher baseline firing rate, and have increased response to tone during and after conditioning. In order to record and distinguish neurons overexpressing CREB and their neighbours in freely moving mice and test this

hypothesis, we designed a miniature microscope that is able to image calcium signals in deep brain region such as LA and distinguish subpopulations of neurons in separate colour channels. Based on previously reported miniature microscope design (Ghosh et al., 2011), we have created mini-microscopes that image two colour channels simultaneously and is compatible with deep brain imaging.

Title: Linking of fear memories by temporally limited changes in both excitatory and inhibitory neuron activity in the lateral amygdala

Authors: ***A. J. RASHID**[1], C. YAN[1], H.-L. HSIANG[1], A. DECRISTOFARO[1], S. PARK[1], C. RAMAKRISHNAN[2], K. DEISSEROTH[2], P. W. FRANKLAND[1], S. A. JOSSELYN[1];

Abstract: Increased excitability downstream of activation of the transcription factor CREB increases the likelihood that a neuron of the lateral amygdala (LA) will be part of a fear engram. As memory formation itself can activate CREB, subsequent formation of a distinct memory within the time window of increased excitability results in co-allocation of memories within the LA. To investigate the mechanisms by which co-allocation may occur, we used an optogenetic approach whereby viral vectors were used to co-express channelrhodopsin2 (ChR2) and red-shifted halorhodopsin (NpHR3.0) in a fraction of neurons (~20%) in the LA of mice *in vivo*, enabling neuronal excitation and inhibition by blue light and red light illumination, respectively, in the same neurons. Activation of ChR2 just prior to auditory fear conditioning resulted in selective allocation of the fear memory to opsin-expressing neurons, as indicated by the ability to reversibly inhibit fear memory expression by activation of NpHR. When mice were given a second distinct fear memory training session without ChR2 stimulation, the second memory could also be inhibited by NpHR activation, but only if the two training sessions occurred within

Deleted: in vivo

the time frame of increased excitability (<6h),supporting the idea that memories can be co-allocated if formed within a limited time window. When training sessions were separated by 24h, outside the window of increased excitability, the second memory was insensitive to NpHR activation and thus allocated to a separate group of LA neurons. We then attempted to prevent memory co-allocation by inhibiting neurons allocated to the first fear memory with NpHR activation during the second training session. Surprisingly, rather than being allocated to a distinct population of neurons, formation of the second fear memory was inhibited, suggesting that activity associated with the first training session prevented surrounding neurons from contributing to subsequent memory formation. This inhibition could be relieved by selectively attenuating the activity of parvalbumin-positive interneurons in the amygdala, using the DREADD hM4Di, concurrent with NpHR activation in principal neurons allocated to the first memory. The resulting memory from the second training session was insensitive to NpHR activation, confirming that each memory was allocated to separate populations in the LA. Collectively, these results provide evidence that memory formation results in increases in both principal neuron and inhibitory interneuron activity, transiently constraining the population of neurons that can be involved in subsequent memory formation, thereby promoting memory co-allocation.

Title: Destructive circuit remodeling mediates neurogenesis-induced forgetting

Authors: ***A. GUSKJOLEN**, J. R. EPP, L. RESTIVO, S. A. JOSSELYN, P. W. FRANKLAND;
Sick Kids Hosp., Toronto, ON, Canada

Abstract: The production and maturation of new neurons in the dentate gyrus of the hippocampus provide a physical substrate for new learning[1]. However, computational models also predict that the addition of new neurons should lead to degradation of previous acquired information (i.e., forgetting)[2,3,4]. Consistent with this possibility, our lab recently demonstrated

that high rates of neurogenesis cause forgetting of hippocampal-dependent information learned one month earlier[5]. Our current model of neurogenesis-induced forgetting is based on the idea that as newborn neurons mature and form synaptic connections, they necessarily remodel the circuitry upon which hippocampal memories are dependent. This 'destructive remodeling' of the circuit likely reduces the probability that a given environmental cue will reactivate the specific pattern of neural activity that mediates successful memory retrieval[6]. If this model is correct, then inhibiting the synaptic integration of newborn neurons into the surrounding circuit should alleviate the forgetting phenotype. To test this hypothesis, we have developed multiple transgenic mouse lines in which the integration of new neurons is selectively disrupted. In one such line, we deleted the Rho GTPase Rac1 from neural progenitors using a cre-loxP strategy. This deletion does not affect the proliferation (Ki67+ cells) or survival (DCX+ cells) of newly generated neurons. However, deletion of Rac1 reduces synaptic integration as indicated by decreased dendritic growth, arborization, and mushroom spine development [7]. To test the idea that forgetting depends upon integration of new neurons, we then trained these mice in a contextual fear conditioning task. Following training, half the mice were allowed free access to a running wheel for a month and the other half were housed conventionally. Whereas post-training running increased hippocampal neurogenesis and induced forgetting in control mice, conditional deletion of Rac1 prevented running-induced forgetting. Since the integration, rather than production, of new neurons is altered in the Rac1-deficient mice, these results suggest that forgetting is mediated by circuit remodeling caused by the synaptic integration of recently generated hippocampal neurons. Critically, deleting the Rac1 gene from mature CaMKII+ forebrain neurons did not block the forgetting phenotype, thereby establishing the cellular specificity of this effect. Furthermore, this effect was not driven by an anxiogenic alteration, as behavior in the open field and elevated plus maze was unchanged. This set of experiments helps elucidate the mechanism underlying neurogenesis-induced forgetting.

[2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Adult neurogenesis continues throughout life in the mammalian hippocampus. The lifelong addition of new neurons provides a unique form of structural plasticity that does not exist in most areas of the brain. Thousands of new neurons are produced each day although many of these do not survive. Integration of new neurons into existing circuitry has implications for hippocampal function (Akers et al.,2007) and is believed to be an activity dependent process. For example, hippocampus-dependent learning increases the survival of immature neurons during a critical time window that corresponds to the time of dendritic and axonal outgrowth (Epp et al., 2007). Furthermore, during this time window the activation of NMDA receptors on individual new neurons increases the likelihood of that neuron surviving to maturity (Tashiro et al., 2007). At the level of individual neurons it remains unclear how activity might influence the growth and development of immature neurons in the adult hippocampus. Here we asked whether lasting structural modifications of immature neurons could be produced by brief but chronic activation of new neurons. To address this question we infected dividing neurons in the dentate gyrus with a Channelrhodopsin2-GFP expressing retrovirus. We then, performed chronic daily stimulation of these neurons. Beginning at 3 days post infection we stimulated the infected neurons for 14 days. Each daily stimulation session involved 3 epochs of 1-minute stimulation spaced 3 minutes apart. The light power and frequency were 0.4 mW and 10 Hz, respectively. Twenty four hours after the final stimulation session the mice were perfused and the brains were prepared for analysis. We used CLARITY to render the brains transparent so that we could examine intact neurons without the need for sectioning and subsequent reconstruction. The labeled neurons were imaged in their entirety using confocal microscopy and were then traced semi-automatically using Imaris (bitplane). When we examined the dendritic morphology of the new neurons we found that 2 weeks of brief stimulation with light produced a robust increase in both the size and complexity of the new neurons. Stimulated neurons had greater total dendrite length and volume as well as an increase in the number of branch points and higher order branches. Additionally, at a time when spines are first beginning to appear on new neurons there was an increase in the spine density on stimulated neurons suggesting that the developmental timeline is shortened by intrinsic activity.

Title: Hippocampal neurogenesis leads to the erasure of a cocaine conditioned place preference

Authors: *L. A. VAN KAMPEN[1,2], P. W. FRANKLAND[1,3,4,2];
[1]Program in Neurosci. and Mental Hlth., The Hosp. For Sick Children, Toronto, ON, Canada; [2]Dept. of Psychology, [3]Inst. of Med. Sci., [4]Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Newborn neurons are generated in the hippocampus during adulthood. Little is known however about the functional role of these new neurons and how they contribute to behaviour. Previous research proposed that ongoing neurogenesis clears established memories from the hippocampus (Frankland et al., 2013). Consistent with this, we recently found that high rates of neurogenesis induce forgetting of hippocampus-dependent spatial (water maze, Barnes maze) and fear (contextual conditioning) memories (Akers et al., 2014). These tasks were all aversively-motivated. To test whether neurogenesis-mediated forgetting generalizes to appetitively-motivated, hippocampus-dependent memories, here we used a cocaine place preference paradigm. In this task mice learn that one side of a two chamber apparatus is consistently paired with cocaine, and when later given a choice test, mice will express a preference for the cocaine paired side. We found that increasing neurogenesis (by voluntary exercise) before training did not impact the acquisition of cocaine place preference. However, increasing hippocampal neurogenesis after training weakened an established weak cocaine place preference memory. These effects were only observed when mice were conditioned using low (7.5 mg/kg) but not high (15 mg/kg), suggesting stronger memories may be resistant to neurogenesis-induced forgetting. These findings indicate that neurogenesis-mediated forgetting in the hippocampus generalizes to appetitively-motivated tasks, and provide a basis for the development of novel interventions for treating addiction and relapse.

Title: *In vivo* and in silico interrogation of a fear memory network

Deleted: *In vivo*

Authors: ***G. VETERE**[1], J. W. KENNEY[1], L. TRAN[1], A. WHEELER[1], S. JOSSELYN[1,2,3,4], P. FRANKLAND[1,5,3,4];
[1]Program In Neurosci. & Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada; [2]Inst. of Med. Sci., Toronto, Toronto, ON, Canada; [3]Dept. of Physiol., [4]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [5]Inst. of Med. Sci., Toronto, ON, Canada

Abstract: Memories are thought to be supported by a broad network of brain regions, but little is known about how such networks are organized. To address this, we previously mapped expression of the activity-regulated gene c-fos following recall of fear memory in mice across 84 brain regions. By computing inter-regional correlations we then identified brain regions that were co-activated and presumably form a network that is engaged by fear memory recall. Graph theoretical analyses of this network identified several highly-connected hub-like regions that most likely have greater overall influence on network function. Here we tested this hypothesis in two ways. First, we modeled deletion of hub and non-hub nodes on overall network function in silico. Second, we used a pharmacogenetic strategy (viral expression of the inhibitory DREADD, hM4Di) to silence neurons in different brain regions, and examine the impact of deletion of hub and non-hub regions on memory consolidation *in vivo*. In this latter analysis we independently targeted 25% of the network (21 brain regions). We found that "hubness" (e.g., degree centrality) predicted the degree of consolidation deficit that was observed, with silencing of the most highly-connected nodes (e.g., Reuniens thalamic nucleus) having the largest impact on fear memory consolidation ($r = 0.50$, $p < 0.05$). Similarly, deletion of highly-connected nodes had greatest impact on network function (e.g., largest giant component, global efficiency) in silico ($r = 0.94$, $p < 0.001$), and importantly predicted the deficits we observed *in vivo* ($r = 0.51$, $p < 0.05$). These results support the idea that memories are supported by distributed circuits (e.g., "mass action") but within these broad networks some regions play more essential roles than others.

Title: Medial prefrontal cortex parvalbumin-positive interneurons modulate spindle-ripple coupling and fear memory consolidation

Authors: ***F. XIA**[1,2], B. A. RICHARDS[3], S. A. JOSSELYN[1,2,4], K. TAKEHARA-NISHIUCHI[4], P. W. FRANKLAND[1,2,4];
[1]Hosp. For Sick Children, Toronto, ON, Canada; [2]Physiol., [3]Cell & Systems Biol., [4]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: After a memory is initially encoded, it undergoes a period of consolidation, during which it becomes less reliant on the hippocampus (HPC) and more dependent on the medial prefrontal cortex (mPFC). Rhythmic oscillations in the mPFC, called spindles, coincide with oscillations in the HPC, called sharp-wave ripples, and this spindle-ripple coupling across brain regions is thought to facilitate memory consolidation. While fast-spiking parvalbumin-positive (PV+) interneurons fire in synchrony with spindles and ripples in the mPFC and HPC, respectively, whether they contribute to the spindle-ripple coupling, and by doing so, modulate memory consolidation, is unclear. Here, we use the designer receptor approach combined with behavior experiments and *in vivo* recording in freely-behaving mice, to directly manipulate the activity of PV+ interneurons in the HPC and mPFC and investigate their roles in memory consolidation. Transgenic PV::Cre mice were infused with Cre-recombinase-dependent virus carrying the designer receptor hM4Di, which allows PV+ interneurons to be silenced by the designer drug clozapine-N-oxide (CNO). After surgery, mice were trained in a contextual fear conditioning paradigm, then we silenced the PV+ interneurons. When mPFC PV+ interneurons were selectively inhibited during the consolidation period following fear conditioning, mice showed memory deficits. To explore the electrophysiological mechanisms, we performed local field potential recordings simultaneously in both the mPFC and HPC in freely-behaving mice following fear conditioning. Our preliminary data shows that fear conditioning enhanced the probability of ripple-spindle coupling. While inhibiting mPFC PV+ interneurons did not alter the density, duration or amplitude of mPFC spindles or HPC ripples, the fear learning-induced enhancement in ripple-spindle coupling was attenuated. This suggests that the mPFC PV+ interneurons may be important in coordinating the oscillations between the HPC and mPFC, and

Deleted: in vivo

interfering with their activity may disrupt the coupling between the two regions, and hence impair memory consolidation.

Title: Restoring ability to form new, and recover old “lost”, memories in mice that model Alzheimer’s disease

Authors: ***V. MERCALDO**[1], A. P. YIU[1], D. SARGIN[1], A. J. RASHID[1], J. CERÓN GONZÁLEZ[1], P. W. FRANKLAND[1,2,3], S. A. JOSSELYN[1,2,3];
[1]Neurosci. and Mental Hlth., The Hosp. For Sick Children, Toronto, ON, Canada; [2]Inst. of medical sciences, [3]Dept. of physiology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The clinical hallmark of Alzheimer's disease (AD) is a progressive decline in cognitive function. Increasing evidence indicates that b-amyloid (Ab) disrupts neurotransmission and synaptic function, possibly by promoting excessive internalization of postsynaptic AMPA-type glutamate receptors (AMPARs). These findings suggest that the memory deficits described both in patients affected by early AD and mice that model AD may be due to high levels of Ab promoting the loss of postsynaptic AMPAR. Here we tested the hypothesis that excessive AMPAR internalization could account for the memory deficits seen in mice overexpressing Ab. We found that increasing Ab either acutely or chronically in various lines of mice (TgCRND8, 5xFAD, HSV viral injection of mutated APP) disrupts both consolidation and reconsolidation of context fear conditioning and spatial memory. Preventing AMPAR endocytosis during memory encoding restored the ability of mice to form new memories (consolidation). Remarkably, preventing AMPAR endocytosis during a memory reminder enabled the recovery of an otherwise inaccessible old memory (reconsolidation) in mice that model AD. These findings elucidate the disruptive role of Ab in synaptic function and raise the possibility that restoring plasticity during memory encoding and/or retrieval by targeting the loss of postsynaptic AMPAR

may help support the ability to form new memories as well as enable recovery of lost past memories in AD patients.

Title: Modeling the effects of brain region inactivation using a functional connectome

Authors: *J. W. KENNEY, G. VETERE, L. TRAN, Y. SOUDAGAR, S. A. JOSSELYN, P. W. FRANKLAND;
Neurosciences and Mental Hlth., The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Functional connectomes are a way of representing brain region interactions underlying a specific behavior using graph theoretical concepts. One way of determining the impact of inactivating brain regions (i.e., graph nodes) in a connectome is to remove individual network nodes and their associated edges and recalculate various global graph measures such as efficiency or size of the largest connected component. However, given the nature of brain region inter-connectivity, the effect of inactivating any individual brain region is also likely to affect the interactions of regions that are indirectly connected to the target region. In an effort to develop a more realistic estimation of the effect of inactivating a specific brain region, we have developed a simple model to propagate the effect of node inactivation beyond its immediate neighborhood. We have applied this model to a functional connectome associated with contextual fear conditioning in mice (Wheeler et al, 2013) and find that the model is able to predict the effect of inactivating various brain regions on consolidation of a contextual fear memory. We discuss the development of the model and its relationship to various other graph theoretical measures of brain region/node importance.

Title: Medial prefrontal cortex inactivation biases hippocampal network representations

Authors: *J. W. RUECKEMANN, R. J. ROBINSON, II, S. M. FOROUSHANI, R. L. LEIB, S. BOVINO, H. EICHENBAUM;
Boston Univ., Boston, MA

Abstract: In a previous study on context-guided object-reward association, we reported that inactivation of the medial prefrontal cortex (mPFC) resulted in a loss of object selectivity but did not affect spatial firing patterns in hippocampal neurons (Navawongse & Eichenbaum, J Neurosci. 2013). Here we examined the generality of these findings by characterizing the effects of mPFC inactivation on hippocampal neuronal activity in rats performing a spatial task in which temporal and spatial firing patterns prominently map paths through the maze. Neurons in CA1 of the hippocampus were extracellularly recorded during pharmacological inactivation of the mPFC as rats perform a delayed-alternation task on a T-maze. Despite profound performance deficits with prefrontal inactivation, we find place cells that selectively fire depending on the intended destination of the rat, and time cells that exhibit temporal tuning curves spanning the delay period with a reliable order. However compared to baseline recording sessions, mPFC inactivation changes the active ensemble of neurons during both running and delay epochs of the task, and alters the representations of temporally and spatially selective neurons without decreasing the information represented. Inactivation of the mPFC therefore results in a coordinated remapping of temporal and spatial representations in the hippocampal network. From these findings, we surmise that although temporal and spatial selectivity in the hippocampus is not dependent on the prefrontal cortex, the mPFC may serve to bias the network level representation of both features. These results indicate that the network driving spatial and temporal selectivity is separate from mPFC circuitry. Furthermore, we take the coordinated remapping of spatial and temporal firing properties as evidence that the two modalities share a common circuitry and are similarly modulated by functional connections with mPFC.

Title: Stimulation of the lateral entorhinal cortex reveals optimal frequencies for rhythmic entrainment of downstream hippocampal neurons

Authors: ***L. M. RANGEL**, K. R. KEEFE, P. D. RIVIÈRE, H. EICHENBAUM;
Boston Univ., Boston, MA

Abstract: Although it is known that the hippocampus plays an important role in associative memory, the circuit mechanisms that allow it to perform this function are not clearly understood. Previously, it has been shown that rhythmic coherence between the lateral entorhinal cortex (LEC) and the CA1 region of the hippocampus is tightly correlated with the onset of learning and successful performance in an associative learning task. We wished to examine whether rhythmic inputs from the LEC in a specific frequency range were sufficient to produce similar temporal coordination of single cell and local field potential activity (LFP) in downstream CA1. In urethane-anesthetized rats, we applied extracellular low intensity alternating current stimulation to superficial LEC. Using this method, we aimed to phase-bias ongoing neuronal activity at a range of different intensities and frequencies (from 1.25 - 70 Hz). Stimulation of LEC produced significant spike-phase coherence of CA1 cells to the stimulation frequency with respect to both the phase of the stimulation signal and the phase of the CA1 LFP. This spike-phase coherence was observed at some, but not all, of the frequencies used, and the spike-phase coherence was stronger with respect to the stimulation frequency than to the CA1 LFP. Together, these results suggest that communication between LEC and CA1 may occur at optimal frequency ranges, and that stimulation of LEC inputs to the hippocampus at these frequencies is sufficient to produce partial LEC-CA1 coherence.

Title: Stability and remapping of large cell assemblies in the hippocampus

Authors: ***N. R. KINSKY**, D. W. SULLIVAN, W. MAU, H. EICHENBAUM;
Boston Univ., Boston, MA

Abstract: Hippocampal cells encode information about space, time, and other relevant dimensions of a task, and disruption of these cells' activity results in impairments in memory. In well-learned tasks or familiar environments, hippocampal representations of space typically remain stable; however certain manipulations, such as changes to an environment or new learning, cause hippocampal neurons to shift the locations of their place fields in a phenomenon known as remapping. While much is known about the coding properties and remapping of hippocampal cells on the timescale of hours to days, little is understood about the persistence of these representations and the tendency to remap over the course of weeks to months. We employed *in vivo* calcium imaging using a microendoscope to visualize activity of dorsal CA1 hippocampal neurons virally expressing GCamp6f in awake, behaving mice in order to investigate how large ensembles of hippocampal neurons maintain representations or remap over longer timescales. We recorded large numbers of cells as mice learned and mastered a spatial alternation task over the course of weeks. Additionally, mice performed a task where they were allowed to explore two separate arenas for several days, after which the two arenas were connected. Preliminary analysis confirms previous findings that ensemble representations of place persist over the course of weeks, but also decay, becoming more dissimilar as time progresses. We also observed evidence of remapping on both the single cell and ensemble level during learning in both tasks. Finally, we observed an overrepresentation of place fields in specific parts of an arena, and an underrepresentation in other parts. This over/under representation persisted despite global remapping of place fields during learning. Our results highlight how learning affects the organization/allocation of hippocampal neurons. Title: Distinct, complementary organization of information in perirhinal cortex within a medial temporal lobe network supporting episodic memory

Authors: ***C. S. KEENE**, J. H. BLADON, J. R. O'KEEFE, C. D. LIU, H. EICHENBAUM; Boston Univ., Boston, MA

Abstract: Recent studies in our lab have focused on determining how the hippocampus and surrounding cortical regions interact in support of episodic memory. Analyses of single neuron activity patterns indicate the individual neurons throughout areas of the entorhinal cotrex and hippocampus have mixed selectivity in representing multiple task features (spatial position, object identity, context, reward association). In contrast, representational similarity analysis (RSA) of population activity revealed that each region represents this information in a uniquely organized hierarchical manner (Mckenzie et al., Neuron 2014; Keene et al., SfN Abstracts 2014). For example, neuronal ensembles in lateral and medial entorhinal cortices encoded both object and position information. However, within medial entorhinal cortex, stimulus representations were organized primarily by position information and then by object information, whereas in lateral entorhinal cortex, stimulus representations were primarily organized by object identity and then by position information. The present study extended these findings by identifying the unique contribution of perirhinal cortex (PRC) by monitoring PRC neuronal activity in rats performing a context-guided object association task in which object-reward associations were opposite in different spatial contexts. Consistent with our previous studies, single unit analysis indicated strong representation of spatial positions within each context, object identities, the different contexts, and reward and non-reward associations. In addition, RSA revealed a

hierarchical organization of information distinct from those previously observed in the hippocampus and entorhinal cortices. PRC neuronal ensembles most strongly distinguished events of opposing reward association (rewarded vs non-rewarded), and within these reward-based schemas distinguished different object-context combinations, and then within those combinations distinguished the places in which objects appeared within each context. These findings, combined with previous observations on entorhinal and hippocampal schemas, challenge us to consider memory as the product of interactions between distinct organizational networks in the medial temporal lobe.

Title: Learning paradigm influences the organization of memory in the hippocampus

Authors: ***D. J. SHEEHAN**, J. W. RUECKEMANN, S. MEHROTRA, H. EICHENBAUM; Psychology, Boston Univ. Ctr. For Memory and Brain, Boston, MA

Abstract: The hippocampus is critical for the association of related events (Eichenbaum et al., 2012), and damage to this region consequently leads to a wide array of cognitive impairments (Eichenbaum & Cohen, 2014). Studies have demonstrated that the hippocampus is central to the rapid creation of relational representations within a given environment (Tse et al., 2007), which together form a schema necessary for solving a task (Preston & Eichenbaum, 2013). In the present study, we investigated the role of the hippocampus in representing the spatial relations between goal locations in a spatial discrimination task, and how hippocampal representations may support flexible utilization of stored memories. Rats implanted with drivable tetrodes in the dorsal CA1 region of the hippocampus were trained to acquire rewards on 6 arms of a 12-arm radial maze, using either go/no-go training on each 12 single arm or a set of 6 left-right discriminations between pairs of adjacent arms. After training, the flexibility of the representation of the maze was probed by requiring animals to choose between pairs of arms that had not previously been presented together. Single-arm training supported the flexibility to

choose the rewarded arm in novel probe tests, consistent with a relational schema of the entire maze including all the arm-reward associations. In contrast, rats trained on paired-arms failed the flexibility probe, consistent with separate learning of a left or right response for each individual pairwise problem. CA1 firing patterns reflected the distinction between relational and individual spatial representations of maze arms as a consequence of training procedure. At the end of single-arm training, CA1 place cells showed graded similarity in spatial coding among rewarded arms, whereas at the end of paired arm training, CA1 cells had largely non-overlapping spatial representations of the rewarded arms. Taken together, these results link relational coding in the hippocampus to schematic memory, and pattern separation in hippocampal coding to resolving competing individual representations.

Title: Gamma oscillations and hippocampal information flow during a context dependent learning task

Authors: *A. JOHNSON[1], S. MCKENZIE[2], A. FRANK[3], H. EICHENBAUM[3]; [1]Psychology, Bethel Univ., Saint Paul, MN; [2]Neurosci. Inst., New York Univ. Med. Ctr., New York, NY; [3]Dept. of Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Fast and slow frequency gamma oscillations within the hippocampus are associated with differential coupling across hippocampal inputs to CA1 (Colgin et al. 2009, Nature). CA1 and medial entorhinal cortex (mEC) are strongly coupled during fast gamma oscillations (60-140Hz) while CA1 and CA3 are strongly coupled during slow gamma oscillations (22-55Hz). Such differential coupling suggests that CA1 switches between distinct information states: a memory-driven state associated with slow gamma oscillations and a stimulus-driven state associated with fast gamma oscillations. An experiment by Colgin and colleagues show a link between gamma oscillations and differential prospective and retrospective spatial coding in a linear track task (Bieri et al. 2014, Neuron). Here we examined whether gamma oscillatory states

also guide memory in rats performing a context dependent object association task. We trained rats on the object association task in order to examine the links between gamma oscillations and memory function. We predicted that object sampling events would be associated with stronger fast gamma oscillations that emphasized mEC inputs and reduced slow gamma oscillations leading to inhibited CA3 input. We further predicted that the memory dynamics that culminated in digging behavior would produce highly similar interactions between fast and slow gamma dynamics - regardless of whether the digging behavior achieved a reward. We observed a strong reduction in the ratio of slow gamma power to fast gamma power at the onset of sampling that is consistent with a hippocampal information shift toward stimulus driven inputs from mEC. The gamma ratio quickly increased when the animal sampled from objects associated with reward consistent with a shift to memory driven inputs from CA3 that maintain an expectation of reward. The gamma ratio showed a slower increase when the animal sampled from objects associated with no reward. The reduction in the gamma ratio was less pronounced during sampling that immediately preceded digging behavior. This result was likely the product of reduced attention to current stimulus as a result of previous sampling within a trial. These results suggest that the flow of information in the hippocampus dynamically shifts during performance of a goal-directed memory task. When the animal samples an object, CA1 displays stronger fast gamma oscillations consistent with memory encoding of current stimuli and inhibited retrieval dynamics. However, when the animal samples from a rewarded object, CA1 displays a fast shift to stronger slow gamma oscillations consistent with memory retrieval and reduced stimulus input.

Abstract: The hippocampus plays a critical role in representing the temporal organization of events that compose episodic memories. As a potential mechanism for temporal organization, several studies have identified hippocampal 'time cells', neurons that fire at specific moments in a fixed interval (much like 'place cells' fire when a rat is in specific places in a fixed space). The appearance of time cells in area CA1 is consistent with several studies that have highlighted the role of this subregion of the hippocampus in temporal processing (e.g., Kesner et al. Behav. Neurosci. 2005; Farovik et al., Learning & Memory 2010) but other subfields of the hippocampus have not been examined for temporal coding. Here we explored whether temporal processing within the hippocampus is limited to area CA1 by comparing temporal and spatial coding properties of CA1 and CA3 neurons in rats running in place on a treadmill in between alternate paths in a delayed alternation T-maze task. CA3 neurons fired at specific moments during running in place, much like CA1 time cells, and CA3 time cells are as numerous as CA1 time cells. In addition, time cells in both CA1 and CA3 were also prevalent when the memory load was eliminated by having rats run in the same path on each trial. Taken together, these results are consistent with the view that the properties of time cells parallel those of place cells in the temporal dimension, and that, like spatial processing, temporal processing is prevalent throughout the hippocampus regardless of memory demand.

Title: Membrane potential dynamics of mouse hippocampal neurons *in vivo*

Deleted: *in vivo*

Authors: ***N. MATSUMOTO**, Y. IKEGAYA;
Lab. Chem. Pharmacol., Grad. Sch. Pharmaceut. Sci., Univ. Tokyo, Tokyo, Japan

Abstract: Ripples, high-frequency oscillations observed in the hippocampal formation, are believed to be associated with memory consolidation or memory replay. They are generated in the hippocampal CA3 recurrent circuits and are transmitted to its downstream networks such as the CA1 and the subiculum. The cellular mechanisms underlying their generation and transmission are, however, still poorly understood. In awake or anesthetized mice, we performed whole-cell patch-clamp recordings from membrane potentials of hippocampal neurons simultaneously with extracellular recordings of CA1 local field potentials (LFPs). After experiments, we identified the cell types and locations of recorded neurons using biocytin labeling. The LFP electrode track was found in the stratum pyramidale or radiatum of the CA1 region. CA2 neurons exhibited burst firings, which consisted of at least three spikes with an inter-spike interval of less than 10 ms. The spike bursts were not time-locked to CA1 ripples. Moreover, its membrane potentials exhibited oscillation-like fluctuations, which often emerged independently of local-field oscillations. When we measured the changes in subthreshold membrane potentials relative to the peaks of individual CA1 ripple events, we found that the CA1 neurons were hyperpolarized during about 70% of the ripple events. When the same analysis was carried out for ripples of anesthetized mice, similar hyperpolarizations were reproduced for CA2 and CA1 neurons. Therefore, a large population of hippocampal neurons are likely to be transiently suppressed during CA1 ripple events.

Abstract: Erucic acid, a monounsaturated omega-9 fatty acid, which is contained in the seed of Raphanussativus L., is known to reduce synthesis of very long chain fatty acids (VLCFAs) and

the accumulation of the VLCFA in the brain which causes the X-linked adrenoleukodystrophy. In the present study, we investigated whether erucic acid ameliorates scopolamine-induced memory impairment using the several behavior tasks. Erucic acid (3 mg/kg, p.o.) significantly ameliorated memory impairment induced by scopolamine on the passive avoidance task, the Y-maze task and the Morris water maze task. Erucic acid also significantly enhanced cognitive performance in normal naïve mice. In addition, erucic acid significantly increased the phosphorylation levels of protein kinase C zeta (PKCζ), extracellular signal-regulated kinases (ERK) or protein kinase B (Akt) in the hippocampus. Consequently, these results suggest that erucic acid has both memory-ameliorating effects and enhancing activites, and the effects of erucic acid are partly owing to the activation of PKCζ-ERK signaling or the increase level of phosphorylated Akt in the hippocampus. Overall, erucic acid may be a potential treatment agent for cognitive deficit, such as Alzheimer's disease (sponsored by NRF-2014M3A9C4066465).

Abstract: Acanthopanax koreanum Nakai (Araliaceae) is one of widely used medicinal plants in Jeju Island, Republic of Korea, and the roots and stem bark of A. koreanum have been traditionally used as a tonic agent. In the present study, we investigated the effect of 70% etanolic extract of A. koreanum (EEAK) on scopolamine-induced memory impairment in mice using several behavioral tests such as the passive avoidance or the Y-maze tasks. Administration of EEAK (100 or 200 mg/kg, p.o.) significantly ameliorated the scopolamine-induced cognitive impairment in mice. In addition, EEAK increased the latency time during the passive avoidance task in normal naive mouse. We also observed that protein kinase B (Akt) and glycogen synthase

kinase-3β (GSK-3β) signal molecules were affected by EEAK, which means EEAK regulates cognitive function through Wnt signaling pathway. Taken together, these findings suggest that EEAK ameliorates cognitive dysfunction induced by cholinergic blockade, in part, through Akt-GSK-3β signaling pathways and would be a therapeutic potential against cognitive dysfunction such as Alzheimer's disease (Sponsored by NRF-2014M3A9C4066465).

Abstract: It is well known that early life experiences induce long-term modifications because many genes can retain a memory of exposure to the initial environment via epigenetic mechanisms. We here checked whether maternal dysmetabolic environment affects cognitive performance and key neuronal gene expression in the brain of descendants via epigenetic mechanisms. C57 adult female mice (F0) were fed with either standard or high-fat diet (SD or HFD) from 4 weeks before mating until the 3rd week of suckling. The first generation of HFD-fed mice, hereinafter referred as F1-HFD, and their descendants (F2-HFD and F3-HFD, respectively) were all fed with SD and were tested by behavioral, electrophysiological and molecular analyses. Our findings demonstrate that maternal overnutrition alters learning and memory in the offspring and next generations. All HFD-descendant mice showed a lower discrimination index than the SD mice in a standard novel object recognition paradigm (F1-HFD

= 56.5 ± 1.1%, F2-HFD = 54.6 ± 1.5%, F3-HFD = 55.9 ± 0.5% vs SD = 68.9 ± 0.6%; n=8 , p<0.01 for each group). These effects were associated with a significant impairment of spatial learning and memory in the Morris water maze. Time spent to reach the platform at the 3rd and the 4th training days was increased by +71.4% and +99.6%, respectively in F1-HFD; +78.1% and +91.3% in F2-HFD; +70.3% and +58.6% in F3-HFD, when compared to SD mice (n=8 , p<0.01 per each group). Electrophysiological analyses on hippocampal brain slices of F1-, F2- and F3-HFD mice revealed severe deficits of long-term potentiation at CA3-CA1 synapses (ranging from -37.3% in F1-HFD to -52.2% in F3-HFD; n = 11 slices from 4 mice per group, p<0.05). Finally, maternal HFD reduced multiple BDNF transcripts and its expression at the protein level via specific epigenetic mechanisms involving BDNF regulatory sequences. More importantly, in caudal epididymis of HFD-descendants male mice we found the same epigenetic marks observed in their hippocampi. Collectively, our data suggest that maternal HFD alters BDNF expression and cognitive performances in the descendants via transgenerational epigenetic mechanisms.

Title: Involvement of muscarinic acetylcholine receptors in conditional discrimination task in eyeblink conditioning in mice

Authors: *A. RAHMAN[1], N. TANAKA[1], K. USUI[1,2], S. KAWAHARA[1,2];
[1]Grad. Sch. of Innovative Life Sci., Univ. of Toyama, Toyama, Japan; [2]Grad. Sch. of Sci. and Eng., Univ. of Toyama, Toyama, Japan

Abstract: In eyeblink conditional discrimination learning, subjects execute the conditioned response (CR) only when a preceding contextual cue is present. In the present study, we investigated the effect of muscarinic acetylcholine receptor (mAChR) antagonist scopolamine on acquisition and expression of the conditional CR in mice. We used a delay paradigm with a 350-ms tone conditioned stimulus (CS) and a 100-ms periorbital electrical shock unconditioned stimulus (US). 8-10-week-old male C57BL/6 mice were injected with saline (n = 8) or scopolamine (n = 8, 1 mg/kg, i.p.) 20 min before a random sequence of 30 CS-US paired trials

and 30 CS-alone trials with an intertrial interval of around 60-70 s. A 2-s light was delivered 3-4 s before the CS-US paired trial (cued trial) but not before the CS-alone trial (non-cued trial). During acquisition sessions, scopolamine group mice successfully developed CRs in both trials, failing to acquire the differential responses to the identical tone, while saline group mice successfully acquired the discrimination between the cued and non-cued trials. In the expression session after 7 consecutive days of acquisition sessions, administration of scopolamine to the saline group did not impair the pre-acquired discrimination as well as the expression of CR in the cued trials. Analysis of the hippocampal local field potential revealed that type 2 theta was elicited by the light cue during acquisition sessions in saline group, which was abolished by scopolamine in the subsequent expression session. These results suggested that mAChRs play an important role in acquisition but not expression of the conditional discrimination. Moreover, the hippocampal type 2 theta oscillation might not be necessary at least for expression of the pre-acquired discrimination.

Title: AMPAkine treatment modulates hippocampal theta power in the juvenile rat during Y-maze exploration

Authors: ***D. G. MCHAIL**, S. HUSSAIN, J. ASHRAFI, M. GREER, A. M. R. LOGHMANI, T. C. DUMAS;
Dept. of Mol. Neuroscience, Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Pathological development of excitatory synaptic transmission is thought to underlie many neurological disorders including epilepsy, schizophrenia, and autism spectrum disorders. A more complete understanding of these disorders is hindered in part because mechanisms that contribute to normal brain development and function remain poorly understood. We have shown that spontaneous alternation (SA) in a Y-maze emerges at the end of the third postnatal week in rats in association with changes in the subunit composition of glutamatergic AMPA receptors in

the hippocampus, a prolonged synaptic AMPA receptor response, and a reduced threshold for the induction of long-term potentiation (LTP) (Blair et al., 2013). These findings prompted interest in changes in hippocampal network oscillatory activity around three weeks of age. In adults, theta (4-12 Hz) power increases when an animal rears to investigate its environment and deliberates at a choice point. Prior work has shown that theta frequency and power increase in area CA1 across the first postnatal month. We implanted Long Evans rats at postnatal day (P) 14 with stereotrodes positioned to record neuronal activity from the cell body layer and synaptic layer of area CA1. Electrophysiological recording synchronized with video capture occurred as animals explored a transparent Y-maze for 15 minutes on P18, P19, P23, and P24. The positive allosteric modulator of AMPA receptors, CX614 (2.5 mg/kg, Cortex Pharmaceuticals), or vehicle was administered 30 min prior to each test (2 drug and 2 vehicle injections per animal). Implanted animals displayed an age-dependent increase in SA and CX614 increased SA at P18-19. CX614 increased the number of arm choice pauses and theta power during arm choice pauses at P23. The dissociation between the effects of CX614 on SA rate at P18-19 and the drug effects on theta power and arm choice pauses at P23 suggest that theta power and SA develop independently. The current findings support an age-dependent increase in theta frequency and power and implicate AMPA receptors in this process. Implanted animals alternated at lower rates than naïve control animals. Experiments testing the effects of isoflurane exposure on spontaneous alternation are underway.

Abstract: Hippocampal long-term depression (LTD) is an active form of synaptic plasticity necessary for learning involved in consolidation of spatial memory, contextual fear memory and novelty acquisition. Proteins of the apoptotic machinery are necessary components of NMDAR-dependent LTD and caspases are involved in postsynaptic remodeling and synaptic maturation. In the present study, we looked at the role of the endogenous inhibitor of caspases X-linked inhibitor of apoptosis (XIAP) in synaptic plasticity in the hippocampus. We initially investigated several behavioral tasks related to memory and interestingly, found that XIAP-/- mice show improved novelty acquisition in spatial and fear memory. Further analysis in both acute brain slices and hippocampal neurons in culture revealed that XIAP deletion results in significantly enhanced LTD, increased AMPA receptor internalization, increased caspase-3 activity and reduced synapse density. Taken together, these results indicate that basal XIAP expression regulates caspase-3 activity within synapses, thereby contributing to optimal synapse stability, synaptic plasticity and memory acquisition.

Title: PGC-1α regulates transcriptional programs in a cell- and region-specific way for distinct impacts on circuit function and behavior

Authors: *L. J. MCMEEKIN[1], A. S. BOHANNON[2], E. W. ADLAF[2], E. K. LUCAS[3], L. S. OVERSTREET-WADICHE[2], L. E. DOBRUNZ[2], J. J. HABLITZ[2], R. M. COWELL[2]; [1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The transcriptional coactivator peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α) has been implicated in multiple psychiatric and neurodegenerative

diseases, however its cell-specific roles in transcriptional regulation are not wholly understood. PGC-1α is highly expressed in GABAergic interneurons, and although it plays a significant role in interneuron function, preliminary data suggests that this coactivator also plays a role in transcriptional regulation within striatal medium spiny neurons (MSNs) as well as cortical and hippocampal pyramidal neurons (PNs). To test this hypothesis, we generated mice lacking PGC-1α in these neuronal populations using cre-lox technology. Mice expressing cre-recombinase driven by the PV, EMX1, or the RGS9L promoter were crossed to those expressing loxP sites flanking exons 3-5 of the *PPARCG1A* gene to delete PGC-1α from parvalbumin-positive (PV+) populations, PNs, and MSNs, respectively. Loss of PGC-1α within cortical PV+ interneurons leads to reductions in genes involved in synchronous neurotransmitter release (synaptotagmin-2, Syt2 and complexin-1, Cplx1), structural maintenance (neurofilament heavy chain, Nefh), and metabolism (phytanoyl-CoA hydroxylase, Phyh and isocitrate dehydrogenase 3 (NAD+) alpha, Idh3a), findings that are similarly seen in PNs of the somatosensory cortex with the exception of Cplx1 and Idh3a. Further, an additional subset of metabolic genes unchanged in cortex of these two conditional knockout lines is dramatically reduced in the hippocampus of animals lacking PGC-1α in PNs, indicating a role for this coactivator in regulating transcripts in a cell- and region-specific way. While these transcripts are reduced by a loss of PGC-1α in these two mouse lines, a loss of PGC-1α in MSNs results in an increase in these PGC-1α-dependent targets indicating a possible non-cell autonomous upregulation of these transcripts in PV+ interneurons. Reductions in PGC-1α-dependent genes translate to altered intrinsic electrophysiological properties and release of either GABA or glutamate onto post-synaptic targets demonstrating a cell-specific effect of a loss of PGC-1α on neuronal signaling and, thus, circuit function. Changes in regional circuitry are evident at the behavioral level in which a deletion of PGC-1α from these neuronal populations contributes to distinct cognitive and behavioral effects. These data shed light on how a reduction of PGC-1α function may contribute to pathophysiology of different diseases, particularly given the diverse array of cognitive and motor deficits associated with disorders in which reductions in PGC-1α have been associated.

Title: Catecholaminergic neurons in mouse locus coeruleus are more strongly activated by novelty than catecholaminergic neurons in the ventral tegmental area

Authors: A. J. DUSZKIEWICZ[1], T. TAKEUCHI[1], P. SPOONER[1], K. DEISSEROTH[2], G. FERNÁNDEZ[3], *R. G. MORRIS[1];
[1]Ctr. for Cognitive and Neural Systems, The Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA; [3]Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: RATIONALE: The 'synaptic tagging-and-capture' theory holds that persistence of memory traces can be altered by prior or subsequent patterns of neural activity that increase the availability of plasticity-related products (PRPs) (Frey and Morris, Nature, 1997). PRP production in the hippocampus is likely stimulated by neuromodulatory activity. Using the event arena, our laboratory has established that novel experiences can boost retention of unrelated spatial memories through activation of hippocampal (HPC) D1/D5 dopamine (DA) receptors (Takeuchi et al., Phil. Trans. R. Soc. Lond. B, 2014). Ventral tegmental area (VTA) has long been implicated as a possible source of DA in HPC (Lisman et al., TINS, 2012). Interestingly, a recent study (Smith and Greene, J. Neurosci., 2012) suggested that DA in HPC comes from axons of locus coeruleus (LC) neurons. METHODS and RESULTS: In order to identify the neuromodulatory structure(s) that may mediate the novelty effect on memory persistence, we recorded single unit activity of optogenetically identified catecholaminergic (CAergic) neurons in mouse VTA and LC in a novelty exploration paradigm. Using tyrosine hydroxylase-Cre knock-in mice and a Cre-dependent adeno-associated viral vector, we tagged CAergic neurons in VTA and LC selectively with channelrhodopsin-2 (ChR2). This enabled us to reliably identify, using an optetrode, CAergic neurons during unit recording sessions in freely moving animals. Neurons were classified as CAergic if they consistently fired spikes time-locked to 5-ms blue light pulses. We recorded activity of these optogenetically identified CAergic neurons during 5-min exploration of environments with familiar and novel floor substrates. We found that CAergic neurons in both VTA and LC selectively increased their firing rate in novel environments, relative to both a familiar environment and a home cage baseline. When normalised to their baseline firing rates, LC neurons were more strongly activated by novelty than VTA neurons, and a decline in this activation was observed as the recording environment became more familiar CONCLUSIONS: Our results suggest that CAergic LC neurons may be more responsive to novelty than VTA neurons, and this may impact novelty-associated neuromodulatory enhancement of memory persistence, and set the stage for optogenetic activation and inactivation of these neurons during behavioural studies of memory persistence. *Supported by European*

Title: Catecholaminergic enhancement of initial memory consolidation in mice

Authors: ***T. TAKEUCHI**[1], A. J. DUSZKIEWICZ[1], M. YAMASAKI[2], D. TSE[1], P. SPOONER[1], M. WATANABE[2], K. DEISSEROTH[3], G. FERNÁNDEZ[4], R. G. M. MORRIS[1]; [1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Hokkaido Univ., Hokkaido, Japan; [3]Stanford Univ., Stanford, CA; [4]Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: RATIONALE: The 'synaptic tagging-and-capture' theory of initial memory consolidation holds that memory persistence can be altered by prior or subsequent patterns of neural activity (Frey and Morris, Nature, 1997). We have developed a realistic model of everyday memory for mice and confirmed that unrelated novel experiences can facilitate the persistence of spatial memory (Takeuchi et al., Phil. Trans. R. Soc. Lond. B, 2014). Our analysis focuses on identifying the specific neuromodulatory systems that mediate this effect. An influential model points to the critical role of catecholaminergic (CAergic) neurons in the ventral tegmental area (VTA) ('hippocampus (HPC)-VTA loop': Lisman et al., TINS, 2011), but recent evidence also implicates locus coeruleus (LC) as a potential source of dopamine in HPC (Smith and Greene, J. Neurosci., 2012). METHODS AND RESULTS: Tyrosine hydroxylase-Cre knock-in (Th-Cre) mice learned the win-stay rule of selectively finding, each day, the varying location of food in an event arena. Persistence of this transient spatial memory, tested 24 hour later, could be enhanced by 5-min exploration of an open field with novel floor substrates 30 min after encoding. Pharmacological blockade of dopamine D1/D5 but not β-adrenergic receptors in HPC during novelty exploration prevented the enhancement of memory persistence. Another cohort of Th-Cre mice, in which channelrhodopsin-2 (ChR2) was expressed in CAergic neurons of both VTA and LC using a Cre-dependent adeno-associated virus, was then trained on the

same task. ChR2-mediated photoactivation of CAergic neurons in LC but not in VTA 30 min after encoding, substituting for novelty, was also successful in enhancing the persistence of memory. Paradoxically, but in keeping with Smith and Greene's results, the effect of LC photoactivation was blocked by a dopamine D1/D5 receptor antagonist in HPC. Anatomical studies using both retrograde and anterograde techniques indicate a much more prolific CAergic projection from LC to HPC than is observed from VTA. NEXT STEPS: Successfully mimicking the memory enhancing effect of post-encoding novelty by selective activation of LC CAergic neurons appears mechanistically distinct from the augmented attention at encoding through activation of CAergic neurons (Kentros et al., Neuron, 2004), but more in keeping with modified versions of the HPC-VTA loop/synaptic tagging-and-capture hypotheses. It would be valuable to know whether optogenetic silencing of LC CAergic neurons during novelty exposure limits the memory enhancing effect of novelty.

Title: Differential consolidation induced by novelty and sleep associated with contrasting behavioural expression of hippocampal and cortical memory traces

Authors: *L. GENZEL, J. ROSSATO, J. JACOBSE, R. G. M. MORRIS;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: BACKGROUND: Distinct forms of memory consolidation (cellular and systems) influence the persistence of spatial memory within the hippocampus (cellular) and following hippocampal-neocortical interactions (systems). Factors influencing these processes include: (1) novelty exposure that enhances the persistence of hippocampal traces via neuromodulation; and (2) sleep that aids systems consolidation and thus cortical memory. Do such hippocampal and

cortical traces differ with respect to their association with immediate early gene (IEG) expression, behavioural expression and/or persistence over time? METHODS and RESULTS: In Expt 1, rats (n=80) were trained in watermaze (2 m diameter, 8 trials, 1 session), followed by sleep (S) or novelty + sleep deprivation (N+SD) during a post-training 6h consolidation period, and then given a probe trial 7d later. Following sacrifice, including home-cage controls, hippocampus and prefrontal cortex were extracted for qPCR analysis of gene expression. The key finding was that post-training S was associated with elevated plasticity-related IEG expression in cortex (tested at retrieval), while N+SD enhanced expression in hippocampus. In Expt 2, rats (n=96) were trained on two competing memories with training to one (8 trials, 1 session) followed by S and then the other (8 trials, 1 session) by N+SD. The escape platform was in opposite locations in the pool for the successive two sessions. Probe trials without any platform present were conducted at 7d. With this baseline protocol (n=32), the hippocampal memory was stronger than the cortical memory. However, when the rats were given pre-exposure to context cues over 3 days (n=32), the cortical memory improved selectively to the same strong level as the hippocampal memory. And when an extinction trial was scheduled at 24 hr after training (n=32), it erased the hippocampal but not the cortical memory. Conventional measures of watermaze performance were supplemented by heat-maps and cluster analysis of time spent exploring relevant regions of the pool. CONCLUSION: These data contribute to other findings suggesting a dynamic interplay of distinct types of memory consolidation that differentially affect hippocampal and cortical memory. Even in the absence of sleep, novelty boosts hippocampal memory, and is also selectively affected by a single session of extinction. In contrast, sleep is essential to stabilise cortical spatial memory, which can also be boosted by relevant prior knowledge. Cortical memory appears to be more resistant to interference and updating. Title: Adipocyte-specific over-expression of ecto-nucleotide pyrophosphate phosphodiesterase-1 leads to memory impairment in mice on a high-fat diet

Authors: *A. MILTON, J. KASPER, H. SALLAM, B. TUMURBAATAR, W.-R. ZHANG, D. TUVDENDORJ, F. LAEZZA, G. TAGLIALATELA, N. ABATE, J. HOMMEL;
Univ. of Texas Med. Br., Galveston, TX

Abstract: Memory impairments typical of dementia and Alzheimer's disease are potentiated by metabolic abnormalities such as type-2 diabetes mellitus and obesity. Obesity is a complex disease associated with of increased consumption of saturated lipids and carbohydrates combined with decreased physical activity. The disease is accompanied by symptoms of metabolic syndrome including decreased insulin sensitivity and dyslipidemia. The relationship between memory impairments and metabolic syndrome is poorly understood, highlighting the need to further explore their molecular, physiological and behavioral underpinnings. One possible link between obesity and memory impairment is Ecto-nucleotide pyrophosphate phosphodiesterase-1 (ENPP1), a transmembrane protein that negatively modulates insulin receptor activation and is over-expressed in people with insulin resistance. Over-expression of ENPP1 in adipose tissue of mice (AtENPP1-Tg) mimic the clinical symptoms of metabolic syndrome including insulin resistance, triglyceride deposition in the liver, and impaired lipid handling. The extent of CNS deficits induced by peripheral changes were studied using the AtENPP1-Tg mouse model. AtENPP1-Tg mice challenged with a high-fat diet display aberrant triglyceride and diacyglycerol content of synaptosomes in the hippocampus, a key brain region in learning and memory. To characterize the functional consequences of this aberrant lipid content, electrophysiological studies were performed on the hippocampus. We observed that CA1 pyramidal neurons of the hippocampus have severely impaired basal synaptic transmission in AtENPP1-Tg mice maintained on a high-fat diet. This is frequently observed in hippocampal circuitry disruptions and lead to memory deficits. AtENPP1-Tg mice were evaluated in the Morris Water Maze, a hippocampal-dependent model of memory in rodents. Mice given a high-fat diet spent decreased time in the goal quadrant compared to littermates on a standard (lean) diet. Additionally, AtENPP1-Tg mice on a high-fat diet spent less time in the goal quadrant compared to wild-type mice also on a high-fat diet. These findings suggest that ENPP1 potentiates memory impairments caused by consumption of a high-fat diet.

Title: Mice consuming a diet containing pectin fiber but not EGCG display cognitive benefits on the Morris water maze

Authors: *T. BHATTACHARYA[1], P. PARK[1], C. RENDEIRO[1], B. D. PENCE[2], Y. SUN[2], A. J. COBERT[1], K. S. SWANSON[3], G. C. FAHEY[3], R. W. JOHNSON[3], K. W. KELLEY[3], R. H. MCCUSKER[3], J. A. WOODS[2], J. S. RHODES[4];
[1]Beckman Inst. for Advanced Sci. and Technol., [2]Kinesiology and Community Hlth., [3]Animal Sci., [4]Psychology, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Dietary supplementation with (-)-epigallocatechin-3-gallate (EGCG), a flavonoid found in green tea, has been widely studied to examine its effects on cognitive function. In papers recently published by our group (Bhattacharya et al., 2015, Gibbons et al., 2014), we found no cognitive enhancements in either young or aged mice fed a diet supplemented with EGCG for 40 days. However, it is possible that longer interventions are needed in order to detect benefits in cognition. Furthermore, we hypothesize that the inclusion of a soluble dietary fiber in the EGCG diet might enhance the absorption of the flavonoid, making it more bioavailable and effective. Therefore, the goal of the present study was to investigate the impact of a diet containing EGCG and/or pectin fiber on cognitive tasks. Twenty C57BL/6J mice 6 weeks old were placed on a control (AIN-93M) or experimental diet (based upon AIN-93M) containing EGCG (1.5 mg/g) and/or pectin fiber. Pectin fiber was directly substituted in equal proportion for cellulose fiber, i.e. 50 g cellulose for 50 g pectin fiber, in the AIN-93M base. After 126 days on the control or experimental diets, animals were tested on the Morris water maze and the active avoidance tasks to measure spatial learning and memory and associative operant learning, respectively. No cognitive benefits were detected following supplementation with EGCG ($p=0.46$) or pectin fiber ($p=0.68$) on the active avoidance task. However, results indicated pectin improved spatial memory. In the 24-hour probe trial, mice given pectin fiber spent significantly more time in the target quadrant ($p<0.01$) and had an overall decreased average distance from the target platform ($p<0.05$) as compared to the other groups. Taken together, preliminary evidence suggests a pectin diet may have cognitive-enhancing properties but EGCG has not shown any effect on cognitive outcomes.

Title: Combination strategies of environmental enrichment, physical exercise and nutritional supplementation enhance the spatial cognition and hippocampal neurogenesis in ventral subicular lesioned rats

Authors: *B. M. KUTTY[1], V. KAPGAL[2], N. PREM[2], P. HEGDE[2], L. T. RAO[2];
[2]Neurophysiol., [1]Natl. Instit Ment Hlt &Neurosci, Bangalore, India

Abstract: Subiculum is positioned between hippocampus and entorhinal cortex and is a part of the hippocampal learning system. Subiculum is involved in coding of spatial information. We have demonstrated that selective lesioning of cholinergic projections to subiculum reduced the subicular theta activity and impaired the spatial learning and memory functions in adult male Wistar rats. Similarly, chemical lesioning of ventral subiculum (VSL) by ibotenic acid resulted in hippocampal neuro-degeneration and cognitive impairment in rats. Post lesion exposure of VSL rats to enriched environment (EE) for 10 days enhanced the spatial learning performances in eight arm radial maze task but not in Morris water maze task. This suggests that functional recovery is task dependent and requires appropriate enrichment strategies. Hence, in the present study, we have developed an animal model of cognitive impairment by selective lesioning of ventral subiculum bilaterally using ibotenic acid (VSL) without hippocampal degeneration. Following lesions of ventral subiculum, the VSL rats were exposed to combination strategies (CS) of EE with voluntary wheel running along with nutritional supplementation for a period of one month. The VSL rats exposed to CS showed significant improvement in spatial navigational abilities in Morris water maze task and also showed enhanced hippocampal neurogenesis. However , the VSL rats exposed to standard housing conditions continued to show significant spatial deficits and reduced hippocampal neurogenesis. The study suggests that subiculum is important for spatial navigation and suitable enrichment strategies facilitate intrinsic plasticity events such as enhanced synaptic plasticity and adult neurogenesis leading to functional recovery. Our study supports that combination strategies of EE, physical exercise and nutritional supplements enhance the ‘cognitive reserve’ capacities of the brain. This may be of great

significance towards developing appropriate strategies to enhance functional recovery in neurodegenerative disorders such as Alzheimer's disease.

Title: 17 β-estradiol regulates gamma-band oscillations in the hippocampus and related cognitive functions

Authors: *A. SCHROEDER;
Florey Dept., The Florey Inst. of Neurosci. and Mental He, Parkville, Australia

Abstract: Cognitive deficits in schizophrenia are functionally disabling and there is currently no treatment to address this core symptom. Schizophrenia patients exhibit reduced gamma-band oscillations (30-80Hz) during the execution of cognitive tasks. Gamma-band oscillations are generated by parvalbumin positive (PV+), fast-spiking interneurons, which are reduced in schizophrenia brains. Estrogens have beneficial effects on cognitive function and we previously showed that estradiol regulates the expression of PV+ interneurons in the hippocampus and influences related cognitive function. The current study demonstrates for the first time that estradiol regulates gamma frequency oscillations in the dorsal hippocampus and hippocampal dependent memory in female mice. We recorded brain activity from the dorsal hippocampus of female sham ovariectomized (OVX) mice, OVX mice and OVX mice with estradiol replacement, while they were in the home cage or performing Y-maze, a short-term hippocampal-dependent memory task. While gamma-band oscillations significantly increased in the control mice when these were put in a novel environment (Y-maze), this increase was absent in OVX mice and simultaneous estradiol replacement recovered this deficit. In addition, OVX mice showed a significant reduction in gamma-band frequency, specifically during decision making, which was accompanied by a significant deficit in short-term memory. Estradiol replacement rescued these deficits. Together with our previous findings, we suggest that estradiol mediates hippocampal gamma oscillations via the expression of PV+ interneurons. This study

unraveled a mechanism underlying beneficial effects of estradiol on cognitive function in schizophrenia.

Title: CB2 receptor agonist GP1a restores neuronal excitability and LTP alteration in epileptic rats

Authors: ***A. BELMEGUENAI**[1,2], M. OGIER[1,2], J. BODENNEC[1,2], B. GEORGES[1,2], L. BEZIN[1,2];
[1]TIGER Team (Translational & Integrative Groupe In Epilepsy Research), Lyon Neurosciences Ctr. - CRNL, Bron, France; [2]Inst. for Epilepsy - IDEE, Bron, France

Abstract: The effects of cannabinoids were primarily described as mediated by two types of cannabinoid receptors, CB1 receptors in the nervous system and CB2 receptors in the immune system. Recent evidence indicates that CB2 receptors are also widely expressed in the brain and are involved in cognitive processes. These observations also suggest that CB2 receptor activation may be a potential therapeutic strategy for disorders associated with different cognitive deficits. Status epilepticus (SE) is one of the most common neurologic emergencies leading to chronic epilepsy. We recently demonstrated in rats subjected to SE at weaning that hippocampal-dependent spatial memory and LTP, a candidate mechanism for learning and memory, are altered following SE (Fares et al., 2013). In this study, we observed that the transcript level of the CB2 receptor was strongly induced in the hippocampus as early as 1 day after SE, and maintained at a plateau until epilepsy onset. We then tested the hypothesis that treatment with the CB2 receptor agonist GP1a in rats subjected to SE can rescue neuronal excitability and LTP induction. Therefore, we performed whole cell patch-clamp recordings from pyramidal cells in hippocampal slices obtained from rats selected 2-3 weeks post-SE. We found that bath application of GP1a selectively enhanced the action potential firing, synaptic transmission and rescued LTP induction in a dose-dependent manner in rats subjected to SE. Altogether, our data demonstrate that molecular and cellular mechanisms underlying learning and memory can be restored in rats subjected to SE by CB2 receptor agonist GP1a treatment. If these effects are confirmed *in vivo* by ongoing studies using behavioural tests aimed at evaluating learning and

Deleted: in vivo

memory, then highly specific CB2 receptor agonists may be beneficial to improve cognitive functions in patients with epilepsy.

Title: 5-HT mediated plasticity in hippocampal learning and memory

Authors: *C. M. TEIXEIRA, Z. ROSEN, M. HERSH, S. SIEGELBAUM, M. ANSORGE; NYSPI-Columbia Univ., New York, NY

Abstract: Heterosynaptic activity modulates homosynaptic strength, the central parameter underlying Hebbian learning models. While the role of serotonin in heterosynaptic modulation is well established in invertebrates, its function in the vertebrate hippocampus is not understood. Here we show that optogenetic activation of serotonergic terminals in murine CA1 is sufficient to potentiate the CA3 to CA1 synapse during low-frequency stimulation of Schaffer Collaterals. Furthermore, serotonergic fiber activity in CA1 regulates behavior, with optogenetic stimulation increasing and inhibition impairing memory expression. These data demonstrate that serotonin participates in heterosynaptic potentiation of the CA3-CA1 synapse and imply a role of this mechanism in memory formation.

Title: Disappearance of the left-right asymmetry of allocation of NR2B in CA1 affects non-spatial memory inβ2-microglobrin KO mice

Authors: ***A. SHIMBO**[1,3], I. ITO[4], S. WATANABE[2];
[1]Keio Univ., Kanagawa-Ken, Japan; [2]Keio Univ., Tokyo, Japan; [3]Riken, Wako, Japan; [4]Biol., Kyusyu Univ., Fukuoka, Japan

Abstract: The left-right asymmetry in the brain is universal phenomena in vertebrate. Such the left-right asymmetry exists in not only a macroscopic level but also a microscopic level. In circuit-level left-right asymmetry, the allocation of NMDA receptor NR2B subunits in CA1 synapses are changing depend on which CA3 inputs come from left or right hemisphere. There are synapses which have high-density expression of NR2B (NR2B predominance synapse) and synapses which have low-density expression (non-dominant NR2B synapse). The NR2B dominance synapse has a smaller size than NR2B non-predominance synapse. The NR2B dominance synapse also changes their plasticity that long term potentiation is easy to produce. However, the impact the circuit-level left-right asymmetry on cognitive functions has not been revealed yet. Therefore, in this study, we compared the behavioral phenotypes of two strains, β2-microglobrin gene knocked out mice(β2m), in which this asymmetry disappears, and c57BL/6j mice(B6). In β2m, NR2B predominance synapse express in CA1 pyramidal cells regardless of CA3 inputs which come from left or right hemisphere, but non-dominant NR2B synapse doesn't express. We hypnotized thatβ2m show deficits in hippocampal-dependent cognition because CA1 pyramidal cells inβ2m may have abnormality in their synaptic plasticity due to the loss of the asymmetry of the NR2B allocation. We compared two strains in four tasks, namely, spatial cognition (Dry type Morris water maze: DWMW), working memory (8 arms radial maze task), response inhibition (Differential reinforcement of low rate: DRL), and non-spatial simple learning and extinction (straight runway task). There were no differences between two strains about DWMW and 8 radial maze task. β2m mice learned DRL and Straight runway task, though the learning speed was significantly slower than that of B6. β2m showed same average extinction speed of B6 but they didn't show spontaneous recovery in extinction of Straight runway task. These results indicate that spatial cognition, working memory and response inhibition are normal inβ2m, but they show deficits about no-spatial learning. In other words, the circuit-level left-right asymmetry is more likely to have a role in non-spatial learning. Increment of the NR2B in the CA3-CA1 synapse may occur by the disappearance of the circuit-level left-right asymmetry, hence changes CA1 pyramidal cells plasticity and their activity. It is also possible that the changing CA1 pyramidal cells activity may affect activities of other brain regions, striatum and prefrontal cortex, which are relate to non-spatial learning and spontaneous recovery.

Title: Modulation of medial entorhinal cortex layer II principal cell circuitry by glucocorticoids

Authors: *J. HARTNER[1], L. SCHRADER[2,1];
[1]Neurosci. Program, [2]Cell & Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Previous research has shown that stress impairs rodent performance on spatial memory tasks, but the underlying mechanisms are unclear. Spatial memory processing is mainly localized to a loop between the hippocampus and the entorhinal cortex. Stellate cells in layer II of the medial entorhinal cortex (MEC - LII) are spatially-tuned and necessary for establishing an internal grid-like representation of the environment. Stellate cells have unique firing characteristics largely due to a significant h-current as well as a complex network of inhibitory inputs. Our preliminary data show that chronic stress causes dendritic atrophy of stellate cells of layer II, suggesting that stress may functionally modulate these cells. MEC - LII is also composed of pyramidal cells, which are anatomically organized in grid-like fashion around the stellate cells and have a seemingly distinct network of inputs and inhibition. The functional interaction between these two principal cells' networks and modulation of these networks by environmental factors, such as stress, are not studied to date. In this study, we use whole-cell patch clamp electrophysiology of MEC slice preparations in mice to test synaptic changes of layer II principal cells in response to bath application of dexamethasone (1-10 μM), a synthetic glucocorticoid. We show that there is no overall effect of dexamethasone treatment on frequency of either miniature or spontaneous excitatory postsynaptic currents in MEC - LII principal cells. Interestingly, the frequency of spontaneous inhibitory postsynaptic currents (IPSCs) is significantly decreased by dexamethasone application in both principal cell types of MEC - LII. We are currently working to further characterize the functional circuitry within MEC - LII and localize the effect by investigating the effects of dexamethasone on the frequency of miniature IPSCs, within MEC - LII principal cells.

Title: Neonatal (+)-methamphetamine exposure in rats: impairments in egocentric, allocentric, working, and contextual fear memory

Authors: *S. A. JABLONSKI[1,2], A. GUTIERREZ[2,3], T. M. TEE[2], K. L. SUTTLING[2], M. T. WILLIAMS[1,2,3], C. V. VORHEES[1,2,3];
[1]Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Cincinnati Children's Res. Fndn., Cincinnati, OH; [3]Univ. of Cincinnati, Col. of Med., Cincinnati, OH

Abstract: Neonatal treatment of rat pups with (+)-methamphetamine (MA) results in long-term egocentric learning deficits in the Cincinnati water maze (CWM) and allocentric learning deficits in the Morris water maze (MWM; e.g., Vorhees et al., 2009). The mechanism for these cognitive effects is unknown. Pretreatment with the spin-trapping agent, N-tert-butyl-α-phenylnitrone (PBN) precludes MA-induced dopamine depletion in adult rats, implicating reactive oxygen species (ROS) in adult MA neurotoxicity (Cappon et al., 1996). Here we examined which cognitive tasks are sensitive to neonatal MA and if PBN could attenuate the MA-included deficits. Using a split-litter design, male/female pairs within each litter were treated with 10 mg/kg x 4/day MA at 2 h intervals on P6-15 or saline (Sal) with or without PBN (40 mg/kg, 30 min prior to each MA or Sal injection) creating 4 groups: Sal-Sal, PBN-Sal, Sal-MA, PBN-MA. Progeny were tested in the CWM, MWM, and radial-arm water maze (RWM) as adolescents (males) or adults (females). Male offspring were tested in a 3-day fear conditioning paradigm consisting of acquisition (day 1), contextual (day 2), and cued (day 3) conditioning. Female offspring were tested in a 2-day one-trial passive avoidance (PA) test. MA-exposed rats were impaired in the CWM, MWM, and RWM at both test ages, and MA-exposed rats were impaired in contextual, but not cued, fear conditioning. There was no main effect or interaction with PBN for any test. In the CWM, MA-treated rats showed increased errors at both ages with no changes in swim speed in a straight channel prior to CWM testing. In the MWM, MA-treated rats, regardless of age, showed impaired acquisition but no changes on probe trials and no differences in swim speed. In the RWM, adolescent male MA-treated rats showed impaired working and reference memory and adult females showed deficits in reference memory. In conditioned fear, MA-treated rats showed significantly less fear to the conditioning context compared with controls, but no cued or acquisition conditioning deficits. There were no treatment group differences during either PA acquisition or 24-h retention. These data show that neonatal MA induces multiple types of cognitive deficits, but these deficits are consistently evident in tasks

associated with hippocampal function, while sparing tests associated with other brain regions (e.g., amygdala). Additionally, maze learning deficits emerge early and persist into adulthood, but are not the result of performance effects. Finally, none of the MA-induced impairments were attenuated by PBN, suggesting that ROS do not mediate the neurobehavioral effects of neonatal MA exposure.

Title: Post-trauma administration of the pifithrin-α oxygen analogue prevents hippocampal neuronal loss and improves cognitive deficits after experimental traumatic brain injury

Authors: *L.-Y. YANG[1,2], J.-Y. WANG[2], N. GREIG[3], J.-Y. WANG[2];
[2]Grad. Inst. of Med. Sciences, Col. of Med., [1]Taipei Med. Univ., Taipei City, Taiwan; [3]Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a major cause of death and disability worldwide. Neuronal apoptosis in the hippocampus has been detected after TBI. The dysfunction of hippocampus will result in cognitive deficits in learning, memory, and spatial information processing ability. Our previous study have demonstrated that a p53 inhibitor, pifithrin-α oxygen analogue (PFT-α (O)), significantly reduced of cortical cell death and improved neurological functional outcome via anti-apoptotic mechanisms. In the present study, we examined the effect of PFT-α (O) on TBI-induced cognitive impairments. To investigate whether p53-dependent apoptosis in hippocampal neuronal loss and associated cognitive deficits, SD rats were subjected to experimental TBI followed by the administration of PFT-α or PFT-α(O) (2 mg/kg, i.v.) at 5 h after TBI. Fluoro-Jade C staining were used to stain within the hippocampal regions, including CA1 and dentate gyrus (DG) of the brain. Neurological functions including somatosensory/motor and recognition memory were assessed by behavioral tests at 24 h or 7 days post injury. PUMA , p53, 4-HNE, COX4,Annexin V and NeuN were identified by double immunofluorescence staining with cell-specific markers. Levels of mRNA encoding for p53, p53-regulated pro-apoptosis genes and caspase-3 were measured by RT-qPCR. Post-injury administration of PFT-α or PFT-α (O) at 5h significantly reduced contusion volume and improved motor outcomes at 24

h and ameliorated cognitive deficits as evaluated by novel object recognition at 7days after TBI. PFT-α or PFT-α (O) significantly reduced (~50%) the number of FJC-positive cells in hippocampus CA1 and DG regions compared with vehicle treatment. Double immunofluorescence staining demonstrated PFT-α (O) treatment decreased and p53 and annexin V positive neurons in the hippocampal CA1 region, respectively. Furthermore, PUMA colocalized with the mitochondrial maker COX4 and the upregulation of PUMA was inhibited by PFT-α (O) after TBI. We also found that that TBI-induced 4-HNE protein levels within the hippocampal CA1 neurons were significantly decreased in the PFT-α (O) treated TBI animals. Our data suggest that both PFT-α and PFT-α (O) significantly reduce hippocampal degeneration, and improve neurological and cognitive deficits *in vivo* via antioxidative and antiapoptotic properties.

Title: The effects of caffeine on performance of rats in the Traveling Salesman Problem

Authors: ***M. STOJANOVIC**, B. CHACON, D. MUHAMMAD-MENZIES, R. BLASER; Univ. of San Diego, San Diego, CA

Abstract: The traveling salesman problem (TSP) is a combinatorial optimization problem that can be used to examine spatial cognition in human and non-human animals. Although rats appear to use a distance-minimization strategy in this task, the mechanism by which they select spatial routes in this task is not yet understood. While the TSP is similar to the radial arm maze and the Morris water maze, it may require involve different processes than other commonly used spatial tasks. Our study examined the effects of acute caffeine exposure on the route choices of rats in the TSP. Animals were given caffeine on alternating days, and tested with six different Traveling Salesman problems with and without caffeine. Caffeine interacted with task difficulty and with testing day, producing improvements only on some problems, with some measures of performance. While caffeine appears to influence behavior in the TSP, the specific processes involved will require further investigation.

Title: Reduced preference for novel social stimuli after knockout of the oxytocin receptor from the hippocampal CA2 area

Authors: J. FASTMAN[1], M. VINCENT[1], A. SMITH[1], S. WILLIAMS AVRAM[1], A. CYMERBLIT-SABBA[1], J. SONG[1], H.-J. LEE[2], *S. YOUNG[1];
[1]NIMH, NIH, DHHS, Bethesda, MD; [2]Dept. of Oral Microbiology, Sch. of Dent., Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: The hippocampal area CA2 plays a functional role in various forms of social behavior. The vasopressin 1b receptor (Avpr1b) is selectively and ubiquitously expressed in CA2 pyramidal cells, and knockout of this receptor gene causes deficits in social memory and offensive aggression. We previously showed that CA2 neurons are responsive to oxytocin (Oxt) (Pagani et al., 2015) and here we show that the oxytocin receptor (Oxtr) is co-expressed with Avpr1b in nearly all CA2 pyramidal cells. We therefore wondered whether Oxtr in CA2 have similar roles as Avpr1b there. We created a Cre recombinase knockin driven by the Avpr1b promoter and crossed this line with our conditional knockout of the Oxtr (fOxtr-Avpr1bcre) in order to determine how the absence of functional Oxtr in Avpr1b-expressing neurons affects a range of social behaviors. Anxiety was measured using the elevated O-maze, Object recognition and olfactory ability were measured using a 5-trial habituation-dishabituation tests. Social recognition was measured using a similar 5-trial habituation-dishabitation test as well as a harder 2-trial test with a 30 min interval. Social novelty preference was measured in a single 5-min exposure to a littermate and a novel male in a 3-chambered cage. Offensive aggression was measured using a standard resident-intruder test. Defensive aggression was measured by placing the mouse in the home cage of a confirmed aggressive male mouse. We found that fOxtr-Avpr1bcre mice fail to exhibit a preference for investigating a novel conspecific mouse over a

littermate when presented simultaneously in a three-chamber test. These mice perform similarly to wildtypes in tests of anxiety, olfactory function, social memory and object memory, and offensive and defensive aggression. Additionally, allogrooming, social contact, and olfactory investigation were normal. We thus conclude that Oxtr in the CA2 contributes to the motivation to investigate novel social stimuli. The role of Oxt signaling to the Avpr1b-expressing neurons is likely to be distinct from the role of vasopressin. This research was supported by the NIMH (Z01-MH-002498-24).

Title: Multifractal complexity of hippocampal neurons after delta-9-Tetrahydrocannabinol administration during working memory and rest

Authors: *D. FETTERHOFF[1,2], R. A. KRAFT[3], R. A. SANDLER[4], I. OPRIS[2], C. A. SEXTON[3], V. Z. MARMARELIS[4], S. A. DEADWYLER[2], R. E. HAMPSON[2];
[1]Neurosci., Wake Forest Univ., Winston Salem, NC; [2]Physiol. & Pharmacol., [3]Biomed. Engin., Wake Forest Univ. Hlth. Sci., Winston-Salem, NC; [4]USC, Los Angeles, CA

Abstract: Fractality, represented as self-similar patterns that repeat at multiple scales and resolutions, is ubiquitous in nature and the brain. Dynamic patterns of hippocampal spike trains are known to exhibit multifractal properties during working memory processing (Fetterhoff et al., Journal of Neuroscience Methods, 2015); however, it is unclear whether the multifractal properties inherent to hippocampal spike trains reflect active cognitive processing. To examine this possibility, hippocampal neuronal ensembles were recorded from rodents before, during and

after a spatial working memory task. In some test sessions, animals received tetrahydrocannabinol (THC), a component of cannabis used to impair cognitive processing. Multifractal analysis was performed on sequences of hippocampal interspike intervals to determine characteristics of monofractal long-range temporal correlations (LRTCs) - quantified by the Hurst exponent, and the degree/magnitude of multifractal complexity - quantified by the width of the singularity spectrum. Our results demonstrate that multifractal firing patterns of hippocampal spike trains are a marker of functional memory processing, as they were more complex during the working memory task and significantly reduced following administration of memory impairing THC doses. Conversely, LRTCs were largest during resting state recordings, therefore reflecting different information compared to multifractality. To investigate the heightened multifractality during the task, distributions of local Hölder exponents were extracted from sample vs. nonmatch task events and differences between drug conditions were quantified using receiver operating characteristic curves. In order to deepen conceptual understanding of multifractal complexity and LRTCs, these measures were compared to classical methods using hippocampal frequency content and firing variability measures. Results showed that LRTCs, multifractality, and theta rhythm represent independent processes, while multifractality and delta rhythm were positively correlated. Additionally, we used coefficient of variation and CV2 (Holt et al., J. Neurophys., 1996) to explain the relationship between multifractality, variability and delta rhythm. Taken together, these results provide a novel perspective on cognitive function by demonstrating that the multifractal characteristics of spike trains reflect hippocampal microcircuit processing that can be used to detect and quantify cognitive, physiological and pathological states.

Title: The NMDA antagonist, MK-801, prevents C57BL6/J mice to orient and acquire a cognitive map in a 3D maze

Authors: *A. ENNACEUR[1], R. M. ABUHAMDAH[3], D. M. HUSSAIN[2], P. L. CHAZOT[3]; [2]Dept. of Pharm., [1]Univ. of Sunderland, Sunderland, United Kingdom; [3]Sch. of Biol. and Biomed. Sci., Univ. of Durham, Durham, United Kingdom

Abstract: The present study investigated whether unfamiliarity, anxiety, or deficit in encoding account for the impaired acquisition of a working memory spatial navigation task following injection of MK-801 (Dizocilpine). In a 3D maze, which is a modified version of the radial arm maze, mice are introduced directly to acquire a working memory spatial navigation task without prior habituation. The first test sessions involve anxiety but this does not prevent mice with different level of emotionality to acquire the memory test within the same number of sessions. The maze consists of 9 stems radiating from a central platform. Each stem is made of 2 segments extended from a nonagonal shaped central hub. The first segment, directly attached to the central platform, can be tilted to form an upward or downward slope and constitutes a bridge; this allows access to the second segment which is maintained level and constitutes an arm. In this maze, Balb/c mice require 4 to 5 sessions to venture onto the arms while C57/BL6J and CD-1 mice require one to two sessions, respectively. In the present experiment we used C57BL6/J mice, and the bridges of the maze were inclined upward by about 40º. Three groups of food-deprived C57BL6/J mice were trained to retrieve a food pellet from the end of each of the 9 arms in 7 consecutive sessions, one session a day. One group received saline (SAL) while a second group received MK-801 (MKD1), both for 7 sessions. A third group received saline in the first 3 sessions and MK 801 in each subsequent session (MKD4). Saline and MK-801 (0.1 mg/kg) were administered 30 min before each test session. All saline treated mice made a number of visits to the arms while MKD4 showed increased entries on the fourth day onward and MKD1 showed reduced arm entries in each session. Examination of the first 9 arm choices revealed that the number of repeated arm entries (memory errors) was significantly increased in MKD1; MKD4 were comparable to control. The present results appear to confirm that MK801 produces spatial navigation deficit in animals that are unfamiliar with the test environment. This deficit may be due to MK-801 preventing animals to establish the initial mental representation of the spatial arrangement of the maze which would enable them to orient and acquire a cognitive map. This is supported by the high number of hesitation responses demonstrated by MKD1 throughout the acquisition of the test. These hesitations are reflected by the arm/bridge ratio which reached in the last session 7/20 in MKD1 and was close to 1/1 in SAL and MKD4.

Title: Midline thalamic lesions lead to impairments on hippocampal-dependent working memory and hippocampal ACh efflux

Authors: *J. M. HALL, L. M. SAVAGE;
Binghamton Univ., Binghamton, NY

Abstract: Several thalamic nuclei are involved in learning and memory, and damage to the anterior, medial and midline thalamic regions can led to amnesia. Our previous work has shown that damage to the anterior thalamus alone impairs spatial working memory in rats as assessed by spontaneous alternation and delayed alternation (Savage et al, 2011). Furthermore, lesions to the anterior thalamus (AT) also disrupt the effectiveness of the hippocampus to mount a cholinergic response during behavior and there are strong negative correlations between behavior, AT lesion size and hippocampal acetylcholine (ACh) release. In the current experiment, we examined whether lesions to the internal medullary lamina (IML), which are known to also impair spatial memory, would also disrupt behaviorally-stimulated hippocampal ACh. We found that after IML damage spontaneous alternation behavior was impaired and the impairment was associated with reduced hippocampal ACh efflux. Furthermore, although delayed alternation was impaired on the initial day of testing, performance of IML-lesioned rats recovered during the second day of testing. These data demonstrate that similar to damage of the anterior thalamus, loss of neurons in the IML region leads to spatial memory dysfunction and this is likely due to dysregulation of the hippocampus.

Title: Orexin deficiency impairs hippocampus dependent learning and memory

Authors: V. MAVANJI[1], C. M. DUFFY[1,3], J. P. NIXON[1,4], *T. A. BUTTERICK[7,1,5], C. J. BILLINGTON[1,6,5], C. M. KOTZ[4,2,4];
[1]Res., [2]Grecc, VAHCS, Minneapolis, MN; [3]FScN, Univ. Minneaota, St. Paul, MN; [4]FScN, [5]Minnesota Obesity Ctr., Univ. Minnesota, St. Paul, MN; [6]Med., Univ. Minnesota, Minneapolis, MN; [7]FScN, Univ. Minnesota, Minneapolis, MN

Abstract: Orexin-A is an endogenous neuropeptide that regulates arousal state, sleep-wake architecture and energy homeostasis. Disruption of orexin signaling leads to sleep disturbances and increased body mass index. In addition to sleep/wake areas, orexin neurons project to medial prefrontal cortex and the hippocampus, implicating a role for orexin in cognitive function. To further understand the role of orexin in cognitive function, we characterized hippocampus-dependent learning and memory in orexin-deficient mice (orexin/ataxin-3; O/A3). We tested 1) the extent of orexin loss in O/A3 mice (immunohistochemistry); 2) whether orexin receptor 1 and 2 gene expression profiles were altered in O/A3 mice (qRT-PCR); and 3) whether orexin deficiency in O/A3 mice results in impaired acquisition and consolidation of two-way active avoidance memory, a task dependent on integrity of the dorsal hippocampus. We found that the number of orexin immunoreactive neurons was significantly reduced in 6 month old O/A3 mice (approximately 84% loss). Surprisingly, orexin receptor mRNA expression was not significantly different between control and O/A3 animals, indicating the animals could be capable of normal orexin responsiveness. The O/A3 mice showed significant impairments in TWAA task learning vs. control mice (higher response latency, $p < 0.001$; lower avoidances, $p < 0.05$; reduced total response (avoidance + escapes), $p < 0.01$). Relative to responses in control mice, learning impairment was also evident one week after initial training (higher response latency, $p < 0.001$; fewer escapes, $p < 0.001$; reduced total response, $p < 0.001$). These data highlight the usefulness of orexin/ataxin mice as a model to understand orexin mediated behaviors and neurodegenerative disorders. Further, this study demonstrates that orexin plays an important role in the consolidation of hippocampus dependent two-way active avoidance memory.

Title: Activation of serotonin 5-HT2A receptor delays the retrieval of spatial memory by male C57BL/6J mice in a Morris water maze task

Authors: *G. ZHANG[1], D. CINALLI[2], R. W. STACKMAN, Jr[2];
[1]Anhui Med. Univ., Anhui, China; [2]Psychology, Florida Atlantic Univ., Jupiter, FL

Abstract: Serotonin 5-HT2A receptor (5-HT2AR) a G protein-coupled receptor distributed extensively in brain regions critical for spatial cognition, in particular the hippocampus and frontal cortex. Accumulating evidence indicates that 5-HT2AR is involved in visuospatial cognition, decision-making, executive function and hallucination. 5-HT2AR abnormalities are evident in the brains of schizophrenia patients. Serotonergic hallucinogens such as psilocybin and lysergic acid diethylamide are partial 5-HT2AR agonists. Systemic administration of 5-HT2AR antagonists impairs spatial reversal learning in an operant task. Ritanserin (a 5-HT2A/2CR antagonist) significantly reduces the escape latency and distance traveled to a hidden platform in the water maze. However, the direct influence of 5-HT2AR on the encoding, consolidation and retrieval of spatial memory remain to be determined. With a hidden-platform Morris water maze (MWM) task, we found that treatment of male C57BL/6J mice with TCB-2 (1.0 mg/kg, i.p.), a 5-HT2AR agonist, prior to or immediately after training session did not affect accurate platform search behavior on the probe test session 24 h later. Interestingly, administration of TCB-2 just prior to the MWM probe test session increased the latency of mice to locate the target quadrant without affecting the heading error to target, or the proper use of distal visual cues. To identify whether the 5-HT2AR agonist impaired visual discrimination in the MWM, a visible platform water maze was used. We found that TCB-2 did not impair the latency in which mice located the visible platform. Together, our data suggest that activation of serotonin 5-HT2A receptor delays the retrieval of spatial memory in the Morris-water maze task.

Title: Dopamine, social learning and sex differences: The effects of blocking dorsal hippocampal dopamine D2-type receptors on social learning of food preferences in male and female mice

Authors: *R. MATTA, E. A. UNDERWOOD, Z. K. LEACH, A. C. VERTES, E. CHOLERIS; Dept. of Psychology and Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada

Abstract: The neurotransmitter dopamine (DA) is involved in many reward related behaviors, such as drug and alcohol addiction, as well as social learning, feeding and social interactions. With systemic drug treatments, our lab has previously found that DA D1-type receptors are involved in social learning, while DA D2-type receptors are involved in feeding behavior in the social transmission of food preferences (STFP; Choleris et al., 2011), however, the site(s) of action are unknown. The ventral tegmental area has direct dopaminergic projections to many limbic structures, including the nucleus accumbens, amygdala, and hippocampus. In particular, the hippocampus is involved in learning and memory processing, as well as social learning in the STFP in rodents. Our lab has previously found that antagonizing DA D1-type receptors in the dorsal hippocampus blocks social learning in the STFP in both male and female mice (Matta & Choleris, 2014). In the present study, we assessed the role of hippocampal DA D2-type receptors in the STFP in male and female mice. To do this, we administered the DA D2-type receptor antagonist Raclopride (at 10, 14, 18 and 20 μg/μL) into the Cornu Ammonis 1 (CA1) region of the dorsal hippocampus of adult male and female observer (OBS) mice 10 minutes prior to a 30 minute social interaction where mice had the opportunity to learn a food preference from a same-sex demonstrator (DEM) conspecific. Early results show that dorsal hippocampal infusions with the highest dose of Raclopride, at 20 μg/μL, impaired social learning in female, but not male, OBS mice. Furthermore, the social learning impairment in females could not be explained by a generalized change in feeding behavior, since total food consumption was not significantly impacted by drug treatment. These results suggest that antagonizing hippocampal DA D2-type receptors in the CA1 region blocks social learning, in a sex-specific manner. Whether the phases of the estrous cycle interacted with drug treatment to influence social learning will be discussed. This study highlights a role for hippocampal DA D2-type receptors on social learning in mice.

Title: Dopamine dependence of hippocampal space coding and spatial learning

Authors: ***A. RETAILLEAU**, S. SINGH, G. MORRIS;
Sagol Dept. of Neurobio., Univ. of Haifa, Haifa, Israel

Abstract: The hippocampus is often referred to as a cognitive map. However, it is still not known whether and how this map is learnt and what parameters it encodes. Several lines of evidence support tuning of representation in the hippocampus by outcome-related information. Here we investigate whether local dopamine (DA) input biases hippocampal representation to a subset of available dimensions in a behaviorally relevant manner. We hypothesize that DA input from the midbrain to the hippocampus serves to mold the cognitive map to represent adaptive (reward-relevant) dimensions of the sensory input, similar to its tuning of cortico-striatal connections to behaviorally adaptive action. We recorded simultaneously from multiple single units and local field potentials in area CA1 of the dorsal hippocampus of behaving rats engaged in a navigation task in which two possible sets of cues are relevant to reward collection. The two sets of cues were manipulated in an independent manner, so as to dissociate between neuronal encoding of each dimension. Once rats had learnt to follow one set of cues (after 4-6 days), the paradigm was shifted and animals had to use the second set of stimuli in order to get reward. Our first results show that CA1 neurons can rearrange to represent the reward-relevant representation, and neuronal activity can follow the behavioral set-shift rapidly after the switch to encode the most relevant parameters. To examine the dependence of this organization on dopamine, we locally infused D1/D5 dopamine antagonists (SCH23390) to bilaterally block dopaminergic receptors in the hippocampus before the set shift. Local injection of DA antagonist slows the set shift significantly. Neuronal activity in infused rats seems to persist in encoding the previously relevant parameters for the first 2-3 days after the switch of paradigm. Then, after more training days, blocking of D1 receptors seems to lead to substantial deficits in place-cell properties. Thus, our preliminary results highlight the specific role of DA in hippocampal representations in learning, decision-making and reward.

Title: The chromatin organizer special AT-rich binding protein 2 is required for synaptic plasticity and long-term memory formation

Authors: C. REDDY[1], N. WHITTLE[3], M. KORTE[4], N. SINGEWALD[3], F. FERRAGUTI[2], G. DECHANT[1], *G. APOSTOLOVA[1];

Abstract: Special AT-rich binding protein 2 (Satb2) is a homeodomain protein which binds to AT-rich DNA sequences, mediates DNA-nuclear matrix interactions and regulates transcription by modulating chromatin architecture. In the brain it is expressed mainly in the cortex and CA1 area of the hippocampus. While being crucial for establishing projection neuron identity in the embryonic CNS, its function in the adult brain remains unexplored. We hypothesized a role for Satb2 in CNS neuronal plasticity based on evidence that i) BDNF and neuronal activity upregulate Satb2 in primary hippocampal neurons and ii) mutations of SATB2 in humans have been reported to lead to severe learning and memory deficits. To study the function of Satb2 in adult CNS we generated forebrain-specific Satb2 conditional knockouts ($Satb2^{CamKII\text{-}Cre}$). The use of CamKII-Cre allowed for postnatal Satb2 deletion thus bypassing the effects of embryonic Satb2 inactivation on circuit formation. $Satb2^{CamKII\text{-}Cre}$ mice developed and bred normally and did not have any gross defects of cortical and CA1 architecture up to 5 months of age. Functional analysis revealed impaired stabilization of long-term potentiation in the CA1 region of hippocampal slices from $Satb2^{CamKII\text{-}Cre}$ mice. When subjected to contextual fear conditioning

Satb2$^{CamKII\text{-}Cre}$ mice showed normal fear acquisition but significantly impaired fear memory 24 h after training. They also performed poorly in other hippocampus and cortex-dependent tasks 24 h but not 1 h after training, establishing a role for Satb2 during memory consolidation. Reinstatement of Satb2 in dorsal hippocampus of Satb2$^{CamKII\text{-}Cre}$ mice by AAV-mediated gene delivery rescued the 24 h-fear memory deficit, further confirming the necessity of Satb2 for learning. The comparison of gene expression profiles of mutant and control CA1s in home cage and following 3 h-exploration of novel enriched environment revealed several differentially expressed genes for the genotype effect, which were further validated by qPCR. Neuroactive ligand-receptor signaling and calcium signaling pathways were enriched among the identified set of differentially expressed genes. There were no significantly regulated genes for the genotype-environment interaction indicating that Satb2 is dispensable for the early wave of transcriptional activity induced by novel environment exploration. Taken together, our behavioral, electrophysiological and gene expression data reveal a crucial role for Satb2 in the long-term adaptation of neuronal functions and long-term memory formation.

Title: Dissociable roles of GADD45a and GADD45b in the rat perirhinal cortex and hippocampus for object memory: Different forms of DNA methylation?

Authors: ***K. A. MITCHNICK**[1], S. D. CREIGHTON[1], B. E. KALISCH[2], B. D. WINTERS[1]; [1]Psychology, [2]Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: DNA methylation, which is catalyzed by DNA methyltransferases (DNMTs), is an epigenetic mechanism necessary for long-term memory in various brain regions, including the hippocampus (HPC). Recently we have demonstrated a necessity for DNMTs in perirhinal cortex (PRh), a structure critical for object memory, as well. More specifically, we have established a double dissociation between the necessity of de novo (DNMT3a) and maintenance (DNMT1) methyltransferases for long-term HPC- and PRh-mediated object-in-place (OiP) memory, a task

that requires object-location processing by the HPC and object identity processing by PRh. As the maintenance methyltransferase, DNMT1 is known to be involved during cell division and following DNA damage. No evidence exists for adult neurogenesis in PRh, but the DNA demethylation pathways do end in DNA damage and repair; therefore we have currently investigated the role of the growth arrest and DNA damage inducible 45 (GADD45a/b/g) family of proteins implicated in DNA demethylation, in HPC- and PRh-mediated OiP memory. Using intra-cranial administration of Accell siRNAs, the contributions of GADD45a and GADD45b were also found to be dissociable, such that only GADD45a siRNA impaired long-term OiP memory in PRh, while GADD45b siRNA impaired in the HPC. Furthermore, GADD45a and GADD45b mRNA levels were upregulated in the PRh and dentate gyrus (DG) of the HPC, respectively, following learning. GADD45b was additionally upregulated in PRh. Collectively these results demonstrate a role for GADD45b and DNMT3a in HPC-mediated object recognition, and GADD45a and DNMT1 in PRh-mediated object recognition, indicating that different epigenetic mechanisms are required for distinct mnemonic processes (spatial vs object identification) in various brain regions. As DNMT1 and GADD45a have been shown to interact and be recruited to DNA following DNA damage, we are currently conducting investigations to assess the possibility that GADD45a helps to modulate learning-induced DNA re-methylation following demethylation-induced DNA damage in PRh.

Title: Dissociable roles for maintenance and de novo DNA methyltransferases in object and spatial memory in the rat perirhinal cortex and hippocampus

Authors: *S. D. CREIGHTON[1], K. A. MITCHNICK[1], A. ALIZZI[1], B. E. KALISCH[2], B. D. WINTERS[3];

Abstract: DNA methylation, catalyzed by DNA methyltransferases (DNMTs), is an epigenetic modification that occurs in response to environmental stimuli and elicits changes in gene expression that support cellular memory. DNA methylation is critical to many facets of long-term memory (LTM), where a dynamic balance between methylation of memory suppressing genes and demethylation of memory promoting genes is necessary. We have previously demonstrated dissociable roles for maintenance methyltransferases (DNMT1) in perirhinal cortex (PRh) and *de novo* methyltransferases (DNMT3a) in the hippocampus (HPC) for long-term object-in-place (OiP) memory. As the OiP task consists of object identity and spatial components, which are likely PRh- and HPC-dependent, respectively, this dissociation suggests that distinct epigenetic mechanisms might apply to different types of LTM. Here we systematically evaluated the unique contributions of DNMTs to object identity (spontaneous object recognition; SOR) and spatial (object location; OL) memory in rats. Disruption of DNMTs during SOR and OL learning by the non-selective DNMT inhibitor, RG-108, revealed a functional double dissociation: intra-PRh DNA methylation was required for long-term (24h) SOR but not OL memory, whereas intra-HPC DNA methylation was required for long-term OL memory but not SOR. Selective inhibition of PRh DNMT1, but not DNMT3a, by short-interference RNA (siRNA) impaired long-term SOR memory. Conversely, intra-HPC administration of DNMT3a siRNA, but not DNMT1 siRNA, impaired long-term OL memory. These results are consistent with differential contributions of maintenance and *de novo* methyltransferases to different facets of object memory processed by different brain regions. Complementary mRNA analysis will explore the expression of genes that regulate learning and memory and neurogenesis 1h following SOR and OL learning. The expression of genes identified by these experiments will also be assessed under conditions of DNMT inhibition to speak to the role of specific DNMTs in the regulation of mRNA expression. Initial results demonstrate upregulation of BDNF in PRh, but not HPC, following SOR learning, consistent with the functional role of PRh and memory promoting genes in SOR. Interestingly, following OL learning BDNF was downregulated in the dentate gyrus (DG) region of the HPC, the memory suppressing gene PP1 was downregulated in PRh, and neurogenesis genes DISC1 and Wnt were upregulated in the DG. This is the first systematic examination of unique contributions of DNMTs to different forms of memory processed in different brain regions.

Title: The role of histone deacetylases in object recognition memory

Authors: *A. SMITH[1], G. R. I. BARKER[1], J. B. UNEY[2], E. C. WARBURTON[1];
[1]Sch. of Physiol. and Pharmacol., [2]Sch. of Clin. Sci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Acetylation of lysine residues on histone tails promotes an open chromatin conformation that favours transcription. The addition and removal of acetyl groups to and from lysine residues is dynamically regulated by the histone acetyltransferase (HAT) and histone deacetylase (HDAC) enzymes. Previous studies have shown that conditional forebrain deletion of HDACs can enhance spatial, fear and object recognition memory in mice, while HDAC overexpression impairs performance in these tasks (Guan et al 2009 Nature 459:55-60). So far, little is known about the action of HDACs in the perirhinal cortex (PRH), an area which is essential for novel object recognition memory (Barker et al 2007 J Neurosci 27(11):2948-57). In this study, adult male Lister hooded rats (n=12) were implanted bilaterally with infusion cannulas targeting the PRH. After recovery from surgery, the effect of different HDAC inhibitors (HDACis) on single item object recognition memory was tested using a novel object preference task. Infusions of either the broad spectrum HDACi trichostatin A (TSA), the HDAC1, 2 and 3-selective HDACi CI-994 or vehicle (DMSO in saline) were performed 15 minutes prior to the sample phase. During the sample phase, animals were allowed to explore two identical copies of an object for a maximum of either 40s in 240s (‘standard’ sample phase) or 20s in 120s (‘subthreshold’ sample phase). Animals were returned to the home cage for a delay of 24h before the choice phase commenced, in which animals were presented with a third copy of the sample (now familiar) object and a copy of a novel object, and allowed to explore freely for 180s. Exploration was scored by an experimenter blind to the condition of the animals. Exploration times were used to calculate a discrimination ratio (DR) using the following equation: DR = (time spent exploring novel object - time spent exploring familiar object) / (total exploration time). Rats infused with vehicle were able to remember objects when given a standard but not subthreshold sample phase. Rats infused with TSA prior to the sample phase were able to discriminate between a novel and a familiar object at test, regardless of sample phase length. However, rats infused with CI-994 were not able to discriminate between familiar and novel objects when allowed a subthreshold sample phase. Together, these results indicate that although perirhinal histone acetylation contributes to object recognition memory encoding, this contribution is not mediated by the class I HDACs 1, 2 and 3.

Title: A histone deacetylase inhibitor, trichostatin-A, induces odor preference memory extension and maintains enhanced AMPA receptor expression in the rat pup model

Authors: ***S. BHATTACHARYA**[1], C. W. HARLEY[2], J. H. MCLEAN[1];
[1]Bio-medical Sci., Mem. Univ. Of Newfoundland, St John's, NL, Canada; [2]Dept. of Psychology, Mem. Univ. of Newfoundland, St.John's, NL, Canada

Abstract: The regulation of histone deacetylase (HDAC) is thought to play a crucial role in synaptic plasticity and long term memory formation. In this study, we test the role of histone acetylation in odor preference memory in week-old rat pups following a single training trial that normally only induces 24 h memory. We predicted that trichostatin-A (TSA), an HDAC inhibitor, would promote a longer term odor preference memory. Our behavioral studies showed that intrabulbar infusion of TSA (0.05µg/µl/olfactory bulb), prior to a 10 min pairing of the conditioned stimulus (peppermint odor) with the unconditioned stimulus (intermittent stroking), prolonged odor preference memory for at least nine days in the neonate rat. Several physiological studies indicate that insertion of AMPA receptors may be responsible for increased synaptic strength in synaptic plasticity models. Increased synaptic strength is proposed to be a basic mechanism underlying natural learning and memory. Previous studies from our laboratory have shown that AMPA receptor (GluA1) membrane expression is increased at 24 h following training, at the time of odor preference memory, while 48 h later, when preference memory is no longer expressed in the one-trial model, AMPA receptor levels are similar to control levels. We hypothesized that HDAC inhibition would maintain enhanced GluA1 receptor levels in our prolonged odor preference memory model. Western blot analysis showed that GluA1receptor membrane expression in the TSA treated group was significantly increased at 48 h in comparison with a saline + odor stroke group. Immunohistochemical data reveal a significant increase of GluA1 receptor expression (measured by optical density of staining) in the dorsolateral olfactory bulb glomeruli (TSA treated vs vehicle) five days after training. These results extend previous

evidence for a close relationship between enhanced GluA1 receptor membrane expression and memory expression. The prolonged odor preference memory was selective for the paired odor and only occurred in a specific temporal window following HDAC inhibition. The ability to compare changes in a one trial training protocol that can induce both 24 h and nine day memories through the manipulation of histone acetylation will permit tightly controlled exploration of the molecular mechanisms, and their temporal patterns, which induce and maintain shorter or longer long-term memories.

Title: Glucose-induced memory enhancement is mediated by epigenetic modulation of BDNF and FGF-1 genes expression

Authors: Y. OOMURA, *T. KATAFUCHI, S. M. HOSSAIN;
Dept Integr Physiol, Grad Sch. Med. Sci, Kyushu Univ., Fukuoka, Japan

Abstract: We have previously reported that intrahippocampal injection of 7 mM glucose, which is similar to the glucose concentration of the cerebrospinal fluid during food intake, facilitates spatial learning and memory in rats. The high glucose enhanced basal synaptic response and tetanus-induced long term potentiation in the rat Schaffer collateral/commissural pathway through increases in CAMKII and PKC autophosphorylations. In the present study, we further sought to clarify the cellular mechanisms of the glucose effects on memory enhancement. When glucose was increased from 3.5 mM to 7 mM, neuronal cell lines (Neuro2A) showed an increase in expression of brain-derived neurotrophic factor (BDNF) and fibroblast growth factor-1 (FGF-1), which were both known as memory related molecules, along with the enhanced phosphorylation of AKT (PKB) and CREB. In addition, the restricted glucose water drinking increased the number of dendritic spines in the mouse hippocampus. Furthermore, the glucose-induced upregulation of *BDNF* was blocked by the knock down of CREB using lentiviruses encoding short hairpin-RNA against CREB, while high glucose increased CREB recruitment onto the *BDNF* and *FGF-1* promoter regions. Interestingly, glucose stimulation reduced histone deacetylase 2 (HDAC2) recruitment and increased the acetylated histones (H3K9 and H3K27) recruitment near the *BDNF* and *FGF-1* promoter regions in the neuronal cell line and

hippocampal tissues. An HDAC inhibitor, suberanilohydroxamic acid (SAHA) increased *BDNF* and *FGF-1* expression. These findings, taken together, suggest that glucose enhances spatial learning and memory by upregulation of BDNF and FGF-1 genes expression through the increases in phosphorylated CREB and epigenetic modulation of the genes.

Title: Lentiviral knock down of inhibitor-2 in the dorsal hippocampus enhances spatial memory and contextual fear conditioning

Authors: ***A. PAHNG**[1], H. YANG[2], H. XIA[2], P. COLOMBO[1];
[1]Program in Neurosci., Tulane Univ., New Orleans, LA; [2]Neurosci. Ctr., LSU Hlth. Sci. Ctr., New Orleans, LA

Abstract: Inhibiting protein phosphatase 1 (PP1) activity has been shown to increase phosphorylation of CREB (Alberts et al., 1994; Bito et al., 1996) and enhance memory (Genoux et al., 2002). Inhibitor-2 (I-2) is a protein that associates with the catalytic domain of PP1 and can modify the activity of PP1. Early on, researchers reported that the I2 protein inhibits protein phosphatase activity *in vitro* (Brandt et al., 1975; Huang and Glinsmann, 1976), whereas more recent experiments with yeast homologs showed that I2 both activates (Tung et al., 1995; Nigavekar et al., 2002) and inhibits PP1 (Tung et al., 1995). A lentiviral construct expressing genomic shRNA that corresponds to the 3' untranslated region of I-2 mRNA knocks down I-2 expression and decreases PP1 activity (Hou et al., 2013). In the current experiment, we tested the hypothesis that localized gene silencing of I-2 in the dorsal hippocampus enhances memory for various hippocampus-dependent tasks in rats and increases levels of phosphorylation of CREB in the dorsal hippocampus due to inhibition of PP1. In comparisons with controls, rats infused with I2-shRNA demonstrated enhanced spatial memory and contextual fear conditioning. In addition, lenti-I2-shRNA infusion significantly increased levels of pCREB in the dorsal hippocampus. Our

Deleted: *in vitro*

results support the hypothesis that knocking down I-2 in the hippocampus enhances memory for aversively motivated hippocampus-dependent tasks and increases phosphorylation of CREB, most likely by down-regulating PP1 activity. These data suggest that I-2 is a novel suppressor of memory.

Title: VGF and its C-terminal peptide TLQP-62 regulate memory formation in the hippocampus via a BDNF-TrkB-dependent mechanism

Authors: ***W.-J. LIN**[1], C. JIANG[1], M. SADAHIRO[1], O. BOZDAGI[2], L. VULCHANOVA[3], C. M. ALBERINI[4], S. R. SALTON[1,5];
[1]Neurosci., [2]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Neurosci., Univ. of Minnesota, Minneapolis, MN; [4]Ctr. for Neural Sci., New York Univ., New York, NY; [5]Friedman Brain Inst., New York, NY

Abstract: Regulated expression and secretion of brain-derived neurotrophic factor (BDNF), which activates TrkB receptor signaling, is known to play a critical role in cognition. Identification of additional modulators of cognitive behavior that regulate activity-dependent BDNF secretion and/or potentiate TrkB receptor signaling, would therefore be of considerable interest. In this study we show that in the adult hippocampus, expression of the granin family gene Vgf and secretion of its C-terminal VGF-derived peptide TLQP-62 are required for fear memory formation. We found that hippocampal VGF expression and TLQP-62 levels were transiently induced after fear memory training, and that sequestering secreted TLQP-62 peptide in the hippocampus immediately after training impaired memory formation. Reduced VGF

expression was found to impair learning-evoked Rac1 induction and phosphorylation of synaptic plasticity markers cofilin and synapsin in the adult hippocampus. Moreover, TLQP-62 induced acute, transient activation of the TrkB receptor and subsequent CREB phosphorylation in hippocampal slice preparations, and its administration immediately after training enhanced long-term memory formation. A critical role of BDNF-TrkB signaling as a downstream effector in VGF/TLQP-62-mediated memory consolidation was further revealed by post-training activation of BDNF-TrkB signaling, which rescued impaired fear memory resulting from hippocampal administration of anti-VGF antibodies or germline VGF ablation. We propose that VGF is a critical component of a positive BDNF-TrkB regulatory loop, and upon its induced expression by memory training, the TLQP-62 peptide rapidly reinforces BDNF-TrkB signaling, regulating hippocampal memory consolidation.

Title: The special phospholipids, plasmalogens, enhance memory via increasing BDNF and other memory related gene expression in murine hippocampus

Authors: ***M. HOSSAIN**[1], T. KATAFUCHI[1], K. MIAKE[2];
[1]Kyushu University, Dept of Integrative Physiol., Fukuoka, Japan; [2]Ctr. Res. Institute, Marudai Food Co. Limited, Osaka, Japan

Abstract: The special phospholipids, Plasmalogens (Pls), are found to be reduced in the brain of Alzheimer's disease (AD) patients, but the precise meaning behind this reduction was unknown. Hippocampus, which plays a role in the formation of memory, is enriched in ethanolamine Pls (PlsEth). To elucidate the possible involvement of Pls in the hippocampus-dependent memory, we have knockdown the GNPAT (glyceronephosphate O-acyltransferase), a Pls synthesizing enzyme, by intra-hippocampal injection of shRNAs. A significant knockdown of GNPAT expression and a reduction of Pls in the hippocampus were observed in those mice after 1 week to 5th week following the shGNPATs injection. Morris water maze test showed a significant

reduction of the spatial memory among the mice of reduced Pls group, suggesting that hippocampal Pls are necessary for the memory formation. We found a reduction of BDNF expression as well as other memory related gene expression in the shGNPATs injected hippocampus. Interestingly, Pls-diet for 6 weeks in C57Bl/6 adult male mice significantly increased the spatial memory associated with the increase BDNF and other memory related gene expression. Increased activation of AKT and ERK along with the enhanced recruitment of CREB onto the BDNF promoters were found in the hippocampus. To the detail mechanism, we also found that Pls are enriched in the lipid rafts and increases the TrkB contents in these rafts to enhance BDNF signaling. Pls-diet also enhanced the synaptic activity associated with the increased LTP (CA1-CA3), number of dendritic spines of the hippocampal neuron. In addition, we also found that Pls-diet mediated memory enhancement was cancelled by shBDNF and shTrkB injection to the hippocampus. Our present study confirms for the first time that Pls in the hippocampus are very important to maintain our memory and do so via enhancing the BDNF signaling through the increasing of TrkB into the lipid rafts.

Title: Cognitive dysfunction in a novel knockout mouse model of ZC3H14

Authors: ***J. FIDLER**[1], J. RHA[2,3], S. K. JONES[2,4], A. H. CORBETT[2], P. S. GARCIA[1]; [1]Anesthesiol., Emory Univ. / Atlanta VAMC, Decatur, GA; [2]Dept. of Biochem., [3]Biochemistry, Cell, and Developmental Biol., [4]Genet. and Mol. Biol., Emory Univ., Atlanta, GA

Abstract: Autosomal recessive mutations of the gene encoding the RNA binding protein, Zinc Finger Cys(3) His #14 (ZC3H14),areassociated with intellectual disability in humans (Pak et al., PNAS 108:12390-5). To assess the function of ZC3H14 *in vivo*, a novel ZC3H14 knockout mouse was generated. The absence of the ZC3H14 protein was confirmed in homozygous ZC3H14 KO mice with no obvious congenital health deficits. To assess cognitive function, the ZC3H14 KO mice (aged 3-4 months) were tested with a battery of behavioral assays focusing on learning and memory. Though a standard novel object recognition (NOR) assay with a 1 hour

Deleted: in vivo

intra-trial interval did not reveal a significant difference between ZC3H14 KO and WT mice (P = 0.77), post-hoc analysis of NOR videos with Noldus EthoVision XT 10.0 software showed a phenotype of hyperactivity in knockout mice as measured by total distance traveled (P = 0.001). This phenotype could be the result of deficient cortico-amygdala processing leading to a lack of healthy fearful behavior in the mice, as seen by a significant increase in frequency of entry into the center of the arena in ZC3H14 KO mice (P = 0.0047) compared to control mice. A 12-day water radial arm maze (WRAM) procedure indicated a trend toward cognitive dysfunction in ZC3H14 KO mice as measured by total latency to find platforms (P = 0.16) and a significant impairment of working memory (P = 0.035) when measured over the nine days it took each genotype to reach a sufficient level of performance on the WRAM so as to indicate having fully learned the task (Figure). Taken together, these results signify a quantifiable phenotype of cognitive dysfunction in ZC3H14 KO mice. These mice can be exploited to explore the critical function of the ZC3H14 RNA binding protein in the CNS.

Title: Proteomic studies of plasma membrane-mitochondrial proteins involved in recognition memory of visual imprinting in chicks

Authors: ***R. O. SOLOMONIA**[1,2], M. MEPARISHVILI[1], G. MARGVELANI[1], M. NOZADZE[1,2], E. MIKAUTADZE[2], T. KIGURADZE[2], B. J. MCCABE[3];

Abstract: Visual imprinting is a learning process by which young animals come to recognize a visual stimulus by being exposed to it (training) and consequently approach it in preference to other stimuli. Converging evidence implicates the intermediate and medial mesopallium (IMM) of the domestic chick forebrain in memory for a visual imprinting stimulus [1]. A number of learning-related, time-dependent changes have been identified in the IMM after training. The results indicate progression from transient to trophic synaptic modification, culminating in stable recognition memory. Several such changes have been found in plasma membrane and mitochondrial proteins [2]. We undertook a proteomic investigation of the plasma membrane-mitochondrial P2 fraction to identify proteins involved in visual imprinting. Two-dimensional gel electrophoresis with subsequent mass spectrometry was employed to identify differentially expressed proteins across chicks with different estimated levels of imprinting 24 h after training. We further inquired whether the amounts of those proteins in the IMM and a control region (posterior pole of the nidopallium, PPN) are correlated with memory for the imprinting stimulus. Memory strength was positively correlated with the amounts of the following proteins in the left IMM: (i) membrane cognin; (ii) a protein resembling the P32 subunit of splicing factor SF2; (iii) voltage dependent anionic channel; (iv) dynamin-1; (v) heterogeneous nuclear ribonucleoproteins A2/B1. Training significantly increased levels of (i)-(iii), suggesting that these proteins change as a consequence of learning. The possibility arises that the changes described are mediated by an increase in the number of mitochondria. However, the copy number of mitochondrial DNA did not change significantly. Of three transcription factors involved in mitochondrial biogenesis, the level of peroxisome proliferator-activated receptor gamma coactivator 1-alpha did not show significant changes, whereas the amounts of mitochondrial transcription factor-A and nuclear respiratory factor 1 increased significantly with the strength of learning. The issue of mitochondrial number is thus as yet unresolved. The results identify membrane and mitochondrial proteins that may contribute to memory and are consistent with the hypothesis [2] that mitochondrial proteins in the IMM exhibit a left-biased specialization with respect to imprinting memory. 1.Horn G (2004) Pathways of the past: the imprint of memory. Title: The involvement of MSK1 in experience-dependent remodelling of hippocampal synaptic plasticity

Authors: *L. PRIVITERA[1], L. MORE'[1], J. S. ARTHUR[2], B. G. FRENGUELLI[1];
[1]Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom; [2]Col. of Life Sci., Univ. of Dundee, Dundee, United Kingdom

Abstract: An enriched environment (EE) provides additional sensory, motor, cognitive and social stimulation over and above that provided by standard housing conditions (SH) for experimental animals. EE strongly influences the connectivity and development of the brain and causes profound changes in neuronal structure and function. The molecular mechanisms underlying the effects of EE are not fully understood, but the involvement of the neurotrophin BDNF has been proposed as one of the key factors in converting sensory experience into enduring changes at the cellular and behavioural level. Mitogen- and stress-activated protein kinase 1 (MSK1) is activated following stimulation of TrkB receptors by BDNF. MSK1 subsequently regulates gene transcription via phosphorylation of its downstream targets CREB and histone H3. We have previously demonstrated that mice carrying an inactivating kinase-dead (KD) knock-in point mutation of the MSK1 gene failed to show enhancement of synaptic transmission in response to EE and showed a blunted increase in dendritic spines [1]. This suggests that MSK1 is a key regulator of experience-dependent synaptic adaptation, an action that likely revolves around its ability to directly influence transcription. Here, we explored whether EE improved hippocampus-dependent basal synaptic transmission and plasticity in an MSK1-dependent manner. To this end, we reared wild-type (WT) and MSK1 KD mice in SH or in EE from birth to 2.5-5 months of age. MSK1 KD mice displayed smaller fEPSPs compared to WT mice but had similar presynaptic fiber volley amplitudes and paired-pulse facilitation. These parameters were not influenced by housing status. In contrast, long-term potentiation (LTP), which was no different between mutant (126 ± 4%, n=7) and WT (130 ± 4%, n=8) slices under SH, was enhanced ($p<0.008$) by EE in slices from WT mice (153 ± 6%, n=9), but not MSK1 KD

mice (125 ± 4%, n=8). These data, and a parallel study of hippocampus-dependent spatial reference and working memory (More' et al.; this meeting), implicate MSK1 as transducer of positive environmental stimulation into long-lasting structural and functional neuronal adaptations that underpin the enhanced cognition associated with enrichment. 1 Correa, S.A., et al., J Neurosci, 2012. **32** 13039-51.

Title: MSK1 is a major contributor to the cognition-enhancing effects of environmental enrichment

Authors: ***L. MORE**[1], L. PRIVITERA[1], J. S. ARTHUR[2], B. G. FRENGUELLI[1];
[1]Life Sci., Univ. of Warwick, Coventry, United Kingdom; [2]Col. of Life Sci., Univ. of Dundee, Dundee, United Kingdom

Abstract: Mice reared in an enriched environment (EE) show enhanced learning and memory, greater resilience to stressful situations, higher resistance to the addictive effects of drugs of abuse and improved recovery in both acquired and neurodegenerative brain injury. As such, considerable interest has arisen in the molecular mechanisms by which EE affects neuronal structure, function and cognition. We have previously shown that mice lacking the kinase activity of mitogen and stress activated kinase 1 (MSK1) did not display the enhancement of hippocampal synaptic transmission observed in wild-type (WT) mice after EE and showed a blunted increase in spine density [1]. We concluded that MSK1 may transduce some of the positive effects of EE into lasting structural and functional neuronal changes. This suggestion is made plausible given that 1) MSK1 is downstream of BDNF-activated TrkB receptors and 2) MSK1 has the ability to regulate gene expression via the phosphorylation of both CREB at S133 and histone H3 at S10. A number of these processes have been implicated in mediating the positive effects of EE. The present work investigated the extent to which EE improved

hippocampus-dependent spatial reference and working memory and cognitive flexibility in an MSK1-dependent manner during an early stage of life, i.e. from birth to 2.5-4 months of age. Our data show that the kinase activity of MSK1 is required for the full expression of the cognition-enhancing effects of EE: MSK1 kinase-dead mice showed less improvement in hippocampus-dependent spatial reference memory and reversal learning tasks in the Water-maze, and made fewer correct alternations during a spontaneous alternation task for spatial working memory. These data suggest that MSK1 is necessary for the full conversion of positive environmental stimulation into the enhancement of cognition. Parallel studies of synaptic transmission and plasticity (Privitera et al.; this meeting) will provide evidence for the cellular underpinnings of such enhancements of cognition. 1. Title: A putative role for neurotensin receptor-2 in hippocampus

Authors: ***M. A. THIBAULT**[1], L. MCQUADE[2], H. WOODWORTH[2], E. POTTER[2], G. LEINNINGER[1], A. ROBISON[1];

Abstract: The neuropeptide neurotensin regulates cells that express Neurotensin receptor-1 (NtsR1) or -2 (NtsR2), and this signaling system has been implicated in control of feeding, locomotor activity and learning. The lack of facile methods to identify NtsR-expressing cells, however, has limited understanding of their function. To overcome this, our lab generated mice that express green fluorescent protein (GFP) in NtsR2 cells (NtsR2GFP mice), thereby permitting identification of NtsR2 cells via immunofluorescent microscopy. Analysis of NtsR2GFP mice revealed many NtsR2-expressing neurons in the basal cell layer of the dentate gyrus. Since this part of the hippocampus gives rise to newly born glia and neurons during adulthood, we hypothesized that NtsR2 cells might arise from adult neurogenesis. Indeed, immunofluorescent labeling for markers of the various stages of neurogenesis identified mature

NtsR2-expressing neurons as well as putative immature or "newly born" NtsR2 neurons. To determine whether new NtsR2-expressing neurons can be generated *in vivo*, we injected NtsR2GFP mice with BrdU, which selectively incorporates into newly generated cells in the adult nervous system. We find that many NtsR2-expressing dentate gyrus neurons are BrdU-positive, suggesting a potential role for NtsR2 in neurogenesis and/or neuronal maturation. We are interested in changes in gene expression that may regulate this process, and because mutant mice lacking the FosB gene have a malformed dentate gyrus as well as reduced neurogenesis, we sought to determine whether FosB gene products are found in NtsR2-expressing dentate gyrus neurons. Indeed, double labeling within NtsR2 neurons in the dentate gyrus reveals high levels of FosB within the nuclei. To determine the role of FosB in NtsR2 cells in dentate gyrus, we are now crossing NtsR2Cre mice with floxed FosB mice. Taken together, these studies reveal a possible role for neurotensin in the hippocampal neurogenesis and pave the way for future studies examining the role of NtsR2 learning and cognitive and psychiatric diseases.

Title: Nogo ligands, receptors, co-receptors and modulators in the developing and adult mouse brain

Authors: *G. SMEDFORS[1], K. WELLFELT[2], T. HJORTENHAMMAR[2], E. NORDLING[2], A. JOSEPHSON[2], L. OLSON[2], T. KARLSSON[2];
[2]Neurosci., [1]Karolinska Institutet, Stockholm, Sweden

Abstract: The Nogo-system, a potent plasticity-restraining system in the CNS, is now in a broad sense known to include at least 16 proteins serving as ligands, receptors, co-receptors and modulators. When activated, it typically inhibits neuronal outgrowth through deregulation of the cytoskeleton. While much is known, no analysis of the expression of the complete system has been made. Therefore, we used quantitative *in situ* hybridization to localize transcriptional activity of Nogo, OMgp, MAG, Blys, NgR1-3, Lingo-1, Amigo 3, Troy, p75, S1PR2, Olfactomedin 1, Lotus, LgI1 and Adam 22, from E15 to P730 mice. Nogo-A mRNA was strongly expressed in the E15 and E17 CNS. At P7 Nogo-A mRNA levels were relatively low in cortex, stronger in hippocampal CA1-3 layers and very low in the dentate gyrus. OMgp mRNA was not observed prenatally, weak at P0 with increasing levels in cortex and hippocampus at later stages. MAG was not robustly observed until P7 with a marked increase in white matter structures and in the form of large punctae in cortex and other gray matter areas at 30 days. At E15 and 17 NgR1 and Lingo 1 has a widespread expression in the CNS, while NgR2 is limited to the cortical mantle and DRGs and NgR3 is barely detectable. At P0 we find NgR2 mRNA to be more abundant than NgR1 and NgR3 mRNA in the cortical mantle, while at P7 NgR1 mRNA has increased. At P14, NgR1 and 2 genes remain active and Lingo-1 mRNA has increased in cortex and hippocampus. Interestingly, NgR3 and Lingo-1 are only weakly expressed in the dentate gyrus, and NgR2 mRNA is not detected in hippocampal area CA2. Ngr1-3 and Lingo-1 mRNA levels are maintained in the brain of 2 year old mice. The spatial and temporal patterns of transcriptional activity of these and additional genes listed above may reflect time windows and areas characterized by increased versus decreased structural plasticity as the brain develops, matures and ages.

Title: Parameters for abolishing conditioned place preference for cocaine from running and environmental enrichment in male C57BL/6J mice

Authors: ***M. L. MUSTROPH**, H. PINARDO, J. R. MERRITT, J. S. RHODES;
Neurosci., Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Recent evidence suggests that four weeks of voluntary wheel running can abolish conditioned place preference (CPP) for cocaine in male C57BL/6J mice, but key parameters need to be worked out before the mechanism behind the observed behavioral effects of running can be understood. The primary objective of this study was to determine the duration and timing of exposure to running wheels necessary to reduce CPP, and the extent to which the running per se influences CPP as compared to environmental enrichment without running. A total of 239 males were conditioned for 4 days twice daily with cocaine (10 mg/kg) and were then split into 7 different intervention groups prior to 4 consecutive days of CPP testing. The short sedentary group (SS; n=20) were housed in normal cages for 1 week. The short running group (SR; n=20) were housed with running wheels for 1 week. The short running group followed by a sedentary period (SRS; n=20) were housed in running wheels for 1 week and then normal cages for 3 weeks. The sedentary group followed by a short running period (SSR; n=20) were housed in normal cages for 3 weeks then 1 week with running wheels. The long sedentary group (LS; n=66) were housed in normal cages for 4 weeks. The long running (LR; n=66) group were housed with running wheels for 4 weeks. The long environmental enrichment group (EE; n=27) were placed in cages with multiple novel toys that were rotated on a weekly basis for 4 weeks. Levels of running were similar in all running animals. Both running and environmental enrichment reduced CPP relative to sedentary groups; however, running tended to produce a greater reduction. One week of wheel running was sufficient to reduce CPP, and it did not matter whether the running was preceded or followed by a 3 week sedentary period. Results suggest the abolishment of cocaine CPP from running is robust and occurs with as low as 1 week of intervention, and both increased physical activity and enrichment likely contribute to the phenomenon.

Title: Neuronal PTEN haploinsufficiency causes memory deficit and potentially alters metabolism

Authors: ***J. CABRAL COSTA**[1], D. Z. ANDREOTTI[1], M. P. MATTSON[2], S. CAMANDOLA[2], C. SCAVONE[1], E. M. KAWAMOTO[1];
[1]Dept. of Pharmacology, Inst. of Biomed. Sci., Univ. of São Paulo, Sao Paulo, Brazil; [2]Lab. of Neurosciences, Natl. Inst. on Aging, Baltimore, MD

Abstract: INTRODUCTION: Phosphatase and tensin homolog deleted on chromosome 10 (PTEN) has been studied recently for its modulatory function on neurogenesis and synaptic plasticity, as it is important for key cellular processes, such as proliferation, migration and survival. However, because PTEN complete knockout is lethal, it is necessary to make use of different models in order to facilitate the study of its functions. In this context, conditional knockout through the Cre-lox system driven by the promoter of the neuron specific enolase (NSE) gene constitute an interesting tool for the assessment of PTEN neuronal functions. METHODS: The aim of this study was to conduct a validation of the model of neuronal Pten partial deletion (NSE-PTEN+/-) in our laboratory and to initiate an investigation of still unknown effects of this deletion on behavior and metabolism. Therefore, 3-4 months old male mice from the NSE-PTEN+/-¬ lineage had metabolic (body and brain weight, food consumption, glucose level and tolerance) and behavioral (anxiety and memory) parameters analyzed. Student t-test followed by Bonferroni post-hoc test was used for statistical analysis, with significance considered for $p \leq 0.05$. RESULTS: We found that NSE-PTEN+/- mice had an increased ratio of food intake per body weight, however there were no significant effect on basal glycaemia or on glucose tolerance. There was also no significant difference on anxiety-associated parameters assessed through the open field test. NSE-PTEN+/- mice did not differ at the Morris water maze learning curve; however they spent less time on target quadrant on the 4h probe. Similarly, NSE-PTEN+/- mice showed a decreased latency in the inhibitory avoidance test. Furthermore, it was confirmed that NSE-PTEN+/- mice were macrocephalic, presenting augmented weight of total brain and cortex. DISCUSSION: with these results we validated the NSE-PTEN+/- mouse model in our laboratory, corroborating the occurrence of macrocephaly and cognitive impairment. Moreover, although glycaemia and glucose tolerance were not affected by the deletion, taking into consideration the increased food intake - which was not associated with augmented activity in the open field test - we reasoned the possibility of a modulatory role of neuronal PTEN on metabolism.

Title: Fear generalization in NLGN3R451C model of autism is associated with aberrant feedback inhibition in the lateral amygdala

Authors: B. UNAL, C. T. UNAL, *M. BOLTON;
Disorders of Neural Circuit Function, Max Planck Florida Inst., Jupiter, FL

Abstract: Autism is a complex neurodevelopmental disorder characterized by social deficits, language impairment and repetitive behavioral patterns resulting from as yet undefined brain circuit imbalances. Given that the proper functioning of the amygdala is imperative for learning contingencies among emotionally charged stimuli and generation of adaptive emotional and social responses, we investigated amygdala circuit function in the neuroligin3R451C mouse model of autism. We found that the principal neurons of the lateral amygdala (LA) were hyper-connected by feedback inhibitory networks. The predominant pathology was enhanced inhibition of principal neurons by low threshold spiking (LTS) interneurons. Yet, the mice exhibited generalized fear in cued fear conditioning paradigms. Enhancing the power of inhibition onto LA principal neurons in wild type mice by pharmacogenetic activation of somatostatin-expressing low threshold spiking neurons resulted in fear generalization. Together these results provide evidence for dysregulation of inhibitory networks in the amygdala in a model of autism and highlight the importance of feedback inhibition in determining specificity of fear learning.

Title: The adenosine A2A agonist, CGS21680 reduces behavioral inflexibility and repetitive grooming in the BTBR Mouse

Authors: *M. E. RAGOZZINO[1], D. A. AMODEO[2], L. CUEVAS[2], J. A. SWEENEY[3]; [2]Psychology, [1]Univ. Illinois Chicago, Chicago, IL; [3]Psychiatry, Univ. of Texas Southwestern, Dallas, TX

Abstract: Autism spectrum disorder (ASD) is defined by social-communication deficits along with restricted interests and repetitive behaviors (RRBs). Based on findings in deer mice, we hypothesize which RRBs that include stereotyped movements and behavioral inflexibility result, in part, from under activation of the indirect pathway within basal ganglia circuitry. Thus, a treatment that enhances the indirect pathway should attenuate behavioral flexibility deficits and stereotyped movements. The BTBR T+ Itpr3tf/J (BTBR) mouse exhibits impairments in probabilistic reversal learning and repetitive grooming. Treatment with the adenosine 2A agonist CGS21680 is believed to facilitate activation of the indirect cortico-striatal pathway. The current study tested whether facilitation of the indirect pathway through stimulation of adenosine 2A receptors attenuates a probabilistic reversal learning deficit and elevated grooming behavior in BTBR and B6 mice. For reversal learning, mice were tested in a spatial discrimination task using an 80/20 probabilistic reinforcement procedure. Acquisition and reversal learning occurred across two consecutive test sessions. Mice learned to obtain reinforcement from the “correct” spatial location (reinforced on 80% of trials) compared with the “incorrect” spatial location (reinforced on 20% of trials). Prior to the reversal learning phase, mice received a systemic injection of 0.01 mg/kg of CGS21680 or vehicle. As observed previously, vehicle-treated BTBR mice required significantly more trials to criterion than B6 mice during probabilistic reversal learning. CGS21680 treatment significantly reduced trials to criterion for reversal learning in BTBR mice compared to that of vehicle-treated BTBR mice and to a level that was comparable to vehicle-treated B6 mice. In BTBR mice, CGS21680 treatment improved reversal learning by significantly reducing regressive errors compared to vehicle treatment. For grooming behavior, mice received an intraperitoneal injection of CGS21860 0.01 mg/kg or vehicle prior to testing. Mice were individually placed in a clear plastic cage for 20 min. The first 10 min served as a habituation period. The second 10 min of testing a trained observer recorded cumulative time spent grooming all body regions. CGS21680 treatment also significantly reduced repetitive grooming in BTBR mice compared to vehicle treatment. Thus, treatment with an adenosine 2A receptor agonist may reduce RRBs in ASD and serve as a novel treatment in ASD.

Abstract: The prefrontal cortex (PFC) is thought to play a central role in the ability to adapt to changing circumstances, including reward value. Methylphenidate (MPH), a psychostimulant used for the treatment of Attention Deficit Hyperactivity Disorder, increases catecholamine levels with the PFC and the basal ganglia, and is thought to interfere with such ability at high doses. Accordingly, we studied the effects of MPH on the performance of a reward-based switching task and tested the hypothesis that its effects on task performance result from changing reward signals within the PFC. Rhesus monkeys were tested using a reward-based oculomotor switching task consisting of alternating blocks of pro-saccades and anti-saccades without an overt cue alerting the switch. The scleral search coil technique was used to measure the subjects' eye movements. Recordings were taken from single units in the dlPFC; MPH or vehicle was administered orally after a unit was isolated and baseline activity was recorded for 5-6 switching blocks. Recording was resumed immediately following drug administration. A variant of Q-learning was used to model the learning of action values following a switch in reward contingency. The subject must detect a true change in reward contingency and update the value of a particular action, either prosaccade or antisaccade, given their perceived current reward state. State-action pair values are learned within the computational model by updating the value of each action according to a temporal-difference rule. Parameters were fit to observed action

choices using the probability of choice logistic function over all trials. The association of trial-by-trial choice probability, action-value and reward prediction error with dlPFC single-unit discharge rates was evaluated using a Poisson-GLM under different doses of MPH. The dosage level had significant effects on the observed action choices, neural activity and the estimated parameter values of the Q-learning model. The difference in probability of choice following a state change was amplified at an optimal dose level compared with the control and higher dosage levels, and there was a decreased tendency to explore when optimally dosed. Both the model and neural prediction errors were enhanced under the optimal dose resulting in a faster recovery following the state switch. Finally, at higher dosage levels the subject was choosing actions randomly, with a near total failure to detect a switch in reward contingency, which correlated with the lack of differentiation of the reward prediction error in both the Q-learning model and neural signals.

Title: Stress-induced anxiety and c-fos immunoreactivity in adulthood following chronic juvenile methylphenidate exposure

Authors: ***M. MCWATERS**, E. ANDERSON, L. MATUSZEWICH;
Northern Illinois Univ., Dekalb, IL

Abstract: Methylphenidate (MPH), or Ritalin, is the most commonly prescribed psychostimulant for the treatment of Attention-Deficit Hyperactivity Disorder (ADHD). While the short-term clinical benefits of MPH have been established, the long-term effects after juvenile exposure has yielded mixed results (Galizio et al., 2009; Dow-Edwards et al., 2008). Long-term alterations of prefrontal cortex (PFC) catecholaminergic circuits may impact stress responses later in life as the same circuits that are targeted by MPH are activated during a stress response. In humans and animals, stress has been shown to increase anxiety-like behaviors (Reis et al., 2011). Therefore the current project tested whether chronic exposure to MPH during pre-adolescence altered anxiety-like behaviors and c-Fos immunoreactivity (IR) in the infralimbic prefrontal cortex (PFC) and hypothalamic paraventricular nuclei (PVN) either during basal conditions or to an acute restraint stress exposure. Juvenile male rats from PD21-35 were fed 2

mg/kg MPH or water on a vanilla wafer cookie daily. At approximately PD120, the rats were either exposed to restraint stress or left undisturbed and then tested in the elevated plus maze (EPM), a measure of anxiety. Following stress and EPM, rats were perfused and brains were sectioned for c-Fos IR. Preliminary findings suggest that there are no significant differences in locomotion in the open field between control and MPH treated rats in adulthood and that there are no significant differences in anxiety-like behaviors as a result of drug condition or stress condition. However, there was a significant interaction between drug and stress conditions ($p=.038$). In rats exposed to restraint stress, juvenile MPH decreased anxiety-like behavior compared to rats that received water. Whereas in rats not exposed to restraint stress, MPH treated rats had greater anxiety-like behaviors compared to control rats. Drug condition did not significantly affect c-Fos IR in the infralimbic PFC or PVN. Restraint stress did not significantly affect c-Fos IR in PVN, but did significantly increase c-Fos IR in the infralimbic PFC ($p=.013$), suggesting that the effect of stress may be more pronounced in the PFC, rather than the PVN. Overall, the long-term effects of juvenile MPH treatment differed in the expression of anxiety-like behaviors depending upon the acute exposure to stress, but the pattern of c-Fos IR did not parallel the behavior. Understanding potential long-term effects of juvenile MPH exposure may be essential for the development of better treatment strategies for individuals with ADHD.

Title: Cocaine self-administration enhances response-outcome encoding in dorsal striatum

Authors: ***A. C. BURTON**, G. B. BISSONETTE, A. C. ZHAO, P. K. PATEL, M. R. ROESCH;
Dept. of Psychology, Univ. of Maryland, Col. Park, College Park, MD

Abstract: Drug addiction is commonly associated with maladaptive decision-making and habit-like behaviors. The development of addiction is thought to reflect a transition from response-outcome (goal-directed) to stimulus-response (habit) driven behavior, functions which are thought to be under the control of ventral (VS) and dorsolateral striatum (DLS), respectively.

Previously, we have shown that VS dysfunction due to lesion, irrespective of drug use, enhanced stimulus-response encoding in DLS while rats performed an odor-guided choice task. Here, we ask if previous cocaine self-administration in rats alters neural encoding in DLS in the same task. To the best of our knowledge, no study has conclusively shown enhanced stimulus-response encoding in DLS after chronic cocaine use. To address this issue, we implemented a two-week cocaine (cocaine group) or sucrose pellet (control) self-administration protocol with a one-month withdrawal period and then recorded from single neurons in DLS while rats performed an odor-guided choice task where reward value was manipulated by changing the delay to or size of reward. We describe data showing that after going through withdrawal, the cocaine group was more impulsive during performance of the task especially during delay blocks. Surprisingly, we show an increase in the number of neurons encoding response-outcome associations in DLS rather than stimulus-response associations. These results suggest that cocaine self-administration impacts behavior and encoding in DLS. Specifically, it suggests that impulsive behavior observed after chronic-cocaine use does not reflect an enhancement of stimulus-response encoding, but instead, an over representation of response-outcome encoding in DLS.

Title: H3 receptor inactivation normalized disrupted histamine transmission during sexual motivation

Authors: ***M. E. RIVEROS**[1,2], F. TORREALBA[1];
[1]Pontificia Univ. Catolica, Santiago, Chile; [2]Facultad de Medicina, Clinica Alemana Univ. del Desarrollo, Santiago, Chile

Abstract: Chronically stressed animals have depressive like symptoms such as reduction in defensive behaviors and reduction in sexual or food motivation. We have proposed that the

histaminergic system has a role in motivated behavior implementation directed by its principal cortical input, the infralimbic cortex (IL), and shown that there is histamine release in the medial prefrontal cortex during appetitive behavior that is proportional to the number of lever presses for food (motivation). Chronically stressed animals have reduced histamine release during appetitive behavior for food together with reduced motivation, but an intra-peritoneal injection of the H3 antagonist thioperamide increases motivation for palatable food in stressed rats. Stress is known to induce histamine release, and it is possible that chronic histamine overstimulation by chronic stress alter histamine transmission. Here we wanted to explore if chronic stress altered histamine response to acute stress and to study the effect of chronic immobilization stress on sexual motivation in relation to histamine release in the prefrontal cortex and nucleus accumbens (nAcc) of male rats. Tail suspension or receptive-female urine sniffing test (FUST) induced histamine release in the prefrontal cortex of control animals but not stressed animals. FUST reduced histamine release in the nAcc of control animals but not stressed animals. Intraperitoneal thioperamide in stressed animals before FUST increased histamine release in the IL and reduced it in the nAcc. In conclusion, chronic stress reduced histamine release in IL in response to acute stress or appetitive sexual stimulus. The systemic inactivation of H3 receptor normalized the response of stressed rats during sexual motivation in FUST.

Title: Role of deltaFosB in aggressive behavior in male mice

Authors: *H. ALEYASIN[1], S. A. GOLDEN[2], M. E. FLANIGAN[1], M. L. PFAU[1], C. MENARD[1], A. R. NECTOW[3], G. E. HODES[1], M. HSHMATI[1], E. HELLER[1], J. MULTER[1], L. K. BICKS[1], R. L. NEVE[4], E. J. NESTLER[1], S. J. RUSSO[1];
[1]Dept. of Neurol. and Neurosci., Mount Sinai Sch. of Med., New York, NY; [2]NIH, Baltimore, MD; [3]Rockefeller Univ., New York, NY; [4]MIT, Cambridge, MA

Abstract: Aggression is an innate social behavior that helps individuals to defend their territory against competitors and increase the probability of successful mating. However, extreme aggression can have devastating consequences on the society. While the mechanisms controlling aggressive behavior are not well characterized, recent studies implicate brain reward system,

including ventral striatum (vStr), in aggressive behavior mice. DeltaFosB is a truncated splice variant of FosB protein that plays a key role in the function of the brain reward system is increased in the vSTR of aggressive mice. Viral overexpression of deltaFosB in the vStr of aggressive mice intensifies aggression, whereas suppression of FosB expression diminishes aggressive behavior. These findings support the notion that deltaFosB in vStr promotes aggressive behavior. Considering the role of deltaFosB in other reward-related behaviors, such as drug addiction, sexual pleasure and alcohol drinking, our data may point to a new role of deltaFosB in regulating motivational aspects aggressive behavior in mice.

Title: Setdb1 histone H3K9 methyltransferase knockout elicits anxiety phenotype

Authors: *B. JAVIDFAR, Y. JIANG, S. AKBARIAN;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: The histone H3-lysine 9 residue is a major target of the methyltransferase Setdb1 (Set domain, bifurcated 1), also known as Kmt1e, in the adult brain. Setdb1 trimethlyation of H3-lysine 9 is associated with repressive chromatin remodeling and downregulation of a select group of target genes, but the behavioral effects of Setdb1 downregulation remain unknown. We previously reported an antidepressant-like phenotype in adult transgenic mice with increased Setdb1 expression in the forebrain. Here, we report that conditional knockout of Setdb1 via AAV-Cre injections in prefrontal cortex results in an anxiety-like phenotype. In conjuction with our previously reported data, these findings suggest that Setdb1 has a profound effect on the modulation of anxiety-related behavior.

Title: A unique dual cortico-striatal action of a beta-arrestin biased dopamine D2 receptor ligand

Authors: *N. URS[1], S. M. GEE[4], T. F. PACK[1], J. D. MCCORVY[5], T. EVRON[1], B. L. ROTH[5], P. O'DONNELL[4], M. G. CARON[1,2,3];

Abstract: The dopamine hypothesis of schizophrenia postulates hypodopaminergia in the prefrontal cortex and hyperdopaminergia in the striatum. Current antipsychotics effectively reverse excess striatal activity, but do not fully reverse cortical deficits, a problem we address here. Using neuron-specific β-arrestin2 (βarr2)-knockout mice and the β-arrestin-biased D2 receptor (D2R) ligand UNC9994A (94A), we show that βarr2 antagonism in striatal D2R+ neurons is sufficient for antipsychotic activity against amphetamine. However, for antipsychotic activity against phencyclidine, 94A displayed a unique regional selectivity, which can be attributed to enhanced cortical D2R/βarr2 agonism through increased excitability of cortical fast-spiking interneurons (FSI). The switch from antagonism to agonism is consistent with higher cortical expression of βarr2 and GPCR Kinase2 (GRK2) compared to striatum. Therefore, unlike current antipsychotics, β-arrestin-biased D2R ligands that behave as agonists in the cortex but antagonists in the striatum may be sufficient for clinical antipsychotic efficacy, with a superior ability to correct cortical hypodopaminergia. Such a drug could have profound implications in the treatment of cognitive and negative symptoms of schizophrenia in addition to ameliorating psychosis.

Title: Phosphodiesterase 2A inhibition and impulsivity

Authors: *P. R. A. HECKMAN[1,2], A. BLOKLAND[2], J. RAMAEKERS[2], J. PRICKAERTS[1]; [1]Dept. of Psychiatry & Neuropsychology, [2]Dept. of Neuropsychology & Psychopharmacology, Maastricht Univ., Maastricht, Netherlands

Abstract: Impulsivity is a multifaceted concept that comes in many different forms. Impulsive behavior is generally divided into ‘impulsive actions’, i.e. an inability to inhibit a response, ‘impulsive choices’, i.e. a distorted judgment with respect to choosing between two different outcomes, and ‘reflection impulsivity’, the ability to evaluate available information prior to deciding. ‘Impulsive actions’ are generally subdivided into ‘action restraint’, i.e. inhibiting a prepotent, inappropriate response and ‘action cancellation’, i.e. response inhibition or volitional control over responding once the response has been initiated. ‘Impulsive choices’ may be subdivided into delay-, uncertainty-, and effort-based decision making. All concepts of impulsivity seem to find their origin in frontostriatal circuitry. Dopamine (DA) is an important moderator of this circuitry. The extracellular effect of DA is largely mediated through the cAMP/PKA signaling cascade. Importantly, the cGMP/PKG signaling cascade is known to modulate the cAMP/PKA cascade in both the striatal direct D1 and indirect D2 pathway neurons. These cascades are thus a potential target for pharmacological intervention of DAergic signaling in impulse control disorders, like addiction or ADHD. Phosphodiesterase type 2 (PDE2A), which degrades both the intracellular messengers cAMP and cGMP, is known to be present in the frontal cortex and the striatum. In the current project we therefore investigated whether the PDE2A inhibitor BAY 60-7550 could reverse both a systemic amphetamine-induced deficit in

impulse control, as well as impulsivity caused by induction of 6-OHDA lesions in medial prefrontal cortex (mPFC), in operant chambers in adult rats by means of conditioned reaction time task schedules of reward. We hypothesized that based on the major presence of PDE2 in the frontal cortex and either the direct or indirect pathway, the effect of the PDE2 inhibitor increases or decrease impulsivity, respectively.

Title: Cholinergic modulation of nicotine-evoked glutamate release within the dorsal striatum

Authors: *D. YOUNG, R. KOZAK, W. HOWE;
Pfizer Inc, Cambridge, MA

Abstract: Aberrant function of the neural mechanisms controlling motivation and goal-directed action contributes to the manifestation of the cognitive and negative symptoms of schizophrenia, as well as the range of impulsive and apathetic behaviors in neurodegenerative disorders such as Parkinson's and Alzheimer's (Barch and Dowd, 2010, Der-Avakian and Markou, 2012). While much work has focused upon dopaminergic signaling within the ventral striatum in the control of such behavior, collective evidence suggests that activity in the dorsal striatum also plays a causal role. The topographic organization of glutamatergic input to DS is central to its function and is hypothesized to be modulated locally by cholinergic interneurons (e.g. Lovinger, 2010). The present experiments make use of enzyme-selective biosensors for sub-second monitoring of neurotransmitter release (~300 ms temporal resolution) to determine the unique contributions of the heteromeric α4β2 and homomeric α7 nAChRs to cholinergic modulation of glutamate release in the dorsal striatum. Blockade of α7 receptors by MLA resulted in a significant attenuation of nicotine-evoked glutamate release (n=5, 50% reduction in evoked glutamate release), while blockade of α4β2 receptors resulted in a robust increase (n=5, 300% above baseline). As α4β2 sit presynaptically on dopaminergic inputs to the dorsal striatum, on-going follow up studies seek to test the hypothesis that nicotine-evoked DA release acts via presynaptic D2 receptors to further modulate glutamate release. The combined results of these studies seek to add to our understanding of the micro-circuitries that mediate excitatory input to the dorsal striatum.

Unbalanced cholinergic-dopaminergic gating of glutamatergic input to the dorsal striatum may contribute to deficits in motivation and other cognitive processes that are attributed to myriad neuropsychiatric disorders.

Title: Catechol-O-methyltransferase affects striatal dopamine transmission and modulates the influence of cue salience on associative learning

Authors: ***A. HUBER**[1,2], L. OIKONOMIDIS[1], J. GAUNT[1], E. M. TUNBRIDGE[2], M. E. WALTON[1];
[1]Dept. of Exptl. Psychology, [2]Dept. of Psychiatry, Univ. of Oxford, Oxford, United Kingdom

Abstract: The enzyme catechol-O-methyltransferase (COMT) plays an important role in the breakdown of dopamine in prefrontal cortex, but has been presumed to have little effect over striatal dopamine. However, several neuroimaging studies have showed an influence of variation in COMT genotype on striatal BOLD signals, particularly during reward-guided learning and decision making. To investigate further the effect of COMT genes on striatal dopamine-dependent behaviours and striatal dopamine release, we used combinations of behavioural testing and fast-scan cyclic voltammetry in a transgenic mouse model of the Val158Met polymorphism found in the human COMT gene. In one set of experiments, mice were implanted with carbon fibre electrodes in the nucleus accumbens core to determine the influence of COMT genotype on stimulus-evoked dopamine release. Mice were initially trained on a variable interval schedule to gain a standard reward size. Subsequently, dopamine release was recorded in a session where standard reward trials were intermixed with decreased or increased reward size trials. While

reward delivery elicited rapid increases in dopamine that scaled with reward size in both groups, there was a significant attenuation in this scaling in the Met-COMT mice, in particular for smaller-than-expected rewards (i.e., negative prediction errors). In a second set of experiments, we tested whether variations in COMT genotype affects appetitive learning, which is known to depend on intact striatal dopamine. Groups of Met-COMT mice and wild type littermates (WT) were first trained on a Pavlovian conditioning paradigm where auditory cues - a 3kHz tone or white noise - were followed by either the delivery of reward or no reward. While both groups on average learned at an equal rate to associate the CS+ with reward, closer analysis showed that the speed of acquisition was significantly faster in Met-COMT mice when the white noise was the CS+, but significantly slower when instead the tone was the CS+. Further experiments demonstrated that learning rates were more strongly modulated by assignment of CS+ cue salience in the Met-COMT mice. Together, these results suggest subtle but influential roles for COMT genotype on reward-elicited dopamine release and reward-guided learning.

Title: Contributions of COMT and DAT to regulation of phasic dopamine release and reward-guided behavior

Authors: ***C. KORN**, C. VAGNONI, M. WALTON, E. TUNBRIDGE;
Oxford Univ., Oxford, United Kingdom

Abstract: Fine temporal regulation of dopamine transmission is critical to dopaminergic mediation of behavior. Dopamine can be cleared from the synapse by several mechanisms. Enzymatic degradation involving catechol-O-methyltransferase (COMT) is one of the main means of clearing cortical dopamine, which modulates executive functions. Recycling by the

dopamine transporter (DAT) predominates in the striatum, where dopamine regulates reward-guided behavior. However, evidence from human functional imaging studies demonstrates interactive effects of COMT and DAT genotype, suggesting that this segregation is not so clear-cut. Given the interdependence of mesolimbic and mesocortical circuitry and the presence of COMT (albeit at relatively low levels) in striatum, it is possible that COMT may interact with DAT to influence dopamine transmission and dopamine-dependent behaviors. Therefore, we used *in vivo* electrochemical recording, pharmacology, and behavioral testing to investigate the contributions of COMT and DAT to regulation of dopamine transmission and reward-guided behavior in male mice. Fast-scan cyclic voltammetry was used to monitor the effects of a DAT blocker (GBR-12909, 6mg/kg) and a COMT inhibitor (tolcapone, 30mg/kg) on dopamine transmission evoked by electrical stimulation of the ventral tegmental area, *in vivo*, in anaesthetized mice. Systemic blockade of DAT significantly increased the peak height of evoked dopamine transients in the nucleus accumbens (NAcc) (n = 14) but not in the medial frontal cortex (MFC) (n = 8). By contrast, COMT inhibition did not significantly alter the peak height of evoked dopamine in either NAcc (n = 14) or MFC (n = 9). However, preliminary analyses of kinetic parameters suggest that there may be interactive effects of COMT inhibition and DAT blockade on dopamine transmission in these regions not captured by the assessment of peak height. Concurrent behavioral tests in awake animals found that only systemic administration of the DAT blocker, but not of the COMT inhibitor, increased motivation to work for reward in a progressive ratio paradigm (n = 22). Thus far, the results of this study support prevailing ideas about how DAT blockade alters striatal dopamine transmission and associated behaviors and do not yet offer clear evidence of COMT-DAT interactions in the regulation of phasic dopamine release or reward-guided behavior.

Title: The mammalian target of rapamycin complex 1 (mTORC1) in the orbitofrontal cortex contributes to habitual responding for alcohol

Authors: *N. MORISOT, J. T. BECKLEY, K. PHUAMLONG, D. RON;
Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: mTORC1 pathway mediates dendritic protein synthesis, synaptic plasticity and thus contributes to learning and memory [1]. Alcohol addiction is a maladaptive form of learning and memory processes [2]. We previously found that excessive alcohol drinking activates mTORC1 in the rodent nucleus accumbens (NAc), a key component of the brain reward system [3]. We further reported that inhibition of mTORC1 by systemic or intra-NAc administration of its specific inhibitor, rapamycin, attenuated alcohol-related behaviors in rodents, including the expression of alcohol-induced locomotor sensitization and place preference, home-cage excessive drinking, as well as operant self-administration and seeking [4]. Finally, we found that systemic administration of rapamycin also disrupted the reconsolidation of alcohol-associated memories, leading to suppression of alcohol relapse in rats [5]. Here we report that mTORC1 is activated in the orbitofrontal (OFC) but not in the prefrontal cortex of rats that consumed 20% alcohol for 8 weeks in an intermittent choice paradigm. The OFC is a critical component of the corticostriatal circuitry that dynamically coordinates the balance between goal-directed and habitual actions, and impairment in this balance as well as OFC dysfunction are associated with alcohol addiction. Thus, we hypothesized that mTORC1 in the OFC is required for the transition from goal-directed to habitual responding for alcohol. To test this possibility, we used an operant paradigm in which rats with a history of excessive alcohol drinking self-administered 20% alcohol under a random ratio (RR) or a random interval (RI) schedule of reinforcement. Then, we used a revaluation test and showed that alcohol devaluation reduces responding for alcohol in RR-trained but not RI-trained rats, revealing goal-directed and habit-driven behavior, respectively. Next, we tested whether mTORC1 inhibition in the OFC alters the sensitivity to devaluation in RR- and RI-trained rats. We found that intra-OFC infusion of rapamycin 3 hrs prior the devaluation test did not affect the goal-directed alcohol responding in RR-trained rats but restored the sensitivity to devaluation in RI-trained rats. Together, these data suggest that alcohol-mediated activation of mTORC1 in the OFC contributes to the expression of habitual alcohol responding. 1.Graber, T.E., et al. Learn Mem, 2013. 2.Hyman, S.E. Title: GCN5 enzymatic activity is required for normal corticostriatal development and function

Authors: *J. WILDE, L. NISWANDER;
Pediatrics, UC Denver, Aurora, CO

Abstract: Defects in corticostriatal circuits and the pathways necessary for their development and maintenance are thought to underlie numerous psychiatric and neurological diseases. GCN5 is an acetyltransferase with established functions in nervous system development and memory, but it is unknown whether it plays a role in corticostriatal development and function or behavior. We find that mice heterozygous for an enzymatically inactive form of GCN5 (*Gcn5*$^{hat/+}$) exhibit phenotypes similar to those seen in *Slitrk5*$^{-/-}$ mice, an established model for OCD. Specifically, *Gcn5*$^{hat/+}$ mice develop severe self-injurious behavior and show signs of anxiety in multiple behavioral assays. In order to further investigate these phenotypes, we developed a longitudinal study examining behavior, molecular markers, cellular morphology, and volumetric changes in *Gcn5*$^{hat/+}$ mice over the course of 15 months. Molecular clues generated by microarray analysis of forebrain tissue from E10.5 embryos completely lacking GCN5 activity revealed disruption of multiple processes implicated in OCD and mood disorders, indicating that developmental mechanisms may underlie the phenotypes seen in heterozygous adults. By 6 months of age, *Gcn5*$^{hat/+}$ mice show significant behavioral differences in a marble-burying assay, with no apparent anxiety phenotypes. Mutants display significantly greater variability in behavioral assays and progress to show signs of anxiety by 8 months of age. Furthermore, 12-month-old *Gcn5*$^{hat/+}$ mice show significantly decreased complexity of striatal medium spiny neurons, increased neuronal activity in the orbitofrontal cortex, and evidence of decreased striatal volume, mirroring the phenotypes seen in *Slitrk5* mutants. Together, our data suggest that GCN5 acetyltransferase activity is required for proper development and function of corticostriatal circuits and that alteration of GCN5 activity may underlie some behavioral disorders.

Title: Corticotropin-releasing factor (CRF) impairs prefrontal cortex-dependent cognitive processes

Authors: ***S. HUPALO**[1,2], R. C. SPENCER[2], C. W. BERRIDGE[2];
[1]Neurosci. Training Program, [2]Psychology, Univ. of Wisconsin - Madison, Madison, WI

Abstract: The prefrontal cortex (PFC) regulates cognitive processes critical for flexible, goal-directed behavior. Dysfunction of PFC-dependent cognition is associated with a variety of psychopathologies. It has long been known that corticotropin-releasing factor (CRF) and CRF receptors are prominent in the PFC. However, despite decades of research into the neurobiology of CRF, the cognitive actions of CRF signaling in the PFC remain largely unknown. To address this, we tested the hypothesis that CRF modulates PFC-dependent cognition. We first examined the effects of intracerebroventricular (ICV; 0.1, 0.2, 1, 3 µg) and intra-PFC (25, 50, 100, 250 ng/hemisphere) CRF infusions on performance in a task of spatial working memory in rats. ICV and intra-PFC infusions of CRF elicited a robust and dose-dependent impairment in task performance. Interestingly, the cognitive effects of CRF signaling in the PFC were topographically organized, such that CRF infusions into the caudal, but not rostral, dorsomedial PFC (dmPFC) impaired working memory performance. Subsequent studies investigated whether endogenous CRF signaling modulates working memory using the CRF antagonist, D-Phe-CRF. Both ICV (2, 4, 10 µg) and intra-caudal dmPFC (50, 200 ng/hemisphere) infusions of this antagonist dose-dependently improved working memory performance. Given all FDA approved treatments for ADHD improve working memory performance in rodents, monkeys and humans, these observations raise the hypothesis that CRF antagonists may be effective in treating ADHD and other disorders associated with PFC-dependent cognitive dysfunction. Additional studies examined whether CRF modulates PFC-dependent cognition more broadly. Specifically, we tested the effects of ICV and intra-PFC CRF infusions in a signal detection task of sustained attention using doses similar to those in the working memory studies. ICV CRF dose-dependently impaired performance in this task. However, in contrast to that seen with working memory, CRF infusions into both rostral and caudal dmPFC subfields had no effect in sustained attention. This indicates that the impairing effects of ICV CRF in sustained attention are not due to CRF action in the PFC. Thus, CRF signaling in the PFC differentially modulates distinct PFC-dependent processes. Ongoing studies are examining the degree to which ICV administration of a CRF antagonist improves sustained attention similarly to working memory. Collectively, this research provides novel insight into the neurobiology of PFC-dependent cognition and may have relevance for treating psychopathologies associated with PFC dysfunction.

Title: Genetic and pharmacologically mediated changes in neural synchrony across the mesocorticolimbic dopamine system during alcohol consumption

Authors: ***A. M. MCCANE**[1], S. AHN[2], L. RUBCHINSKY[3], S. S. JANETSIAN[1], D. N. LINSENBARDT[1], C. L. CZACHOWSKI[1], C. C. LAPISH[1];

Abstract: Alterations in the mesocorticolimbic (MCL) dopamine (DA) pathway have been implicated in alcohol use disorder (AUD). The neural responses to stimuli that predict drug availability have been postulated as a clinically relevant target for AUD therapies. The present experiments sought to first characterize changes in network-level neural activity of the MCL system during cued drug seeking in a rodent model of AUD. Secondly, we sought to determine the consequences of modulating cortical DA on neural synchrony and associated changes with alcohol seeking behaviors. Subjects were alcohol preferring (P) and Wistar rats engaged in a Pavlovian conditioning paradigm where the illumination of a stimulus light signaled the availability of an ethanol solution. Upon reaching stable responding (i.e, approach behavior) in this task, animals were implanted with microelectrodes in VTA, PFC, and NA to acquire local field potentials (LFPs) during the conditioning task. LFPs were digitally filtered in the theta band (5-11 Hz). Recordings were segregated into three 10-second epochs (before CS, during US, after US) and the phase locking index γ was calculated as a measure of the strength of phase locking between signals from any two brain regions. The enzyme catechol-O-methyltransferase (COMT) is the primary mechanism of DA metabolism in the PFC. To assess how cortical DA modulation impacted neural synchrony and corresponding behavioral measures, the COMT inhibitor Tolcapone was administered prior to conditioning sessions on drug test days. In both strains, overall synchrony was significantly stronger between the NA and PFC than the PFC-VTA or VTA-NA. However, P rats showed reduced NA-PFC synchrony relative to Wistars. During

drinking epochs, robust increases in theta synchrony were observed in P rats, and to a lesser extent in Wistars. A transient decrease in VTA-NA synchrony during drinking was also observed in P rats but not Wistars. Administration of Tolcapone reduced both alcohol consumption and PFC-NA synchrony in P rats but not Wistars. Alterations in PFC-striatal connectivity has been reported in individuals with AUD. Impaired frontal-striatal connectivity is correlated with both alcohol craving and dependence severity. Moreover, alterations that occur between the PFC and NA are hypothesized to be linked to an enhanced reactivity to drug paired stimuli in addicts. These data implicate aberrant connectivity between the PFC and NA and suggest the clinical utility of COMT inhibition as a therapy for AUD.

Title: Which anatomical substrate is reflected by MRI-based connectomics? lessons from the Allen mouse brain connectome atlas

Authors: ***V. ZERBI**[1], J. GRANDJEAN[2], Z. PRÖHLE[3], M. RUDIN[2,4], N. WENDEROTH[1]; [1]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland; [2]Inst. for Biomed. Engineering, ETH and Univ. Zurich, Zurich, Switzerland; [3]Dept. of Physics, ETH Zurich, Zurich, Switzerland; [4]Inst. of Pharmacol. and Toxicology, Univ. Zurich, Zurich, Switzerland

Abstract: Resting-state fMRI (rs-fMRI) and diffusion weighted imaging (DWI) are widely used MRI techniques in the field of neuroscience. These MRI tools offer insights into the brain's functional and structural connectivity by measuring coherence of intrinsic neural activity and axonal anatomical pathways, respectively. However, for both modalities connectivity measurements are indirect and it is not clear in how far they reflect the anatomical connectome. For example, regions that are functionally connected based on rs-fMRI do not always have direct structural connections as measured with DWI-based tractography, as found for the extra-striate visual cortices(1). While an intermediate region could form the anatomical relay between these areas, such a putative region may not be apparent from the functional maps of these networks. These observations raise the question which anatomical substrate is reflected by the functional and structural networks commonly observed via MR based methods in humans and in rodents.

Here we investigate the relationship between MRI-based connectomics analyses and mono-synaptic connectivity measures in the mouse brain. The connectivity data from the Allen Brain Institute derived from viral injection experiments(2) provides unique information on monosynaptic connectivity in the mouse brain. Our goal in this study is to directly compare the results from connectome analyses obtained either by rs-fMRI and DWI-based tractography, with the anatomical ground truth provided by the Allen Brain Institute. Rs-fMRI and DWI datasets were acquired in C57BL/6J mice on a 9.4T scanner (Bruker BioSpec 94/30) equipped with a gradient system capable of a maximum gradient strength of 400 mT/m with an 80 ms rise time. Best-practice methods are applied to obtain resting-state whole brain connectivity maps(3), using over 400 injection areas from the Allen institute as seed regions. A structural connectome is also obtained from gray matter ROIs in the mouse brain, using anatomical constrained probabilistic tractography and SIFT correction for white matter density(4). The resulting connectome matrices will be directly compared to the viral injection-based connectivity maps from the Allen institute. The results of this study will link MRI measurements of structural and functional connectivity to the anatomical ground truth, which is an important step to better interpret MRI-based studies of the connectome in rodents and in humans. 1) van den Heuvel et al. Title: Functional and structural changes associated with recovery of function following lesions to principal sulcus in macaques

Authors: ***M. AINSWORTH**[1,3], H. BROWNCROSS[2], D. J. MITCHELL[3], A. S. MITCHELL[2], J. SALLET[2], M. J. BUCKLEY[2], J. DUNCAN[2,3], A. H. BELL[2,3];
[2]Dept. of Exptl. Psychology, [1]Oxford Univ., Oxford, United Kingdom; [3]MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom

Abstract: It has been shown that there can be recovery of function following damage to certain areas of cortex, the nature and degree of recovery depending on the specific area. However, it is currently unknown how brain areas outside the damaged region(s) compensate to drive this recovery. Here we collected BOLD fMRI and structural imaging data across multiple time points following lesions to the left and right principal sulcus in two macaque monkeys. The objective was to examine the functional and structural changes that occur over an extended period in brain areas following sequential lesions to the prefrontal cortex. Monkeys were trained to perform two delayed-match tasks. In the “match-to-object” task, a target stimulus was presented, which the monkey was required to touch. After a variable delay (2-16s), the same stimulus appeared in a random location embedded within a number of distracting stimuli, and the monkey was required to again ¬touch the target stimulus, irrespective of its location. In the “match-to-location” task, the monkey was required to indicate the location of the previously presented target stimulus, irrespective of the identity of the stimulus currently presented there. Once animals had reached a criterion level of performance on both tasks (>70%), we collected functional and structural imaging data under general anaesthesia at periodic intervals (4 times approximately once every 3 weeks). Several days prior to each scanning session, the animals were tested on both the object and location tasks (2-3 testing sessions for each task across 2-3 days). After four such testing sessions, the animals received a lesion to both banks of the left principal sulcus. Following a post-operative recovery period, we resumed periodic testing and scanning sessions (4 times approximately once/3 weeks). Once the animals had returned to pre-lesion performance levels, they received a lesion to the right principal sulcus. The animals were once again tested and scanned (4 times, approximately once every 3 weeks). Animals showed impairment followed by eventual recovery in both tasks following each lesion. The drop in behavioural performance was accompanied by disturbed functional connections (as measured by resting state correlations) between specific regions in both hemispheres that were identified to be strongly functionally connected to the principal sulcus in a control dataset. Following the lesions, we also observed reduction in grey matter volume across multiple brain areas. These data suggest that, following a focal frontal lobe lesion, behavioural impairments reflect not just the functions of the lesioned area, but disturbance of an extensive cortical network.

Title: Characterizing circuits for positive and negative social interactions in mPFC

Authors: *L. CHUNG, K. SAKURAI, S. ZHAO, F. WANG;
Neurobio., Duke Univ., Durham, NC

Abstract: Identifying specific neurons relevant to complex behaviors is the key step to understand the neural mechanisms generating behaviors. A newly developed technology called CANE* (Wang lab, manuscript submitted) is able to selectively tag neurons activated during brief ethologically relevant behaviors. This study is focused on social behaviors involving neurons in medial prefrontal cortex (mPFC). Two types of social interaction behaviors are elicted: (1) a social fear behavior in which an intruder male mouse is attacked by an aggressive resident mouse for 10 minutes; and (2) a male-female interaction behavior in which the male is exposed to a female for 30 minutes. mPFC neurons are activated in both behaviors as revealed by anti-Fos staining. We asked whether “social fear” neurons are the same or are distinct from the “mating behavior” neurons in mPFC, and whether they project to the same or different downstream targets. Using the CANE* technology, we expressed GFP in either the “social fear” or the “mating behavior” neurons which allowed us to characterize them. The “projectome” and electrophysiological properties of mPFC “social fear” and “mating” neurons are investigated.

Title: Projections from the prefrontal cortex and medial and inferior temporal cortices converge in a critical node in the striatum

Authors: *E. CHOI[1], S.-L. DING[2], G. W. VAN HOESEN[3], S. N. HABER[1];
[1]Dept of Pharmacol. & Physiol., Univ. of Rochester Med. Ctr., Rochester, NY; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Dept. of Anat. & Cell Biol., Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: Interactions between the prefrontal cortex (PFC) and the temporal cortex are critical for high-order cognitive functions involving sensory information, memory, and emotion. Both the PFC and medial and inferior temporal cortex (M/ITC) strongly project to the ventral striatum (VS), a major integration site central to making selections and forming associations. However, it is not fully known whether and how PFC and M/ITC projections converge in the striatum. While prefrontal projections to the VS have been mapped in detail previously, the topography of M/ITC projections is only partially known. Here, we undertook a comprehensive mapping of M/ITC projections to the VS and compared this to the topography of PFC-striatal projections. Retrograde injections showed that all parts of the VS receive strong projections from the anterior medial temporal cortex. In contrast, the anterior inferior temporal cortex sends projections primarily to the lateral VS, while the posterior parahippocampal region (pPHR) projects most strongly to the ventral VS. Anterograde injections in the M/ITC confirmed these results and identified at least two types of prefrontal-temporal convergence in the striatum. Projections from the temporal pole (area TG) and the anterior inferior temporal cortex (area TEav) overlap primarily with those from cortical regions involved in emotion processing as follows. Temporal pole projections terminate in the medial and ventral portions of the VS, highly similar to vmPFC (areas 14, 25) projections. They also overlap with OFC (areas 11, 13) and ACC (area 24) projections. Anterior inferior temporal cortex projections terminate in the lateral and mid-dorsal portions of the VS and overlap with those from OFC and ACC. Interestingly, however, projections from the pPHR are split. These terminate in the ventrolateral VS, overlapping with ACC and OFC projections, and also at the dorsal edge of the caudate, where they overlap with dlPFC and premotor projections. Thus, pPHR projections overlap with both emotion and cognitive cortical projections in the striatum. Lastly, the ventral part of the VS appears to be a special region. This region receives input from areas throughout the M/ITC, as well as from the vmPFC, ACC, and OFC. This site of high convergence in the ventral VS may be a critical node that integrates information from diverse functional regions and may be particularly susceptible for disorders. Together, these results indicate that PFC and M/ITC projections have specific convergences in the striatum that involve one or more functional domains. In addition, the ventral VS may contain a critical node of PFC and M/ITC projections.

Title: Projection pattern of the ventrocaudal part of the intralaminar thalamic nucleus to the caudate putamen in the rat brain

Authors: *H. IWAI, E. KURAMOTO, A. YAMANAKA, T. GOTO;
Dept. of Oral Anat. and Cell Biol., Kagoshima Univ., Kagoshima, Japan

Abstract: The rat intralaminar thalamic nuclei are enclosed with the internal medullary lamina of the thalamus, and receive input from the brain stem and send output to the cerebral cortex and caudate putamen (CPu). Recently, the medial parabrachial nucleus relaying a visceral sense is reported to project to the ventrocaudal part of the intralaminar thalamic nuclei such as the caudal part of the central medial nucleus and ventral part of the parafascicular thalamic nucleus. Generally, the intralaminar thalamic nuclei project topographically to the CPu, however, it is unclear whether the ventrocaudal part of the intralaminar thalamic nuclei projects topographically to the CPu. Thus, we examined topographical arrangement of neural pathways between the ventrocaudal part of the intralaminar thalamic nuclei and CPu using an anterograde tracer, biotinylated dextran amine, and a retrograde tracer, cholera toxin B subunit. We revealed that the oval paracentral thalamic nucleus mainly projected to the ventrocentral part of the CPu; the ventrolateral part of the parafascicular thalamic nucleus mainly projected to the ventrolateral part of the CPu; and the caudal part of the central medial thalamic nucleus, ventromedial part of the parafascicular thalamic nucleus, and retroreuniens area mainly projected to the ventromedial part of the CPu. In contrast, the parvicellular part of the posteromedial ventral thalamic nucleus mainly projected to the caudal part of the interstitial nucleus of the posterior limb of the anterior commissure. These results suggest that efferent fibers from the ventral part of the intralaminar thalamic nuclei to the ventral part of the CPu are topographically organized. Because the ventral part of the CPu reportedly regulates food intake, fat intake, and jaw movement, visceral information from the medial parabrachial nucleus is likely to influence feeding behavior in the ventral part of the CPu via the ventrocaudal part of the intralaminar thalamic nuclei.

Title: A morphological analysis of thalamocortical projections arising from the rat mediodorsal nucleus: A single neuron-tracing study using viral vectors

Authors: *E. KURAMOTO[1], S. PAN[2], T. FURUTA[2], H. HIOKI[2], H. IWAI[1], A. YAMANAKA[1], S. OHNO[1], T. GOTO[1], T. KANEKO[2];
[1]Dept. of Oral Anat. and Cell Biol., Kagoshima Univ., Kagoshima, Japan; [2]Dept. of Morphological Brain Sci., Grad. Sch. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: The rat mediodorsal thalamic nucleus (MD) is subdivided into 3 portions, the medial (MDm), central (MDc) and lateral segments (MDl), mainly on the basis of the cytoarchitecture and myeloarchitecture. These 3 MD segments have been reported to receive different inputs from a wide variety of the subcortical structures, and project topographically to the different areas of the prefrontal cortex. However, it is unknown whether the single MD neurons send their axons to only a single cortical area or project widely to multiple areas of the prefrontal cortex. In the present study, the axonal arborization of single MD neurons was examined by a single neuron labeling method with a Sindbis viral vector expressing fluorescent proteins. The location of single MD neurons infected with the Sindbis virus was examined by Nissl-like staining, and further confirmed in immunohistochemistry for calbindin D28k, because the differential distribution of calbindin immunoreacitivity is useful for a distinction among the 3 MD segments; calbindin immunoreactivity is more intense in the MDm and MDl than in the MDc. The single MD neurons were completely visualized by immunoperoxidase staining for fluorescent proteins, and their axonal arborization was reconstructed. In the subcortical region, the reconstructed MD neurons emitted axon collaterals always to the thalamic reticular nucleus, and frequently to the striatum. In the cerebral cortex, the main target areas of the MDc, MDm and MDl neurons were lateral orbital, prelimbic/lateral orbital and cingulate/prelimbic areas, respectively. Interestingly, the most MD neurons formed another axonal arborization in the prefrontal cortex. Thus, the single MDl, MDm and MDc neurons innervated multi-areas with a considerable overlap, indicating that the 3 pieces of information conveyed via the 3 MD segments would be integrated in the thalamocortical projection pathway. On the basis of their different cortical projections, thalamic neurons are divided into two types: core-type and matrix-type neurons project to the middle layers and superficial layer, respectively. Since the axon fibers of most MD neurons were abundantly distributed in layers 2-5, MD neurons were classified to core-type, and their axon fibers might target to the basal dendrites of layers 2-5 pyramidal neurons. These results suggest

that even when a small number of MD neurons are activated, a large number of Layers 2-5 pyramidal neurons in multi-areas would be simultaneously activated, and that the coordinated activation of multi-areas may be lead to an appropriate execution of prefrontal functions, such as behavioral flexibility, recognition memory and attention.

Title: Cell-type-specific control of innate behaviors by the dorsal raphe nucleus

Authors: ***A. R. NECTOW**[1], B. FIELD[2], J. M. FRIEDMAN[2];
[1]Dept. of Mol. Genet., Rockefeller Univ., New York, NY; [2]Mol. Genet., Rockefeller University/HHMI, New York, NY

Abstract: The dorsal raphe nucleus (DRN) has been implicated in the modulation of a number of critical, survival-related functions such as reward, food intake, and locomotion. In addition to being the single largest serotonergic nucleus in the mammalian brain, the dorsal raphe also houses a number of other cell types such as glutamatergic neurons (expressing VGluT3) and GABAergic neurons (expressing Vgat). In the current studies, we used a combination of molecular profiling, optogenetics, and viral tracing to establish the network function of the dorsal raphe nucleus in controlling survival-related behaviors. These studies have elucidated novel, unexpected roles for both the glutamatergic and GABAergic neurons in bidirectional modulation of food intake, as well as differential contributions to locomotor function. Together, these data demonstrate a significant, previously unappreciated role of the dorsal raphe's non-serotonergic neurons in controlling diverse innate behaviors.

Title: The role of median raphe GABA and glutamate neurons in reward

Authors: *A. TAN, S. IKEMOTO;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Previous pharmacological research has shown that rats will self-administer GABA receptor agonists, AMPA receptor antagonists, and NMDA receptor antagonists into the median raphe region (MR). However, there are diverse populations of neurons_serotonergic, glutamatergic, and GABAergic_in the MR, and the roles they play in reward are unclear. To resolve this issue, the present study utilized optogenetics to selectively excite or inhibit particular populations of MR neurons. Wild-type C57 mice received a viral vector encoding halorhodopsin (NpHR) in the MR, and learned to self-administer photostimulation, suggesting that net inhibition of MR neurons is rewarding. Transgenic vGat-Cre mice received NpHR in the MR, resulting in selective expression of the opsin in GABA neurons. These mice learned to self-administer photostimulation at a greater level than C57 mice, suggesting that inhibition of GABA neurons is one part of the circuitry underlying MR reward. Transgenic vGluT3-Cre mice received channelrhodopsin (ChR2) in the MR, resulting in selective expression of the opsin in glutamate neurons. These mice also learned to self-administer photostimulation at a greater level than C57 mice, suggesting that excitation of glutamate neurons is another part of the circuitry underlying MR reward. Taken together, inhibition of MR GABA neurons may disinhibit MR glutamate projection neurons, which activate global reward circuits. The MR may be another important region to study in order to understand the neurobiology of affect and addiction.

Title: Coding of dorsal raphe reward signals by the orbitofrontal cortex

Authors: ***J. ZHOU**[1,2], C. JIA[1], Q. FENG[1], J. BAO[1], M. LUO[1,3];
[1]Natl. Inst. of Biol. Sciences, Beijing, Beijing, China; [2]Peking Univ., Beijing, China; [3]Tsinghua Univ., Beijing, China

Abstract: The orbitofrontal cortex (OFC) is important for the cognitive processes of learning and decision making. Previous recordings have revealed that OFC neurons encode predictions of reward outcomes. The OFC is interconnected with the dorsal raphe nucleus (DRN), which is a major serotonin center of the brain. Recent studies have provided increasing evidence that the DRN encodes reward signals. However, it remains unclear how the activity of DRN neurons affects the prospective reward coding of OFC neurons. By combining single-unit recordings from the OFC and optogenetic activation of the DRN in behaving mice, we found that DRN stimulation is sufficient to organize and modulate the anticipatory responses of OFC neurons. During Pavlovian conditioning tasks for mice, odorant cues were associated with the delayed delivery of natural rewards of sucrose solution or DRN stimulation. After training, OFC neurons exhibited prospective responses to the sucrose solution. More importantly, the coupling of an odorant with delayed DRN stimulation resulted in tonic excitation or inhibition of OFC neurons during the delay period. The intensity of the prospective responses was affected by the frequency and duration of DRN stimulation. Additionally, DRN stimulation bidirectionally modulated the prospective responses to natural rewards. These experiments indicate that signals from the DRN are incorporated into the brain reward system to shape the cortical prospective coding of rewards.

Title: Differential involvement of dopamine and opioid signaling in food preference and effort-related decision-making in rats

Authors: I. MORALES[1], P. J. CURRIE[1], T. D. HACKENBERG[1], *R. PASTOR[1,2];
[1]Dept. of Psychology, Reed Col., Portland, OR; [2]Area de Psicobiología, Univ. Jaume I, Castellón, Spain

Abstract: Motivation is a complex process that involves appetitive and consummatory components. A number of neurotransmitters and neural circuits have been shown to be involved in this process. Dopamine (DA) signaling is often suggested to mediate reward, but the precise nature of this involvement seems to be more specific; DA receptor antagonists decrease operant responding for food reinforcers, but leave consummatory and hedonic responses relatively unchanged. Opioid signaling mediates consummatory behavior, an effect suggested to be associated with altered palatability and hedonic responses to food reinforcers. Opioid receptor antagonists also decrease operant responding for food on progressive (PR) ratio schedules, indicating that this system may also be involved in appetitive, instrumental behavior. The present study examined the role of opioid and dopamine receptors in food reinforcement using an effort-related decision-making task (i.e., a progressive ratio/chow feeding task). With this task, rats can choose between working for a preferred food (high-carbohydrate banana-flavored sucrose pellets) by lever pressing on a PR schedule vs. obtaining less preferred laboratory chow that is freely available concurrently in the chamber. Haloperidol (0, 0.05, 0.1 mg/kg; i.p.) decreased the breakpoint (highest PR achieved), lever presses, and number of reinforcers earned, and increased chow intake (an effect found with 0.05 and 0.1 mg/kg). By contrast, naloxone (0, 1.5, 3 mg/kg; i.p.) decreased breakpoint and number of reinforcers earned (using 3, but not 1.5 mg/kg) but had no effect on chow consumption. A preference test measured the relative intake of both foods (banana pellets vs. chow) under effort-free conditions. Haloperidol (0.1 mg/kg) produced a decrease in intake of both foods but did not affect preference. Opioid receptor blockade (naloxone 3 mg/kg) selectively reduced banana pellet intake but had no effect on chow. The present findings support evidence suggesting that DA signaling mediates activational components of appetitive motivation, particularly those related to exertion of effort, while leaving some aspects of consummatory behavior (i.e., palatability or food preference) unaffected. Opioid signaling appears to selectively affect intake of relatively preferred foods. Based on previous literature, we hypothesize that a naloxone-induced decrease in palatability for preferred food in our experiment resulted in reduced willingness to exert effort. Our results argue against a general suppression of appetite by either compound as appetite suppressants have been previously shown to alter intake of both types of food regardless of the task.

Title: Low frequency rTMS to monkey STS moderates neuronal sensitivity to social reward

Authors: *A. UTEVSKY[1], M. L. PLATT[2];
[1]Ctr. for Cognitive Neurosci., [2]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: The superior temporal sulcus (STS) region of cortex contributes to various aspects of social cognition, including face perception, biological motion detection, joint attention, empathy, and theory-of-mind. Recent brain imaging studies have also implicated this area in social decision-making. The precise neuronal mechanisms mediating STS contributions to social decisions remain unknown. To answer this question, we used a combination of repetitive transcranial magnetic stimulation (rTMS) to STS and simultaneous neuronal recordings in the same area in monkeys performing a social reward-allocation task (Chang et al., 2011, 2012, 2013). Monkeys chose to allocate juice rewards to self, another monkey, both, or no one. Consistent with our prior published studies, monkeys preferred to reward the recipient monkey over no one, but preferred to reward self over both monkeys. Single and multi units in the middle STS responded strongly during the choice commitment and reward-outcome phases of the task. Moreover, firing rates varied systematically with the social context of decision, responding most strongly to “both” and “self” trials and significantly less to “other” and “none” trials. Importantly, firing rates were significantly higher when monkeys chose “other” over “none,” and these preferences were magnified in a second condition that cued different magnitudes of reward. Critically, 10 minutes of low-frequency (1Hz) rTMS - a stimulation regime thought to suppress neuronal activity - to the STS abolished social preferences expressed behaviorally and simultaneous neurophysiological distinctions between social reward outcomes. Sham stimulation had no impact on social preferences or neurophysiological activity. Together, these findings suggest STS neurons signal predicted and experienced social reward outcomes and that these

signals contribute directly to social decisions. Our data also demonstrate that low-frequency rTMS impairs behavior by disrupting neurophysiological activity at the site of stimulation.

Title: Low-frequency deep brain stimulation of the ventral striatum facilitates the extinction of morphine place preference

Authors: ***F. J. MARTINEZ**[1], J. RODRIGUEZ-ROMAGUERA[1,2], M. E. LLORET-TORRES[1], J. M. MIRANDA-FAJARDO[1], F. H. DO MONTE[1,2], G. J. QUIRK[1,2], J. L. BARRETO-ESTRADA[1];

Abstract: Recently, research in humans and rodents has indicated that DBS of the ventral striatum (VS) may be an effective treatment for drug addiction (Luigjes et al., 2012). However, we recently found in rats that high-frequency DBS (HF-DBS) of the VS impaired extinction of morphine-induced conditioned place preference (CPP; Martinez-Rivera et al., SFN 2013). Furthermore, low-frequency DBS (LF-DBS) has also been suggested as a treatment of neuropsychiatric disorders in humans (Hernando et al., 2008). In rats, LF-DBS of the VS attenuated cocaine sensitization (Creed et al., 2015) and relapse (Hamilton et al., 2014). However, no studies have applied LF-DBS of the VS during the extinction of drug-associated memories. In this study, we examined whether LF-DBS of the VS facilitates the extinction of morphine-CPP. Rats were implanted with DBS electrodes in the VS and conditioned to prefer a side paired with morphine. Subsequently, rats expressing morphine-CPP received extinction

sessions, together with 60 min of LF-DBS (20 Hz) or sham stimulation. Our results showed that LF-DBS of the VS had no effect during extinction training, but strengthened extinction memory when tested 2 days (p=0.005) or 9 days (p=0.04) after stimulation was turned off. In addition, LF-DBS increased c-Fos immunolabeling in the infralimbic cortex (p=0.03) and medial portion of central amygdala (p=0.04), key regions in the extinction of drug seeking behaviors (Gass and Chandler, 2013). Our results support the idea that LF-DBS (rather than HF-DBS) of the VS represents a possible therapy for treatment-resistant opioid addicted patients, who undergo extinction-based therapies.

Title: Intact anterior insular response to punishment magnitude, despite dACC related error-learning deficits in heroin dependent participants

Authors: *D. J. UPTON, D. A. O'CONNOR, J. MOORE, K. P. CHARLES-WALSH, S. ROSSITER, R. HESTER;
Sch. of Psychological Sci., The Univ. of Melbourne, Melbourne, Australia

Abstract: Deficits in error processing and error-related learning are well documented in substance dependent individuals (SDIs). While evidence suggests the dorsal anterior cingulate cortex (dACC) is involved in learning from errors, other regions such as the anterior insula (AI) appear to mediate behavioural adjustments in response to the level of punishment an error may produce. The aim of this study was to examine the roles of dACC and AI in error-related learning in SDIs. A group of opiate dependent participants (N=22) and non-dependent controls (n=20) performed a paired-associate recall task that delivered a monetary penalty for incorrect responses (5c, 50c). dACC and AI BOLD responses following error feedback and target encoding were used to predict subsequent recall performance in both groups. dACC activity during target encoding in the control group, but not in the heroin dependent group, was

associated with subsequent recall performance following an incorrect response; however activity in this region was not sensitive to punishment magnitude. In contrast, AI activity was higher in both groups following the larger penalty, and higher AI activity during penalty feedback was associated subsequent recall performance. These data confirm previous findings in SDIs implicating the dACC in error-learning deficits, but suggest that an AI mediated punishment response is intact.

Title: A new model to study reward discounting in mice living in groups

Authors: ***L. SZUMIEC**, J. RODRIGUEZ PARKITNA;
Inst. of Pharmacol. PAS, Krakow, Poland

Abstract: Here we present a new model of testing reward discounting in group-housed mice. A cohort of 12-16 mice (C57-BL/6J females) is implanted subcutaneously with radiofrequency identification chips and placed in a cage equipped with sensors for automatic tracking (IntelliCage Plus). Each of the cage's corners has 2 drinking bottles, accessed through a slight chamber that allows only one mouse inside and it can be individually monitored and restricted to model the effects of reward discounting. We have tested three types of discounting related to the delay, probability or risk of a reward. The effect of the delay was assessed by first allowing mice free access to water or 0.1% (w/v) saccharin solution and then progressively increasing the delay till gate blocking the saccharin bottle raised. In line with expectations, while mice initially showed 95.4% preference for saccharine it decreased to 50% at 17s delay and finally to 12% at 55s delay. In case of the probability discounting model we have tested a choice between 3 types of reward (saccharin 0.1% or 0.01% and water). Mice were able to access saccharin with a probability of 0.25 or 0.75 and had normal access to water. Preference of the 0.1% saccharin with at 0.75 probability was 69%, compared to 9% preference of the bottle with 0.01% saccharin

at 0.75 probability. In case of the risk discounting model we have tested the effect a 0.25 probability of punishment (an airpuff to the back) on preference of 0.1% saccharin. As expected, while preference of saccharin was initially 95%, the risk of punishment decreased it to 39%. To validate the model we tested the effects of an irreversible inhibitor of the monoamine oxidase - tranylcypromine on delay discounting. In line with expectations, the drug-induced increase in monoamine levels caused acceleration of delay discounting. Observed preference at 17s delay was 4% in the drug-treated group compared to 51% in controls. The main advantages of the new model are the ability to test behaviour in the home cage, in group-housed mice, during natural activity cycles, no interaction with the experimenter and without food deprivation. We hope this model will be useful to study the effects of pharmacological treatments or genetic on modifications on reward discounting.

Title: Ventral tegmental area and substantia nigra pars compacta exhibit similar neural responses to reward-related cues and events

Authors: *M. A. WEGENER[1], B. MOGHADDAM[2];
[1]Ctr. For Neurosci. Univ. of Pittsburgh, Pittsburgh, PA; [2]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Research investigating motivation and psychiatric disorders has identified dopamine neurons as a crucial part of the mechanism behind reward-mediated behavior. Much of this work has revolved around the limbic system in rodents by closely examining the activity of dopamine neurons in the ventral tegmental area (VTA) and their influence on the nucleus accumbens. Recently, research has recognized the potential contribution of the substantia nigra pars compacta (SNc), a separate dopaminergic region with distinct efferent and afferent projections, toward guiding motivated behavior. However, little is known about how SNc neurons process reward-related events. Here we aimed to directly compare the response pattern of VTA and SNc neurons within the same animal during reward-mediated instrumental behavior. Adult rats were

implanted bilaterally with microelectrode arrays to conduct single-unit recordings in the VTA and SNc during task acquisition and maintenance. In this task, rats learned to execute a naturalistic nose poke during presentation of a cue to receive a single sugar pellet. Electrophysiological data from these animals suggest that neurons within the VTA and SNc exhibit similar phasic responses to cues predicting the availability of reward and reward delivery. This parallel population activity persists across all sessions of the task. Future analyses will compare population and single unit activity within the same animal and will seek to identify any subpopulations within regions that encode specific task-related events. These data so far suggest that reward responsiveness of VTA neurons generalizes to the SNc.

Title: Physical activity deficits in obese animals are linked to dysfunction of striatal D2-receptors

Authors: *D. M. FRIEND[1,3], K. DEVARAKONDA[3,2], V. ALVAREZ[4,2], K. HALL[3,2], A. KRAVITZ[3,2];
[1]NIH, Arlington, VA; [2]NIH, Bethesda, MD; [3]Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD; [4]Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: Obese individuals report low levels of physical activity, despite knowledge that increased physical activity improves cardiovascular health and may lead to weight loss. However, it is not clear why obese individuals have low levels of physical activity. Based on clinical studies demonstrating impairments in dopamine D2 receptor (D2R) function in the striatum of obese individuals and data heavily implicating striatal circuits in physical activity, we hypothesized that 1) impaired striatal D2R function alters basal ganglia circuitry, which decreases physical activity in obese animals; and 2) this decrease in physical activity contributes to further weight gain. To test this hypothesis, we fed mice a high-fat diet and found that striatal D2R function decreased as the animals gained weight. In parallel with decreased D2R function was a reduction in physical activity. To more explicitly test whether eliminating the D2R in striatal neurons was sufficient to decrease physical activity, we selectively eliminated D2Rs from indirect pathway striatal neurons using a novel conditional knock out strategy (Drd2-KO mice).

Drd2-KO mice were hypoactive relative to wild-type (WT) mice, confirming our first prediction that decreases in striatal D2Rs are sufficient to decrease physical activity. We examined our second prediction by measuring weight gain in Drd2-KO mice and WT mice on a high fat diet. However, despite having decreased physical activity, Drd2-KO gained weight at the same rate as WT mice. We conclude that high-fat diet reduces striatal D2Rs, causing low physical activity levels in obese animals; however, this decrease in physical activity does not contribute to further weight gain but improves metabolic health. We are currently performing experiments using novel chemogenetic techniques to specifically manipulate activity of D2R-expressing cells in obese animals to restore physical activity. These findings help explain at a biological level why obese people have low rates of exercise, while also addressing the efficacy of exercise as an intervention in human obesity.

Title: Food intake better predicts weight gain than physical activity and D2 receptor availability

Authors: *K. DEVARAKONDA, D. M. FRIEND, J. GUO, K. D. HALL, A. V. KRAVITZ; NIDDK, Bethesda, MD

Abstract: Nearly two-thirds of adults in the United States are overweight or obese. Physicians generally advise patients to “eat less” and “move more” to combat weight gain and metabolic syndrome. However, it is unclear why individuals consume more calories than they burn. The striatal dopamine system has been linked to compulsive food intake and obesity, as well as the regulation of movement. To better understand the role of diet, physical activity, and dopaminergic function in the development of obesity, we measured food intake, physical activity, energy expenditure, and dopamine D2 receptor (D2R) expression prior to placing male C57BL/6 mice on a long-term high-fat diet alongside weight-matched controls that remained on chow. In a multiple regression analysis, we found that caloric intake was a better predictor of weight gain than physical activity, energy expenditure, or D2R binding. Our data contradicts

previous findings that striatal D2R availability predicts future weight gain in humans and suggests that changes in diet play a larger role in weight gain than changes in physical activity.

Title: Modulation of reward seeking by changes in energy balance: a 3D perspective

Authors: ***S. NOLAN-POUPART**[1], K. CONOVER[2], P. SHIZGAL[2];
[2]Ctr. for Studies in Behavioural Neurobio., [1]Concordia Univ., Montreal, QC, Canada

Abstract: The relationship between peripheral energy balance and reward seeking has long been studied in rats working for rewarding electrical stimulation of the lateral hypothalamus (LH). When the electrode tip is dorsolateral to the fornix, decreases in body mass potentiate operant performance. When the electrode is located outside this area, performance is typically unaffected by energy manipulation, suggesting that the substrate that supports brain stimulation reward (BSR) is functionally heterogeneous. Prior studies were carried out using two-dimensional (2D) measurements: the vigor of performance was measured as a function of stimulation strength, and the effect of energy manipulation was quantified by the stimulation strength required to produce half-maximal performance. The interpretation of such findings has been questioned by the introduction of a three-dimensional (3D) method that measures reward seeking as a function of both the strength and cost of reward. This new method eliminates an ambiguity inherent in 2D measurements while providing information about the stage(s) of neural processing at which energy balance affects reward seeking. We reexamined the effect of energy manipulation on BSR using the 3D approach. To this end, 10 male Long-Evans rats were trained to hold down a lever so as to earn trains of LH stimulation. A stimulation train was delivered when the cumulative hold time reached a criterion that defined the cost of BSR (the “price”). Stimulation

strength was set by the frequency with which current pulses were delivered within 0.5 s fixed-duration trains. A plot of lever hold time as a function of pulse frequency and price yields a 3D surface resembling the corner of a plateau (the "reward mountain"). Displacement of the mountain along the pulse-frequency axis reflects changes in early reward processing consistent with altered reward sensitivity, whereas displacement along the price axis reflects changes at later stages, such as alteration of the rat's proclivity to invest effort in reward seeking. Following baseline testing, the rats were food restricted until their weight reached 75% of the baseline mean. This caused a multiplicity of changes, including shifts in either direction along the pulse-frequency axis (reflecting changes in reward sensitivity) and along the price axis (consistent with changes in the proclivity to invest effort in reward seeking). Thus, application of the 3D method has shed further light on the heterogeneous effects of energy manipulations on reward seeking. Moreover, reliable changes were seen more frequently than in prior 2D studies, thus attesting to the increased power of the 3D approach.

Title: Brain areas involved in detecting valuable objects: a functional MRI study in macaques

Authors: *A. GHAZIZADEH[1], W. GRIGGS[1], D. A. LEOPOLD[2], O. HIKOSAKA[1];
[1]LSR NIH, Bethesda, MD; [2]NIMH, Bethesda, MD

Abstract: Reward attracts attention and gaze. When humans and monkeys experience visual objects with large rewards repeatedly, their attention and gaze are attracted by the objects even if reward is no longer given. The basal ganglia, especially their posterior part, play an important role in such learned attention/gaze orientation (Hikosaka et al 2014). However, other brain areas may also be involved in learned attention/gaze. To address this issue, we performed functional magnetic resonance imaging (fMRI) using monocrystalline iron oxide nanoparticles (MION) in two rhesus monkeys. Before the fMRI scans, the monkeys were shown many computer-generated fractals (n>80), each of which was rewarded consistently with either a large or small juice amounts over >10 days. These objects became 'good' (automatically attracting gaze) or 'bad' (rejecting gaze). During the fMRI scan, monkeys fixated centrally while passively viewing fractals. In one block of trials, all fractals were either good or bad and were presented in either

the left or right hemifield (2value x 2hemifields=4 block types). Each of the task blocks was preceded by a rest block in which monkeys fixated centrally with no objects presented. To keep animals motivated, occasional rewards were given in all blocks with the same random distribution. Comparison of good vs bad blocks revealed stronger activations by good than bad objects in temporal cortical areas (V4, TEO, TE), lateral prefrontal cortex (lPFC), and lateral intraparietal area (LIP). Some value coding was found in subcortical areas, including posterior-ventral putamen, caudate tail, and amygdala. Importantly, many of these value sensitive regions also showed a laterality effect, responding more strongly to contralateral than ipsilateral objects. These results show that valuable objects receive enhanced processing in temporal cortical areas involved in object recognition and in areas involved in attention such as LIP and lPFC. This enhanced processing can explain the attentional capture by valuable objects following long-term reward association. Such a visual skill and its underlying brain mechanisms would be important for reward-maximization and survival.

Title: Pupillary correlates of vicarious reward in rhesus macaques

Authors: ***J. A. JOINER**[1], N. A. FAGAN[1], M. L. PLATT[2], S. W. C. CHANG[1,3]; [1]Psychology, Yale Univ., New Haven, CT; [2]Neurobio., Duke Univ., Durham, NC; [3]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Pupil diameter is thought to reflect the internal states of animals like motivation and emotion. In the motivational domain, pupil diameter scales with the magnitude of experienced reward (1). In the social domain, reward experienced vicariously (i.e., through social observation) powerfully shapes behaviors, suggesting that there is a close relationship between

vicarious reward and internal state. However, it remains unknown whether pupil diameter also reflects vicarious reward. In order to determine the link between pupillary response and vicarious reward, we examined pupil dilation during a social decision-making task in rhesus macaques (*Macaca mulatta*). In this task, actor monkeys prefer to deliver juice reward to themselves (Self) over both themselves and a recipient monkey (Both) on one trial type but prefer to deliver juice to the recipient (Other) over no one (Neither) on the other trial type, suggesting a context-specific role of vicarious reinforcement (2). We quantified changes in pupil diameter using a generalized linear model (GLM) for the different reward outcomes (Self, Both, Other, Neither) while controlling for any changes due to saccades directed at the recipient by the actors following reward delivery. The pupil diameter for each outcome differed and systematically tracked the subjective decision preferences, correlating inversely with reaction times of choosing each reward option. As expected, the pupil size was larger when actors received reward compared to when they did not. Notably, pupil size was larger for Self compared to Both rewards despite the fact that either option resulted in the same amount of reward to the actors. Crucially, pupil size was also significantly larger for Other than Neither rewards even though either option always resulted in no reward to the actors, suggesting that vicarious reward is reflected by changes in pupil size. By contrast, on non-social trials, in which the recipient was replaced by a juice collection bottle, the pupil size simply differentiated actors' rewarded (Self, Both) and unrewarded (Other, Neither) outcomes but did not differentiate between Other and Neither nor Self and Both. Our results suggest that vicarious reward corresponds to a change in a motivational state and emphasize a potentially important role of the autonomic nervous system in mediating social interactions. Title: Seeing eye-to-eye: live gaze interactions in pairs of rhesus macaques robustly capture dominance behavior

Authors: ***O. DAL MONTE**[1], M. PIVA[2], J. A. JOINER[1], W. PACK[1], A. C. NAIR[1], S. W. C. CHANG[1,2];
[1]Dept. of Psychology, Yale Univ., New Haven, CT; [2]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: The most important feature of social interaction is the dynamic exchange between two individuals. In humans and non-human primates, gaze behavior is an important component of social communication and interaction that allows identification of group members and social status, interpretation of facial signals, and formulation of appropriate behavioral responses. To study real-time social interaction, we developed a novel paradigm to assess live free viewing in pairs of rhesus macaques. In this paradigm, two monkeys were placed in front of each other while eye positions were recorded from the two animals simultaneously. To compare our new paradigm with more traditional experimental setups, we also measured eye gaze patterns directed toward static images of the paired monkey. Each monkey was additionally tested for dominance with a food-grabbing task and a social encounter task, in which head and body orientation were measured for each monkey with respect to the other. We examined differences in dynamic exploration patterns including mutual gaze between dominant and subordinate monkeys. As expected, the dominant animal looked at the face and eye region of the other more frequently and for longer, whereas the subordinate animal actively avoided the dominant by looking away from his face or even closing his eyes. These results recapitulate the two independently measured food-grabbing and social encounter tasks, in which subordinate monkeys grab less food and orient their head and body away from dominant. Of particular interest, monkeys explored each other's faces for a shorter duration and less frequently in the live context compared to the static context. Strikingly, differences in gaze behavior between dominant and subordinate monkeys were less pronounced when exploring static images of the monkeys as opposed to interacting with other animals. Given the difference in gaze patterns between live and static contexts, increased ecological validity in the live gaze interaction setting could elicit meaningful differences in interactive behaviors that might not be captured in more traditional experimental settings. Our paradigm allows for analyzing real-time gaze interaction between two individuals with a level of granularity that is not possible in other social interaction paradigms. This methodology could be implemented in both experimental and clinical contexts to evaluate nuanced and dynamic social behaviors.

Title: Counterbalancing prosocial decisions across egocentric and allocentric reward contexts in rhesus macaques

Authors: *W. D. PACK[1], J. A. JOINER[1], S. W. C. CHANG[1,2];
[1]Psychology, Yale Univ., New Haven, CT; [2]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: A reward outcome experienced by others could be vicariously rewarding or perceived as competitive and even aversive depending on various contexts, promoting either prosocial or antisocial behavior. Rhesus macaques (*Macaca mulatta*) show such context-dependent social preferences when making decisions impacting reward outcome of self and other. In a dictator game, an actor monkey prefers to deliver juice reward to a recipient over no one in one (allocentric) context but prefers to deliver juice reward to himself over simultaneously to both himself and the recipient in the other (egocentric) context. One possible explanation for the antisocial preference in the egocentric context is that consuming rewards simultaneously with a conspecific instigates a competitive process. To test this idea, we examined social behaviors of rhesus macaques in a modified dictator game in which the relative timing between juice rewards delivered to the actor and the recipient was systematically varied for shared juice rewards. Relative to simultaneous reward delivery, the amount of competition should be lower when the actor receives the reward before the recipient, but higher in the reverse order. Consistent with this, when the actor's reward was slightly delayed relative to the recipient's reward, the frequency of sharing greatly decreased relative to the no-delay condition (simultaneous reward onset). In contrast, when the actor's reward was followed by the recipient's reward, the frequency of sharing increased relative to the no-delay condition. These observations suggest that competition may be driving the antisocial preference in the egocentric context. Most strikingly, we observed that the actor actively counterbalances his decision preferences across the egocentric and allocentric contexts in order to compensate the timing-induced increase or decrease in sharing in the egocentric context by decreasing or increasing reward donation in the allocentric context, respectively. These behaviors suggest that the actor keeps tally on the desired reward intake of the recipient across trials. Taken together, our results paint a complex picture of social preference as the intersection of two different processes, competition and vicarious

reinforcement. Furthermore, the counterbalancing behavior of prosocial and antisocial decisions across the two fundamentally different reward contexts reveals advanced social cognition in rhesus macaques.

Title: Impulsivity and accubofrontal white matter integrity

Authors: *T. IKUTA[1], K. H. KARLSGODT[2,3,4];
[1]Univ. of Mississippi, University, MS; [2]Zucker Hillside Hosp., Glen Oaks, NY; [3]Feinstein Inst. for Med. Res., Manhasset, NY; [4]Hofstra North Shore-LIJ Sch. of Med., Hempstead, NY

Abstract: Glutaminergic innervation from the prefrontal cortex (PFC) to the nucleus (NAcc), also known as the accubofrontal tract, has been shown to be a part of the circuitry for decision making. However, this mono-synaptic innervation has not well been studied in human samples until recently (Karlsgodt et al, forthcoming). Here we aimed to examine the association of the white matter integrity of the tract and impulsivity in decision making. Using Diffusion Tensor Imaging (DTI) samples from Nathan Kline Institute / Rockland sample, the accubofrontal tracts were estimated by probabilistic tractography for 145 individuals who are 21 years or older (Fig 1). Fractional anisotropy (FA) was extracted for the bilateral accubofrontal tracts in each individual. To estimate the impulsivity of each individual, the UPPS Impulsive Behavior Scale (Whiteside and Lynam, 2001) total score was used from the NKI-Rockland sample. The association between Impulsivity and FA were tested along with age and sex as covariates. The accubofrontal tract white matter integrity showed significantly positive association ($p=0.037$, Fig 2). The current preliminary results suggest that the strength of the anatomical connectivity in accubofrontal tract predicts impulsivity. Not only does the current finding re-affirms the role of the frontal dopaminergic circuitry to impulsivity, but also shows that accubofrontal connectivity at least partly accounts for the variance in impulsivity across individuals.

Title: Parcellating the effects of medial orbitofrontal cortex lesions on value-based decision-making

Authors: *J. PETERS[1], M. D'ESPOSITO[2];
[1]Dept. of Systems Neuroscience, Univ. Medical-Center Hamburg-Eppendorf, Hamburg, Germany; [2]Helen Wills Neurosci. Institute, Univ. of California, Berkeley, CA

Abstract: Parcellating the effects of medial orbitofrontal cortex lesions on temporal discounting. Jan Peters & Mark D'Esposito Background. Damage to orbitofrontal cortex (OFC) increases impulsivity (Bechara et al., 1997), i.e. action with little forethought or deliberation. One way to measure impulsive choice is via temporal discounting tasks, where participants choose between smaller-sooner (SS) and larger-later (LL) rewards. OFC damage leads to an increase in SS choices (Sellitto et al., 2010), i.e. steeper temporal discounting, similar to addiction (Bickel et al., 2014). By what mechanism might OFC damage increase temporal discounting? We examined two possibilities. First, OFC lesions lead to more random decisions (Fellows & Farah, 2007; Henrio-Barghava et al., 2012). This can be erroneously taken to reflect increases in discounting (Franco-Watkins et al., 2006). Second, OFC is part of a network involved in representing reward values (Bartra et al., 2013). Damage to OFC might thus impair LL reward representations, thereby increasing SS choices. Methods. Traumatic brain injury patients with MRI-confirmed damage to OFC (n=9, maximum lesion overlap in centro-medial OFC) and matched controls (n=13) performed a temporal discounting task where one condition involved immediate SS rewards (Would you prefer $10 now or 20$ in 60 days?). Another condition involved only delayed rewards (Would you prefer $10 in 30days or 20$ in 90 days?). In a simple rating task (Figner et al., 2010) participants rated the attractiveness of different individual reward options (e.g. 40$ in 10 days, 10$ tomorrow) on a visual-analogue scale. The slope of the amount-attractiveness relation was taken as a measure of individual reward sensitivity. Results. Patients tended to discount steeper (main effect group: p=.08), in particular when an immediate reward was available (group x condition interaction: p=.025). Choices were numerically more random in OFC patients but this effect was non-significant and unrelated to temporal discounting. In contrast, reward sensitivity from the rating task correlated with temporal discounting (r=-.55, p=.0075) and this effect was qualitatively similar in patients (r=-.38, p=.32.) and controls (r=-.57, p=.04). Reward sensitivity was significantly reduced in OFC patients (p=.036). Discussion. Our findings extend previous results regarding OFC lesion effects on temporal discounting (Sellitto et al., 2010): reward magnitude sensitivity was correlated with discounting, and impaired in OFC patients. Increased temporal discounting following OFC damage may thus be due to a disruption of reward valuation processes.

Title: The neuronal population in monkey ventral striatum encodes both reward size and delay to obtain it

Authors: *R. FALCONE, D. WEINTRAUB, G. CHEN, B. RICHMOND;
NIMH, Bethesda, MD

Abstract: Two factors that influence the subjective value of a reward are its size and the amount of time that passes before the reward's delivery. After bilateral damage to the ventral striatum animals become appear to lose motivation. We recorded neuronal responses in the ventral striatum in two monkeys while they performed a task in which we offered 9 combinations of reward by mixing 3 sizes (2, 4 or 6 drops of water) and 3 delays (1, 5 or 10s). A cue indicating the combination being offered was presented throughout the trials. There were two response periods. On appearance of a yellow dot, the monkeys could refuse the offer by releasing a bar immediately or accept by releasing when a purple dot appeared. If a purple dot appeared, the monkeys could accept by releasing immediately or refuse by waiting for the yellow dot. The probability of accepting the offered reward was highest for the largest reward with the shortest delay, and became progressively smaller as the reward became smaller and/or the delay became longer. The probability of accepting was modeled using a logistic regression model with two continuous explanatory variables, reward size and delay. We analyzed the firing rate of the ventral striatum neurons in the initial period after the cue appeared on the screen, but before any action was required. In this task the firing of individual ventral striatal neurons was related to reward size, delay, or both (ANOVA, significant main effects). In terms of population analysis, we asked if the coding of the reward size and the delay has an aspect in common across the ventral striatal neurons. Specifically, we explored if the neural responses were related enough so that they can all be treated as if there were related mappings between the experimental factors and neural firing. To this end, we considered all of the neurons as a single group in a generalized linear mixed-effects model (GLMM), with neurons and the number of trials as random factors, and linear and quadratic terms of reward size and delay as fixed factors. The neural responses were well predicted by the GLMM when both linear and quadratic terms were included for the fixed effects for both monkeys.

Title: Neurotensin mRNA expression in the medial preoptic nucleus and Area X positively correlates with sexually-motivated song in male European starlings

Authors: ***D. P. MERULLO**, M. A. CORDES, M. S. DEVRIES, S. A. STEVENSON, L. V. RITERS;
Zoology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Vocalizations coordinate social interactions in many species and often are important for behaviors such as mate attraction or territorial defense. Although the neural circuitry underlying vocal communication is well-known for some species, such as songbirds, the motivational processes that regulate vocal signals are not as clearly understood. Neurotensin (NT) is a neuropeptide implicated in motivation that can modulate the activity of dopaminergic neurons. Dopaminergic projections from the ventral tegmental area (VTA) are key to mediating highly motivated, goal-directed behaviors, including sexually-motivated birdsong. However, the role of NT in modifying vocal communication or other social behaviors has not been well-studied. Here in European starlings (*Sturnus vulgaris*) we analyzed relationships between sexually-motivated song and NT and NT1 receptor (NT1R) expression in VTA. Additionally, we examined NT and NT1R expression in three regions that receive dopaminergic projections from VTA and are involved in courtship song: the medial preoptic nucleus (POM), Area X, and HVC. Relationships between NT and NT1R expression and non-vocal courtship and agonistic behaviors were also examined. NT expression in POM and Area X positively related to sexually-motivated song production. NT expression in POM also positively correlated with non-vocal courtship behavior and agonistic behavior. These results are the first to implicate NT in the POM and Area X in birdsong, and further highlight NT as a potential neuromodulator for the control of vocal communication and other social behaviors.

Title: Independent contributions of testosterone and a nesting site to sexually-motivated behaviors and gene transcription in male European starlings

Authors: *J. A. SPOOL, S. A. STEVENSON, C. S. ANGYAL, L. V. RITERS;
Zoology, Univ. of Wisconsin Madison, Madison, WI

Abstract: In many vertebrates, acquiring a limited resource alters the production of sexually- and agonistically-motivated behaviors. For example, male European starlings that acquire a nesting site go from ignoring females and tolerating other males to vigorously courting females and defending territory from other males. Seasonal elevations in testosterone (T) are necessary but not sufficient to induce these behavioral changes. Males must also acquire a nesting site before they will display these behaviors. This suggests that obtaining a nesting site and a rise in T both contribute to shifting a starling's motivational state. T or its metabolite estradiol (E2) are proposed to modulate sexually-motivated behaviors in part by altering activity in motivation circuits in the brain, such as dopaminergic systems, yet this has not been well studied. The medial preoptic area (POM) plays a role in sexual motivation, and androgen receptor (AR) immunolabeling in this region is greater in nest box owning birds with elevated T than in either males with high T or a nest box alone. If T and a nesting site are sufficient together but not separately to induce this shift in motivational state, then male starlings with both T and a nesting site, but not either alone, will alter gene transcription in the POM to support behavioral changes. To provide insight into this hypothesis, we examined the individual contributions of T and a nesting site to changes in male behavior and the transcription of genes important for dopamine and steroid hormone activity in the POM and other brain regions. Castrated male starlings were given subcutaneous empty or T-filled implants and introduced to an aviary with or without a nesting site for 10 days. Behavioral responses to the introduction of a female and nesting material were observed for 3 days, and neural tissue was subsequently collected. Quantitative real-time PCR (qPCR) was used to quantify relative changes in the mRNA expression of D1 and D2 dopamine receptors, AR, estrogen receptor alpha, and aromatase.

Title: Endocannabinoid CB1 receptor expression in social and vocal control brain regions correlates with status-appropriate agonistic- and sexually-motivated behavior in male European starlings

Authors: *L. V. RITERS, M. S. DEVRIES, M. A. CORDES, J. D. RODRIGUEZ, S. A. STEVENSON;
Dept. of Zoology, Univ. of Wisconsin, Madison, WI

Abstract: Successful social interactions require individuals to adjust behavior to match emerging social or environmental circumstances, yet the neural mechanisms underlying status-appropriate behavior are not well characterized. European starlings provide a robust system for study of this topic. Prior to acquisition of a nesting territory, male starlings appear to ignore females and to avoid other males. In contrast, once a male acquires a nesting site he socially dominates other males, defends the nesting site, and sings high rates of courtship song. Past studies show that status-appropriate changes in behavior involve dopamine and opioids and are accompanied by altered activity in brain regions involved in social behavior and vocal production. Endocannabinoids richly innervate many of these regions, modulate dopaminergic and opioid systems, and are implicated in both agonistic and vocal behaviors; yet, the role they play in adjusting social behavior to match social status has not been explored. Here we observed flocks of male starlings in outdoor aviaries during the breeding season. Ten males acquired nesting sites and 10 males did not. Brains were collected and quantitative real time PCR was used to measure expression of the endocannabinoid CB1 receptor in social (lateral septum [LS], ventral tegmental area [VTA], and the medial preoptic nucleus [POM]) and vocal control regions (Area X and RA). Males with nesting sites sang to females and displaced other males more than males without nesting sites. They also had higher levels of CB1 receptor expression in both LS and RA. CB1 expression in VTA correlated positively with song rate. CB1 expression in LS correlated positively with territorial and agonistic behaviors. Finally, feeding behavior correlated negatively with CB1 expression in VTA and Area X but positively with expression in RA. Results are consistent with the possibility that CB1 expression in LS may gate status-appropriate agonistic/territorial behavior; whereas CB1 in VTA may gate sexually-motivated vocal

production. Associations between CB1 expression in RA and Area X are consistent with past studies showing food restriction to alter CB1 activity in auditory regions. Overall, results support prior work suggesting that endocannabinoid signaling functions as a behavioral switch, adjusting behavior so that it is appropriate given emerging environmental or social factors.

Title: Neuroestrogen modulation of auditory processing across development

Authors: *D. M. VAHABA[1], L. REMAGE-HEALEY[2];
[1]Neurosci. & Behavior Grad. Program, [2]Dept of Psychological & Brain Sci., Univ. of Massachusetts, Amherst, MA

Abstract: Brain-derived steroid hormones can act as neuromodulators of sensory encoding. Therefore, neurosteroids may play a significant role in facilitating the formation of auditory representations during development. In particular, 17β-estradiol (E2; a centrally synthesized neuroestrogen) enhances auditory encoding through increased neuronal firing in adult songbirds. Neuroestrogens may also participate in consolidating auditory memories required for vocal learning during the critical period of language acquisition in human infants, and song acquisition in birds. At present, it is unclear how E2 impacts auditory-evoked neuronal activity during early development. Here, we collected unit recordings in the caudomedial nidopallium (NCM) of juvenile and young adult male zebra finches (*Taeniopygia guttata*). NCM is a higher-order sensory area functionally homologous to secondary auditory cortex in mammals. Moreover, NCM is a requisite brain region for auditory memory consolidation, contains a significant population of aromatase-positive neurons, expresses nuclear and membrane-bound estrogen receptors, and shows dynamic E2 fluctuation in adult and developing zebra finches when presented conspecific song. Anesthetized subjects were presented with conspecific auditory playbacks during simultaneous retrodialysis of E2 and extracellular recordings in NCM. The neuromodulation of auditory-evoked neuronal activity was analyzed by subjects' age/phase of

their song development. Preliminary findings indicate that the E2 modulation of auditory-evoked neuronal activity is age-dependent, divergent from prior findings on adult neuroestrogen function. This ongoing study extends our understanding of estrogen-dependent neuromodulation of auditory processing across development. This work was supported by NSF IOS1354906.

Title: Neural representation of a shared behavior in two individuals

Authors: *M. J. COLEMAN[1], A. ROESER[2], F. DUQUE[3], E. S. FORTUNE[2];
[1]Keck Sci. Dept., The Claremont Colleges, Claremont, CA; [2]Dept. of Biol. Sci., New Jersey Inst. of Technol., Newark, NJ; [3]Univ. San Francisco de Quito, Quito, Ecuador

Abstract: Male and female plain-tailed wrens (Pheugopedius euophrys) sing duet songs in which participants rapidly alternate syllable production. The duet is so precisely timed that it sounds like one bird is producing it. The ongoing coordination of timing between individuals during duets is mediated in part via auditory feedback between the participating birds. Further, although the pattern of syllable production appears to be stable, each bird produces an unexpectedly large number of syllable variants. In other words, behavior evidence suggests that the songs of these birds are more like jazz riffs rather than highly stereotyped song performances. We want to understand the neural mechanisms for the temporal coordination these variable duet performances. We captured duetting pairs of wrens, recorded their duet singing over a period of one to two days, and then made acute (urethane anesthesia) extracellular recordings of neurons in HVC of both individuals. Auditory stimuli included duet variants, conspecific songs, and experimentally altered song stimuli. Previous work showed that HVC neurons respond more strongly to duet stimuli than to the individual performances of each bird. Here we want to examine the temporal structure of HVC activity to better understand how sensory and sensorimotor information is encoded and processed. Specifically, we predict that the timing of responses in each bird should map onto different time points in the duet. This timing of activity might correlate to time points used in the coordination of duet singing, or perhaps to the motor

output of each bird, or both. We recorded from three pairs of male and female wrens. Our initial analyses suggest a surprising result. Rather than the activity alternating in time between the two birds, as is seen in the behavior, the activity appears to be synchronized across birds. This result suggests that HVC activity is not a traditional form of direct premotor activity, but is used for the coordination of the timing of the singing performance. If the role of HVC, generally speaking, is the temporal coordination of song performances, then HVC may be the main site for the coordination of duetting.

Title: Neural substrates of courtship song perception in female zebra finches: a role for the avian 'prefrontal cortex'

Authors: *L. VAN RUIJSSEVELT[1], Y. CHEN[2], G. DE GROOF[1], S. C. WOOLLEY[2], A. VAN DER LINDEN[1];
[1]Bio-Imaging Lab. / Univ. of Antwerp, Antwerpen (wilrijk), Belgium; [2]Biol., Mc Gill Univ., Montreal, QC, Canada

Abstract: Like humans, zebra finches (ZF) adjust their vocal performance depending on social context. Adult male ZFs subtly alter the characteristics of their song when courting females compared to when singing alone. In particular, female-directed song ('DIR') is faster and has syllables with significantly less spectral variability than 'undirected' song ('UDIR') [1]. Previous data indicate that females prefer DIR to UDIR and that this behavioral preference is correlated

with greater EGR1 expression in a higher-level auditory area the caudomedial mesopallium (CMM) [1]. To investigate the neural representation of this social perception at the level of the whole brain, we used blood oxygenation level dependent (BOLD) functional magnetic resonance imaging (fMRI) in 17 adult isoflurane-anesthetized female ZFs. We assessed BOLD responses to DIR and UDIR stimuli and to manipulated versions of these 2 types of song ('mDIR', 'mUDIR') to study the role of specific acoustic features. mUDIR stimuli contained the DIR temporal pattern but were composed of UDIR syllables while mDIR songs contained DIR spectral and temporal characteristics but controlled for the manipulation. We found higher, lateralized neural activation for DIR vs UDIR in three distinct brain regions: the CMM, HVC (proper name) and the caudolateral nidopallium (NCL; Figure 1). In addition, the results indicate that this selective higher response to DIR in the CMM is preserved for mDIR but not mUDIR vs UDIR. In contrast, HVC and the NCL appeared to be only selectively activated by the unmanipulated DIR songs. Together these data indicate a potential gradual specialization of the network for specific acoustic features. Moreover, through visualization of responses of the entire brain to socially relevant stimuli, fMRI highlights the potential role of regions beyond the auditory system, including the NCL, which is the avian analogue of the prefrontal cortex [2], in the neural processing of acoustic social cues. **References:** [1] Woolley and Doupe, 2008, PLoS Biol; [2] Güntürken, 2005, Curr Opin Neurobiol

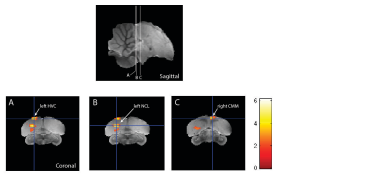

Figure 1. Neural substrates of directed song perception in adult female zebra finches. 3 clusters indicated at the position of the crosshairs in A, B and C show statistical significant differences between BOLD responses elicited by directed song > undirected song (t-test; $p < 0.001$, uncorrected). The images represent statistical maps superimposed on images from the MRI zebra finch atlas. T values are color coded according to the scale displayed in the figure and only voxels exceeding a threshold of $t = 1.746$ ($p<0.05$, uncorrected) are displayed. Cluster A corresponds to region left HVC, part of the song control system; Cluster B to region left caudolateral nidopallium (NCL), analogue of the human prefrontal cortex; Cluster C to region right caudomedial mesopallium (CMM), a central auditory area previously already identified as neural substrate for directed song perception in [1]. Validation of these results in awake ZFs is ongoing using EGR1 expression assays.

Title: Pair bond quality influences song preferences and EGR1 expression in a female songbird

Authors: H. E. SCHUBLOOM[1], *S. C. WOOLLEY[2];
[1]Integrated Program in Neurosci., [2]Biol., McGill Univ., Montreal, QC, Canada

Abstract: Pair bonding has been characterized in a handful animal species, and considerable progress has been made in understanding the neurobiology of social interactions and affiliation that lead to and immediately follow pair bonding. However, given the complexity of pair bonding, we know substantially less about how the intricate relationships between individuals shape brain and behavior. For example, little is known about how the history of interactions between paired individuals influences their subsequent interactions, or their perception of and preference for their mate, especially in animal models. Here, we investigated how variation in social relationships in a pair bonding songbird, the zebra finch, relates to female song preferences and neural responses to song. We assessed variation in the types of interactions between individuals in a pair and found that the nature of those interactions was correlated with the degree of female preference for her mate's song over the song of an unfamiliar male. In particular, female preferences were influenced most strongly by whether their mate performed more courtship or non-courtship song. In addition, we investigated how pair quality affected the neural expression of the immediate early gene EGR1 in response to playback of the mate's courtship song. In songbirds, EGR1 expression has been associated with auditory memory as well as the perceived quality or salience of song, making, EGR1 expression a useful metric for investigating neural responses to socially relevant song stimuli. We found that variation in pair quality was correlated with the amount of EGR1 expression in females in response to their partner's song in nuclei within the associative auditory cortex and the social behavior network. Our data highlight that the quality of social interactions within a pair influences female perception, behavioral preferences and neural activity in response to categorically similar stimuli, perhaps through changes in activity in auditory and social behavior neural networks.

Title: Male lays eggs: chromosomal and mate preference abnormalities in a chimeric zebra finch lineage

Authors: ***M. JONES**[1], R. A. CUMMINS[1], E. JENKINS[1], R. J. PEREZ[2], M. BARKER-KAMPS[1], H. WITTCHEN[1], C. GANN-VACULCIK[1], A. L. HRIBAR[1], L. B. DAY[1];
[1]Biol., [2]Univ. of Mississippi, University, MS

Abstract: In birds, males have ZZ sex chromosomes and females have ZW sex chromosomes. In zebra finches, sexually dimorphic plumage patterns are determined by genes on the sex chromosomes. Steroid hormones are known to organize aspects of the reproductive system and nervous system while also activating growth of the neuromuscular male song system and singing. The exact contribution of genes on sex chromosomes, genes on autosomes, and circulating hormones on sexual differentiation in zebra finches is not completely understood. Birds that have mixed ZZ and ZW chromosomes in different tissues of their body can help us understand the role of sex chromosome genes in sexual differentiation. We discovered a bird in our aviary that has male plumage, lays eggs, has a apparently seemingly typical male partner, and produces viable offspring with this partner. Using PCR for two different sex-linked genes, we found the suspected chimera does not have a W-linked gene in the blood but a W-linked gene is present in its unfertilized eggs. We also found that in all female-plumage offspring, a W-linked gene is present, while in the male-plumage offspring a W-linked gene was not present. We are currently analyzing feather samples and other tissues for multiple W-linked genes in the chimera and its offspring. In addition to examining the linkage between genes and sexual differentiation, this unusual bird and its offspring allow us to explore mate choice for visible plumage characteristics versus cryptic abnormalities that may be present in chimeric offspring. Using a two-choice mate preference paradigm, we tested whether our chimeric bird, its partner, and their offspring were preferred as highly as control birds in our aviary, and if birds in the chimeric lineage preferred opposite sex-plumaged birds at frequencies comparable to typical zebra finches. We used the two-choice mate preference test counterbalanced across days for sides, and tracked the proportion of the total 30 minute time chooser birds spent with each choice bird after a 2 hour habituation period. Our data suggests the chimeric line has cryptic abnormalities that are not preferred by other birds in our aviary and that the chimeric line has abnormal biases for same sex birds.

Title: Anatomical specificity of testosterone in the regulation of song and the associated neuroplasticity in canaries

Authors: *B. A. ALWARD[1], S. E. PARKER[1], J. BALTHAZART[2], G. F. BALL[1,3]; [1]Psychological & Brain Sci., The Johns Hopkins Univ., Baltimore, MD; [2]GIGA Neurosciences, Univ. of Liege, Liege, Belgium; [3]Psychology, Univ. of Maryland, Col. Park, College Park, MD

Abstract: Steroid hormones can affect multiple features of complex social behaviors and the interconnected brain regions that subserve these behaviors. A fundamental question is how steroid hormones acting in distinct brain areas coordinate the activation of a complex behavior. In songbirds, a circuit called the song control system (SCS) regulates many different aspects of song behavior. In the posterior SCS, HVC (acronym is name) projects to the robust nucleus of the arcopallium (RA)--these two nuclei regulate the production of song. RA in turn projects through the hindbrain to regulate the muscles of the syrinx, the avian vocal organ. HVC also projects to Area X, an anterior striatal nucleus critical for learning song. HVC and RA are characterized by cells expressing a high density of androgen receptors. Moreover, T in the medial preoptic nucleus (POM) is critical for regulating the motivation to sing but not the acoustic structure of song. During the spring when T is high, birds sing more and with higher quality and the SCS almost doubles in volume compared to the winter months. Notably, HVC recruits more new neurons during these spring conditions. Also, singing activity can drive SCS neuroplasticity independently of T acting directly in the SCS. Hence, while it is clear that T regulates plasticity of song and the SCS, it is unclear where T acts to coordinate these changes. We investigated these questions using canaries. We castrated males and let them acclimate in sound-attenuated chambers set on a photoperiod of 14L:10D to simulate long days associated with the breeding season for 1 week. Birds were either treated with T peripherally (PER-T) so it acted everywhere, T implanted in the POM and HVC (HVC-POM T), T only in the POM (POM-T), T only in HVC (HVC-T) or with no T contacting either HVC or POM (HVC-POM NO T). We recorded song for two weeks and then collected all brains. We confirmed implant sites and the volumes of HVC, RA, and Area X using Nissl stains. We also stained for doublecortin (DCX), a protein that marks new neurons. T in the POM increased song rate to PER-T levels. Birds with HVC-POM T produced higher quality songs compared to POM-T birds and no different from PER-T birds. Singing activity in itself increased the volume of the SCS but T acting only in HVC also drove such changes. T in HVC caused a recruitment of neurons to this nucleus but song may also play a role in causing these neurons to undergo differentiation. Thus steroid hormones act directly and indirectly to modulate behavioral output and the underlying

neural substrate. These results highlight the complex roles played by steroid hormones in the regulation of brain and behavior.

Title: Acceleration of maturation by estradiol during adolescence in prepubescent male zebra finches

Authors: *W. E. GRISHAM[1], N. ASKARINAM[1], M. NELSON[2], I. T. DAHILIG[3], A. A. CARLSON[4], D. SAXON[4];
[1]Dept Psychol, [2]Mathematics, UCLA, Los Angeles, CA; [3]Dept. of Chem., Trinity Col., Hartford, CT; [4]Dept. of Neurosci., Claremont McKenna Col., Claremont, CA

Abstract: The song system is sexually dimorphic: vocal control nuclei are up to six times larger in males than females (Nottebohm & Arnold, 1976) and most song regions have larger neurons and dendritic extensions (DeVoogd & Nottembohm, 1981). These sex differences in neural structure are manifested behaviorally_males engage in singing, unlike females. Implanting estradiol (E2) in young females masculinized the song system up to post-hatching day 40 (Konishi & Akutagawa, 1988). Little work has yet to be done on examining the effects of estradiol in adolescent males. Our study examined the effects of administering estradiol on the sexual differentiation of the song system's neural circuitry in prepubescent males. Ten subjects at 28-33 days of age were assigned to groups: treated males (n=4), implanted controls (n=4) or non-implanted controls (n=2). Treated males were implanted with 4-5 mm Silastic pellets packed with estradiol, which results in a slow, sustained release of hormone. On day 39-45 subjects were sacrificed; brains were fixed in formalin, frozen sectioned at 40 microns, and stained with thionin. Dependent variables included volume, cell density, cell counts, size and total number of neurons in IMAN, RA and HVC. Volume of Area X was also examined. Cell counts and sizes were examined under 400X. E2-treated males had a significantly greater number of neurons in HVC than controls; $t(8) = 2.05$, $p = 0.037$. This result was paralleled with a trend toward larger HVC volume found in E2-treated males compared to controls; $t(8) = 1.80$, $p = 0.055$. Anecdotally, the treated birds were brought into full song precociously. No other variables including volumes of Area X, RA, and IMAN, cell sizes in HVC, RA and IMAN, and cell counts

in RA and IMAN were significantly different between treated and control birds. Estradiol may have its impact on the song system via its ability to upregulate the expression of brain-derived neurotrophic factor (BDNF), which may in turn stimulate neuronal migration, proliferation and survival. BNDF mRNA expression in HVC was higher in estrogen-treated 20-25 day old males than their age-matched controls (Dittrich et al., 1999). Once the estrogen implant was removed, HVC's BNDF expression dropped (Dittrich et al., 1999). Therefore, estradiol could have increased the number of HVC neurons, and consequently HVC volume via its upregulation of BDNF.

Title: Coping with stress: does having a single parent affect offspring of typically biparental zebra finches (Taeniopygia guttata)?

Authors: *L. S. PHILLMORE, J. FISK, S. D. AITKEN, T. M. E. YOUSEF, T. S. PERROT; Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Stressful events during childhood, such as having a single parent, shape how a child's body and brain respond to stressors later in life. Previous work modeling the effects of developmental stress have primarily used a rodent model, however a disadvantage of using rats, for example, is that only mothers provide care for the young, meaning the potential contribution of fathers to offspring rearing, and the effects of single vs. biparental care cannot be examined. Avian species such as zebra finches typically provide biparental care, and therefore we can examine how removal of one parent (either the father or the mother) affects both the remaining parent and the offspring. There is some research on how single zebra finches attempt to compensate for the lack of a mate behaviourally, but research on single fathers is minimal. In this study we examined how being a single parent and having a single parent affected behaviour (e.g.

feeding, begging), physiology (corticosterone (CORT levels), and the brain (glucocorticoid receptor GCR levels). Offspring reared by single parents did not weight less than offspring reared by both parents, however, single males compensated differently than single mothers. Single parents did not have increased circulating CORT compared to parents with a partner, and CORT results for offspring were mixed. These preliminary results may indicate that offspring of single zebra finches respond with resilience, rather than compromise.

Title: Predicting plasticity: Context-dependent changes to vocal performance predict age-dependent changes to adult birdsong

Authors: L. S. JAMES[1], *J. T. SAKATA[2];
[2]Biol., [1]McGill Univ., Montreal, QC, Canada

Abstract: The performance of ethologically important behaviors can change substantially over an individual's life. Understanding the factors that predict and guide such behavioral change can lend insight into mechanisms of motor plasticity and individual differences in behavior. The performance of adult birdsong changes with age; the songs that young adult Bengalese finches produce in isolation (undirected or UD songs) become faster and more stereotyped over time. The extent to which these features change varies among individuals, and little is known about how to predict such variation in plasticity. Social context affects song in ways that resemble age-dependent changes: the songs that young adult finches direct to females (female-directed or FD songs) are faster and more stereotyped than their UD songs. As such, we investigated the degree to which variation in the direction and magnitude of context-dependent changes predicted variation in age-dependent changes to adult Bengalese finch song. Using a repeated-measures design, we found that variation in context-dependent changes to inter-syllable gap durations,

variability of syllable sequencing, and probabilities of individual sequence transitions significantly predicted variation in age-dependent changes to such features. On the other hand, variation in context-dependent changes to syllable structure (fundamental frequency) provided less predictive insight into variation in age-dependent plasticity. The temporal structure of a bird's UD song converged over time onto the structure of the FD song that the bird produced as a young adult. One model that could explain this convergence is that the FD song of young adults represents a stable target for age-dependent changes to song. This model predicts that FD song remains unchanged over time and that, since the UD song of older adults have reached this target, older birds should no longer exhibit context-dependent changes to song. An alternative explanation is that age- and context-dependent changes represent changes to vocal performance. According to this model, the performance of FD song could also change over time, and social context could continue to affect vocal performance in older adults. Consistent with the performance but not target model, we found that the FD songs produced by birds as older adults were faster and more stereotyped in sequencing than both the FD songs these birds produced as young adults and the UD songs these birds produced as older adults. Overall, these data suggest that age-dependent changes reflect changes in vocal performance and that mechanisms regulating vocal performance could shape vocal motor plasticity.

Title: Differential and developmental expression of genes with potential involvement in the specificity, maintenance, and modulation of long-distance projections in the oscine song system

Authors: *C. V. MELLO, C. R. OLSON, M. WIRTHLIN, P. V. LOVELL;
Dept. of Behavioral Neurosci., Oregon Hlth. Sci. Univ., Portland, OR

Abstract: The oscine song control system consists of discrete interconnected forebrain nuclei that play distinct roles in the acquisition and production of learned vocalizations. While these

nuclei have been extensively studied in terms of cell composition, connections, and electrophysiological properties; much less is known about the genetic factors that regulate the formation and maintenance of the projections that interconnect them. Molecular screenings (e.g. with microarrays) and *in situ* hybridization studies conducted while building our zebra finch molecular atlas of brain gene expression (ZEBrA; http://www.zebrafinchatlas.org/) have revealed that several genes with known roles in the establishment and specificity of long-distance axonal connections are differentially expressed in song nuclei of adult male zebra finches. These findings suggest that markers such as SEMA3E, SEMA6A, PLXNC1, NRP1, UNC5A, and RELN, which are known to participate in specific ligand/receptor interactions based on data from other organisms, may play a role in the formation and/or maintenance of song system projections. To gain further insights into the role these genes might play, we have used *in situ* hybridization with non-radioactive riboprobes to study the expression of these molecular markers along with their presumed ligand/receptor partners (i.e. SEMA3E/PLXND1 and NRP1, SEMA7A/PLXNC1, SEMA6A/PLXNA4, LRRC4C/NTNG1 and G2, RELN/VLDLR and LRP8) in adults and in juvenile male zebra finches during the early phases of the formation of the song system connections. Our results provide evidence for the differential and developmental regulation of these markers in song nuclei and/or their projection targets, further supporting a possible role in the formation or maintenance of specific projections, including HVC to X, HVC to RA, LMAN to RA, and RA to midbrain/brainstem targets (e.g. DM, nXIIts). These studies lay important groundwork for future studies that will use gene manipulation strategies to investigate the functional role that these genes play in establishing connectivity in the song system.

Title: ZEBrA Redux: An improved digital atlas for exploring brain gene expression in the adult male Zebra Finch (www.zebrafinchatlas.org)

Authors: ***P. V. LOVELL**[1], M. WIRTHLIN[1], C. V. MELLO[2];
[1]Dept. of Behavioral Neurosci., [2]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: ZEBrA (Zebra Finch Expression Brain Atlas; www.zebrafinchatlas.org) is a publicly accessible online collection of high-resolution (0.46 µm/pixel) digital images representing the expression patterns for a large set of transcripts in brain of the adult male zebra finches (*T. guttata*), a representative songbirds species. ZEBrA represents the most comprehensive resource available for investigating the brain distribution of genes involved in the physiology, development, and maintenance of functional circuits in the brain of songbirds. Each gene has been selected based on its relevance for understanding the physiology of the song system (e.g. neurotransmitter receptors, ion channels, signaling systems), or its importance for clarifying issues of vertebrate brain evolution and homology. Among its major features, ZEBrA contains: (1) The *In situ* database – the actual collection of high-resolution *in situ* hybridization images presented along with annotated drawings derived from Karten/Mitra Histological Atlas. ZEBrA currently houses more than 2,000 images (>100 GB) corresponding to several hundred genes expressed in the zebra finch brain, including the major nuclei that comprise the song system; (2) A Gene Family Search Page – A feature that facilitates searches for genes based on their membership in specific gene families; (3) A Histological Atlas Browser – A set of 18 annotated drawings prepared in registration with Nissl- and Myelin-stained images of sagittal brain sections derived from the Karten/Mitra atlas; and (4) A Neuroanatomical Marker Search Page - A search engine that allows users to retrieve a list of genes that are markers of a given structure, or of multiple structures. The main update reported here is the addition of 200 patterns, including a range of molecular markers that are high relevance for understanding brain evolution, and a suite of genes that are physiological important to the biology of songbirds. Our on-going mission is to continue to release additional batches of images until we have covered ~1,500-2,000 genes.

Title: Promoter motif analyses reveal unique transcriptional regulatory networks in distinct cell types within the oscine song system

Authors: ***M. WIRTHLIN**, P. V. LOVELL, C. R. OLSON, J. CARLETON, C. V. MELLO; Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The oscine song control system is comprised of a unique collection of cell types that that possess anatomical and physiological properties that are specialized for the acquisition and production of learned vocalizations. These properties are, in turn, determined by the distinct transcriptional networks that co-regulate the expression of genes in each cell type. Identifying these networks is a critical first step towards identifying the underlying genomic features (e.g. promoter motifs) that determine the anatomical and physiological properties of these circuits. Unfortunately, disentangling and characterizing the gene expression profiles of unique cell types within heterogeneous structures has proven technically challenging. To overcome this challenge, we have recently examined the expression of genes in the premotor nucleus HVC of the zebra finch. HVC, required for the production of learned song, is comprised of several distinct cell types, which have been well characterized in terms of their connectivity, electrophysiological properties, and dynamics of adult replacement; properties that are likely to be supported by distinct gene networks. To identify these networks we have developed a novel suite of in silico promoter motif analysis algorithms that identify key regulatory modules within co-expressed gene networks. These analyses are guided and validated by molecular techniques (e.g. *in situ* hybridization). Briefly, we started with a 'seed' set of known molecular markers of HVC projection neurons previously identified by co-localizing expressed gene transcripts with retrogradely labeled cells. By identifying DNA binding motifs common to the promoters of these seed sets, we were then able to identify, and validate by *in situ* hybridization, an additional cohort genes that were predicted to be co-expressed in each cell type. This process was continued iteratively in order to identify regulatory elements motifs predictive of cell type expression, and to build gene expression networks that characterize these cell types. The identified gene networks include previously known and unknown cell type markers, provide candidate molecular substrates for the known properties of these song system cell types, and reveal previously unknown functional pathways that may be critical for various aspects of vocal learning. Our study also provides proof-of-principle for a novel methodology for identifying gene regulatory networks within cell types within complex neural structures.

Title: The NAP snippet of activity-dependent neuroprotective protein (ADNP) is highly conserved in migrating and monogamous non-song birds

Authors: *I. GOZES[1], G. HACOHEN KLEIMAN[1,2], A. YEHESKEL[3], A. BARNEA[2]; [1]Sackler Sch. Med/Tel Aviv Univ., Tel Aviv, Israel; [2]Open Univ., Raanana, Israel; [3]Life Sciences/Tel Aviv Univ., Tel Aviv, Israel

Abstract: Activity-dependent neuroprotective protein (ADNP), discovered and extensively studied at the laboratory of Prof. Illana Gozes, is crucial for brain development and function in mice and men. Despite great evolutionary distance, ADNP of the songbird zebra finch was found to be highly homologous to human ADNP. As we recently reported, ADNP mRNA presents a sexually dichotomous expression in human and mouse with a significantly higher expression in the male hippocampus [1]. In our latest paper, we presented dichotomous and age-dependent ADNP mRNA expression in the zebra finch brain [2]. In young birds, ADNP was mainly expressed in the cerebrum with higher concentrations in males compared to females. With aging, ADNP levels dramatically decreased in the cerebrum of both males (3-fold) and females (2-fold). The high ADNP conservation suggests an important function throughout evolution and a significant function in neurodevelopment in birds. Here, bioinformatics comparative analyses of the protective ADNP snippet, NAPVSIPQ (NAP), sequence among 48 bird species, was performed. We compared singing behavior, social behavior, breeding strategy (monogamous or polygamous), migration/sedentary and male parental care. Results revealed a highly conserved NAP sequence in non-passerine species compared to passerine ones, especially in migratory and monogamous birds. This conservation in the NAP sequence in migrating and monogamous birds points out the importance of studying ADNP in birds exhibiting both migrating and social behaviors [2]. Title: Autonomously tunable interfaces for intracellular recordings

Authors: ***S. SAMPATH KUMAR**, J. MUTHUSWAMY;
Arizona State Univ., Arizona State Univ., Tempe, AZ

Abstract: Current technologies used to record intracellular potentials have three major drawbacks: 1) they are large, bulky and require cumbersome positioning systems for steering their tips to neurons in specific circuits 2) their use requires extraordinary skill and tedious operations 3) the sheer size and weight of the system allows recording only from one neuron or a few neurons belonging to different neural circuits at a time. Here, we will present a novel microscale robotic intracellular recording system that has 3 main features: 1) electrothermal microactuators that allow microscale navigation in brain and precise positioning of electrode inside neuron; 2) polysilicon microelectrodes integrated with glass micropipettes to penetrate neurons and record intracellular potentials; 3) closed loop control algorithm to enable autonomous isolation and impalement of neurons. In this study, we demonstrate the ability of this technology to autonomously isolate, penetrate and record from single neurons in abdominal ganglion of *aplysia* californica. The performance of the system was assessed in n= 50 attempts of single neuron penetrations. The results of yield and quality of neuronal recordings after the penetrations were carefully quantitated. Resting membrane potentials of 40 mV and action potentials ranging from 60-70 mV were consistently recorded in every attempt. Experiments to test the above technology in rodent brain slices are ongoing. The proposed system offers the unique advantages of significant reduction in size and weight, ability to seek neurons autonomously and readily scalable approach to realize multi- channel intracellular recording system.

Title: Using multi-electrode array technology to evaluate *in vitro* neuronal firing parameters and network complexity

Deleted: *in vitro*

Authors: *R. KESILMAN (KORN), S. PARMENTIER-BATTEUR, J. J. RENGER, M. J. MARINO;
Early Discovery Neurosci., Merck & Co., Inc., West Point, PA

Abstract: Multielectrode Arrays (MEAs) enable simultaneous extracellular recording from multiple neurons in culture to evaluate *in vitro* firing parameters and network complexity. This technology has the potential to inform on cellular phenotypes expressed at the network level which may be more subtle when studied by single cell or biochemical methods. Changes in these *in vitro* parameters may provide an assay of cellular phenotype underlying complex psychiatric disorders and could therefore enable the identification and validation of novel molecular targets. The goal of the present study was to utilize the MEA platform to investigate NMDA receptor blockade-induced changes in *in vitro* firing parameters and network complexity in rat hippocampal neurons.Neurons were cultured on electrode arrays in the presence of the NMDA receptor antagonist D-APV (25 μM) beginning on day 5 in culture, and cell activity was recorded from day 5 until day 21 in culture. Firing of neurons in culture was evaluated using traditional time series analytic methods to evaluate firing frequency, inter-spike interval (ISI), and the coefficient of variation of the ISI (ISI CV). Time series analysis suggested that treatment with D-APV had no significant effect on the number of active neurons in the cultures, firing frequency, or ISI. However it was noted that the variability in these statistics was higher in untreated cultures. Consistent with this observation, the ISI CV was significantly decreased by D-APV treatment at 12-16 DIC ($p<0.05$ 2 Way ANOVA, Sidak post hoc). Theoretical network structure was assessed through correlation of firing pattern and graph theory analysis. This analysis suggested that the networks formed under control conditions were highly dynamic and would increase and decrease in complexity during the 21 DIC. In contrast, networks formed in the presence of D-APV tended to monotonically increase in complexity. This observation was supported by a significant effect of D-APV on the network global clustering coefficient (2 Way ANOVA, $p<0.05$) and a large decrease in the variability of this statistic from DIC 12 on. Taken together, these results suggest that D-APV treatment in this *in vitro* system leads to a decrease in network plasticity resulting in the premature locking of network structure. Current efforts are directed at the use of high content imaging to determine if these network measures correlate with markers of synapse formation and plasticity.

Abstract: Several technologies have been developed for interfacing with the brain such as microwires, electrode arrays, and electrocorticography (ECoG) arrays. While each of them has strengths and weaknesses, they all share a common disadvantage of limited device longevity due to a variety of failure modes; these include scar tissue formation and material failure, among others. A particularly pronounced problem is the failure of the insulating material at the insulator-conductor interfaces (e.g. recording sites and insulated conducting traces). Damage to these vital interfaces compromises device performance by altering the impedance of recording sites, or more deleterious, results in total device failure due to shorting between traces or between a trace and physiological fluid. To address these material issues, we have focused on the fabrication of silicon carbide (SiC) electrode arrays. As a surface coating, polycrystalline SiC has been shown to promote negligible immune glial response compared to bare silicon when implanted in the mouse brain. Additionally, due to its mechanical and chemical stability, SiC serves as stable platform and excellent diffusion barrier to molecules present in the physiological fluid. Moreover, and of particular interest to the neuroengineering community, the ability to deposit either insulating or conducting SiC films further enables SiC as a platform material for robust devices. Leveraging these unique properties, we have developed a fabrication process that integrates conducting and insulating SiC into 64-channel ECoG arrays. Recording sites 40 um in diameter are made of n-doped SiC while the insulating layers are either amorphous SiC or undoped polycrystalline SiC. To allow for low impedance interconnects, a metal stack of

titanium/gold/titanium or a single layer of molybdenum is completely embedded in between layers of SiC. The result is an ECoG array that, to the physiological fluid, appears simply as a single SiC sheet wherein boundaries between conducting and insulating layers are seamless. The inner metal layer is well protected by SiC and therefore cannot be reached by molecules present in the physiological fluid. We believe this basic platform can be extended to a variety of electrophysiological devices, including penetrating probes of various geometries, and help mitigate the failure modes of the present technologies.

Title: Dorsal root ganglia neural recordings with a novel non-penetrating thin-film microelectrode array

Authors: *Z. J. SPERRY, J. P. SEYMOUR, F. WU, S. E. ROSS, K. KIM, J. T. BENTLEY, E. YOON, T. M. BRUNS;
Univ. of Michigan, Ann Arbor, MI

Abstract: A neural interface with dorsal root ganglia (DRG) can provide a rich source of sensory neural activity from peripheral limbs and organs. There are presently no devices designed specifically for interfacing with DRG, so penetrating electrode arrays designed for the brain are typically used. Cortical arrays are inefficient DRG interfaces as they are not designed for the small, curved features of spinal roots, and their penetrating shanks can cause tissue trauma and immune responses. A recent study demonstrated single-unit neural activity from the DRG surface, taking advantage of superficial cell bodies, though the electrodes were not suitable for long-term recordings and required downward force to yield signals. To address these shortcomings, a new thin-film electrode array was designed to provide a close fit to the surface of the DRG. The 64-channel electrode array was microfabricated on an ultrathin (3.6 μm) polyimide substrate to provide flexibility to conform to the natural curvature of the spinal roots (~1 mm radius). The iridium electrode sites (1130 μm2) have varying pitch (25-300 μm), with

impedances of 160 ± 24 kΩ at 1 kHz. Functionality of the array was tested *in vivo* in an anesthetized feline model after a lumbosacral laminectomy. When the array was placed on lumbar DRG, surface tension yielded a contoured fit to the tissue without the need for additional downward force. Thresholded neural activity was manually sorted offline using commercial spike sorting software. Single-unit activity associated with a tactile stimulus was observed on 18 unique channels, and multi-unit activity associated with a tactile stimulus was observed on 27 unique channels. The mean signal to noise ratio for these signals, calculated as peak to peak amplitude over three times the noise standard deviation, was 1.85 with a standard deviation of 0.57. These results demonstrate the ability of this novel surface array to record high-fidelity neural signals at the DRG. Future work will include optimization of the electrode and studies with chronic placement.

Title: Data-driven model comparing the effect of the glial scar and electrochemical interface on chronic neural recordings in non-human primates

Authors: ***K. A. MALAGA**[1], K. E. SCHROEDER[1], P. R. PATEL[1], Z. T. IRWIN[1], D. E. THOMPSON[1], J. N. BENTLEY[2], C. A. CHESTEK[1], P. G. PATIL[1,2];
[1]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI; [2]Neurosurg., Univ. of Michigan Hlth. Syst., Ann Arbor, MI

Abstract: The ability to reliably record single-unit activity with intracortical microelectrode arrays is hindered by low signal-to-noise ratio. This can stem from a variety of biological, material, or mechanical failure modes, with the chronic foreign body reaction being one of the more studied failure mechanisms. In this study, we characterize electrode stability over twelve

weeks of electrophysiology recordings from four chronically-implanted Utah arrays in two rhesus macaques and quantify the effect of the glial scar and electrochemical interface on recording quality using a data-driven model. A finite-element model of a single Utah array microelectrode implanted in neural tissue was coupled with a compartmental model of a neuron to analyze the effect of encapsulation thickness, encapsulation resistivity, and interface resistivity on electrode impedance and waveform amplitude. The coupled FEM-neuron model was then reconciled with the neural data. Histology was obtained from one subject to assess the extent of gliosis. Mean impedance increased at a rate of 115.8 ± 239.3 kΩ/week during the first three weeks post-implantation. During this time, mean amplitude increased at a rate of 23.1 ± 48.9 µV/week. This initial ramp in impedance and amplitude was observed across all four arrays, and is nominally consistent with biofouling and reduction of edema, respectively, in the mathematical model. Beyond the third week, mean impedance (-0.7 ± 47.4 kΩ/week) and amplitude (-1.1 ± 11.7 µV/week) stabilized. Histology confirmed that relatively thin scars (16 ± 10 µm) formed around the implanted electrodes. In the model, macroscopic scarring alone was not enough to account for the large impedance changes observed experimentally. However, the addition of a thin interface layer around the recording site was able to match the data. While interface resistivity had a large effect on impedance, the model did not predict it to have a significant effect on amplitude. Overall, this study suggests that the glial scar does not cause an electrical problem. Specifically, macroscopic scarring does not appear to: (1) be the principal contributor to increased electrode impedance over time, and (2) impact waveform amplitude, unless it is thick enough to displace nearby neurons. This, in turn, suggests that if the recording site is able to coexist with the first few microns of biofouling, then neural signals can still be obtained reliably. Therefore, microelectrodes may be improved by focusing on the interface between the recording site and scar tissue, and its accompanying impedance increase.

Title: An increased throughput platform for acute slice electrophysiology with *in vitro* microelectrode arrays

Deleted: *in vitro*

Authors: ***M. S. TRUJILLO**[1], S. YASUOKA[2];
[1]Alpha MED Scientific, Benicia, CA; [2]Alpha MED Scientific, Ibaraki Osaka, Japan

Abstract: *In vitro* multielectrode arrays (MEA) offer many unique advantages for probing the electrophysiological properties of excitable tissue. These advantages can be applied to investigating neuronal models of learning and memory, development, aging, disease, and much more. While several high-throughput MEA platforms have been developed in recent years to address electrophysiological properties in cultured cell applications, there have been limited platforms designed to study such attributes in acute or cultured brain slice applications. Here we present the capabilities of the MED64 Quad-II system, a novel medium-throughput MEA designed specifically for acute or cultured slice applications. We demonstrate the reliability and reproducibility of inducing LTP in acute hippocampal slices from 6-7 week old male ICR strain mice. First, I/O curves were obtained from CA1 in response to current driven stimulation delivered to the Schaffer collaterals in ACSF perfused (1-2 mls/min.) acute hippocampal slices heated to 32° C bath temperature. The high capacitance electrodes (55k pF) reliably produced greater than 1mV amplitude fEPSP at less than 30µA stimulus amplitude. The relatively large amplitude fEPSP in response to the relatively low stimulating current is due to the low impedance of the platinum black (10 kΩ at 1 kHz) and carbon nanotube (7 kΩ at 1 kHz) electrodes. Baseline amplitude and slope of the fEPSP was recorded for 15 minutes in response to stimulating current set to 30% of the current required to saturate the fEPSP amplitude. Following theta burst stimulation, amplitude and slope were monitored for an additional 60 minutes. We also explored the feasibility of chemically induced LTP and LTD using the MED64 Quad-II system. Furthermore, we demonstrate the throughput of the Quad-II system by acquiring extracellular recordings from four slices simultaneously, at 16 electrodes per slice. The results of this study can be applied to drug discovery, target validation, compound screening, *in vitro* mechanistic assays, as well as toxicology and pharmacology studies in acute brain slice applications.

Title: A 3D neural probe with 1024 electrodes II: Dynamics and functional organization of reward circuitry

Authors: *J. L. SHOBE[1,2], L. D. CLAAR[2], K. I. BAKHURIN[2], S. PARHAMI[2], S. C. MASMANIDIS[2];
[1]UCLA, Irvine, CA; [2]Neurobio., UC Los Angeles, Los Angeles, CA

Abstract: We used a newly developed 3D silicon microprobe to simultaneously record activity and functional interactions in the frontal cortex and several basal ganglia nuclei, structures that are known to support reward-guided behavior. Specifically, we conducted parallel recordings in the orbitofrontal cortex, anterior and posterior regions of the striatum, the globus pallidus, and the ventral tegmental area/substantia nigra nuclei with alert head-restrained mice performing a Pavlovian odor discrimination task. We conditioned mice on two trial types: 1) they learned to associate a specific odor with a reward (CS+ trial) and 2) they were presented with a different odor without reward (CS- trial). Our recordings revealed neural activity patterns that varied according to trial type. The relationship between the cortex and the basal ganglia structures was especially revealing. During the CS+ trials, the cortex had the lowest response to the reward-predicting cue and had the fewest number of neurons that discriminated between CS+ and CS- trials. However, relative to the basal ganglia, the activity in the cortex showed a dramatic increase in activity when we introduced surprise reward trials suggesting that it is tuned to detect unexpected events. Furthermore, we used principle component analysis (PCA) to visualize the neural dynamics between CS+/CS- and surprise trials revealing unique trajectories. For instance both CS+ and CS- trajectories shared a common pathway during the odor presentation, but shortly after odor offset CS- quickly diverged to its original state likely representing the rapid recall of a discriminatory representation. We also found interregional correlated firing patterns (using k-means clustering analysis) suggesting that discrimination behavior utilizes ensembles linked across the recording field. Interestingly these cue-discriminating cells may be predisposed to fire together through common wiring because we found a significant relationship between resting state functional connectivity and task-evoked correlations. Taken together, our observations demonstrate the capabilities of our 3D microprobe to simultaneously capture network dynamics at multiple scales relevant to understanding reward circuit function.

Title: Tracking the activity of multiple individual neurons over one month in organotypic hippocampal slices grown on high-density multi-electrode arrays

Authors: ***W. GONG**[1], J. SENČAR[2], D. JÄCKEL[1], D. BAKKUM[1], A. HIERLEMANN[1]; [1]BSSE, ETH Zurich, Basel, Switzerland; [2]Fac. of Electrical Engin., Univ. of Ljubljana, Ljubljana, Slovenia

Abstract: The hippocampus is a well-characterized brain region for investigating neuronal plasticity, neurodegeneration, epilepsy and neurotoxicology, because of its relatively simple neuronal circuitry and cell types. Organotypic hippocampal slice cultures partially preserve the synaptic circuits and cytoarchitecture, while aspects of neuronal development can be observed in detail, beginning after slice preparation during the early postnatal days. In the current project, we established a method to cultivate organotypic hippocampal slices directly on high-density microelectrode arrays (HD-MEA) over long-term periods. The HD-MEA has an array area of 2x2 mm2 containing 11,011 platinum electrodes at a pitch of 17 µm (U. Frey et al., 2009). Sagittal hippocampal slices (300 µm thickness) were obtained from newborn mice and affixed to HD-MEA chips with chicken plasma and thrombin. The slice cultures on the HD-MEAs were maintained in custom culturing chambers, designed to implement the roller tube method (B.H. Gähwiler, 1981). During the recordings, 126 electrodes can be arbitrarily selected for simultaneous recordings. Sequences of high-density configurations were used to record from the whole electrode array area. Spike amplitude and frequency on each electrode were analyzed to obtain comprehensive network activity maps. An unsupervised iterative spike sorting algorithm was developed, based on PCA and k-means clustering, in order to obtain the spike-triggered average extracellular waveforms across subsets of recording electrodes ("neuron footprints"). The slice cultures were recorded from for over 30 days *in vitro*. Footprints of individual neurons

Deleted: in vitro

only exhibited slight changes between consecutive days, which indicates that the position of the neurons remain relatively stable. Our results demonstrate that multiple individual neurons within a developing hippocampal network can be identified and that their activity can be tracked during long-term cultivation.

Title: Implantable, yet adaptive computer-controlled multi-electrode positioning system for intracortical recordings in primates

Authors: ***E. FERREA**[1], L. SURIYA-ARUNROJ[1], D. HOEHL[2], U. THOMAS[2], A. GAIL[1,3,4]; [1]Cognitive Neurosci. Laboratory, Sensorimotor Group, German Primate Ctr., Goettingen, Germany; [2]Thomas RECORDING GmbH, Giessen, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany; [4]Fac. of Biol. and Psychology, Georg-August Univ., Goettingen, Germany

Abstract: Neuronal recordings with depth-adjustable microwire electrodes in non-human primates are a key method to investigate the neural basis of behaviors. Conventional micromanipulators for electrode positioning, however, are not chronically implantable and do not allow to record from many neurons simultaneously, limiting their use for brain computer interface applications or network analyses among populations of neurons. On the contrary, chronically implantable multi-electrode arrays allow recording from many neurons for a prolonged time, but electrodes are typically immovable. Hence, they do not allow optimizing the signal quality during and after implantation and are affected by tissue responses that progressively impair the transduced signal quality. This limits de facto the number of independent neurons that can be recorded over the lifetime of the implant. A third class of multi-channel recording methods makes use of chronically implanted matrices containing a higher count of individually movable electrodes to partially overcome these limitations. Yet, this latter technology does not provide ways to control electrode movements in a computerized fashion.

Instead, reposition the electrodes requires manipulation of manual actuators resulting in long-lasting interaction of the operator with the implant-holding animal. Here we demonstrate a chronically-implantable adaptive multi-electrode positioning (AMEP) system with detachable micro-positioning system for computerized depth-adjustment over several millimeters of each individual electrode after implantation. We show that by means of this semi-chronic 16 channel system we were able to record from many neurons simultaneously at variable depths from the cerebral cortex of a rhesus monkey. The system allowed recording of local field potential as well as single units while being able to reposition the electrodes in a computer-controlled fashion at micrometric precision and without interacting with the animal. Importantly the electrode-holding device is designed to remain within the recording chamber for a prolonged amount of time or can be used for acute recordings. The system is therefore paving the way towards chronic recordings with movable electrodes particularly suited for brain computer interface applications.

Title: Electrophysiological monitoring of neural stem cell differentiation

Authors: *J. COLLINS[1,2], H. C. WONG[1], J. KOHANA[1], M. G. BANUELOS[3], P. H. SCHWARTZ[3];
[1]Biopico Systems Inc, Irvine, CA; [2]Univ. of California Irvine, Irvine, CA; [3]Children's Hosp. of Orange County, Orange, CA

Abstract: Statistical assessment of the electrophysiological characteristics of neural stem cell (NSC)-derived neurons through single cell and field potential recordings have been of great interest in stem cell research. Here, we describe a microelectrode array cell culture assay

allowing for the differentiation of NSCs on the electrodes and evaluation of the resulting neuronal population activity and responses. NSCs were allowed to reach confluence on the electrodes and differentiated in the presence of an overlay of cortical mouse glia. Electrophysiological characterization was carried out using multichannel microelectrodes in a well of volume ~1ml. Limited electrical activity was observed in 2 weeks of differentiation with two distinct types of signals across the cells. One type featured only hyperpolarization with a valley height of ~100 uV, and the other type included both positive and negative potential changes with magnitudes of ~100 and ~40 uV, respectively. After 2.5 weeks of culture there was a pronounced increase in activity. With applied stimulation, pulses with amplitudes of 0.5 mA, widths of 0.2 and 1 ms, and frequencies of 0.5 Hz increased the burse rate to 3.2 kHz. The spikes' peak and valley heights varied from 30 to 125 uV. After 4 weeks of culture, the cells reached full maturity and there were consistent groups of spike trains as cells fired at faster rates of up to 3.5 kHz. In addition, these signals featured strong hyperpolarization as valley heights increased up to 1 mV for both lower (50 uA, 2ms, 0.5 Hz) and higher (0.5 mA, 0.2 ms, 0.5 Hz) levels of stimulation. Peak heights varied up to 125 uV, so these were not as prominent as the negative signals. Similar trends carried over to the fifth week of culture, where we also observed signals with valley heights of up to 1 mV for both spontaneous activity and with applied stimulation (0.5 mA, 0.2 ms, 0.5 Hz). By using this multielectrode array cell culture assay, we will statistically explore spontaneous and stimulus-induced population responses from neurons under different disease and drug conditions for high-throughput applications.

Abstract: In an effort to establish high-resolution, chronic, scalable, and bi-directional communication with peripheral nerves, a novel micro-electrode array has been developed. The array is oriented in a “micro-channel” format and leverages the regenerative properties of peripheral nerve fascicles. The device was chronically implanted in ferret, rabbit, and rat models for recording and stimulation of motor, sensory, and mixed nerves respectively. To improve axon regeneration, a novel collagen scaffolding was incorporated into the design for the prevention of inflammatory-mediated losses. During the regeneration phase, electrophysiological activity was measured in parallel with mechanical stimulation thresholds and biomechanical dynamics to identify any associated functional deficits. Furthermore, a new immunofluorescence technique was employed to characterize axons by subtype within each channel (e.g., motor, sensory, sympathetic) as a way of associating peripheral nerve composition with biomechanical dynamics and electrophysiological activity.

Title: Intracranial measurement of intracranial electric fields in monkeys and humans reveal spatiotemporal structure of transcranial electric stimulation

Authors: ***A. OPITZ**[1], C.-G. YAN[1], A. FALCHIER[1], E. YEAGLE[2], P. MEGEVAND[2], G. LINN[1], D. ROSS[1], C. CRADDOCK[1], S. COLCOMBE[1], A. THIELSCHER[3], M. MILHAM[1], A. MEHTA[2], C. SCHROEDER[1];
[1]Nathan Kline Inst., Orangeburg, NY; [2]Hofstra North Shore LIJ Sch. of Med. and Feinstein Inst. for Med. Res., Manhasset, NY; [3]Danish Res. Ctr. for Magnetic Resonance, Copenhagen Univ. Hosp. Hvidovre, Copenhagen, Denmark

Abstract: Introduction Transcranial electric stimulation (TES) is an emerging technique to non-invasively modulate brain function. However the spatiotemporal distribution of electric fields during TES remains poorly understood, and some question how much current actually reaches the brain. In this study we perform intracranial measurements of the electric field generated by each of two common TES modalities (transcranial direct current stimulation [tDCS], transcranial alternating current stimulation [tACS]) in epilepsy patients and a cebus monkey to investigate its spatial and temporal characteristics. **Methods** *Patient recordings* Four presurgical refractory epilepsy patients, with intracranially implanted electrodes participated in a single TES session. Two sponge electrodes (25cm2) were attached over the left and right temporal and a current of 1mA was applied for 2 min. We measured electric fields of tDCS and tACS with frequencies of 1Hz, 5Hz and 10Hz. *Monkey recordings* Three electrodes, with a total of 32 contacts (5mm apart) were permanently implanted through a skull incision over the left occipital cortex with posterior-anterior orientation. In multiple sessions intracranial EEG was recorded during TES. Small round stimulation electrodes (3.14 cm2, Ag/AgCl with conductive gel) were used in all sessions. We systematically varied the current strength to test for linearity of the conducting medium. To investigate the temporal course of electric fields during tACS and to test for possible frequency dependent effects on field strength or phase shifts, we parametrically varied the frequency of stimulation from 0.2 Hz to 150 Hz. **Results** We found a

linear relationship between the input current and the recorded intracranial voltage, thus indicating a linear resistive medium. Analysis of the frequency response indicated that power magnitude did not change with stimulation frequency. We observed only very small phase differences up to 3 degrees. We found measured potentials to be in accordance with predictions from computational models with spatially continuous varying potentials from the anode to the cathode for each montage. **Discussion** We conducted a comprehensive evaluation of the intracranial electric field during TES in both human patients and monkeys. Our results indicate that TES currents spread in a linear ohmic manner. Capacitive effects are if present very small. We did not observe frequency dependent attenuation of recorded signals. Our measurements can be useful for optimizing stimulation protocols and to understand physiological or behavioral effects from TES experiments.

Title: A test platform to evaluate the long-term safety and performance of peripheral nerve electrodes for brain-computer interface application

Authors: *S. VASUDEVAN, C. WELLE;
Food and Drug Administration, CDRH/OSEL/ Div. of Biomed. Physics, Silver Spring, MD

Abstract: Injuries causing limb loss or amputation can have deleterious effects on the quality of life. In the U.S. alone, there are ~1.6 million individuals suffering limb amputation. For this population, signals from the nervous system can be used to control advanced prostheses. Residual peripheral nerves after amputation offer safer and easier access for electrode implantation, as compared to brain. Studies show the availability of motor signals from peripheral nerves long after amputation and that these nerves can be stimulated to elicit sensory percepts (Rossini et al., 2010; Tan et al., 2014). This study aims to develop a test platform to evaluate the long-term safety and performance of electrodes implanted in the peripheral nerves.

We evaluated Floating Microelectrode Arrays (FMA) using bench and animal tests. Bench tests were performed by measuring impedance of the electrodes in PBS once a week for three weeks under dry (dried between measurements) and soaked (submerged in PBS throughout) conditions. For animal studies, electrodes were implanted in the rat sciatic nerve and connectors were secured using custom 3D-printed mounts. Electrode impedance was measured before and after implantation, until device failure. Motor function was evaluated using walking-track analysis and sensory deficits were assessed using Von Frey test. Electrodes were harvested for analysis using SEM and tissues were subjected to IHC. Bench tests showed minor fluctuations in impedance under dry conditions, while soaking caused drastic decrease. In animal studies, impedance of electrodes increased upon implantation and then stabilized. Electrophysiological recordings showed neural activity in ~25% of the electrodes, while the ability of an electrode to record over time was inconsistent between recording sessions. Between FMA and sham operated animals, there was no significant difference in motor function or sensory deficits. However, there was significant difference in sciatic and tibial function index between FMA group and uninjured animals at 1 wk. Devices failed between 6 and 13 wks, primarily due to lead wire breakage, although SEM revealed alterations to insulation and gaps between metal which may have contributed to loss of performance. Myelinated and unmyelinated axons around electrodes were observed using IHC. This regulatory science research study serves as a test platform to evaluate peripheral nerve interface technologies. Abstract: Drug resistant focal epilepsy may be treated by localizing and resecting the epileptic focus. The precise pre-operative localization of the focus is based on stereoelectroencephalography (SEEG) probes implanted intracranially [1, 2]. The spatial resolution of this approach is however limited by the low number of recording sites, i.e. up to 18 electrodes, provided by commercial technologies. Here we report on the fabrication, characterization and *in vivo* application of a 64-channel depth probe with recording sites of 35 µm in diameter. In order to validate the probe in the macaque posterior parietal cortex (PPC), the length was chosen to be 32 mm based on preliminary MRI scans of the monkey's brain. The probe has an outer diameter of 800 µm, similar to clinically approved probes, and is realized by reshaping a planar layer stack made of two polyimide films and a patterned metallization sandwiched in-between [3]. The cylindrical probe geometry of the polyimide foil rolled inside a metallic mold is secured during the reshaping process using a dry adhesive. The probe is further stiffened by a polymeric refill resulting in a mechanical stiffness comparable to that of commercial devices. The probe was implanted manually in one monkey (Macaca mulatta), spanning the PPC from the inferior parietal convexity to the mesial parietal cortex, through a dedicated bone screw. The connectors interfacing the probe with the hardware-software platform from OpenEphys were protected by a custom-made recording chamber anchored to the skull. Already 24 hours after probe implantation we could record simultaneously well isolated single units activity (SUA) from 12 distinct sites. A modulation of local field potentials, multi-unit activity, as well as SUA was observed while the monkey performed various hand-arm motor tasks. The long-term recording stability demonstrated with the probes exceeds the usual time (1 week) needed for focal epileptic focus localization. **References** [1] J.M. Title: Carbon nanotube multi-electrode arrays for high sensitive extracellular measurements in cultured human iPSC derived neurons

Authors: ***I. SUZUKI**[1], N. MATSUDA[1], A. ODAWARA[1], M. FUKUDA[2], H. JIKO[2];

Abstract: Multi-electrode arrays (MEAs) can be used for noninvasive, real-time, and long-term recording of electrophysiological activity in cultured neuronal network. Functional characteristics of human induced pluripotent stem cells (iPSC) derived neurons on their long-term spontaneous activity and drug responsiveness may be monitored by MEAs but many lack, cell affinity, sensitivity, signal-to-noise ratio (S/N), and durability. In this study, we describe the development of planar carbon nanotube (CNT)-MEA chips for high sensitive extracellular measurements in cultured human iPSC derived neurons. These CNT-MEA chips were fabricated by electroplating the indium-tin oxide (ITO) microelectrode surfaces. At1kHz, the impedance of CNT electrodes with a diameter of 50 μm was approximately 8 kΩ. CNT electrodes exhibited both low impedance and high durability. Human iPSC derived neuron culture experiment reveal excellent biocompatibility and adhesion of CNT-MEA surface. In addition, action potential signals were recorded from human iPSC derived neurons with high S/N ratio and for > 9 months with long-term spontaneous activity. Drug responsiveness using synapse agonist and antagonist were also observed. Our CNT-MEA chips may be beneficial for clarifying the functions of human neuronal circuits and for drug screening applications.

Title: The Encephalophone: A novel brain-computer music interface and cognitive rehabilitation device using conscious control of electroencephalogram (EEG)

Authors: ***T. A. DEUEL**[1,2], J. PAMPIN[5,2], J. SUNDSTROM[3], F. DARVAS[4];
[1]Swedish Neurosci. Inst., Seattle, WA; [2]Ctr. for Digital Arts and Exptl. Media (DXARTS), [3]Sch. of Music, [4]Dept. of Neurosurg., Univ. of Washington, Seattle, WA; [5]Sch. of Music, Unive, Seattle, WA

Abstract: A novel musical instrument was created using electroencephalogram (EEG) motor imagery to control a synthesized piano, and is herein named the Encephalophone. Alpha-frequency (8-12 Hz) signal power, originating from either posterior dominant rhythm (PDR) in the visual cortex or from mu rhythm in the motor cortex, was used to create a power scale which was then converted into a musical scale which could be manipulated by the individual. Subjects could then generate different notes of the scale by activation (event-related synchronization) or de-activation (event-related desynchronization) of the PDR or mu rhythms in visual or motor cortex, respectively. In a pilot study with 13 normal subjects, subjects were tested in their ability to hit target notes presented within a five-minute trial period. All 13 subjects were able to perform more accurately than a random note generator when using either visual cortex/PDR signaling or motor imagery/mu signaling. The Encephalophone's accuracy will be improved by training within the musical context, and has future applications as a novel musical instrument without requiring movement, as well as a potential therapeutic device for patients suffering from motor deficits (e.g. Amyotrophic lateral sclerosis, brainstem stroke, traumatic amputation).

Title: Chronic *in vivo* electrophysiology and histology stability assessment of carbon fiber microelectrode arrays

Deleted: *in vivo*

Authors: ***P. R. PATEL**[1], H. ZHANG[2], M. T. ROBBINS[1], J. B. NOFAR[1], S. P. MARSHALL[1], M. J. KOBYLAREK[1], T. D. Y. KOZAI[3], N. A. KOTOV[2], D. R. KIPKE[4], C. A. CHESTEK[1]; [1]Biomed. Engin., [2]Chem. Engin., Univ. of Michigan, Ann Arbor, MI; [3]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [4]NeuroNexus Technologies, Ann Arbor, MI

Abstract: Recording stable, low-noise, high-amplitude unit activity in the motor cortex is crucial for the long-term stability of any brain machine interface system and can be equally important in many neuroscience studies. To accomplish this goal, a system of electrodes should ideally elicit

little to no immune response, have the capacity to concurrently record from a large population of neurons, and demonstrate the ability to chronically record neural activity. To this end we have developed a 150 µm pitch, multi-electrode array, using carbon fibers (d=8.4 µm), which have been shown to be minimally damaging to the brain. To demonstrate the viability of this design as a chronic electrode technology we implanted 5 Long Evans rats with carbon fiber arrays using a poly(ethylene glycol) coating to assist in insertion. A subset of the animals implanted with carbon fiber arrays (n=2) and a separate cohort (n=3) were implanted with a planar silicon electrode (177 µm2 site size, NeuroNexus Technologies) in the contralateral hemisphere's motor cortex. Animal implant durations ranged from 3-5 months. Results from electrophysiology recordings show that on average 37% of carbon fiber electrodes (n=60 fibers) were able to detect unit activity for at least 3 months with an average amplitude of 203.1 µV over that time. In addition, units detected on the carbon fibers had an average SNR of 4.22 for the first 3 months. The chronically implanted silicon electrodes (n=5, 16 sites each) detected very few units, with an average amplitude of 95 µV during the 3 month implant period. The overall lack of detectable unit activity on the silicon electrodes may be partially attributable to the small site size. Histology intensity values were calculated by averaging the fluorescent signal within the first 50 µm of the implant site(s). This value was then normalized by the control value which was calculated by averaging together the intensities of each corner (500 µm x 500 µm) of the image. Analysis from one rat showed the reactive response to the carbon fiber arrays was minimal with a normalized astrocytic intensity of 2.29 and microglial intensity of 0.75. Reactive response to the silicon electrodes was characterized by the formation of a scar with an astrocytic intensity of 8.68 and microglial intensity of 2.62. This work has demonstrated the ability of carbon fiber electrodes to chronically record unit activity in the rat motor cortex out to 16 weeks with minimal scarring. The units detected were of large amplitude and showed a high SNR. Future work will seek to improve array packaging to allow for even higher density arrays with higher channel counts that will allow us to record from all neurons in a given cortical layer.

Title: Carbon fiber based microelectrode array for intracortical neural recording

Authors: *Y. LEE[1], Y. LIM[2], S. HWANG[1], H. YOO[1], S. JUN[1,3];
[1]Ewha Womans Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Ctr. for Robotics Research, Robotics and Media Institute, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [3]Dept. of Brain and Cognitive Science, Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Microelectrode arrays are commonly used for electrophysiological recording from individual neurons to study neural pathways in the brain or to develop brain-computer interface. However, the long-term recording is still limited due to the tissue reaction around the implanted microelectrodes even though the chronic neural recording is becoming more and more essential for long-term applications. It is believed that the geometry of the electrode such as the size is the most critical component which can determine the degree of the chronic tissue damage. In this study, in order to reduce the reactive tissue response, carbon fiber-based microelectrode arrays are developed. Since the diameter of the carbon fiber (7 μm in diameter) is much smaller than the conventional micro-wires, it is expected that the carbon fiber neural probe is appropriate for the long-term neural recording. We introduce the multi-channel microelectrode array whose channels are composed of multiple carbon fiber bundles and show the preliminary neural responses recorded in motor cortex of anesthetized rat. While each carbon fiber is too flexible to be inserted in the rat brain, the bundle of carbon fibers can sustain each other to insert the electrode into the brain. Each neural signal from a carbon fiber is merged into a single electrical channel and the individual neural spikes can be identified via the spike sorting afterwards.

Title: Differential impact of anesthetics on real-time electrochemical recordings of glutamate neurotransmission in the rodent brain

Authors: *T. COLBURN;
Univ. of Arizona, Phoenix, AZ

Abstract: Across physiological recording paradigms, urethane is commonly used as a minimally confounding anesthetic. A paper published by Hara and Harris implicated urethane in affecting multiple neurotransmitter systems, bringing into question the utility of urethane in neurophysiological recordings. Isoflurane is commonly used for neurological studies due to minimal side effects, rapid post-operative recovery, and a high level of control over its administration. We test the hypothesis that isoflurane is a viable alternative to urethane for *in vivo* amperometric recordings of glutamate neurotransmission in the rodent brain. We used novel glutamate-selective microelectrode arrays (MEAs) to measure glutamate clearance kinetics in the cortex and thalamus of anesthetized adult male Sprague-Dawley rats. In separate cohorts of animals, isoflurane was delivered at 2% (in O2) via nose cone throughout the recordings or urethane (~1.25g/kg) was given as serial intraperitoneal injections until loss of pedal reflex was achieved. *In vivo* local applications of glutamate and potassium chloride were administered within each region of interest in order to assess real-time glutamate dynamics. Preliminary results indicate that potassium-chloride evoked release of glutamate tends to be greater in isoflurane anesthetized rodents in comparison to urethane, regardless of anatomical loci. These data suggest that the choice of anesthetic in anesthetized recordings of real-time neurotransmission can influence glutamate release and uptake dynamics, confounding comparisons between experimental paradigms.

Title: Deep brain stimulation in mice using magnetic resonance imaging-compatible carbon electrodes

Authors: *D. R. GALLINO, V. KONG, G. DEVENYI, A. MATHIEU, M. CHAKRAVARTY; Cerebral Imaging Ctr., Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada

Abstract: Deep brain stimulation (DBS) is used to deliver chronic high-frequency electrical stimulation to brain circuits that are compromised by neuropsychiatric disorders. DBS has been used effectively in the treatment of Parkinson’s disease, and there are several new investigations of DBS in the context of other disorders (e.g. major depression, Alzheimer’s disease). Preclinical longitudinal magnetic resonance imaging (MRI)-based investigations of novel targets are hampered by the use of traditional non-MR compatible electrodes. Here we investigate the feasibility of using carbon-based electrodes for delivering DBS in mice with respect to MR compatibility, biocompatibility, and electrical properties. Monopolar electrodes were constructed using carbon-fiber rods of 0.25 and 2 mm diameters, bound with conductive carbon epoxy and insulated with polyvinyl alcohol. Electrodes were implanted in C57BL/6 male mice, perpendicularly to the skull plane at bregma, +/- 1 mm laterally and at a depth of 3.75 mm to target the body of the fornix. Animals were imaged in a 7T Bruker USR magnet (20 cm bore) using a TrueFISP 3D acquisition with 100 μm isotropic voxels. Monophasic stimulation was delivered at 120 Hz, 200 μA, 1 V with pulse width of 100 μs. Mean and standard deviation of electrode resistance was 1379 and 248 Ω respectively. Neither electrode implantation nor stimulation caused noticeable adverse side-effects in mice. Stimulation at 200 μA required 1 V, less than comparable metal electrodes, and indicating a total circuit resistance of ~5 kΩ. High resolution MR images were generated in under 90 min and contained no noticeable artifacts generated by the electrodes. The lack of artifacts allowed for accurate confirmation of electrode placement and imaging of the surrounding fine structures (Fig.1). We believe that these images are suitable for further structural analyses. Our findings suggest carbon fibre to be an appropriate replacement material for metal in DBS electrodes due to its high conductivity, biocompatibility and the absence of MRI acquisition artefacts.

Title: Standardized regions of interest for population analyses using electrocorticography (ECoG)

Authors: *J. B. COCJIN[1], S. R. DAMERA[3], Z. S. SAAD[4], S. K. INATI[2], K. A. ZAGHLOUL[1]; [1]Surgical Neurol., [2]Office of the Clin. Director, NINDS, Bethesda, MD; [3]Georgetown Univ., Washington, DC; [4]Scientific and Statistical Computing Core, NIMH, Bethesda, MD

Abstract: The high spatiotemporal resolution of electrocorticography (ECoG) renders it invaluable for characterizing focal activity such as that associated with recurrent seizures or cognitive functioning. Unlike other recording modalities such as fMRI or scalp EEG, ECoG lacks standardized means for attributing electrode activity to spatially similar regions across subjects. Current methods either limit analyses within the confines of presumably relevant anatomical structures, ignoring possible effects in other areas of electrode coverage, or conduct averages over broad regions such as gyri, reducing the spatial specificity of the analyses. Here, we attempt to balance spatial coverage and specificity appropriate for ECoG by defining regions-

of-interest (ROIs) as the nodes of low-density standard pial meshes generated in SUMA, which have indices of similar location across subjects. We first localize electrodes to an envelope about a reconstructed pial surface via a semi-supervised projection algorithm. We then assign high-density standard mesh nodes to each electrode through a combination of capture within the electrode's model volume and geodesic growth along the mesh surface. Finally, we use a nearest neighbor mapping to gather high-density nodes into the low-density ROIs. We demonstrate that group analysis across varying mesh densities for a motor task yields similar regions of activation. We expect that the adoption of standardized low-density ROIs that match the spatial properties of ECoG has the potential to yield insights not possible with current mapping schemes.

Abstract: Our goal was to develop an electrophysiological recording system capable of monitoring neural data at multiple scales in the mouse brain. Existing recording technologies

have a limited ability to interrogate local microcircuit activity as well as systems-level dynamics spanning multiple brain regions in parallel. To this end, we developed a three-dimensional (3D) electrode array via a multilayered assembly method to bond together four microfabricated planar silicon microprobes that are precisely aligned using motorized micromanipulators to target different anatomical regions of the mouse brain. The 3D array contains a total of 1,024 simultaneously accessible recording sites, which are densely patterned across multiple silicon prongs. For this work, we targeted key regions implicated in reward processing and movement (orbitofrontal cortex, striatum, globus pallidus, ventral tegmental area, and substantia nigra). To minimize the device's external wiring, we developed multiplexed head stage modules that coupled with each layer of the assembly. To verify the functionality of the recording system we performed acute recordings in awake, head-fixed mice performing a Pavlovian odor discrimination task (see linked poster by Shobe et al). We developed a custom single-unit spike sorting algorithm designed for high electrode density recordings that can distribute spike sorting tasks on multiple computers to reduce computation time. Recordings yielded an average of over 300 well-isolated units across the electrode array. With the precise, micrometer-level control we have over the relative positioning between each electrode in three dimensions, these 3D microprobes can be designed to combinatorially study a large number of brain structures. The ability to record from multiple areas in parallel presents new opportunities to address important questions regarding the multi-scale functional organization of brain circuits that exists in health and disease.

Title: Induction and characterization of synaptic transmission induced synchronized population bursts of the induced pluripotent stem cell-derived neurons

Authors: ***N. MIYAMOTO**, K. SAWADA;
EISAI Co., Ltd., TSUKUBA, Japan

Abstract: Many drugs have been reported to cause seizures. It has been reported that the causes of drug-induced seizures are $GABA_A$ antagonism, $GABA_B$ agonism, adenosine antagonism, and enhanced excitation through NMDA in the neurons. So far, there is no good *in vitro* assay system for predicting drug-induced unexpected seizure-risks. Spontaneous neuron activity recordings by multi-electrode array (MEA) system from networks of cultured neurons could be a good risk evaluation system for such drug-induced seizure events [1]. It was reported that long-term electrophysiological activity and pharmacological response of human induced pluripotent stem cell (hiPSC)-derived neurons were accelerated by co-culture with rat astrocytes [2]. In this study, we observed time course generation of population burst spikes from iCell neurons with conditioned medium of mouse primary astrocytes by MEA system. Humoral factor(s) from mouse primary astrocytes was sufficient to generate synchronized population burst spikes in the iPSC-derived neurons. GABA antagonism enhanced the periodic synchronized burst spikes in a dose-dependent manner. P/Q-type and N-type calcium channel blockers eliminated the periodic synchronized burst spikes, suggesting that the burst spikes are mediated by synaptic transmission. We concluded that the observed astrocyte-induced population bursts by MEA system are mediated by synaptic transmission and the periodic synchronized population burst signals could be a good prediction marker of $GABA_A$ antagonism. Title: Automated spike sorting across electrodes in large-scale recordings from the mammalian retina

Authors: ***M. SORBARO SINDACI**[1], G. HILGEN[2], S. PIRMORADIAN[1], I. KEPIRO[3], S. ULLO[3], O. MUTHMANN[4], L. BERDONDINI[3], D. SONA[3], E. SERNAGOR[2], M. H. HENNIG[1]; [1]Inst. for Adaptive and Neural Computation, Sch. of Informatics, Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Inst. of Neurosci., Univ. of Newcastle, Newcastle-upon-Tyne, United Kingdom; [3]Inst. Italiano di Tecnologia, Genova, Italy; [4]Natl. Ctr. for Biol. Sci., Bangalore, India

Abstract: Microelectrode arrays (MEAs) are a powerful tool, capable of sampling, at high frequencies, the electrical potential at hundreds or even thousands of locations simultaneously, and are widely used to record the responses of large neural populations. Currently, spikes observed by each electrode are sorted according to their waveform, whose shape shows variations across neurons; significant challenges, however, arise when working with high-density MEAs, where individual neurons may be recorded simultaneously by multiple neighbouring electrodes. Waveform clustering, moreover, often needs an amount of human intervention that makes it highly time-consuming for large arrays, and shows poor performances at sampling frequencies below 10-20 kHz. We integrate this approach with a novel technique, based on the pair of spatial coordinates associated to each spike by interpolation across neighbouring electrodes. Simultaneous events observed on different channels are associated to a point in space by comparing the amplitudes measured by each channel. Events are found to be mostly grouped in well-localised units, which we believe correspond to single neurons and we separate thanks to the Mean Shift clustering algorithm applied to spatial and waveform dimensions simultaneously. Both position and shape of an event can also be used to classify it as noise or signal. Our results show that this method -- applied to 4096-electrode MEA recordings from the mouse retina -- avoids the duplication of units observed by multiple electrodes and sorts spikes better than the sole principal component analysis of the waveforms. Furthermore, it gives information, at a resolution higher than that of the array grid, on the location of the units. The comparison with micrographs of green fluorescent protein-labelled neurons confirms the correct localisation and clustering of spikes from single neurons.

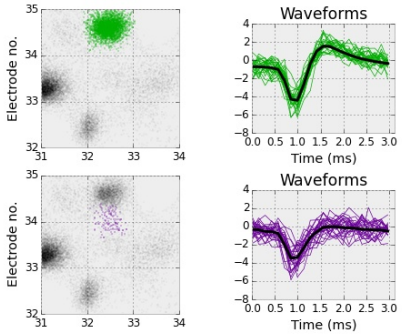

Figure: the two clusters shown are distinct in location (the first is centred on an electrode, the second between electrodes) and, consistently, show different spike shapes. Electrode spacing is 42 µm.

Title: Construction of two-site multi-channel optrode system in freely moving mouse

Authors: *Y. TANG;
Shenzhen Inst. of Advanced Technol., Shenzhen Inst. of Advanced Technol. (SIAT), Guandong, China

Abstract: Objective Optogenetics technology provides an opportunity to control the activity of neurons for exciting or inhibiting the brain networks . Real-time observing and recording the neurons' activity in the illuminated and related brain region become critical and powerful for exploring the principle of brain works. Here, we try to construct a two-site multi-channel optrode

system in freely moving mouse. **Methods** We integrated the optogenetic stimulation technology and multi-channel recording technology, to form a two-site multi-channel optrode system. This system contains two bundles of electrodes, one bundle combines a φ230μm multimode optical core for optical illumination and 8 tetrodes surrounding the optical fiber for neuron activity recording, the tips of 8 tetrodes are 0.5-0.7mm longer than the end of optical fiber. All of the electrode tips were plated with platinum(chloroplatinic acid solution) to a final impedance of 0.5-0.8MΩ. Both of bundles can be driven independently and have a range of 5mm for moving, the optrode advanced 300μm once the screw driver turn a circle. Thus, the optrode system can illuminate and record in every depth in a certain two-site at the same time. **Results** The two-site optrode system got the action potentions credibly from the illuminated brain region and the related area at the same time. **Conclusion** The two-site optrode system is an appropriate option for research in freely moving mouse.

Abstract: Introduction:Deep brain stimulation (DBS) is an effective neurosurgical treatment for Parkinson's disease and essential tremor, and it is now being evaluated for treatment of psychiatric disorders. Despite its clinical success, there is still only a limited understanding of the therapeutic mechanisms behind DBS. Attempts to elucidate these mechanisms by measuring electrophysiological activity have thus far been inconclusive. We hypothesize that understanding the underlying therapeutic mechanism of DBS will require a combination of electrophysiological and electrochemical analysis. Since electrophysiological measuring techniques are well established in the literature, we developed the Wireless Instantaneous Neurochemical Concentration Sensing (WINCS) Harmoni system to characterize stimulation-evoked neurochemical responses. WINCS Harmoni can modulate neuronal activity in real-time response to neurochemical events. Method: WINCS Harmoni employs fast-scan cyclic voltammetry (FSCV) to characterize the neurochemical events during the application of DBS. WINCS Harmoni incorporates a microcontroller, Bluetooth transceiver, configurable and synchronizable isolated neurostimulator, and a custom four-channel integrated circuit for interleaved neurochemical and electrophysiological measurements, all powered by a pair of batteries. PC-based software provides real-time control of stimulation, data acquisition, and data visualization. Here, we examine WINCS Harmoni's efficacy *in vivo* in the rat, pig, and non-human primate. We stimulated and recorded neurochemical measurements in parallel using a carbon fiber microelectrode (CFM) implanted in the striatum. FSCV was conducted by applying a series of pyramidal voltage waveforms to the CFM and measuring the currents produced by the resulting electrochemical activity. Results: In this proof-of-principle study, WINCS Harmoni successfully evoked and detected striatal dopamine release by DBS in the rat, pig, and the non-human primate. Notably, the synchronization of stimulation with interleaved FSCV scans eliminated the stimulus artifact that would have otherwise obscured the neurochemical measurements. Importantly, we were able to record FSCV data from four channels simultaneously during DBS with stimulation provided by WINCS Harmoni. Conclusions: WINCS Harmoni represents a major improvement in electrochemical sensing for neuromodulation control. The ability to simultaneously record electrochemical events and translate them into stimulation programming changes in real time will be a powerful tool toward closed-loop DBS.

Title: Real-time functional ultrasound imaging of brain activity on freely moving rats during active tasks

Authors: ***A. URBAN**[1], D. CLARA[2], M. GUILLAUME[2], B. CLÉMENT[2], M. EMILIE[3], M. GABRIEL[2];

Paris Descartes, Sorbonne Paris Cité., PARIS, France; [3]Neural Circuit Laboratories, Friedrich Miescher Inst. for Biomed. Res., BASEL, Switzerland

Abstract: Innovative imaging modalities are required to investigate the complex relationship between brain activity and behavior in freely moving animal. Functional ultrasound (fUS) is a recent strategy for recording cerebral blood volume (CBV) dynamics in the whole brain but has so far only been used in head-fixed and anesthetized rodents. Here a fUS device was designed for performing tethered brain imaging in freely moving rats based on a miniaturized ultrasound probe and a custom designed ultrasound scanner. CBV changes were monitored in various behavioral states such as quiet rest, after whiskers or visual stimulations and also in a food-reinforced operant task. fUS imaging in a freely moving condition was fully efficient to decode brain activity in real-time based on analysis of CBV during reward collection. These results support the viability of fUS in future minimally invasive brain-machine interfaces. Figure Legend: Miniaturized device for functional ultrasound in freely moving rats. (a) Miniaturized ultrasound probe (b) CAD drawing of the magnetic head fixation system. The head plate (purple) is surgically implanted on the skull with 6 screws. The probe holder (brown) allows quick connections and disconnections of the probe using magnets (yellow). (c) Pictures of the rat at rest or during fm-fUS. A magnetic head shield protects the brain between imaging sessions. The probe is inserted in the probe holder and then connected to the head plate during experiments. (d) Coronal view of the imaging plane. The red square indicates the field of view of the probe allowing cortical and subcortical imaging of the hemodynamic signal. Barrel field (BF) cortex, motor (M) cortex, thalamus (TH) and hippocampus (HPC). (e) CBV images in freely moving conditions with the probe positioned on the left (top left, red square) or the right hemisphere (top right). Composite image of the entire brain after merging of left and right CBV images. Scale bars, 5 mm.

Title: Single-synapse analysis of long-term potentiation by flow cytometry

Authors: ***G. A. PRIETO**, B. H. TRIEU, G. LYNCH, C. W. COTMAN;
Inst. for Memory Impairments and Neurolog. Disorders, Irvine, CA

Abstract: Long-term potentiation (LTP), a lasting increase in the efficiency of synaptic transmission, was first recorded in a cortical-hippocampal circuitry and has been studied for decades using electrophysiological protocols for stimulation and recording. While *in vivo* and *in vitro* recordings have provided valuable information on LTP underlying mechanisms, the study of LTP would benefit from a simplified system intermediate between *in vivo* and *in vitro* approaches. Here we describe a novel approach to study LTP. This method focuses on the insertion of AMPA (α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptors

Deleted: in vitro

(AMPAR) into the post-synaptic surface, the essential event for the potentiation of synaptic transmission. Our approach consists of chemical LTP stimulation (cLTP) directly in fresh hippocampal synaptosomal fractions, immunofluorescence-labeling and flow cytometry analysis. Accordingly, we named this approach 'Fluorescence Analysis of Single-Synapse Long-Term Potentiation' (FASS-LTP). Fluorescence analysis after cLTP induction (45 min) identified an increased proportion of potentiated synapses (GluR1+) over basal levels, demonstrating that FASS-LTP detects activity-dependent plasticity in synaptosomes. Time course analysis revealed that the early (15 min) increase in the proportion of GluR1+ synaptosomes after cLTP stimulation is sustained up to 75 min, thus resembling the long-lasting increase in excitatory postsynaptic potentials (EPSPs) in hippocampal slices after electrical stimulation. We found that the NMDA receptor (NMDAR) antagonist AP5 blocks the cLTP-induced increase in GluR1+ synaptosome level. Finally, we evaluated cLTP response at 15, 25 and 45 min in young (3-4 months) and aged (12-15 months) 3xTg mice, a well-known model of Alzheimer's disease (AD). While young 3xTg mice exhibited normal GluR1+ levels after chemical stimulation, cLTP response was utterly absent in aged 3xTg mice, a profile consistent with electrophysiological recordings in 3xTg showing intact LTP at 3-4 months but significant deficits in 6-7 month old mice26. Overall, these data demonstrate that FASS-LTP is a sensitive approach to study synaptic plasticity.

Title: OpBox: Open-source development of customized and cost-effective hardware and software for behavioral neurophysiology

Authors: *B. F. COUGHLIN[1], B. E. SHANAHAN[1], G. PIANTONI[1,2], S. S. CASH[1,2], E. Y. KIMCHI[1,2];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA

Abstract: Open-source technologies, made available to use and modify without licensing or restrictions on use, is having a major impact on the development of laboratory software and hardware. The rise of technologies such as 3D printers has spurned the growth of the "maker" community, which seeks to build and adapt equipment from existing designs for customized purposes, rather than use less-than-ideal equipment that may not cover every need. A growing number of labs, including our own, are adopting this movement, allowing not only for customization of equipment, but also for collaborative improvements in design deemed most useful by the field. We have developed a modular, open-source behavioral neurophysiology system, collectively called OpBox. We have integrated several open-source technologies spanning the range from hardware to software: 1) 3D desktop printing, allowing us to model, fabricate, and use devices within the same day, as well as share them digitally so distant labs can have the same hardware to within μm of precision; 2) embedded microcontrollers such as Arduinos which allow for interfacing hardware and software via printable electronic circuit boards; and 3) multithreaded software to process multiple data streams concurrently in real-time. Using these three technologies we have developed a behavioral neurophysiology system for rodents called OpBox, capable of performing operant conditioning, tracking of locomotor activity, recording of electrophysiological activity, and video recording. We have dramatically cut costs down by up to an order of magnitude through a modular design which can be cheaply modified or replaced part-by-part as deemed necessary. This also allows for better collaboration with other labs performing similar experiments. We have created an online repository for our designs and how-to tutorials so that the broader community download and modify our designs/code. While there is a learning curve to open-source development, as more labs adopt these methodologies, there is a greater likelihood of finding designs/code that already fulfill customized needs or need only minor modifications to do so. Overall, open-source systems like OpBox promise to have tremendous impact on the practice of neuroscience research.

Title: Optical interrogation of ultrasonic neuromodulation in transgenic mice

Authors: ***T. SATO**, D. TSAO;
Caltech, Pasadena, CA

Abstract: Transcranial focused ultrasound (tFUS) is a highly promising tool for non-invasive neuromodulation. Recent studies have shown the potential for modulating and inducing sensations in the human somatosensory cortex (Legon et al. 2014, Lee et al. 2015). However, the mechanisms for how ultrasound affects neurons and what parameters are critical are unknown. Human studies have shown large variability within subjects, and it is very difficult to optimize parameters in humans. A refinement of our understanding is needed to apply ultrasonic neuromodulation in humans in safe, systematic manner. Many of the studies so far *in vivo* and *ex vivo* in animal models have utilized electrophysiological means or coarse imaging methods (BOLD, PET) requiring intensive labor with invasive probes that could affect how ultrasonic energy interacts with neurons, or offering poor spatial and temporal time scales. Calcium imaging of neural activity provides a non-invasive means of studying large populations of neural activity with high temporal and spatial resolution. Widefield imaging can provide a quick readout of population level activity and provide information about the spatial pattern of neuromodulation, while two-photon imaging can give cellular level resolution activity within an intact and unperturbed neuronal network. Here, we develop a system that allows easy optical means of observing neuronal responses to ultrasonic neuromodulation in transgenic mice with widespread cortical GCaMP6s expression and describe results from our studies.

Title: Improved sensitivity and measurement stability of fast scan cyclic voltammetry measurements using the 'elastic net'

Authors: H. LONG[1], K. T. KISHIDA[2], J. P. WHITE[2], *R. J. MORAN[2], T. LOHRENZ[2], P. PHILLIPS[3], P. DAYAN[4], P. R. MONTAGUE[2];

Abstract: Dopamine and serotonin are two neuromodulators implicated in a wide range of human psychiatric conditions. *In vivo* monitoring of these neuromodulators in model organisms and humans during ongoing behavior and decision-making will provide invaluable information about the role these neurotransmitters play in human cognition and mental health. Fast scan cyclic voltammetry (FSCV) on carbon fiber microelectrodes permits *in vivo* measurements of electrochemically active neurotransmitters such as dopamine and serotonin with sub-second temporal resolution. Current state-of-the-art approaches for determining the chemical identity and concentration from background subtracted cyclic voltammograms include the use of qualitatively determined oxidation peaks of relevant neurochemicals or waveform analysis using principal components regression (PC-regression). These approaches work well when chemical concentrations are high and background subtracted cyclic voltammograms result in qualitatively recognizable waveforms; however, at lower concentrations or in more complex chemical environments these methods have shown limitations. We employ a modern machine learning approach, the 'elastic net' (EN), to train multivariate penalized linear regression models for estimating and discriminating dopamine and serotonin concentrations from FSCV measurements. We compare the performance of the EN-based, PC-regression, and univariate approaches. We use *in vitro* measurements of prepared dopamine solutions to reproduce known limitations of oxidation peak and PC-regression based approaches. In contrast, we show that our EN-based procedure overcomes these issues, and offers more sensitive and stable FSCV-based estimates of dopamine and serotonin levels. Further, we use the EN-based model trained on *in vitro* data to reanalyze previously published FSCV measurements made in the striatum of freely moving animals and estimate dopamine levels evoked by electrical stimulation of the medial forebrain bundle.

Title: *In vitro* assessment of biased signaling: a duplex assay approach to detect functional selectivity of 5-HT_{2C} agonists

Authors: ***V. LAKICS**, B. RAUPRICH, M. H. BAKKER, A.-L. RELO, H. MACK, A. HAUPT, W. BRAJE, G. C. TERSTAPPEN, K. DRESCHER;
Abbvie Deutschland Gmbh and Co. KG, Ludwidshafen, Germany

Abstract: Agonists of seven-transmembrane receptors often do not activate all linked signaling pathways to the same extent, but they rather differ in their ability to signal through G-proteins or activate other signaling pathways. This phenomenon, termed biased signaling or functional selectivity, offers possibilities to design novel drugs with potentially better efficacy or therapeutic index. 5-HT_{2C} receptor agonism is a promising mechanism to target in multiple neurological conditions, like drug abuse and various neuropsychiatric conditions, including schizophrenia. In this study, we have developed a novel approach for detecting functional selectivity in a series of 5-HT_{2C} agonists and have also characterized these compounds. To reliably detect biased signaling, a duplex assay has been set-up, first measuring calcium-mobilization, then assessing beta-arrestin recruitment in the very same U2OS cells expressing the human 5-HT_{2C} receptor. Performing both readouts from the same cells significantly decreased the variability of our measurements and allowed for a more reliable detection of bias by our agonists. Using these two readouts, we have compared the *in vitro* potency of over 50 selected 5-HT_{2C} receptor agonists to that of a reference agonist, serotonin. No beta-arrestin preferring compounds were found, but several 5-HT_{2C} agonists with G-protein signaling bias were identified. The well described selective 5-HT_{2C} reference agonists, vabicaserin, lorcaserin and CP-809,101, showed no detectable bias in our system. G-protein-preferring compounds were inactive in an *in vitro* receptor internalization assay, while non-biasing agonists were capable of inducing beta-arrestin-mediated internalization. So far, no differential vivo activity of our biased 5-HT_{2C} agonists was detected, using the amphetamine-induced hyperactivity assay in mice - additional *in vivo* assays are currently being applied to characterize these compounds. Taken together, our duplex cell-based assay is well-suited to identify 5-HT_{2C} agonists, preferentially signaling through G-protein vs. beta-arrestin. The principle of our approach can easily be extended to other seven-transmembrane receptors to identify biased agonists within a specific lead series, increasing diversity and potentially resulting in better profiles for drug candidates.

Title: Nanomechanical characterization of synapses in live hippocampal neurons via torsional harmonic atomic force microscopy

Authors: ***J. YANG**[1], N. MANDRIOTA[1], J. JONES[1], D. KIM[1,2], R. LEFORT[3], R. YUSTE[1,4,5], O. SAHIN[1,2,4];
[1]Biol. Sci., [2]Physics, [3]Pathology and Cell Biol., [4]NeuroTechnology Ctr., [5]Neurosci., Columbia Univ., New York, NY

Abstract: Synapses are mechanically interesting structures. They are enriched with dynamic actin networks and undergo fast twitching. Also, axons are under physiologically critical mechanical tension and a variety of trans-synaptic adhesion proteins tightly connects pre- and post-synaptic terminals. While biochemical, morphological and electrophysiological characteristics of synapses and neurons have been widely investigated, little is known about the mechanical behaviors of synapses and measuring their mechanical properties remains difficult. Here we develop an approach to study the mechanical behaviors of synapses using torsional

harmonic atomic force microscopy (TH-AFM). TH-AFM relies on a T-shaped cantilever and is capable of mapping mechanical properties and topographic features in living neurons with low indentation distance (<30 nm), low force (picoNewton scale) and high speed, suitable for delicate biological samples. We report that active mature synapses are substantially stiffer (up to 20 fold) than other neuronal structures (e.g. somas, dendrites) and the stiffness of synapses falls into a wide range. We combined optical microscopy with TH-AFM to record the morphology and stiffness of synapses in live rat hippocampal neuron cultures. To verify the identity of synapses, we performed post hoc immunofluorescence staining after AFM imaging and found that all stiff synapses are mature excitatory synapses. On the other hand, not all mature excitatory synapses reveal high stiffness under AFM. High magnification fluorescence images indicated that there are two subtypes of synapses: spiny and shaft. We hypothesize that the stiff synapses revealed by AFM are spiny synapses. To elucidate such heterogeneity, we are combining transmission electron microscopy with TH-AFM and aim to acquire the ultrastructure of stiff synapses and compare them with synapses that do not show high stiffness. Additionally, we monitored the activity of synapses with FM dyes, which bind to cell membrane and get internalized after presynaptic terminals release neurotransmitters, generating fluorescent puncta at active synapses. We showed stiff synapses are also active, suggesting stiffness may be related to synaptic activity. The extremely high stiffness could help maintain the unique morphology of synapses in the presence of strong adhesion forces and those mechanical processes may be important in synapse formation and function.

Title: Conductive polymer based silk electrode for cell activity measurement

Authors: *K. TORIMITSU, H. TAKAHASHI, Y. TAKIZAWA, S. WATANABE;
Tohoku Univ., Sendai, Japan

Abstract: Usage of conductive polymer as a biocompatible soft electrode for neural activity measurement is one of our interest. We reported already a poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT-PSS) improved the biocompatibility and the impedance of the electrode. Continuous monitoring of neural stem cell differentiation (from rat embryo striatum), neural cell development and network formation was achieved using this material. Here we report the formation of flexible electrodes using silk fiber for implantable electrode. Polymerization of the fiber with the conductive polymer allowed us for less-destructive and longer measurement. Brain neural activities or muscle activities of mouse and chick were measured with this electrode. Stimulation experiments with this electrode indicated stable contacts during measurements. Flexible characteristics of the electrode would be important for stable measurements. As the conductive polymer modified silk electrode is a flexible and biocompatible method, stable activity monitoring could be achieved for a primary evaluation of physiological cell conditions.

Title: Micro-cautery based on photodeposition of zinc nanoparticle onto an optical fiber to prevent internal hematoma in abdominal and pelvic regions in adult rats

Authors: *C. F. PASTELIN, P. ZACA-MORÁN, G. F. PÉREZ-SÁNCHEZ, F. CHÁVEZ, C. MORÁN;
Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: This study shows an experimental setup of a micro-cautery based on zinc nanoparticles photodeposited onto the core of an optical fiber (Figure 1). This micro-cautery represents an attainable option for the cauterization and coagulation processes that perform blood vessel hemostasis. The interaction between the laser radiation source and the metallic nanoparticles produces a precise micro-heat source, which is controlled by the power source’s

intensity. That source can reach temperatures up to 200 ºC / 392 ºF, which cover a diameter of ~10 µm. The aim of the experiment was the containment of the bleeding in a rat model with 3 to 4 months old coming from the CIIZ-V strain. The results show that the micro-heater obliterates smooth muscle from blood vessels and joins the tissue in approximately 3 seconds. At the same time, the coagulation processes is activated thermically, which makes the containment of hematoma possible. This is the first micrometric cautery based in the performance of nanoparticles.

Title: Engineering a system to monitor home cage feeding behavior in rodents

Authors: ***A. V. KRAVITZ**, K. P. NGUYEN;
NIDDK, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Studies have stressed the role of energy imbalance in the development of obesity, with food intake exceeding energy expenditure. To study mouse models of obesity, researchers need to accurately measure food intake; however, the most common method for monitoring food intake involves manual periodic weighing of food, which is time consuming, imprecise, labor intensive, and cannot measure feeding patterns. Commercial systems exist that can automatically capture high-resolution information about food intake, but can cost thousands of dollars for each cage, making it difficult to run high-throughput feeding experiments. Here, we engineered a feeding system that: (1) is low-cost, (2) is home cage compatible, and (3) can measure both food

intake and feeding patterns over multiple days. The device combines a custom-designed 3D printed housing with a microcontroller and off-the-shelf electronic parts to automatically deliver food tablets and record the frequency of food retrieval - all of this is achieved at a low battery consumption of approximately 0.15µAh. Pellet removal is sensed by a photointerrupter containing an infrared emitter with an opposing detector - when a tablet is sitting in the well, it interrupts the light signal, which then sends a low signal value to the system. The opposite occurs once a tablet is removed; this action then propagates the recording of a timestamp ofed food retrieval retrieval to an SD card and initiates the delivery of a replacement tablet.into the well. Additionally, the design allows for interchangeable parts to accommodate food tablets of differing sizes such as 20 and 45mg. To validate the operation of the device, food retrieval was measured with the activation of agouti-related peptide neurons (AgRP) expressing in the arcuate nucleus (ARC) in mice, which have been implicated in driving food consumption and food-seeking behaviors. Data analyzed showed an overall increase in grams consumed, and more interestingly, demonstrated a marked increase in frequency of eating bouts of irregular patterns during the onset of photostimulation. Collectively, the dispenser offers a reliable method to accurately administer and record food retrieval for running low-cost, high-throughput feeding experiments.

Title: Extending the viability of acute brain slices

Authors: P. B. BREEN[1], J. W. MORLEY[2], J. TAPSON[3], A. VAN SCHAIK[4], *Y. BUSKILA[5]; [1]The MARCS institute, Univ. of Western Sydney, Penrith, Australia; [2]Sch. of Med., Univ. of Western Sydney, Campbelltown, Australia; [3]The MARCS institute, Univ. of Western Sydney, Bankstown, Australia; [4]Univ. of Western Sydney, The MARCS institute, Australia; [5]The MARCS institute, Univ. of Western Sydney, Campbelltown, Australia

Abstract: The lifespan of an acute brain slice is approximately 6-12 hours, limiting potential experimentation time. We have designed a new recovery incubation system capable of extending

their lifespan to more than 36 hours. This system controls the temperature of the incubated artificial cerebral spinal fluid (aCSF) while continuously passing the fluid through a UVC filtration system and simultaneously monitoring temperature and pH. The combination of controlled temperature and UVC filtering maintains bacteria levels in the lag phase and leads to the dramatic extension of the brain slice lifespan. Brain slice viability was validated through electrophysiological recordings as well as live/dead cell assays. This system benefits researchers by monitoring incubation conditions and standardizing this artificial environment. It further provides viable tissue for two experimental days, reducing the time spent preparing brain slices and the number of animals required for research.

Title: Magnetic resonance imaging/diffusion tensor imaging of defunct baroreflex that underpins mortality in a rat model of hepatic encephalopathy

Authors: *C.-Y. TSAI, S. H. H. CHAN;
Ctr. for Translational Res. in Biomed. Sci., Kaohsiung Chang Gung Mem. Hosp., Kaohsiung, Taiwan

Abstract: Hepatic encephalopathy (HE) is a common syndrome observed in patients with liver cirrhosis. In acute HE, it is a clinical emergency associated with 50-90% mortality in patients without liver transplantation. Since baroreflex is responsible for maintaining blood pressure (BP) and heart rate (HR), we reasoned that dysfunction of this regulatory mechanism underlies the high mortality associated with HE. In this study, we tested this hypothesis using a thioacetamide (TAA)-induced acute liver failure model of HE. In Sprague-Dawley rats, injection intraperitoneally of TAA (300, 400 or 500 mg/kg) at 24 h intervals for 3 consecutive days dose-

dependently increased the clinical grade of HE severity, mortality rate, and liver damage. 24-h BP and HR signals recorded by radiotelemetry in conjunction with on-line and real-time spectral analysis showed that HR was essentially maintained and cardiac vagal baroreflex was sustained until the abrupt occurrence of asystole that signifies cardiac death. On the other hand, drastic reduction in BP began to appear on Day 3, and at an accelerated rate on Day 4. More intriguingly, an index for baroreflex-mediated sympathetic vasomotor tone began to decrease on Day 2, and reached zero on Day 4, signifying clinically the occurrence of brain death. Tractographic analysis using magnetic resonance imaging/diffusion tensor imaging of the medulla oblongata revealed that the functional connectivity between the nucleus tractus solitarii (NTS) and nucleus ambiguus (NA), the origin of the vagal innervation of the heart, was sustained until shortly before asystole took place during experimental HE. On the other hand, the connectivity between the NTS and rostral ventrolateral medulla (RVLM), the origin of sympathetic innervation of blood vessels, was progressively disrupted, concurrent with impairment of baroreflex-mediated sympathetic vasomotor tone as detected by radiotelemetry. We conclude that sequential disruption of the connectivity between the NTS and NA and NTS and RVLM that underpins impairment of both arms of baroreflex accounts for the high mortality associated with HE.

Title: Design of a neurovascular unit device using tissue engineering techniques for the study of cerebral microvascular permeability in stroke

Authors: *D. M. SANCHEZ-PALENCIA, M. SAINT-GENIEZ, J. ARBOLEDA-VELASQUEZ;
Schepens Eye Res. Inst., Boston, MA

Abstract: Our objective is to develop an *in vitro*, flow perfused, 3D biologic neurovascular unit (NVU) device, that stimulates the self-organization of vascular and perivascular cells into a sprouting capillary bed connecting with neural components for oxygenation. This model may be useful in the study of cerebrovascular permeability as relevant to stroke. We manufactured a 1 mm inner diameter (ID), 10 mm long, 75 um thick microvascular graft using dehydrated small intestinal submucosa (SIS) as a functional acellular extracellular matrix scaffold. SIS is a material widely used in tissue engineering applications and has been found to promote the *in vivo* regeneration of small and large arteries (4.5-8.0 mm ID). The micrograft was attached to a perfusion loop (3.0 ml/min flow rate, 5.4 dyn/sqcm shear stress) within an airtight chamber, and was cultured for 3 days with human umbilical vessel or retinal endothelial cells (HUVECs, HRECs respectively) seeded on the luminal surface and human or bovine retinal pericytes (HRPs, BRPs respectively) on the abluminal surface. Graft was imaged afterwards using immunofluorescence for lectin and smooth muscle actin (SMA). Monocultures with no perfusion showed that HUVECs, HRECs and HRPs adhered to SIS grafts and migrated inside the scaffold after seeding for 2h (HUVECs and HRPs). When placing the graft on top of confluent HRPs seeded on a culture dish, HRPs detached from the dish and attached to the graft after 6 days. Studies of the extent of cellular coverage and infiltration of the graft with HUVECs and BRPs in coculture and under flow perfusion for 3 days are ongoing. Further studies are forthcoming for assessing the ability of the neovessels to connect with neurospheres located in the vicinity. So far, our NVU device has promising results as a useful tool for modeling the increase of vascular permeability after cessation of flow in stroke.

Title: Evaluation of the N-Methyl-D-Aspartate gated ion channel by an automated electrophysiology instrument designed for fast fluidic exchange

Authors: J. WEBBER, J. TANG, M. KASSINOS, B. ZOU, *P. MIU;
Drug Discovery, Mol. Devices, LLC, Sunnyvale, CA

Abstract: Automated electrophysiology instruments have become indispensable tools in enhancing throughput requirement for compound validation in drug screening. IonFlux is an automated electrophysiology instrument with a state-of-the-art microfluidic system that enables rapid solution exchange. In this study, we explored the capability of IonFlux solution exchange system to measure the N-Methly-D-Aspartate (NMDA) receptor mediated currents. The NMDA gated ion channel is activated by glutamate, the primary excitatory neurotransmitter in the central nervous system (CNS). Functional impairment of the NMDA receptor causes a variety of CNS-related diseases thereby making it a prime therapeutic target for drug discovery. Upon glutamate binding, the agonist-bound NMDA receptor complex transitions from an activated (open) state to a desensitized state, which is characterized by a reduction in ion permeation through the transmembrane ion channel pore. Hence, precise measurement of maximum current flux through an open NMDA ion channel pore depends on the capability of a rapid solution exchange in order to mitigate the role of desensitization. Using HEK293 cells stably expressing NR1-NR2B subtype of the NMDA receptor, we characterized biophysical properties of NMDA ion channel in the presence and absence of extracellular magnesium. We compared data gathered on IonFlux with known NMDA receptor agonists, antagonists and positive allosteric modulators to those reported in literature using conventional patch clamp techniques. Our results showed that potency measurements are comparable to those obtained from conventional patch clamp. In conclusion, the microfluidic design of IonFlux has proven to be as effective as the piezo driven perfusion system, which is typically used in conventional patch clamp recordings for desensitizing ligand-gated ion channels.

Abstract: The blood-brain barrier (BBB) acts as the gatekeeper between the central nervous system and the rest of the body. It is the responsibility of the BBB to facilitate the entry of required nutrients into the brain and exclude potentially harmful compounds; however, this critical and complex structure remains difficult to model *in vitro*. Accurate *in vitro* models are necessary for understanding how the BBB forms and functions and for evaluating drug penetration across the barrier. Many models fail to support all the cell types involved in BBB formation and/or lack the shear forces created by flow needed for mature tight junction formation. To address these issues and establish a more faithful *in vitro* BBB model, we have designed and fabricated a microfluidic neurovascular unit (NVU) that comprises a vascular chamber and a brain chamber separated by a porous membrane that allows cell-cell communication between endothelial cells, astrocytes, and pericytes. The NVU permits independent perfusion of both sides of the membrane and allows for the delivery of high shear flow on the luminal endothelial surface while simultaneously providing low flow to co-cultured cells within the brain chamber. The integrity of the blood-brain-barrier within the NVU has been validated with both FICT-dextran diffusion and transendothelial electrical resistance. The NVU has enabled *in vitro* modeling of the BBB using all human cell types and sampling of effluent from either side of the barrier.

Title: Muscle stimulation for haptic feedback in immersive environments

Authors: ***D. Y. BUCKLEY**[1], Y. CHAI[1], A. SERENA[1], C. PIANCASTELLI[1], Y.-C. CHOU[1], C. BIANCHINI[1], M. MARCHWICKI[1], A. VENDITTI[1], L. FENES[1], J. GRAUBINS[1], G. BOISSELET[1], P. S. BLOOMFIELD[2];
[1]UNIT9 Ltd., London, United Kingdom; [2]Inst. of Clin. Sci., Imperial Col. London, London, United Kingdom

Abstract: Interfaces between users and technology are developing rapidly in the gaming industry. Haptic feedback in controllers and joysticks has provided users with a level of immersion for consoles, however feedback remains an artificial sensation, relatively far removed from the appropriate physiological context. The development of Oculus rift virtual reality (VR) for consumers has created opportunities for more immersive environments. A large disconnect from the VR setup relates to the lack of environmental feedback. Here we present the latest from out Pretender Project (working title), where haptic feedback utilising transcutaneous electrical nerve stimulation (TENS) is being developed to provide sensation and muscle movement control to be applied to a VR environment. Using a TENS Arduino setup with electro-myographic (EMG) style electrodes we demonstrate how utilizing computer programmed muscle group stimulation, we are able to control limb movements with temporal and spatial accuracy. The experimental setup we have developed operates in a safe range of current (0-80 mA), voltage (0-40 V, 500 ohm) and frequency (up to 250 Hz). The current project aim is to develop the technology for muscle movement with full spatial control, however TENS stimulation can be used for sensory feedback as well as control of movement, which is a future advance to be made. The present investigation demonstrates the muscle groups we can functionally manipulate to provide accurate stereotyped movements in this haptic feedback paradigm. While this technology

is currently being developed primarily for haptic feedback and a gaming environment, there is scope for it to be applied to rehabilitative medicine and can be combined with other technology and research platforms for experimental application.

Title: Information content of video tracking and pressure-sensor derived signals for the discrimination of mouse behaviour in health versus disease

Authors: M. CARRENO MUNOZ[1], K. LÓPEZ DE IPIÑA[2], S. PIETROPAOLO[3], A. MOUJAHID[2], A. FRICK[1], *X. LEINEKUGEL[1];
[1]Neurocentre Magendie, INSERM U862, Bordeaux, France; [2]Univ. del País Vasco, San Sebastian, Spain; [3]CNRS, UMR 5287, Talence, France

Abstract: Behavioural phenotyping is a required step to exploit the multitude of transgenic mouse models and potentially useful pharmacological agents made available by academic and industrial pharmaceutical research. It is based on the detection of animal movement. Pressure sensors using the piezoelectric technology can provide extremely detailed and precise information regarding animal movement, that can be a nice complement to video signal to analyze laboratory animal behaviour in a variety of protocols, including freely moving in an open field. One interesting thing about such movement-related signal is that it reflects the summed activity of all the muscles of the animal. Depending on the coordination of these myriads of muscles, their mechanical piezo signature can sum up or cancel each other. This is therefore a very rich but also very complex signal, that can be used to characterize the behavioural phenotype of the animals under study. However, behavioural phenotyping is a very complex issue and the more precise and sensitive tool, the more potential categories to classify behaviours, so that it becomes a very tedious and difficult task. Accordingly, it has been reported recently that trained human operators requested to attribute each second of time to a specific behaviour have major problems classifying up to 44% of individual seconds to any specific behaviour. This has lead our interest towards synthetic parameters such as Permutation Entropy,

which can grasp biological system's complexity in a quantified manner. Permutation Entropy measurement can be performed automatically without human supervision and is cost effective. It has already been used with some success to detect the effects of drugs on rat locomotor behaviour or to detect differences between the behaviour of fishes exposed to pollution. We have tested the use of Permutation Entropy applied to spatial tracking and piezo signal, and report that it could discriminate between wild type and transgenic mice models of pathology affecting behaviour in an open field.

Title: How to visit 0.5% of 15,000 possible posters? Automated poster visit scheduler for SfN

Authors: *D. ACUNA[1], T. ACHAKULVISUT[2], K. KORDING[3];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Biomed. Engin., [3]Northwestern Univ., Chicago, IL

Abstract: SfN is one of the largest scientific conferences in the world, with around 15,000 posters presented over 4 days. Any visitor faces a hard question: which poster should I visit? Here we apply a large-scale matching between visitors and posters that produces an automated scheduler for each of the visitors. Our solution assigns no more than 50 visitors per poster and schedules around 20 posters per day per visitor. The program also considers that visitor should not visit posters of his or her own lab. Importantly, our algorithm only uses the abstracts of the posters being presented, requiring little human intervention. Our work would be better suited for a presentation as **dynamic poster**, where we will display the web-based tool and let fellow scientist try it live. There will be two ways to obtain a schedule. If a visitor is the co-author of a poster, the schedule will be precomputed. Otherwise, the visitor can select posters and the system will suggests a schedule with posters that are similar to those chosen. We built a proof of concept based on SfN 2014's abstracts: http://sfn.scienceofscience.org Being SfN one of the largest conferences in the world, deciding which poster to visit is a time consuming problem that can be readily solved using machine learning. Our future goals are to extend this work to other massive conferences and also specialize it to other neuroscience conferences such as COSYNE 2016.

Title: Multidimensional imaging of brain slices or cell cultures: acquisition and analysis

Authors: ***N. N. KARPUK**, T. KIELIAN;
Pathology & Microbiology, Univ. Nebraska Med., Omaha, NE

Abstract: Brain slice imaging is successfully used in numerous studies. However, changes in cellular integrity and tissue structure during brain slice preparation can augment autofluorescence and non-specific staining. In addition, fluctuations in dye photo-bleaching and fluorescence intensities in living tissues create challenges to obtain reliable imaging data on brain slices using conventional single-spot acquisition methods. This issue is further confounded by difficulties arising when comparing data between different slice preparations. Here we describe an automated method that simplifies image acquisition in multiple locations from one or more brain slices using a programmable 3-dimensional motorized stage (3DMS-285, Sutter Instruments) synchronized with AxioVision software (Zeiss, Germany) through a parallel PC port and tracked in real-time by video monitoring using a low resolution objective (2.5x) and image panorama settings. For image acquisition, we have developed software integrating Visual Basic of AxioVision and a modified demo version for the MP-285 controller (Sutter Instruments). By imaging multiple locations, this design effectively reduces light exposure in any one area that together minimizes dye photo-bleaching, improves statistical values, and improves data reliability.

Title: Test-retest reliability of cortical parcellations in 165 healthy adults for multi-site analyses in the ENIGMA consortium

Authors: *J. FASKOWITZ, D. P. HIBAR, P. M. THOMPSON, N. JAHANSHAD; Imaging Genet. Ctr., Marina Del Rey, CA

Abstract: ENIGMA, and other large neuroimaging consortia, pool results from different imaging studies to maximize power to detect subtle, yet common, effects on brain structure including those from single DNA variants. A challenge of multi-site collaboration is harmonizing imaging measures derived from different MRI scanning protocols. FreeSurfer software is widely used for the automatic parcellation of various cortical regions of interest (ROIs). Given the key role of the human cortex in cognition and disease, discovering factors that shape the cortex is critical. Here, 165 healthy elderly participants from the ADNI dataset (49.1% F; mean age: 74.0 +/- 6.3) were scanned across 45 sites within North America with T1-weighted MRI (3.0 tesla; (1.2 mm)^3 voxel) at two time points 3 months apart. We assessed test-retest reliability within and across 4 releases of FreeSurfer (5.3, 5.1, 5.0, and 4.5) on a Unix HPC-cluster. Each version of the recon-all pipeline was run with only one non-default set of parameters (--proto-iters 1000; --distance 50) to optimize the procedure for 3T scans, as suggested by developers. ENIGMA protocols were used to perform quality control of the outputs to find visual and statistical outliers, and then to obtain measures for 68 ROIs. Test-retest reliability was calculated using the intra-class correlation coefficient (ICC) for each ROI and across numerous versions of FreeSurfer. ICC for ROIs within a version was generally high. ICC specifically for the medial orbito-frontal, temporal pole, and entorhinal region was lower (ICC<0.80), possibly due to common image artifacts in these areas. Between versions, ICC was high, but comparisons to v4.5 were least consistent. This line of research has the potential to aid the neuroimaging community to make informed decisions when assessing the reliability of meta-analyzed results across studies.

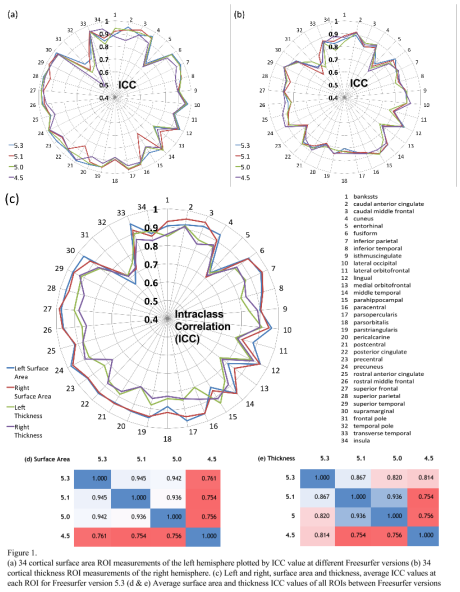

Figure 1.
(a) 34 cortical surface area ROI measurements of the left hemisphere plotted by ICC value at different Freesurfer versions (b) 34 cortical thickness ROI measurements of the right hemisphere. (c) Left and right, surface area and thickness, average ICC values at each ROI for Freesurfer version 5.3 (d & e) Average surface area and thickness ICC values of all ROIs between Freesurfer versions

Title: A MATLAB toolbox to tame the torrent: efficient video processing routines for wide-field Ca^{2+} fluorescence imaging in awake behaving animals

Authors: ***M. BUCKLIN**[1], H.-A. TSENG[2], A. I. A. MOHAMMED[2], X. HAN[2];
[1]Biomed. Engin., Boston Univ., Chelsea, MA; [2]Boston Univ., Boston, MA

Abstract: The latest generation of genetically encoded calcium sensors deliver a substantial boost in signal strength. This - combined with equally critical advances in the semiconductor

technology available in scientific cameras - enables high-throughput detection of neural activity in behaving animals using traditional wide-field fluorescence microscopy1. We are now able to record continuous activity of greater than one thousand neurons in a behaving mouse for hours at a time over several weeks. This breakthrough in signal strength is manifested by a considerable increase in the spatial and temporal resolution we may use to detect and record neural activity, which will undoubtedly strengthen our competence to conduct brain research. However, the tremendous concomitant increase in data flow forces new challenges in downstream image processing and data analysis, and prompts a reexamination of traditional routines used to process data in neuroscience. We developed an open-source MATLAB toolbox for efficiently analyzing and visualizing large imaging data sets. The toolbox is capable of interactive or fully automated use. The widespread usage of MATLAB in neuroscience communities lends potential for greater usability and easier adaptation to software developed in this environment. While easier development has traditionally presumed crippling sacrifices to computational performance, we've constructed an assembly of efficient routines - exploiting updated toolboxes for multi-core and GPU parallel computing among other advancements - that enables processing and distillation of massive experimental stores of data into rich yet usable form in a practical timely manner. This software package makes provides a library of image pre-processing routines such as for motion-correction and contrast enhancement, optimized for batch-processing of dynamic fluorescence video, and additionally automates a fast unsupervised ROI detection routine, a necessary feature for imaging data-sets where the numbers of identifiable single cells reach into the thousands. This is achieved through various spatial morphological enhancements mixed with probabilistic functions that consider the local spatial and temporal characteristics from an image sequence to generate, correlate, combine and refine distinguishable regions of cellular activity.

Title: Automated control of associative learning and spatial decision making in freely swimming zebrafish, danio rerio

Authors: *B. SINGH[1], L. ZU[3], J. SUMMERS[1], J. GIORDANO[1], E. GLASGOW[2], J. S. KANWAL[1];
[1]Dept. of Neurol., [2]Dept. of Tumor Biol., Georgetown Univ. Med. Ctr., Washington, DC; [3]Univ. degli Studi di Roma 'La Sapienza', Roma, Italy

Abstract: Associative conditioning is an important neural mechanism that allows animals to adapt their behavior to environmental demands. Current methods used for associative conditioning often involve human intervention, which is labor-intensive, stressful to animals, and can introduce noise in the data. We have developed a relatively simple yet flexible paradigm for training zebrafish, Danio rerio, and possibly other experimental animals, that requires minimal human intervention. Our methodology combines stimulus presentation through LED's and/or an underwater output transducer with video tracking of fish (e.g. using iDTracker, Pérez-Escudero et. al., 2014). Food reward is delivered through a microprocessor (Arduino) controlling a small robotic arm and feeder via stepper motors. This allows full automation of reward-based place preference conditioning of adult zebrafish to visual and auditory stimuli. "Ardulink", a JAVA facility, allows simultaneous implementation of communication protocols with Arduino via a user-friendly interface (Version 0.4.2; Zu, 2013). Our software's user-definable settings enable either classical or operant conditioning via customized multi-day scheduling of training parameters, as well as precise control of the timing, location and intensity of stimulus presentation. During operant conditioning, zebrafish trigger motion sensors to obtain a small reward. The standardized training and tracking procedure facilitates comparison of results across multiple training runs within a multi-day trial. We have been successful in training zebrafish to discriminate between visual cues (different colored LEDs) over a 3-day session with 6 training runs per day. Discrimination of auditory cues can take 4 or more days. Our method provides a quick and efficient way to exhaustively test sensory capabilities of freely swimming zebrafish and to screen drugs as well as test effects of CRISPR-based and optogenetic modification of neural circuits on learning and memory under naturalistic conditions.

Title: Optimization of *ex vivo* high-resolution mouse diffusion tractography at the gray/white matter border

Deleted: *ex vivo*

Authors: P. KABARIA[1,3], *G. DAI[4], E. TAKAHASHI[2];
[1]Div. of Newborn Medicine, Dept. of Med., [2]Boston Children's Hosp., Boston, MA; [3]Dept. of Behavioral Neurosci., Northeastern Univ., Boston, MA; [4]Radiology, Martinos Center/Mgh, Charlestown, MA

Abstract: One commonly used method for creating three dimensional brain fiber trajectories is diffusion tractography. A major challenge with using this method is to identify accurate, continuous fiber pathways through the gray/white matter where axons turn in close to 90 degrees. This study seeks to determine optimal sets fiber reconstruction parameters in order to increase the accuracy of diffusion tractography. The sets of parameters examined consist of combinations of six algorithms (DTI-FACT, DTI-2nd-order Runge Kutta, DTI- Interpolated Streamline, DTI-Tensorline, HARDI-FACT, HARDI-2nd-order Runge Kutta), nine weight masks options (No Weight Mask, 1.25, 1.50, 1.75, 2.00, 2.25, 2.50, 2.75, 3.00), and seven angle thresholds (20, 30, 40, 50, 60, 70, 80 degrees). These parameters were examined over ten adult mice with two different pathways: motor and callosal. The accuracy of the images with each set of parameters was compared to the "gold standard" set by tracer studies in the Allen's Brain Atlas for the motor pathway, and to the well-known description of corpus callosum tracts for the callosal pathway. Each set of parameters were scored using a scoring method that took into account the amount of accurate tracts and the amount of spurious tracts. An average score was determined for each set of parameters for each pathway, resulting in a compilation of average scores for every combination of algorithm, weight mask, and angle threshold for each pathway. For the motor pathway, DTI-FACT and DTI-Interpolated Streamline have the overall highest average scores compared to the other algorithms (scores of 1.74 and 1.69, respectively) for all of the weight mask variables. Weight Mask 2.50 has the overall highest average scores for four of the six algorithms, more than the other weight masks. The angle threshold of 20 degrees has the highest average scores for three of the six algorithms, more than the other two angle thresholds. For the callosal pathway, DTI-FACT and DTI-2nd-order Runge Kutta have the overall highest average score (2.9 for both), for all of the weight mask variables. Weight mask 3.0 has the overall highest average scores for three of the six algorithms, more than the other weight masks. The angle threshold of 20 degrees has the highest average scores for four of the six algorithms, more than the other two angle thresholds. From these findings, the optimal sets of parameters are combinations of DTI-FACT, DTI-Interpolated Streamline, or DTI-2nd-order Runge Kutta, with weight masks of 2.50 or larger, and angle thresholds of 50 degrees or smaller. It can be

concluded that using sets of parameters involving these range of variables will result in more accurate images.

Title: Spyking circus: a new software for fast, scalable spike sorting of large-scale extracellular recordings

Authors: ***P. YGER**[1], O. MARRE[2];
[1]Inst. De La Vision, Paris, France; [2]Inst. de la Vision, Paris, France

Abstract: Understanding how assemblies of neurons encode information requires to record large populations of cells in the brain. In recent years, large multi-electrode arrays and silicon probes have been developed to record simultaneously from hundreds of electrodes packed with high density. However, these new devices challenge the classical way to do spike sorting in several ways. First, the large number of electrodes preclude approaches based on manual clustering, and even automatic approaches need to be fast enough to handle the growing amount of extracellular data. Second, the density of the electrodes is now high enough so that a single spike is often detected on many electrodes, so that the different channels must be processed simultaneously. Third, within those large and dense array of electrodes, overlapping spikes are becoming the rule rather than the exception, perturbing the classical clustering methods that cannot easily capture the synchronous occurrences of spikes from different cells. Here we developed a new software solving these issues and allowing fast and scalable spike sorting of large-scale recordings. To do so, we developed a highly automated algorithm composed of two main steps: 1) a "template-finding" phase to extract putative cell's templates, i.e. patterns of activity evoked over many electrodes when neurons fire an action potential; 2) a "fitting" phase where the templates are matched onto the raw data to resolve the location of the spikes. For the template-finding phase, performed only once on a subset of the data, we start by detecting all the possible times in the raw data that could contain a spike. Spikes are then clustered into groups using state of the art density-based clustering [1]. We then extract the template corresponding to each group, and in

the fitting phase, we match those templates onto the raw data with a matching-pursuit method allowing amplitude variation for each template, inspired from [2]. The algorithm is written in Python and is entirely parallelized on CPU and GPU to handle large amount of data, almost in real-time. Moreover, a graphical user interface is provided to check the output of the algorithm and refine the results of the sorting. We are currently testing our algorithm with large-scale data from *in vitro* and *in vivo* recordings, estimating its performance on data with "ground truth", i.e. cases where the solution to the sorting problem is at least partially known. Title: Spatial features of reliably constructed structural brain networks

Authors: M. Y. MAHAN[1], *A. P. GEORGOPOULOS[2];
[1]BICB, [2]Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: Structural connectivity analyses rely on various methods to build graphs representing the anatomical brain. Reliable construction of these graphs is central to identifying valid network assessments across different study populations. Typically, reproducibility studies rely on multiple subject sessions and compare network measures across these sessions to categorize the validity of network metrics. However, many existing datasets contain only one session for each subject. Therefore, a fresh approach to constructing graphs with reliable network metrics requiring one session per subject would be valuable. For that purpose, we present a permutation-based approach to identify which structural graphs are reliable. Using the reliable graph, we apply novel spatial graph algorithms for discovering structural network patterns with age. To construct structural graphs, sMRI and DTI data were collected from 65 cognitively health women (32-74 years old). Four node definitions were used: (1) automated anatomical labeling (AAL), random construction with the number of nodes (2) ≅ AAL, (3) > AAL, and (4) < AAL. Then, for each node definition, two edge definitions were used: streamline and probabilistic white matter tractography. For each node-edge construction method, both thresholded binary

matrices and nonthresholded weighted matrices were used. With each graph-construction type, 100 random permutations of the data were performed and graphs were constructed, resulting in 101 matrices for each graph-construction type. Characteristic network metrics were calculated for all graphs. To determine which graph-construction types are reliable, distances between subject and permuted matrices for each graph-construction type were calculated. The distances were evaluated for each graph-construction type, whereby longer distances indicate higher reliability. Based on these results, the most reliable graph-construction type was retained for further analysis. The final analysis focused on constructing an inclusive structural network. To accomplish this, additional metrics were added on the nodes, namely, three labels: gray matter thickness, volume, and surface area. For this cohesive structural graph, novel and characteristic spatial graph metrics were calculated from each brain area, lobe, hemisphere, and whole brain, resulting in a structural network assessment for each subject. The effect of age was measured by performing a multivariate regression. Through an iterative, stepwise procedure those metrics that varied systematically with age were retained and used to construct an overall assessment of how structural network patterns changing with age.

Title: A probabilistic latent factor approach for multi-subject fMRI data modeling

Authors: ***P.-H. CHEN**, P. J. RAMADGE;
Princeton Univ., Princeton, NJ

Abstract: A critical aspect of multi-subject fMRI analysis is the aggregation of data across multiple subjects, each of whom has a distinct functional topography. Recently, considerable progress has been made on this problem using both anatomically local functional alignment [Sabuncu 2009, Conroy 2009, Conroy 2013], and subject specific rotations of the data within anatomically selected regions of interest [Haxby 2011, Lorbert 2012]. We examine a factor analysis model for determining a small set of features that are shared within a local anatomical region of interest (ROI), or searchlight, across a group of subjects. If this ROI contains n voxels,

We seek to reduce the dimensionality of the fMRI data in this ROI from n time series per subject, to k brain maps (each containing n voxels), for each subject, and a shared set of k time series. We study a generative model to accomplish the stated across-subject factor analysis. We then formulate a probabilistic extension of this generative model. This leads to a constrained expectation-maximization (EM) algorithm for associated maximum likelihood estimation. Compared with previous approaches, e.g., [Haxby 2011], our formulation has the benefit of improved regularization of the estimate of the shared elicited response across subjects and better generalization to new data. More generally, a probabilistic formulation forms the basis for Bayesian treatments, enabling the natural incorporation of neuroscience domain knowledge into alignment modeling. Since it is a latent variable model, it can also be used as a building block for more complex models. We assess the effectiveness of the proposed method using fMRI datasets with distinct characteristics, and a various anatomical ROIs varying from ventral temporal cortex to the posterior medial cortex. In a first experiment, we use one half of the fMRI response to a movie viewing to learn the shared factors. Then using a held out subject, we pick a segment from the unused half of the movie data, and attempt to locate the matching segment using other subjects data with one-nearest neighbor classification based on the correlations between response segments. In a second experiment, we use movie viewing fMRI responses to learn the shared factor representation. Then for a held out subject, we conduct stimulus prediction on image viewing responses with support vector machine classifier with other subjects data as training set. In these experiments, we observe 5% to 18% average improvement in generalization accuracy over related methods including anatomical and functional alignment as well as several factor models.

Title: Multi-echo fMRI enhances reliability of brain-wide BOLD responses to a naturalistic movie

Authors: D. C. JANGRAW[1], D. A. HANDWERKER[1], J. GONZALEZ-CASTILLO[1], B. GUTIERREZ[1], V. ROOPCHANSINGH[2], *P. BANDETTINI[1,2];
[1]Lab. of Brain & Cog/Sect Function Imag, [2]Functional MRI Facility, NIMH-NIH, Bethesda, MD

Abstract: As fMRI researchers increasingly tackle naturalistic, complex experimental paradigms, response reliability is often used in place of response amplitudes as a metric of each voxel's responsiveness to a stimulus. A voxel's response from one run is used as a model for the same voxel's response in the other runs, a process that is repeated for each possible pairing of runs. Voxels with "reliable" responses are those that consistently show positive correlations across pairings (Hasson et al., 2004, *Science*). This approach is especially useful in cases where the mapping from stimulus to response is not well characterized, such as the free viewing of a naturalistic movie. Such studies have revealed many areas of consistent activation in both across-subject and within-subject groupings, inspiring more researchers to adopt the approach. But the relatively unconstrained nature of these paradigms translates to a low contrast-to-noise ratio, so response reliability measures have much to gain from de-noising techniques. To this end, we apply multi-echo independent component analysis (MEICA), a recently developed technique that has shown great promise in resting-state and task-based analyses, to data from the free viewing of a naturalistic movie. The MEICA technique uses a pulse sequence that collects signals from three echoes per TR, and then uses the variation of signals across echoes to distinguish BOLD-like signals from non-BOLD-like noise (Kundu et al., 2012, *NeuroImage*). In the current study, two subjects watched a 7-minute cartoon movie 16 and 17 times respectively across multiple days. We then analyzed the intra-subject correlations (intra-SC) of voxels across runs. The response reliability was assessed in this way both with and without MEICA de-noising. The MEICA results demonstrate that the movie evokes reliable brain-wide activation that is much more extensive than standard data collection and processing methods might suggest. When MEICA was used instead of standard single-echo processing, the number of voxels showing significant activation (FDR corrected $q<0.05$) increased from 21% to 47% in subject 1 and from 22% to 34% in subject 2. The voxels whose response reliability was revealed by MEICA but not by single-echo processing are significantly more likely to be in gray matter than in-brain voxels chosen at random (one-tailed binomial test, $p<1e-15$), suggesting that they are driven by neural activity. Preliminary analyses indicate that some of these areas are driven by high-level properties of the movie such as the presence of faces, emotional content, and motion.

Title: Probabilistic maps identify spatially variable features of large-scale resting-state functional connectivity brain systems

Authors: ***E. M. GORDON**[1], T. O. LAUMANN[1], B. ADEYEMO[1], S. E. PETERSEN[2]; [1]Neurol., [2]Neurology, Psychology, Radiology, and Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The human cortex is organized into large-scale, spatially distributed systems that can be described *in vivo* using a functional magnetic resonance imaging (fMRI)-based technique known as resting state functional connectivity (RSFC). The topologies of these systems have been described in group average data (Power et al., 2011). However, our recent work in single subjects suggests that individuals' brain systems may have complex topological features that cannot be observed in group average data (Laumann et al., under review). This effect is likely because cross-subject averaging blurs small, spatially variable system features. Here, we use a novel approach to identify individual-level system features that show some consistency across a group of 120 healthy adults. We applied a template matching procedure to delineate brain systems in each individual. We then matched the discrete, discontiguous patches of these systems between each pair of subjects based on the geodesic distance along the cortical surface between two patches. Finally, we applied a community detection procedure (Infomap) to identify sets of system patches likely to represent the same cortical object across subjects. These sets were visualized as probabilistic maps of matched system patches. We observed that all system patches present in the group average systems were also present in more than 95% of subjects, and that the probabilistic maps of these patches tended to have very dense spatial distributions, with little variability in their location on the cortical surface. Notably, we also observed a number (~60) of system patches that were not observed in the group average systems. These patches were identified across many subjects (30% - 95%), but were relatively small (<250mm2 median size across subjects). They also tended to have diffuse spatial distributions, indicating a large amount of spatial variability. Despite their small size and variable position, many of these

Deleted: in vivo

patches 1) were homotopically paired across cortical hemispheres; 2) replicated in a separate dataset of 108 healthy adults acquired on a different scanner; and 3) replicated using a different set of template systems. These findings increase confidence that the patches described here represent "true" system features in individuals' brains. The identification of many small, spatially-variable features of large-scale brain systems suggests that the systems-level organization of the human brain is more complex than may have been previously appreciated. Further, the spatial variability of features described here may confound studies that assume equivalent brain systems are present across individuals in a cortical region.

Title: Biomarkers of Neurodevelopmental disorders in Early Childhood: pilot study using functional near infrared spectroscopy

Authors: *A. A. ANDERSON[1], E. SMITH[2], V. CHERNOMORDIK[1], N. KARAMZADEH[1], F. CHOWDHRY[1], A. THURM[2], A. GANDJBAKHCHE[1];

Abstract: To understand the development of brain function there is a crucial need to quantitatively assess brain activation in early childhood, specifically for early intervention of neurodevelopmental disorders. The current brain imaging modalities (such as fMRI or PET), however, make it challenging to study the brain function at a young age, mostly due to patient movement or invasive nature of the study. Functional near infrared spectroscopy (fNIRS) is an emerging non-invasive brain imaging technology that is affordable, compact, and less susceptible to patient movement. Therefore, it becomes suitable for imaging the cortical activation in young cohorts. In this study, we used an fNIRS to assess functional biomarkers, oxy- and deoxy-hemoglobin, based on activation in prefrontal cortex (PFC) using specific tasks. We conducted two studies to compare the functional development of the brain: 1) in typical children from ages of 4-8 performing a Go/No-Go task and 2) in a group of 3-year-old typical and language delay (LD) toddlers watching a video. We introduced a novel parameter, Oxygenation Variability Index (OV index), directly obtained from fNIRS data. This index

measures the changes in oxygen saturation in PFC in frequencies related to cerebral autoregulation (<0.1 Hz). In a group of seventeen typical children, our results indicate that the OV index increased significantly with age between 4 and 6 years and decreased afterward, reaching a plateau. In 3-year-old toddlers, we noticed a significant difference in OV Index between LD (N=4) and typical toddlers (N=5), with the latter showing a higher level of OV Index in left PFC. Moreover, compared to the typical group, LD toddlers exhibited significant unilateral activation in PFC. These findings for the first time provide preliminary evidence to describe the relationship between the OV index and age in children, and differentiate the brain function at the early stage of neurodevelopmental disorders using fNIRS methodology.

Title: Structure and function of the sources of thalami-cortical dysrhythmia in human, revealed by magnetic encephalography

Authors: ***R. R. LLINAS**[1], M. N. USTININ[1,2], S. RYKUNOV[3], A. I. BOYKO[2], K. D. WALTON[1], G. RABELLO[1];
[1]Physiol. and Neurosci., New York Univ. Sch. Med., New York, NY; [2]Russian Acad. of Sci., Inst. of Mathematical Problems of Biol., Pushchino, Moscow Region, Russian Federation; [3]Russian Acad. of Sci., Inst. of Mathematical Problems of Biol., Pushichino, Moscow Region, Russian Federation

Abstract: Magnetoencephalographic (MEG) results from patients suffering from thalamo-cortical dysrhythmia syndrome were studied using a novel data analysis methodology. Spontaneous brain activity data sets from xx patients were obtained using a 275-channel gradiometer VSM Medtech, at the Center for Neuromagnetism at Bellevue Hospital in of New York University School of Medicine. The NYU Institutional Review Board and Bellevue Hospital Research Protocol Review Group approved the study and an informed written consent was obtained from all subjects prior to the recording event. Detailed multichannel Fourier

spectrum was calculated from activity collected during 240 sec recording time sets, resulting in high frequency resolution (0.0024 Hz). Patients with thalamocortical dysrhythmia, are characterized by their abnormally high amplitude at Theta-band frequency. Such activity, observed in all patients, was then selected for computational further analysis. These multichannel spectrum recordings, were then decomposed to sets of functionally invariant entities, each one characterized by distinct frequency, amplitude and phase. Frequency-pattern analysis of these recording sets made it possible to find the spatial distribution of the MEG energy sources, and to estimate the activity dominant direction for each point in space. The next step of analysis included the generation of individual magneto-resonance images which made it possible to extract partial spectrum relating to thalamic spontaneous activity. The characteristic time series of this activity were then reconstructed from partial spectrum. The excellent localization results obtained, in fact, better than two cubic millimeters, allow us to conclude, that magnetic encephalography, combined with the novel methodology concerning precise frequency-pattern analysis, effectively reveals localization of the spontaneous activity of the deep brain sources. This novel method, allowing the reconstruction, via cooperative analysis, of time series from distinct brain localities, will provide new clues concerning both normal and abnormal human brain function.

Title: Using multi-echo fMRI to increase task-based contrast-to-noise and response stability

Authors: *B. GUTIERREZ[1], D. HANDWERKER[2], J. GONZALEZ-CASTILLO[2], V. ROOPCHANSINGH[3], L. BUCHANAN[2], P. BANDETTINI[3,2];
[2]Section on Functional Imaging Methods, [3]Functional MRI Facility, [1]NIH/NIMH, Bethesda, MD

Abstract: Multi-echo fMRI denoising is based on the idea that the magnitude of a BOLD-weighted signal will increase with echo time (Posse 1999). Multi-echo independent component analysis (ME-ICA) takes advantage of this by looking to see if a signal's strength increases across echoes implying a BOLD-like character. ME-ICA splits the data into ICA components, removes the components unlikely to represent BOLD fluctuations, and then reconstructs a

denoised time series with the remaining components (Kundu 2012,2013). ME-ICA has been shown to effectively remove artifacts in resting-state fMRI, improving connectivity maps (Kundu 2013, Evans 2015). Here, we show how multi-echo processing techniques affect the results and stability of a single run block design task. Using the same task as Gonzalez-Castillo et al. 2012, we collected 103 and 104 5:28 minute block design runs for two subjects respectively across 9 days each. Statistical results were calculated on the middle echo (Echo2) time series (TE=29.7ms), an Optimally combined (a TE weighted average of the 3 echoes) time series, and a ME-ICA Denoised time series. Using two anatomically defined regions of interest, the Calcarine Sulcus (CS) and the Lateral Genticulate Nucleus (LGN), we investigate stability, reliability, and signal quality across runs in our single-echo and multi-echo time series. We fit a General Linear model (GLM) using a finite impulse response model to each run in each processing method. This allowed us to look at the hemodynamic response function (HRF) variability and calculate the contrast-to-noise ratio (CNR: magnitude of HRF/stdev of residual). For a single run in the CS, we observe a 0-20% increase in CNR from Echo2 to Optimally Combined and a 0-40% CNR increase from Echo2 to ME-ICA Denoised respectively. We also see CNR improvement from Optimally Combined to ME-ICA Denoised on average. In the LGN, a region showing significance in approximately 50% of runs (FDR corrected $q < 0.05$) and lower CNR in general, we see that over half of the time we get increases in CNR from Echo2 to Optimally Combined and from Echo2 to ME-ICA Denoised, but no visible improvement from Optimally Combined to ME-ICA Denoised. These results suggest reliable improvements in the CNR of single runs by using Multi-echo imaging and processing techniques. The variability in the amount of improvement across runs points to the potential to improve the multi-echo denoising algorithm to increase the consistency of the improvements.

Abstract: In previous work, we developed a model called Hierarchical Topographic Factor Analysis (HTFA) for efficiently discovering, representing, and computing with full-brain functional connectivity patterns in large multi-subject fMRI datasets. HTFA works by representing full-brain functional connectivity patterns using a set of spherical network "hubs" placed throughout the brain. Given an fMRI dataset, we can use Bayesian inference to compute the most probable number of hubs, the hub locations and sizes, and their activations over time (which are in turn used to infer hub-to-hub connectivity patterns). The result is a highly compact (low dimensional) representation of the full-brain connectivity matrix that is more efficient to compute with than voxel-by-voxel connectivity matrices. Here we present a series of analyses aimed at comparing the connectivity patterns derived using HTFA with those derived using other more commonly used approaches for studying connectivity in fMRI data (such as voxel-by-voxel functional connectivity analyses). We also describe steps that we have taken to maximize the computational efficiency of the hub-fitting algorithm.

Abstract: We present a novel feature extraction technique, Relative Brain Signature (RBS) that enables signifying differences between a finite numbers of populations. To evaluate our technique, we have used a set the EEG dataset of the "UCI Machine Learning Repository" of 77 alcoholics and 43 control subjects. For every subject, one RBS vector with respect to alcoholic and control populations were computed. An RBS vector denotes the relationship of a subject to one of the control or alcoholic populations. We employ the extracted RBS vectors to identify functional biomarkers over the cortical area of the alcoholics that had manifested distinct functional behavior in comparison to the control subjects. Moreover, we have evaluated the efficacy of the RBS vectors in correctly categorizing the subjects with respect to their original populations. To achieve this goal, a machine-learning algorithm to classify the subjects was employed. Subjects were correctly classified into alcoholic and nonalcoholic populations with accuracy up to 85%.

Title: ParceNIP: parcellating neural images using PICo, a graded approach

Authors: ***C. J. BAJADA**, M. A. LAMBON RALPH, G. J. M. PARKER, H. A. HAROON, H. AZADBAKHT, L. L. CLOUTMAN;
The Univ. of Manchester, Manchester, United Kingdom

Abstract: In recent years, diffusion tractography has presented itself as a unique neuroimaging approach that allows large-scale *in vivo* parcellations of the cortex based on patterns of white

Deleted: in vivo

matter connectivity. While many approaches have been used to delineate distinct cortical regions, to date all parcellation schemes have focused on identifying discrete areas within the cortex that can be differentiated into hard clusters with clearly defined boundaries. However, there is evidence that this may not reflect the true underlying nature of the cortex, which instead may be better represented by a more graded approach with zones of transition instead of solid boundaries. We present a tractographic parcellation approach which allows for both graded and hard parcellations of the cortex. As an example of the approach we present a graded parcellation of the temporal lobe. A dataset containing diffusion weighted MR images from 24 healthy participants was used. Probabilistic tractography was performed from every voxel within the temporal lobe along the interface between the grey matter and white matter. From the output, a connectivity-based similarity matrix was obtained using the cosine similarity metric. A spectral reordering algorithm was then run on the laplacian of the similarity matrix, which reordered the voxels such that voxels with strong similarity were positioned close together within the matrix. Points that lie close together in the matrix were given similar intensities and back projected into brain space to generate a cortical similarity profile that automatically identifies the major axis of connective similarity across the cortex. The temporal parcellations produced were highly consistent across participants. They revealed a dorso-ventral and medio-lateral gradient consistent with current theories regarding the functional architecture of the temporal lobe. The dorso-ventral split potentially underlies the phonological and semantic divide in the temporal language network while the ventro-medial axis may underpin the memory and language divide in the temporal lobe.

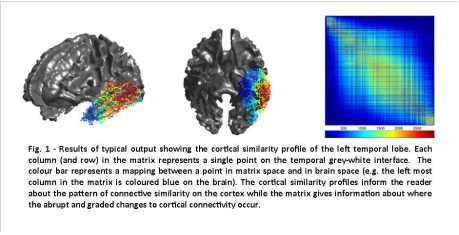

Fig. 1 - Results of typical output showing the cortical similarity profile of the left temporal lobe. Each column (and row) in the matrix represents a single point on the temporal grey-white interface. The colour bar represents a mapping between a point in matrix space and in brain space (e.g. the left most column in the matrix is coloured blue on the brain). The cortical similarity profiles inform the reader about the pattern of connective similarity on the cortex while the matrix gives information about where the abrupt and graded changes to cortical connectivity occur.

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by social deficits, communication impairments and restrictive, repetitive behaviors. Converging lines of evidence support the view that ASD is not a focal but a distributed disorder, in which abnormalities in the coordination of functional activity across large-scale networks give rise to core features and associated cognitive differences. Default-mode network (DMN) is the set of brain regions that are active during wakeful rest and are de-activated during attention demanding tasks, and is implicated in self-referential processing. It has been suggested that abnormalities in the DMN play a critical role in ASD. Whereas some studies that investigate the perturbations of brain activity during rest show increased DMN connectivity in ASD, others report a decrease. These studies have been hampered by several limitations such as failure to account for motion and small sample size as well as methodological issues; e.g. independent component analysis provides spatially independent networks and fails to fully characterize the complex spatiotemporal structure of brain function. The goal of the present work is to investigate the spatial and temporal alterations of the DMN in ASD. For that purpose, we utilized the innovation-driven coactivation patterns (iCAPs) method that can capture spatially and temporally overlapping networks. Resting state functional MRI was acquired from 51 ASD (ages 8-21 yrs) and 36 typically-developing (TD) participants (ages 8-25 yrs). In order to ensure data quality, the samples were matched for age, sex and motion; i.e., participants with head motion >1.5 SD above the sample mean were excluded (18 ASD, 3 TD). We identified the group specific iCAPs, and compared spatial alterations. The results were corrected for multiple comparisons using

Monte-Carlo simulations ($p<.05$). In the combined groups, we found three variations of DMN based on the involvement of the posterior cingulate, precuneus, and angular gyrus but with spatial variations in frontotemporal regions. The ASD group had greater activity in dorsal anterior cingulate and ventromedial prefrontal cortex and decreased activity in the right middle frontal gyrus relative to the TD group. These results provide evidence of altered coordination of activation in DMN in ASD using a well-matched sample. Future plans include investigating whether these differences are clinically relevant. Specifically, we will explore how the spatial and temporal variations of DMN activation relate to the severity of core features and cognitive dysfunction in ASD using neuropsychological measures and clinical ratings.

Title: Detecting activation patterns from functional MRI datasets with undetermined event onsets using support vector machines

Authors: *E. BAGARINAO, S. MAESAWA, H. WATANABE, H. ISODA;
Brain and Mind Res. Center, Nagoya Univ., Nagoya City, Aichi, Japan

Abstract: Task-based functional MRI (fMRI) studies often rely on a priori knowledge of event onsets to identify activation patterns associated with the tasks. Detecting activation patterns in imaging studies where event onsets are unknown is very challenging. In this work, we proposed a method to detect activation patterns from fMRI datasets, even if event onsets are unknown, using support vector machines (SVMs). Neuroimaging datasets from 8 healthy volunteers (6 males/2 females, mean age = 21.62 years old) participating in a real-time fMRI study were used in the simulations. The data include a functional localizer scan, three feedback scans, and a test scan. All scans were designed in a block manner with alternating rest (30s) and task (30s) blocks. The tasks consisted of imagined finger tapping, word generation, and serial subtraction tasks. For this study, we used the datasets from the localizer scans to train SVMs to identify images belonging to each of the three tasks. The trained SVMs were then used to classify images from

the feedback and test scans. For each scan, a prediction time series for each task was obtained by assigning a value of 1 if the SVM predicted the task and 0 otherwise. Activation patterns associated with the tasks were generated by convolving the prediction series with the hemodynamic response function and using the convolved series as regressors in a general linear model analysis. The resulting activation maps were then compared to the one obtained using the actual onsets of the task blocks. We computed the spatial correlation between the two maps to quantify their similarity. Classification accuracies of the trained SVMs for the three tasks were about 91% on average. Correlation values of the generated maps were as high as 0.94, although cases with low correlation were also observed. On average, we got correlation values equal to 0.658 for imagined finger tapping task, 0.661 for word generation task, and 0.807 for serial subtraction task. These high correlation values implied that the obtained activation maps using SVM-derived prediction series closely resembled that obtained using actual onset timings. The primary advantage of the former is that it does not require knowing a priori the timing of the task onsets. Instead, it relied on the trained SVM to generate the needed regressors in constructing the corresponding activation maps. This is important as it would enable experiments where participants can freely switch from one task to the other and still be able to obtain the relevant activation maps. In particular, real-time fMRI studies in which the participant's real-time performance dictates the task to perform could benefit from this added flexibility.

Title: Time series analysis of pupillometric data

Authors: ***A. ZENON**;
Inst. of Neurosci., Brussels, Belgium

Abstract: In addition to its response to light variation, the pupil diameter is also influenced by cognitive factors, such as cognitive workload, surprise or the exploration/exploitation trade-off and it is viewed as a proxy for noradrenaline release from the Locus Coeruleus. From a methodological point of view, a common issue with the analysis of the pupil size data is the

slowness of the pupil diameter variation, which prevents analyzing the pupil response related to fast-paced events. In a previous work addressing these issues, Hoeks and Levelt (1993) have proposed the use of a deconvolution technique to analyze the pupil size data. However, this method does not take into account the strong low-frequency spontaneous changes in pupil size or of the high between-subject variability in the shape of the impulse response and in the delay between the event onset and the beginning of the response. Here we propose to use a system identification framework to optimize the analysis of pupillometric data. We first modeled the spontaneous changes in pupil diameter with an autoregressive moving average model (ARMA) and showed that using the residual from this model, or innovation error, uncovered subtle information from the data which was not accessible with standard techniques. We also modeled the responses to visual and auditory stimuli by means of exogenous inputs (ARMAX), allowing us to make inferences directly from the estimated parameters of the model. This approach was tested on a series of datasets involving different tasks. In conclusion, this new framework for the analysis of pupil size data improves significantly the sensitivity of the measure for subtle and/or fast-paced events.

Title: Cognitive function-based whole-brain parcellation using functional connectivity from voxels to regions labeled with cognitive terminology

Authors: *H. KURASHIGE[1,2], Y. YAMASHITA[3], R. OSU[4], Y. OTAKA[2,5], T. HANAKAWA[3], M. HONDA[3], T. HISATSUNE[1], H. KAWABATA[5];

Abstract: The brain is a complex system consisting of components with functional diversity. Our highly developed adaptability and creativity emerge from the combinations of such diverse functions. To understand the whole-brain information processing, therefore, we must resolve the brain into functional parts, know the computational characters of them, integrate the knowledge and construct the views for the whole brain as an integrated system. Whole-brain parcellation where the brain is decomposed into the interpretable components is important first step. While the parcellations based on structural and cytoarchitectural properties roughly correspond to functional segmentation of the brain, close investigation of brain functions has revealed the insufficiency and incorrectness of such anatomical parcellations. Recently, several researchers propose the ways to decompose the brain on the basis of the activity and connectivity. But the resultant parcels are often difficult to interpret. Here, we propose the novel way of whole-brain parcellation whose parcels are intrinsically labeled by the functionalities. First, using neuroimaging database Neurosynth, we assessed pseudo-activation maps for 109 cognitive functions (e.g., working memory and object recognition). From each map, mask for region of interest (ROI) corresponding to each cognitive function was generated. Then, resting-state functional connectivity (RSFC) from each voxel in whole brain to ROI masks were calculated. Thus we represent each voxel as 109 dimensional vector whose components are intensities of RSFCs. Applying clustering to the voxels, we obtained the whole-brain parcellation. It is noteworthy that all obtained parcels are intrinsically labeled by RSFCs to the ROIs corresponding to cognitive functions and are interpretable in a straightforward manner. Additionally, we analyzed the network whose nodes are obtained parcels and whose edges are RSFCs among parcels. Degree analysis revealed that the parcels strongly associated to the central executive (e.g. cognitive control and reasoning) tend to be at the influential positions in the whole-brain network. Centrality analysis revealed that parcels strongly associated to “search” and “mental imagery” are located at the highly separated position in the network. Moreover, we found that centrality is negatively correlated to the intensities of intra-ROI connectivity. In this study, we presented the highly interpretable whole-brain functional parcellation and showed the usefulness of it in the understanding of brain as an integrated system. More detailed systematic analysis based on the presented parcellation is a future direction.

Title: Migration of thalamic neurons and development of thalamocortical pathways in humans revealed by diffusion tractography

Authors: M. WILKINSON[1,2], R. WANG[3,4], *E. TAKAHASHI[5];
[1]Dept. of Behavioral Neuroscience, Northeastern Univ., Boston, MA; [2]Div. of Newborn Medicine, Dept. of Med., Boston Children's Hosp., Boston, MA; [3]Div. of Newborn Medicine, Dept. of Med., Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [4]Dept. of Radiology, Guizhou Provincial People's Hosp., Guiyang, Guizhou Province, China; [5]Div. of Newborn Med., Boston Childrens Hospital, Harvard Med. Sch., Boston, MA

Abstract: Thalamocortical (TC) pathways were identified using high-angular resolution diffusion MRI (HARDI) tractography in postmortem fetal brains with no neurological histories ranging from 17 gestational weeks (GW) to 40 GW, as well as *in vivo* newborns to 28 years. Anterior, middle, and posterior TC pathways were segmented. No hemispheric asymmetry of the TC pathways was observed quantitatively during development. In fetal brains, pathways likely linked with neuronal migration to the immature thalamus structure were successfully imaged with regional differences in numbers and volumes. Evidence for protracted development in the anterior TC was observed both in fetal and postnatal data. We believe that the current study will be a useful reference for the normal TC development in future clinical imaging studies.

Title: Electroencephalograph (eeg) study of brain bistable illusion

Authors: *Q. MENG[1], E. HONG[2], F.-S. CHOA[1];
[1]UMBC, Baltimore, MD; [2]Dept. of Psychiatry, Univ. of Maryland, Baltimroe, Baltimore, MD

Abstract: Bistable illusion reflects two different kinds of interpretations for a single image, which is currently known as a competition between two groups of antagonism of neurons. Recent research indicates that these two groups of antagonism of neurons express different comprehension, while one group is emitting a pulse, the other group will be restrained. On the other hand, when this inhibition mechanism becomes weaker, the other antagonism neurons group will take over the interpretation. Since attention plays key roles controlling cognition, is highly interesting to find the location and frequency band used by brain (with either top-down or bottom-up control) to reach deterministic visual perceptions. In our study, we used a 16-channel EEG system to record brain signals from subjects while conducting bistable illusion testing. An extra channel of the EEG system was used for temporal marking. The moment when subjects reach a perception switch, they click the channel and mark the time. The recorded data were presented in form of brain electrical activity map (BEAM) with different frequency bands for analysis. It was found that the visual cortex in the on the right side between parietal and occipital areas was controlling the switching of perception. In the periods with stable perception, we can constantly observe all the delta, theta, alpha and beta waves. While the period perception is switching, almost all theta, alpha, and beta waves were suppressed by delta waves. This result suggests that delta wave may control the processing of perception switching.

Title: Thetaburst TMS to the right posterior superior temporal sulcus disrupts resting state connectivity across the face-processing network as measured with multi-echo fMRI

Authors: *D. A. HANDWERKER[1], G. IANNI[3], B. GUTIERREZ[1], V. ROOPCHANSINGH[2], J. GONZALEZ-CASTILLO[1], L. G. UNGERLEIDER[3], P. A. BANDETTINI[2,4], D. PITCHER[3]; [1]SFIM/LBC, [2]FMRIF, NIMH, NIH, Bethesda, MD; [3]SN/LBC, [4]Sfim/lbc, NIMH, Bethesda, MD

Abstract: Thetaburst transcranial magnetic stimulation (TBS) to the right posterior superior temporal sulcus (rpSTS) or the right occipital face area selectively disrupts BOLD responses within face-selective regions, both local and remote to the initial stimulation site (Pitcher et al., 2014). Given this modulation of task-evoked responses, we hypothesized that TBS delivered over the right posterior superior temporal sulcus would selectively disrupt functional connectivity within face-selective regions, as measured by resting state fMRI. Subjects participated in three separate fMRI sessions across different days. In the first, a high-resolution T1 weighted anatomical scan, as well as functional localization data were collected to identify individualized target sites for stimulation. The voxel within the rpSTS exhibiting peak activation using a contrast of faces greater than objects was identified for stimulation, as well as the anatomically defined hand-knob region (rHk) within the right primary motor cortex. In the remaining two sessions, multi-echo fMRI data were collected on a 3T GE MRI (TR=2s, TE=14.8, 27.1, & 39.5ms, 3mm^3 voxels). Subjects completed two 10-min resting fMRI runs before and two runs after receiving TBS to the rHk or rpSTS. The order of site stimulation was counterbalanced across subjects. Both target sites were located using the BrainSight TMS-MRI coregistration system. A MagStim Super Rapid stimulator delivered TBS via a figure-eight coil with a wing diameter of 70 mm. The TMS coil handle pointed upwards and parallel to the midline. TBS was delivered at an intensity of 30% machine output over each subject's functionally localized rpSTS or anatomically defined rHk. The stimulation paradigm consisted of 3 pulses at 50 Hz repeated at 200 ms intervals for 60 seconds. fMRI signal fluctuations that were unlikely to be due to blood oxygenation changes were removed using the multi-echo independent component analysis (ME-ICA) method (Kundu et al 2011). A mean time series was extracted from a sphere centered on the rpSTS stimulation site for each subject and each run and correlated to the rest of the brain. Areas with group correlation strength differences between the first run

before and the first run after TBS were identified. Consistent with our hypothesis, TBS delivered over the rpSTS decreased connectivity to face-selective regions in the fusiform, middle occipital, and middle temporal gyri. There was no decrease in connectivity to these regions when TBS was delivered over the rHk. These results show that TBS to the rpSTS selectively decreases functional connections to face-selective regions even without task-evoked responses.

Title: Using multi-echo cardiac gated fMRI to better denoise brainstem data

Authors: *J. GONZALEZ CASTILLO[1], L. C. BUCHANAN[2], D. A. HANDWERKER[2], V. ROOPCHANSINGH[3], J. A. DERBYSHIRE[3], B. E. GUTIERREZ[2], P. A. BANDETTINI[2]; [1]SFIM/LBC/NIMH/NIH, Bethesda, MD; [2]Section on Functional Imaging Methods, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Functional MRI Core, NIH, Bethesda, MD

Abstract: Brainstem activity is difficult to detect with fMRI due to pulsatile motion. While cardiac gating (CG) can correct this by imaging the brainstem at the same relative position, resulting irregular repetition times (TR) induce variable baseline magnetization and hinder detection. In the past, a modeling approach to correct for such baseline shifts in CG-fMRI was proposed (Guimaraes et al. 1998). Here we evaluate a fully data-driven alternative based on Multi-Echo ICA (ME-ICA; Kundu et al. 2012), which can automatically separate BOLD (e.g., activations) from non-BOLD (e.g., T1-related fluctuations, hardware instabilities) fluctuations based on differences in TE-dependence. In principle, ME-ICA should automatically detect and remove CG-fMRI baseline fluctuations given their non-BOLD nature. To evaluate this possibility, we acquired gated and non-gated multi-echo fMRI data with an auditory block paradigm and focused our analysis in regions of the ascending auditory pathway, and particularly in the inferior colliculus (IC) located in the brainstem. The goal is to evaluate if CG-fMRI combined with ME-ICA can be used to reliably detect activation in the IC at the single-

subject/single-run level. METHODS: Four functional runs (2 gated, 2 non-gated) were acquired in each of 5 subjects (3T, FA=60°, TE=13.9/31.7/49.5ms, #Slices=33, #Acq=136, Res=3x3x3mm3, nominal TR=2.5s). Three different analyses were conducted. First, we produced activation maps using only the middle echo to reproduce standard fMRI analyses (SE). Second, analyses were conducted using an optimal combination of the echoes (OC; Poser et al. 2006), and ME-ICA denoised time-series. Finally, analyses were also conducted using the Guimaraes et al. modeling approach for comparison purposes. RESULTS: In CG-fMRI, activation within the IC is not reliably detected in the SE and OC analyses, yet after the use of ME-ICA activation was found within this region in all runs and all subjects. In non-gated data, activity in IC can be detected in many instances, yet detectability improves substantially in the OC and MEICA analyses. Regarding MEICA, the auditory task component was always marked as good. In CG-fMRI runs, a component that resembles a T1 map and correlates with TR shifts was always marked as noise. In addition, several rejected components correlated significantly with physiological and motion traces, confirming the denoising power of ME-ICA. CONCLUSIONS: ME-ICA can reliably capture and eliminate baseline signal fluctuations due to variable TR in CG-fMRI. Moreover, combined use of CG-fMRI and ME-ICA permits reliable detection of activity in the IC at the single-subject/single-run level.

Title: Spike rate homeostasis tunes networks to sub-criticality

Authors: ***V. PRIESEMANN**, J. WILTING;
Max Planck Inst. For Dynamics, Göttingen, Germany

Abstract: How do information processing capabilities arise from the brain’s collective spiking dynamics? A popular hypothesis is that neural networks operate close to a critical state [1,2], because in models criticality maximizes information processing capabilities [3]. However, criticality also comes with the risk of spontaneous runaway activity [4]. We addressed two

questions: A. How far from the critical state does the brain operate, and B. How is that state maintained? A. Quantifying the distance to criticality d can be biased due to subsampling, i.e. only a small fraction of neurons can be recorded in parallel [2,4]. We mathematically derived a novel estimator for d, which is reliable even under strong subsampling. The estimator is based on multiple linear regressions. Applying the estimator to spike recordings *in vivo* from rat hippocampus, cat visual cortex, and monkey prefrontal cortex consistently showed that the brain operates in a slightly subcritical regime with $d \sim 0.02$. This corresponds to an effective reduction in the mean excitatory synaptic strength w of ~2% compared to criticality. B. What mechanism promotes self-organization to *subcriticality*? A natural candidate mechanism is homeostatic plasticity [5]. We studied the effects of spike rate homeostasis (H) on the distance to criticality in two types of networks (integrate and fire or stochastic point neurons). H was implemented globally: The excitatory synaptic strength was initially set to a mean value w, and then updated proportionally to the difference between past spike rate R, and target spike rate $R_0 = 1$ Hz, using a slow time constant of $T = 1000$ s, as follows: $dw/dt = (R_0 - R) / T$. Indeed, H assured that the networks assumed a slightly subcritical state, independent of the initial synaptic strengths. Notably, an increase in the external input (stimulus strength) altered the set-point of the network to a more subcritical state. Overall, the analysis of *in vivo* spiking activity across species, and the theoretical study of homeostasis suggest that the brain organizes itself to a subcritical state, not to criticality proper. We suggest that spike rate homeostasis is a key mechanism to maintain subcriticality. Compared to criticality, subcriticality implies a reduction in processing capability, but avoids instability. Title: Chronic administration of THC and SR141716-precipitated cannabinoid withdrawal in the rat brain: a complex network analysis

Authors: *G. SENTHINATHAN, G. WILLEMS, S. SKRZYPCZAK, C. LECKIE, P. E. MALLET, B. E. MCKAY;
Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: The pattern of behavioural and neural changes associated with the chronic administration of Δ9-tetrahydrocannabinol (THC) suggests that tolerance develops quickly. Previously, we investigated neural activation among anatomically discrete reward-related brain areas in adolescent and adult rats by quantifying c-Fos immunoreactivity (Fos-IR) in response to: 1) acute SR141716 (a selective cannabinoid receptor antagonist), 2) chronic THC (10 mg/kg, IP, twice daily for 6 days), and 3) SR141716-precipitated cannabinoid withdrawal following chronic THC exposure (Senthinathan et al., 2014). To further analyze the Fos-IR data set, we have applied complex network analyses to assess the functional connectivity among these reward-related brain structures. For each group, Spearman's rho for the Fos-IR data was calculated for all possible pair-wise combinations of the ~40 brain areas. The weight of the correlation coefficient indicates the strength of the functional relationship between a pair of structures. We found that chronic exposure to THC was associated with an increased number of functional connections in brain reward systems. Additionally, following chronic THC exposure, this increased number of functional connections seemed to be blunted by the administration of SR141716. An age-related difference was revealed by the analysis of the cluster coefficient (the main measure of the local structure of a network, defined as the ratio of the actual number of functional connections and the maximum possible number of connections). Among adult rats, chronic THC increased clustering. Chronic THC treatment did not seem to impact clustering among adolescent rats. Further, only among the adolescent rats, acute administration of SR141716 was associated with increased clustering. A rigorous set of complex network analyses will be applied to further investigate these functional neural networks. Applying the complex network analysis technique to c-Fos IR data sets brings forth new methods for visualizing and conceptualizing neural activation.

Title: The default mode network is spatially but not temporarily consistent

Authors: *E. SHOKRI-KOJORI[1], D. TOMASI[1], N. D. VOLKOW[1,2];
[1]Natl. Inst. on Alcohol Abuse and Alcoholism, [2]Natl. Inst. on Drug Abuse, NIH, Bethesda, MD

Abstract: Much attention in fMRI research has been paid to the default mode network (DMN), a set of parietal, temporal, and medial frontal regions that appear to fluctuate in synchrony at a slow rate (< 0.1 Hz) during rest and, occasionally, task states. It has been suggested that these fluctuations reflect spontaneous thoughts and mind wandering. While DMN has been reliably detected in many studies, the nature of the slow rate synchrony within DMN regions remains elusive. To shed further light on this phenomenon, we assessed spatiotemporal consistency of DMN within subjects. For spatial consistency, the reproducibility of voxels showing DMN-related activity was measured. For temporal consistency, the reproducibility of the frequency contents of the DMN time course was measured and its association with respiration time course was evaluated. Data from four high resolution (2-mm isotropic, TR = 0.72 sec) resting-state sessions, each 14.4 minutes long, on 260 subjects were included in this study. Spatial map and time course of DMN were extracted per session per subject using an automated independent component selection approach. Average-score intraclass-correlation (ICC) analysis was used to measure within-subject reproducibility of DMN spatiotemporal characteristics. We found that the location of voxels within DMN is highly reproducible within subjects (mean ICC = 0.79; Bonferroni, $p < 0.05$). For temporal characteristics, we found the 0.1-0.55 Hz frequency range was the only reproducible part of the total spectrum (0-0.69 Hz) within subjects (mean ICC = 0.40; Bonferroni, $p < 0.05$). But the 0-0.1 Hz frequency range, accounting for about 90% of the power of DMN time course, did not show consistent rates of fluctuation within subjects (mean ICC = 0.10). We further hypothesized that the reproducible part of DMN spectrum corresponds to respiration rate. Additional ICC analysis on coherence between respiration and DMN time courses supported this hypothesis and showed significant reproducibility in the association between the two spectrums in 0.15-0.5 Hz frequency range (mean ICC = 0.46; Bonferroni, $p < 0.05$). In summary, we report that brain regions related to DMN are spatially consistent within subjects. Yet, the main rates at which these regions fluctuate together (within 0-0.1 Hz) is not reproducible within subjects across sessions. We conclude that the high-power low-frequency content of DMN time course may not be an index of systematic slow rate fluctuations in neuronal populations and may be confounded by a complex of physiological factors such as respiratory rhythms and characteristics of the vascular system, as well as fMRI aliasing artifacts.

Title: Quantifying small-worldness in weighted brain networks: small-world propensity

Authors: S. E. F. MULDOON[1], E. W. BRIDGEFORD[3], *D. S. BASSETT[2];
[1]Dept. of Bioengineering, [2]Dept. of Physics, Univ. of Pennsylvania, Philadelphia, PA; [3]John Hopkins Univ., Baltimore, MD

Abstract: Brain networks have repeatedly been shown to have small-world properties, with high local clustering yet short average path length between any two nodes. Recently, the small-worldness of the brain has been challenged by the observation that new data from structural brain networks indicates a high level of connectivity between brain regions, making the network too dense to have small-world properties. However, this claim is based on traditional measures for assessing small-worldness that do not take the weighted nature of connections between brain regions into account. By relying on analysis of binary networks, the network density is artificially inflated, and the fact that strong and weak connections will differentially contribute to the overall network structure is ignored. Additionally, the fact that these measures are dependent on network density, makes comparison of brain structure between different groups (e.g. diseased versus healthy) or different task states difficult. We therefore present a novel diagnostic of small-world structure called the Small-World Propensity (SWP) that quantifies small-world structure in a density independent manner and can be applied to both weighted and binary networks. We apply this new measure to a variety of structural and functional brain networks and show its usefulness in quantifying small-worldness in order to gain insight into differences between network organization across systems. While all brain networks examined show small-world characteristics, surprisingly, the neuronal network of *C. elegans*, the original example of a biological small-world network, shows the least amount of small-world structure.

Title: Analysis of motifs' spontaneous and evoked dynamics in patterned cortical neuronal networks

Authors: ***M. BISIO**[1], Y. PIASETZKY[2], M. OLIVEMBOIM[2], S. KANNER[3], M. CHIAPPALONE[1], P. BONIFAZI[2];

Abstract: Cultured neuronal networks cultivated on Micro Electrode Arrays (MEAs) are a widely tool for the investigation of neuronal network mechanisms, providing structural framework for long term recordings of electrophysiological activity, as well as the response to electrical stimulations. Patterned networks are composed of distinct functional modules with highly connected neurons within the modules and sparse connectivity between them. The structure of each module can be treated as a uniform network, with all neurons in the modules firing in a quasi-synchronized way, while the whole network can perform more complex patterns of temporal activity that propagate from one module to another. The occurrence of Network Events (NEs), i.e. " network motifs", composed by a specific temporal sequence of activation between the modules or electrodes has been investigated. The used experimental protocol to consists of the following steps: i) 1-hour recording of spontaneous activity; ii) a stimulation session, which consists of stimulating one electrode of each module using a train of 50 stimuli (0.2 Hz); iii) 1-hour recording of spontaneous activity. Overall, 18 patterned networks have been recorded. The analysis can be carried out both at single electrode and at single module resolution, during both spontaneous and evoked activity. The single electrode resolution provides a higher spatial resolution including also the temporal activation within each module. The single module resolution aims at highlighting the connections between the modular structures and the inter-module activity propagation. We tested the hypothesis that consecutive NEs display higher similarity than randomly played NEs, namely, patterned networks have a "dynamical working memory" state which persists on specific motifs which share high similarity. So, the average similarity between pairs of NEs has been reported as a function of the inter-NE intervals. In particular, it has been found that, in spontaneous conditions, motifs have an inter-NE distances distribution which is significantly different from a Poissonian distribution, i.e. obtained when motifs are randomly played. Then, it was also observed that at the evoked activity level the average similarity's profile computed between the different stimulation trials is not significantly different from a Poisson distribution. This allows to conclude that stimulation induces a deterministic response, i.e. similar motifs are observed after each stimulation trial. These results constitute an important step in investigating possible 'memory' processes arising in cortical networks *in vitro*.

Abstract: While there has be great progress researching neurodevelopmental disorders such as Autism Spectrum Disorders (ASD); findings (ranging from protein structure to whole brain connectivity) are often difficult to integrate into a compressive theory about the biological basis underlying such disorders. Taking ASD as an exemplar, the use of electrophysiological signatures as 'biomarkers' (biologically based markers) exhibits great promise, with signatures (M100 delay and Gamma-band (30-100 Hz) dysfunction) being observed repeatedly across both clinical populations and pre-clinical models. In addition, these biomarkers provide a convergence point for the different perturbations seen across multiple levels of study for ASD. Here we highlight the promise of these biomarkers in unifying electrophysiological findings across multiple modalities. Using the Matlab toolbox Fieldtrip, data spanning multiple levels of study (clinical MEG, pre-clinical EEG and in-vitro electrophysiology (lFPs and VSDi)) were analyzed utilizing near identical analysis routines.

Title: Global delayed propagation of electrical signals in primate cortex

Authors: ***S. TAJIMA**[1], M. SHIMONO[2,3];
[1]Univ. of Geneva, Geneva, Switzerland; [2]Dept. of Physics, Indiana Univ., Bloomington, IN;
[3]Harvard/MGH, Charlestown, MA

Abstract: The brain is a highly non-uniform organ that consists of a complex neural network, where neurons communicate with each other through within- and between-area axonal projections. In the past decades, neurophysiological studies using single unit recording (SUR) in primates have revealed relationships among neuronal activities, cross-area anatomical connectivity, and cognitive behaviors. Unfortunately, however, the number of simultaneously observable brain regions with SUR is usually limited to less than ten. Although many innovative technologies, including multi-electrode array recording, are expanding the recordable spatial scale, it is currently difficult to record the brain-wide activity at single-cell resolution in primate. On the other hand, recent wide-field electrocorticogram (ECoG) complements the limitation of SUR, by simultaneously observing the electrophysiological signals at the scale of entire cortex. However, since the ECoG signal reflects activity of neural population rather than single cells, its relevance to the previous SUR studies needs to be clarified. To fill this gap, we compared the cross-area signal propagation in ECoG data from the whole cortical surface in macaque monkey (Nagasaka et al., 2011) with spike delays reported in a number of previous SUR studies, as well as with the large-scale anatomical network (Lewis & Van Essen, 2000). Our preliminary results suggest that (1) the time lag of cross-correlation peaks in ECoG signal predicts spike delay in cross-area information propagation, (2) the both time delays can be accurately predicted by path length in anatomical connectivity network rather than physical distances among areas, and (3) the correlation between anatomy and ECoG signal propagation delay are modulated by the arousal levels of monkey. These results demonstrate that ECoG signal preserves the temporal information of single-unit spike propagation across areas, as well as that effective cross-area network switches depending on the brain state.

Title: An examination of delta-9-tetrahydrocannabinol-induced alterations of neural activity using a novel "complex network analysis" approach

Authors: E. L. COLDIN, S. A. RANA, J. SCANTLEBURY, M. SCHAUS, B. E. MCKAY, *P. E. MALLET;
Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Administration of delta-9-tetrahydrocannabinol (THC) results in a wide array of behavioural effects via its action on the brain's endocannabinoid (eCB) system. The current study examined the effects of THC on neural activation throughout the brain using complex network analysis, which is a relatively novel method of analysis that permits the quantification of functional connectivity in large neural networks, clusters of activity, and individual regions. Rats were injected with 5 mg/kg THC, or its vehicle, and then transcardially perfused two hours later. Brains were sectioned and immunochemistry was used to label Fos—the protein product of the immediate-early gene *c-fos*. Neural activity was quantified by counting immunoreactive nuclei in a total of 81 brain regions. Functional connectivity matrices were generated for each group and

significant connections were analyzed. THC administration resulted in increased number, strength, and clustering of functional connections across the network. Further analyses will investigate the properties of network connections and clusters of activity. These results provide novel information on the neural effects of THC administration, as well as on the use of complex network analysis in behavioural neuroscience. Support for this research was provided by NSERC and Wilfrid Laurier University.

Title: Unsupervised hierarchical clustering of resting state functional connectivity data to identify patients with mild tinnitus

Authors: S. A. SCHMIDT[1], M. SCHUBEL[1], A. N. HIRANI[1], Y. BARYSHNIKOV[1], *F. T. HUSAIN[2];
[1]Univ. of Ilinois at Urbana-Champaign, Champaign, IL; [2]Univ. Illinois, Champaign, IL

Abstract: In this study, unsupervised hierarchical clustering of resting state functional connectivity data (from Schmidt et al, PloS One, 2013) was performed to separate tinnitus patients from controls. Hierarchical clustering on tinnitus patients using neuroimaging has not previously been employed, but has the potential to identify subgroups within the heterogeneous tinnitus population. Such methods may also clarify the discrepant results seen in multiple studies of resting state functional connectivity in tinnitus patients. Clustering was performed on correlations between the average time courses between voxels. Different time windows (20, 40 and 60 second in addition to the full five minute data) were used when averaging the data to examine any short-term effects. Data were clustered in two forms: directly as preprocessed fMRI data, and also as weighted graph Laplacian eigenvectors. For the eigenvector data, three different distance cutoffs (5, 10 and 20 mm) were used to weight the edges of the constructed graph Laplacian. Finally, correlations were examined across the whole brain as well as in sets of regions of interest selected based on the results of our previous study (Schmidt et al, PloS One,

2013) and included regions of the default mode, dorsal attention, auditory networks and the limbic system. The number of clusters was fixed at two, as we were interested in dividing subjects into two groups: tinnitus and non-tinnitus. The non-tinnitus group consisted of either normal hearing or hearing loss controls. Clustering success was determined via calculation of the Rand index. In general, clustering was more successful when separating tinnitus patients from normal hearing controls using regions of interest; this produced the best Rand index of 0.80 when Ward linkage hierarchical clustering was applied to correlations in regions of interest located in auditory and limbic regions. Our results suggest that unsupervised hierarchical clustering can successfully differentiate tinnitus patients from controls based on their connectivity patterns. The technique used here will also be applied to different tinnitus subgroups, in particular groups of differing tinnitus severity, to assess the sensitivity of the technique in organizing heterogeneous patient groups.

Title: Assembling the multimodal, multidimensional brain network

Authors: *M. Y. MAHAN[1], A. P. GEORGOPOULOS[2];
[1]BICB, [2]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The majority of brain connectivity studies focus on either structure or function, while a few studies aim to unite them. Unfortunately, these combination studies fall short of true multimodal integration and instead provide comparisons of networks across modalities. Although meaningful insights have been gathered from these studies, the development of a comprehensive network that describes both brain structure and function simultaneously is still missing. For that reason, a novel multimodal, multidimensional network was derived. In addition, both spatial and temporal components are incorporated in order to capture the innately spatiotemporal properties of the brain. Structural (sMRI and DTI) and functional (fMRI and MEG) data were collected from 65 cognitively healthy women (32-74 years old). Graph construction is based on a combination of previous work whereby multiple graph construction methods were examined. First, the number nodes in the graph were generated randomly and

labeled with sMRI measures of gray matter volume, thickness, and surface area. Next, multiple edges were defined from the remaining data, namely, (1) DTI measures of white matter tractography, (2) fMRI measures of correlations, and (3) MEG measures of correlations. Taken together, the measures are incorporated into one multidimensional graph characterizing structural and functional connectivity. For the multimodal, multidimensional graph, characteristic network measures were calculated and compared across the sub-networks. In addition, graph theory algorithms were adapted and used to calculate network measures from each area, lobe, hemisphere, and whole brain, resulting in a comprehensive network assessment for each subject. Using these results, the effect of age was calculated for each network metric. Furthermore, spatiotemporal data mining approaches, informed by previous results, were used to capture spatiotemporal processes of brain connectivity patterns. Taken together, the results are used to construct a model of how brain communication patterns change with age, in such a way that brain function remains healthy.

Title: Comparing MDPV's and cocaine's induced modulation of resting state networks

Authors: ***L. M. COLON-PEREZ**[1], M. FEBO[2];
[2]Psychiatry, [1]Univ. of Florida, Gainesville, FL

Abstract: Drug abuse has detrimental effects on the brain that lead to drug use disorders. *In vivo* non-invasive biomarkers are needed to determine the neurobiological outcomes of addictive drugs on the brain. Analysis of functional brain network organization using graph theory measures offers a robust and objective analytical approach to address this need. It is anticipated that this could provide a useful biomarker of drug action in the brain of animals and humans for neuroimaging studies. In the present study we determined the effects of two potent and addictive psychostimulant drugs, 3,4-methylenedioxypyrovalerone (MDPV) and cocaine, on various graph measures of network connectivity. MDPV is a designer cathinone drug that is present in formulation of street drugs known as 'bath salts'. It shares a similar mechanism with cocaine,

Deleted: In vivo

inhibiting the reuptake of dopamine (DA), but with a greater affinity for the DA transporter. Resting state functional magnetic resonance imaging (fMRI) datasets were collected 1 h after i.p. administration of 1.0 mg kg-1 of MDPV, cocaine of 15 mg kg-1, and a control group administered with saline. To determine the differences of MDPV and cocaine induced alterations in connectivity we compared network relevant measures (i.e. degree, path length, and clustering coefficient) to controls. Images were processed for seed-based functional connectivity analysis using a segmented atlas of the rat brain. By modifying the threshold that generate networks for each group (Cocaine = 0.1, MDPV = 0.1 and control = 0.4) graph densities were maintained the same (25% of all possible pairs) for all groups in order to avoid differences in connectivity due to graph density differences. We observed a reduction in degree, indicator of nodal connectivity with the entire network, among cortical amygdala and ventromedial striatum, while lateral amygdala and infralimbic cortex in response to both cocaine and MDPV. The global characteristic path length did not show any difference between control and drug treated groups. Overall the clustering coefficient, an indicator of network integration, was reduced for the accumbens core and shell and ventromedial striatum for both drug groups. These results suggest that the brain under the effects of drugs maintain efficient information transmission through short path lengths; however, their integration is affected by reducing the clustering of local communities. This suggests a mechanism of disruption of local information processing in key areas of the brain (e.g. accumbens). The long-term objective of the present work is to develop a useful approach for distinguish the network-level effects of addictive drugs.

Abstract: Electrical stimulation has been in use for decades as a tool to elicit activity in neuronal systems, both *in vivo* and *in vitro*: traditionally, the most common method to probe neural activity has been the delivery of regular stimulation, with fixed frequency and amplitude. While it is a well-known fact that input variability is fundamental in single neuron responses, the effects of variable input sequences at the network level is a seldom investigated subject. Within this work, we studied the capability of *in vitro* neural networks to follow input stimulations with an increasing degree of regularity. Furthermore, we interfaced an *in silico* neuronal network to an *in vitro* one, with the ultimate goal of performing a closed-loop bidirectional connection in future studies. As neural substrates, we used cortical cultures dissociated from embryonic rats (E18) and kept alive over Micro Electrode Arrays (MEAs) for 3-4 weeks. Our stimulation sequences consisted in identical stimuli with different inter-stimuli intervals (ISIs): the ISIs in our experiments followed a distribution, with regularity increasing with the value of β (values tested were 0, 0.5, 1, 1.5, ∞). Comparisons occurred on the correlation between low-passed (rectangular window, 0.1s in length) stimulation and network-wide spike trains. *In silico* networks were interfaced to biological ones through their network bursts: stimulus delivery was triggered by the detection of a 'network burst' in the *in silico* network. We analyzed evoked network responses in order to evaluate whether biological activity correlates with stimulation. Our results show that cultures are largely unable to synchronize network-wide responses with regular stimulation at the considered stimulation rate (0.5Hz), while this occurs to a much higher degree for irregular stimulations.

Title: Extracting non-linear spatiotemporal dynamics in active dendrite: data-driven statistical approach

Authors: *T. OMORI[1], K. HUKUSHIMA[2];
[1]Kobe Univ., Kobe, Hyogo, Japan; [2]Univ. of Tokyo, Tokyo, Japan

Abstract: Recent findings suggest that active dendrite contributes more important roles in neural information processings such as directional selectivity [Sivyer and Williams, Nature Neurosci., 2013], integration of sensory and motor inputs [Xu et al., Nature, 2012] , and so on. For example, recent experimental results showed that active dendritic computation plays a key role in directional selectivity for visual stimuli in retinal ganglion cells [Sivyer and Williams, Nature. Neurosci., 2013]. However, the mechanism of active dendritic computation is still unclear, since the spatiotemporal dynamics of active dendrite remains unknown. Great advances in measurement technology enable us to deal with spatiotemporal data from neural systems including dendrites as imaging data. However, the observable information in the measurements are limited, compared with the complexity of the entire neural system. Some estimation techniques are proposed using the state space modeling approach to extract the spatiotemporal dynamics of the dendrites. In some of previous methods, only membrane potentials are estimated while assuming the parameters underlying spatiotemporal dynamics are known, and most of previous methods only consider the estimation of linear dynamics in multi-compartment models or nonlinear dynamics in single-compartment models [Paninski, 2010, Omori et al., 2013; Omori, 2014], although it is important to establish nonlinear dynamics for spatiotemporal membrane evolution in multi-compartment models to reveal the active dendritic computation. In this study, we propose a statistical method to estimate nonlinear spatiotemporal membrane dynamics of active dendrites in order to extract nonlinear dynamics of dendritic membrane. We employ a framework of probabilistic information processing to extract the nonlinear spatiotemporal dynamics from partially observable data. First, we formulate generalized state-space model of active dendrite, based on multi-compartment model. Next, sequential estimation algorithm is derived for the generalized state space model. By employing sequential Monte-Carlo method and other statistical methods, membrane dynamics and its underlying electrical properties are simultaneously estimated in the proposed method. Using the proposed method, we show that nonlinear spatiotemporal dynamics in active dendrites can be extracted from partially observable data.

Title: A comparison of single and multi-shell diffusion-weighted MRI imaging in the anesthetized macaque for thalamocortical tractography

Authors: ***K. BROWN**[1], R. A. SHEWCRAFT[1], P. VELASCO[2], B. PESARAN[1];
[1]Ctr. for Neural Sci., [2]Ctr. for Brain Imaging, New York Univ., New York, NY

Abstract: White-matter tractography using diffusion-weighted MRI imaging (DWI) is widely used to study anatomical connections in the primate brain. Recent advances in multi-shell imaging sequences have promised greater accuracy in reconstructing anatomical pathways. However, a direct comparison of single and multi-shell methods for tractography across a single non-human primate *in vivo* has not been reported. Here, we compare the efficacy of single-shell and multi-shell acquisition schemes for *in vivo* macaque DWI tractography. To judge the effectiveness of each scheme, we reconstructed thalamocortical projections using a probabilistic tracking method designed to distinguish crossing fibers, segmented the thalamus according to the most likely cortical target, and compared this classification to known thalamic subdivisions. Each subject was anesthetized with a constant IV infusion of 0.5mg/hr/kg of atracurium and 4mg/hr/kg of sufentanil, or isoflourane alone and scanned in the sphinx position. Data were acquired with a 3T Siemens Allegra (Erlangen, Germany) using 3 elements of a 4-channel phased array (Nova Medical Inc., Wilmington, MA), in a 2D single-shot twice-refocused DW-SE-EPI sequence, with 64 gradient directions in 1.2 mm^2 in-plane resolution (TR = 7000ms; TE = 110ms; B-values: 0, 750, 1500, 2250 s/mm^2; FOV: 80x72 pixels; slices: 45; slice thickness: 1.2 mm; DWI to b_0 ratio 65:1). To correct geometric distortions from field inhomogeneities caused by the non-zero off-resonance fields, the runs for each b-value were collected twice, one with reversed phase-encode blips, forming pairs of images with distortions going in opposite directions. For each b-value, we collected an extra pair of images without diffusion gradients and with a TE of 74ms, but otherwise identical to the DWI. From these pairs the off-resonance field was estimated and used to combine the DWI pair into a single corrected one. A total of 21 pairs were recorded. Eddy currents were subsequently corrected for using FSL's eddy tool. We modeled diffusion for each voxel as up to two crossing fibers using a resampling procedure and obtained path distributions using FSL's bedpostX and probtrackx tools. Recent observations suggest that communication across cortex depends on intermediate thalamic relay sites. As a result, correct identification of anatomical pathways depends not only on resolving cortico-cortical tracts, but constituent thalamic relay tracts as well. Our data hold implications for *in vivo* approaches to identify macrocircuits for same-subject functional imaging and electrophysiological recording.

Title: Testing the statistical significance of dynamical structure in neural population responses

Authors: *G. F. ELSAYED[1], M. T. KAUFMAN[3], S. I. RYU[4], K. V. SHENOY[4], M. M. CHURCHLAND[1], J. P. CUNNINGHAM[2];
[1]Neurosci., [2]Statistics, Columbia Univ. In the City of New York, New York, NY; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [4]Stanford Univ., Stanford, CA

Abstract: Many hypotheses consider the role that population dynamics play in the computational structure of various neural systems. One common question is whether there exist consistent population dynamics across different experimental conditions. To illustrate this, consider the joint neural responses of N neurons to each experimental condition, which can be viewed as a point moving over time forming a trajectory through N -dimensional neural space. In neural spaces, dynamics are modeled as a single flow field that governs the evolution of many neural trajectories. Here, we test for the existence of consistent dynamics, defined as a single fixed dynamical rule that governs the evolution of neural trajectories for all conditions. In particular, we are interested in the basic question: do neural data show any dynamical consistency beyond what would be expected by non-dynamical 'null' data? The main difficulty in addressing this question is that the notion of null data is ill-defined. For example, white noise is a null dataset that may make any collection of neural data look dynamically consistent in comparison, due to the surface features of real data such as temporal smoothness, across-

condition smoothness, and pairwise neural correlations. Thus, the central challenge is to create null data with similar surface features to the real data. Here, we demonstrate procedures to create surrogate (null) data that preserve the surface features of the real neural data. To generate these surrogate datasets, we use ideas from permutation tests, which assume exchangeability of conditions under null hypotheses, to disrupt any dynamical consistency across neurons in real data. More importantly, via permutation techniques and matrix optimization methods, we enforce exchangeability of the surface features. If a dataset truly follows dynamical systems rules, it should be distinguishable from these surrogate datasets even though both share the same surface features. These permutation tests provide a conservative statistical test for dynamical structures and give guidance as to the number of neurons, conditions and time points needed to provide statistical power to these tests. As a first application, we test for the dynamical consistency of data from the motor cortex. The results show significant dynamical structure in the motor cortical population responses ($R2 = 0.6$, $p < 0.001$), providing statistical support to recent hypotheses [Churchland & Cunningham et al., 12].

Title: One man's prediction is another man's error - quantifying predictive coding at the retino-geniculate synapse independent of the observer's assumptions

Authors: ***M. WIBRAL**[1], D. RATHBUN[2], W. M. USREY[3], A. BASTOS[4], P. WOLLSTADT[5]; [1]MEG Unit, Brain Imaging Ctr. Frankfurt, Frankfurt a.M., Germany; [2]Inst. for Ophthalmic Res., Eberhard Karls Univ., Tübingen, Germany; [3]Dept. of Neurol., Univ. of California Davis, Davis, CA; [4]Picower Inst. for Learning and Memory, MIT, Boston, MA; [5]MEG Unit, Brain Imaging Ctr., Goethe Univ., Frankfurt a.M., Germany

Abstract: Predictive Coding Theory (PCT), the idea that brains exploit statistical regularities to facilitate perception based on noisy sensory evidence, has become a successful paradigm in organizing empirical findings in neuroscience. Exploiting regularities can happen either by

passing on sensory evidence matching internal predictions (reliability coding), or by passing on sensory evidence not matching predictions (error coding). If we knew which strategy the brain used, we could objectively decide from neural data whether sensory input results in an error or a confirmed prediction. Conversely, if we knew exactly when an error should arise, we could decide from neural data which strategy the brain used. Without this knowledge, the assignment of neural signals to errors or confirmed predictions depends on the observer's view on what the system predicted - a circular approach. This problem is amplified at the level of cells, as predictions there can only relate to statistics of incoming spike trains. Thus, a cell's predictions are remote from semantics imposed by the observer. Moreover, cells in a brain that globally supports reliability coding might still locally code errors. Therefore, we need a way to state the type of coding without semantics. This can be done using local information dynamics. In this framework, local active information storage (LAIS) measures the predictable information in a time series, while local transfer entropy (LTE) measures the information passed to the next cell. Evaluating the correlation between the two distinguishes reliability coding from error coding. We applied this framework to spike train recordings from 17 pairs of retinal ganglion cells (RGC) and lateral geniculate nucleus (LGN) cells in the anesthetized cat. We computed LAIS and LTE using nearest neighbour estimators from TRENTOOL/JIDT on spike trains convolved with synthetic post-synaptic kernels. We found a significant correlation of LAIS and LTE in 14/17 pairs ($p<0.05$). Of these, 8 had a positive LAIS-LTE correlation, indicating reliability coding, while 6 had a negative correlation, indicating error coding. The LAIS-LTE correlation in turn was strongly positively correlated ($r=0.79$; $p<0.0002$) with the contribution of an RGC input cell to the LGN cell's output, suggesting that the main retinal inputs to LGN cells are passed on when reliable, whereas secondary ones are passed on when surprising. We believe that our framework will improve the understanding of PCT at the circuit level.

Title: Clustering Analysis of Crayfish Agonistic behavior

Authors: J. MIRANDA-VELAZCO[1], K. MENDOZA-ANGELES[1], *G. R. ROLDAN[2], J. HERNÁNDEZ-FALCÓN[1];
[1]Univ. Nacional Autónoma de México, México, Mexico; [2]Natl. Univ. Mexico, 04510 D.F., Mexico

Abstract: Agonistic behavior results in the establishment of a hierarchical order of dominance-submission which determines access to resources and remains stable in time. Agonistic interactions can be divided in two types: positive contacts, all actions that a particular crayfish exerts on its conspecifics, and negative contacts, all actions that a particular animal receives from the other.Positive contacts are: threat, attack and fight; negative contacts are: retreat and avoidance. The first purpose of this work was to study agonistic interactions by clustering analysis, in an attempt to determine what are the contacts that have the greater impact on the establishment of the social hierarchy. We used male crayfish, Procambarus clarkii, organized in triads whose weight and size differ by less than ten percent. We analyzed agonistic interactions by clustering analysis, which consists in a mathematical algorithm used to classify data. It calculates similarities and dissimilarities and organizes data in groups according to these properties. In establishing the social hierarchy, positive contacts occur most frequently in the first few days, while the negative contacts are presented markedly in the last days. Results show that when forming groups with three agonistic contacts, if we choose a negative contact and two positive contacts, groups are more defined than if we choose two negative contacts and one positive contact; the contacts that allowed us to identify more clearly the groups were: threat, attack and retreat. The second purpose was to determine the effects of interference experiments (interaction with unfamiliar animals) using clustering analysis. Results showed a displacement of groups whose magnitude and direction depends on the original social status of a given crayfish.

Title: Nonuniform weights and connectivity patterns on macaque cortical connectome

Authors: *M. SHIMONO[1,2];
[1]Harvard / MGH, Masanori Shimono, Boston, MA; [2]Indiana Univ., Bloomington, IN

Abstract: Our brain is an organization based on highly non-uniform networks. The connectivity pattern generates another “closeness” which is more than the simple idea of short anatomical distances, and it is spoken that the non-uniform pattern helps us to understand the high computational efficiency etc. of the brain [Bullmore, Sporns, 2012]. In graph theory, when characterizing the network organization, there are two clear distinct characteristics, “weighted” and “non-weighted” networks. In macroscopic brain networks, the weights indicate relative strengths of fiber bundles connecting brain regions, and the strengths are not considered in non-weighted networks. This study focuses on relationships between “weights (strengths)” of connections between pairs of brain regions and “connectivity patterns” surrounding the respective brain regions. This comparison is currently a critical topic to understand brains of higher primates such as monkeys because, currently, all neuroscientists in the world do not have complete connectivity data including “weights” of high primate brains. Therefore, at this moment, in order to reach a better understanding of brains of higher primates, we need to complement information from both of “non-weighted networks covering whole brain regions” and “weighted networks covering partial regions”, and use them synergistically (Fig. A). Better understandings of high primates help us to understand detailed brain processes, this is what non-invasive technologies cannot capture. This knowledge could eventually help us to determine “What is uniquely human” in evolutional streams. From these backgrounds, this study compared weighted networks provided by Drs. Markov and Kennedy et al. [Markov et al., 2011] and non-weighted networks [Kötter, 2004; Bakker et al., 2012] as used in our previous report [Shimono, 2013]. This comparison declared several general principles between “weights” of connections between brain regions and “connectivity patterns” surrounding the brain regions (Fig. B), which should be representing information processes in the brain.

Title: Definition of sensory-evoked functional area in optical intrinsic signal imaging using a segmentation method

Authors: *C. YEON, D. KIM, H. CHOI, K. KIM, E. CHUNG;
DMSE, GIST, Gwangju, Korea, Republic of

Abstract: Optical intrinsic signal imaging (OISI) is a wide-field label-free functional brain optical imaging method that has been used to define functional brain area as it provides high spatiotemporal resolution. Single-color OISI has been used for simple functional area definition combined with other functional brain imaging modalities, meanwhile, multi-color OISI for tracing hemoglobin concentration changing and flow. Especially, single-color OISI takes quite simple experimental procedures thus, making it advantageous for stable baseline conditioning. However, signal processing methods to define sensory-evoked response area is not well established. In this work, we demonstrated single-color OISI system and segmentation method for quantification and simple definition of functional mouse brain area in the sensory area. We used Olympus BX51WI microscope body combining with Andor NEO sCMOS camera and 625 nm LED. Cranial window models (C57BL/6 male mice, n = 5) were used for brain optical imaging. We set pre-stimulation state as a baseline period and bipolar current stimulation state as a stimulation period. We calculated a ratio of two representative images, baseline and stimulation periods. We converted a single ratio feature of each pixel to CIELAB coordination to expand three-dimensional features. Then we calculated similarity and dissimilarity to find segmented regions based on the quantitative differences through features of pixels with a simple linear iterative clustering (SLIC) algorithm. Finally, we obtain the distinguishable area under the stimulation. We defined hind paw sensory areas from 5 cranial window mouse models. The hind paw area was distinguished into core and periphery area by OIS intensity. We applied a novel and simple segmentation method for our purpose of sensory brain area definition by using single-color optical intrinsic signal (OIS) that is reproducible and applicable to individual mouse and effectively distinguish the sensory-evoked functional area of hind paw. Fig. 1. (Left) White light image of the left hemisphere. (Right) segmented brain area.

Abstract: Time-frequency analysis techniques such as short-time Fourier transform and wavelet transform are used to analyze the neuronal dynamics of spike trains. However, because of the prerequisites of data continuity and time interval equalization, these techniques can be applied only to the continued neural signals. In addition, the recorded spike train processed using the spike-sorting algorithm is a point sequence of unequal time interval sampling, and well-known time-frequency methods cannot be directly applied. A typical strategy for transforming the time-point data from uneven to uniform sampling is the preprocess of binning or kernel fitting, which equalizes the intervals of data points. However, it is difficult to select a suitable bin size or kernel width. In the present study, we used the interspike interval to generate the amplitude of the point sequence to retain the uneven property, and we extended the application of the weighted wavelet Z-transform (WWZ) from astronomy to manage the uneven data. We also considered the effects of spike-sorting-induced errors in neural firing properties by using 6 spike sorting error models. We explored the tolerance of the WWZ to spike sorting errors in time-frequency data, and the results demonstrate that the WWZ is effective in processing sorted neuronal spiking trains. In conclusion, the WWZ is a state-of-art, promising tool for electroneurophysiological study.

Title: Modeling brain hierarchical structure using graph-based manifold learning

Authors: ***W. LIM**[1], J. LEE[1], Y. LIM[1], K. JUNG[2], D.-S. KIM[1];
[1]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Hierarchical organizations of information processing in the brain networks have been known to exist and widely studied. However, there are some limitations on the main technique of the conventional methods, which extracts pairwise hierarchical relationships by utilizing observable anatomical criteria based on tract tracing experiments. Therefore, we need to design a new methods computing hierarchy levels given the limited amount of hierarchical information. In this study, we suggest a new framework that can discover hierarchical structures of the brain networks with only the connectivity matrix and hierarchical information of a very few areas. Our strategy decomposes into three parts. In the first part, we use the graph Laplacian eigenmap which is one of graph-based manifold learning technique, to extract the character of each cortical area given the only adjacency matrix. Then the characteristics of each area are represented as a k-dimensional Euclidean vector. In the second part, we derive inherent pairwise relationship by using obtained k-dimensional vectors, and define pseudo hierarchical distances for every pair of areas. In the third part, we fix the hierarchy levels of only a few nodes, and compute hierarchy levels of areas by minimizing the objective function which is the sum of the square of the hierarchical distance error for all the pairs. We selected two brain connectivity data sets which are the macaque vision and somatosensory-motor networks. The hierarchical levels of the two data sets are known. We compared the results of our algorithm with Felleman & Van Essen (1991) model on the two data sets by plotting the linear regression line and the correlation between them, and our results were well fitted with the results of Felleman & Van Essen model. Thus, we can conclude that our method is able to capture the hierarchical organizations by using a small amount of information, and this study will help to investigate diverse brain hierarchical organizations.

Title: Bayesian model inversion of coupled mean-field integrate-and-fire populations: application to voltage-clamp currents and firing rates of CA1 neurons during gamma oscillations

Authors: ***M. F. LEITE**[1], P. FIGUEIREDO[2], K. FRISTON[3], D. KULLMANN[4], L. LEMIEUX[4];
[1]Inst. of Neurol., London, United Kingdom; [2]Dept. of Bioengineering. Inst. for Systems and Robotics, Inst. Superior Técnico, Univ. de Lisboa, Lisbon, Portugal; [3]Wellcome Trust Ctr. for Neuroimaging, [4]Dept. of Clin. and Exptl. Epilepsy, UCL Inst. of Neurol., London, United Kingdom

Abstract: The scientific investigation *in vivo*, *in vitro*, or via computational modelling of gamma oscillations has now a long history, yet it continues to attract great interest in the scientific community due to the critical role these oscillations play in active states of the healthy and diseased mammal brain (e.g. [1]). Here we introduce and showcase a new methodology that bridges the gap between these different investigative approaches. Namely, we build a mean-field population model of conductance-based integrate and fire neurons that is able to make specific predictions about both trans-membrane currents and neuron firing rates. When coupled, these population models can show a wide repertoire of behaviours. Here, we couple one population of pyramidal cells and one population of inhibitory interneurons in accordance with previous successful modelling studies of the mechanisms of gamma oscillations [2]. Further, we extend a Bayesian model inversion technique, Dynamic Causal Modelling [3], to handle dynamics in limit-cycle (or generally in closed orbit) regimes. We use prior parameter distributions for CA1 neurons from a public database [4]. We then use cycle averaged data recordings of voltage clamp currents at -70 mV and +10 mV, and firing rates from one sample pyramidal neuron and one inhibitory interneuron, showing firing rate phase coupling with the on-going carbachol induced gamma oscillation, in the CA1 region of a rat hippocampal slice preparation. The empirical data and predictions from the fitted model are presented in figure 1 and demonstrate good agreement. Following model inversion, one can now make predictions about new data independent of the fit, for example, inter-spike time interval (ISI) distributions, and identify the dominant mechanism and ways of modulating the underlying gamma oscillation (e.g. E-I vs I-I). Abstract: Large-scale recording methods make it possible to measure the statistics of neural population activity, and thereby to gain insights into the principles that govern the collective activity of neural ensembles. One hypothesis that has emerged from this approach is that neural populations are poised at a thermodynamic critical point, and that this may have important functional consequences. Support for this hypothesis has come from studies that identified signatures of criticality (such as a divergence of the specific heat with population size) in the statistics of neural activity recorded from populations of retinal ganglion cells. What mechanisms can explain these observations? Do they require the neural system to be fine-tuned to be poised at the critical point, or do they robustly emerge in generic circuits? We show that indicators for thermodynamic criticality arise in a simple simulation of retinal population activity, and without the need for fine-tuning or adaptation. Using simple statistical models, we demonstrate that peak specific heat grows with population size whenever the (average) correlation is independent of the number of neurons. The latter is always true when uniformly subsampling a large, correlated population. For weakly correlated populations, the rate of divergence of the specific heat is proportional to the correlation strength. This predicts that neural populations would be strongly correlated if they were optimized to maximize specific heat, which is in contrast with theories of efficient coding that make the opposite prediction. Our findings suggest that indicators for thermodynamic criticality might not require an optimized coding strategy, but rather arise as consequence of subsampling a stimulus-driven neural population.

Title: Network analysis of prefrontal cortical microcircuit dynamics after chronic stress hormone exposure and ketamine treatment

Authors: *R. N. MODA[1,2], J. WITZTUM[3], C. LISTON[2];
[1]Neurosci., [2]Brain Mind Res. Inst., [3]Physiology, Biophysics, and Systems Biol., Weill Cornell Med. Col., New York, NY

Abstract: Chronic stress has been shown to alter neuronal morphology within the prefrontal cortex (PFC). This includes dendritic retraction and spine loss. Additionally, clinical studies have shown that low doses of ketamine, an NMDA antagonist, can act as a fast-acting antidepressant in treatment-resistant depressed patients. This is thought to be mediated in part by a ketamine-induced increase in postsynaptic dendritic spine density in PFC pyramidal cells. How changes in synapse number and dendritic morphology affect PFC microcircuit function is not well understood. To address this question, we investigated neural network dynamics in PFC microcircuits using two-photon calcium imaging. Mice were intrancranially injected in the prefrontal cortex with a pan-neuronal GCaMP-expressing AAV virus, and a glass window was implanted in the skull for visualization of GCaMP-expressing cells. PFC microcircuit activity was quantified by two-photon calcium imaging before and after a chronic, 21-day exposure to corticosterone, the principal murine stress hormone, via corticosterone tablets that were implanted subcutaneously. The mice were then injected with an acute intraperitoneal dose of ketamine, and repeat imaging was performed 24 hours later from the same neural population. PFC microcircuit activity and network properties were analyzed, and results suggest that chronic corticosterone exposure reduces individual cell activity and functional connectivity in the PFC. Further, analysis of graph metrics of functional connectivity in PFC networks support the hypothesis that chronic corticosterone exposure reduces network efficiency, the strength of neural connections, and nodal clustering. Importantly, a single injection of ketamine partially modulates these deficits, resulting in increased cell activity and functional connectivity.

Title: Path-analytic Structural Equation Modeling to evaluate connections between primary sensorimotor cortical regions in chronic stroke

Authors: *K. JUNG[1], M. R. BORICH[2];
[1]Pediatrics-CLI, Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [2]Rehabil. Med., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Previous studies of sensorimotor control have demonstrated the primary motor and sensory cortices are dynamically coupled during movement. In chronic stroke, measures of cortical grey and white matter morphology have been correlated to altered cortical excitability and cortical connectivity. However it is not yet evident how these regions are connected and influence one another to support sensorimotor control after stroke. Here, we employed a path-analytic structural equation modeling (SEM) approach for such a brain connectivity analysis, called path-analytic generalized structured component analysis (GSCA; Hwang & Takane, 2014). Path-analytic GSCA enables specification and estimation of the relationships among ROIs. For parameter estimation, path-analytic GSCA applies a least squares estimation method, and the standard errors of parameter estimates are estimated by the bootstrap method. As such, Path-analytic GSCA is computationally efficient in dealing with more elaborate and complicated brain connectivity models without recourse to distributional assumptions. We applied path-analytic GSCA to a bi-directionally connected structural model of cortical thickness data extracted from four ROIs chosen a priori to investigate primary sensorimotor regions bilaterally (M1_ipsilesional(i), S1_i, M1_contralesional(c), and S1_c) in particpants with chronic stroke (n=8) and four ROIs (M1_Right(R), S1_R, M1_Left(L), and S1_L) in healthy controls (n=8). Then, we examined the difference between the stroke group and healthy controls on the structural paths in the hypothesized model. The result of our analysis revealed that there were statistically significant differences for the following structural paths: (1) bidirectional paths between M1_i and S1_i (controls: M1_R and S1_R); (2) a unidirectional connection from M1_i to M1_c (controls: M1_R and M1_L); (3) a unidirectional connection from S1_i to S1_c (controls: S1_R and S1_L); (4) a unidirectional connection from S1_c to M1_c (controls: S1_L and M1_L). These preliminary findings suggest there are differences in intra- and inter-hemispheric primary sensorimotor structural coupling. All participants with stroke demonstrated minimal-moderate motor impairment. Thus, the observed differences in structural connectivity may provide insights into the mechanisms and behavioral consequences of sensorimotor reorganization after stroke. Future work will apply Dynamic GSCA to time-series data to further delineate connections within the sensorimotor control network and the influence of reorganization of these connections on motor performance in individuals with stroke.

Title: Statistics of brain functional networks: Classification and Testing

Authors: *D. FRAIMAN[1,2], N. FRAIMAN[3], R. FRAIMAN[4];
[1]Depto. Matemática y Ciencias, Univ. San Andrés, Buenos Aires, Argentina; [2]CONICET, Buenos aires, Argentina; [3]Dept. of Mathematics, Univ. of Pennsylvania, Pennsylvania, PA; [4]Ctr. de Matemática, Univ. de la República, Montevideo, Uruguay

Abstract: It is common today to describe neuroimaging data by using network or graph theory. Nevertheless, techniques for statistical analysis of these networks are not very developed. We herein address some statistical problems associated with the time evolution of brain functional networks constructed from EEG, MEG, or fMRI data. The approach presented here is non-parametric, i.e. it does not rely on a particular network model. Natural notions of center, variance and a depth function for networks that evolve in time are introduced. This allows us to develop several statistical techniques including testing, supervised and unsupervised classification, and a notion of principal component sets in the space of networks. Among other things, the results presented are important for the development of new diagnostic methods based on brain functional or structural network data. We show some examples, as well as a real data example.

Title: Noise assisted empirical mode decomposition and phasor analysis for the characterization and detection of oscillations in the local field potential

Authors: *J. M. MIKKILA;
Psychology, York Univ., North York, ON, Canada

Abstract: Oscillations in the local field potential of cortical and subcortical structures are inherently non-stationary and comprised of an unknown number of components. The most common methods for characterizing the power spectrum (PSD) of the various oscillatory components of the local field potential require assumptions which are inherently violated by the data in question [1]. Namely the discrete Fourier transform requires a signal be periodic in the sampling time, and therefore stationary, while analyses based on the analytic representation of convolved bases require there to be a single component within the filtered band. These assumptions are routinely violated by researchers in neuroscience, and the results of these analyses compromised. In the case of quantifying the PSD of a segment of non-periodic signal, energy is spread to other frequency bins in such a way that the actual peaks in power can cease to exist, and non-existent ones occur [1]. While in the case of time-domain analysis, co-existent near components become conflated and are not suitable to characterization by a solitary pair of phase and amplitude measures. In place of analysis utilizing the Fourier transform, we demonstrate a variant on the complete ensemble empirical mode decomposition (CEEMD) [2] hybridized with heuristics on improving the accuracy of the EMD [3]. While phasor analysis using the Fourier assumptions inherent in the inverse DFT are subject to Gibbs artifacts. We leverage an assumption free set of phasor analyses [4] which can provide a highly accurate measure of the power spectrum and constituent oscillatory components. This scalable design allows for parallelization of the noise assisted realization of the CEEMD on GPUs or computing clusters. Furthermore, without assumptions, or time windows of analysis, this procedure alleviates both time and frequency uncertainty bounds providing a lossless description of the signal in the finite and minimum number of component descriptors. Title: Functional graphical models of mouse visual cortex

Authors: *E. TARALOVA, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Despite a century of intense research, neuroscience still lacks computational models of visual stimuli and the spatio-temporal firing patterns they elicit in the visual system of animals or humans. Traditional imaging techniques like functional magnetic resonance imaging (fMRI) indirectly measure responses of large numbers of neurons (voxels). However, to understand how neural activity gives rise to cognition, we need to model how collections of hundreds of neurons engage in complex interactions over time. In contrast to whole-brain or micro scale imaging of a small number of neurons, new imaging methods like two-photon calcium imaging can record the firing of hundreds to thousands of neurons in living animals. Imaging the operation of neural circuits at this mesoscale will enable better understanding of the cortical information processing algorithms relating the activity of neurons to visual stimuli. We develop machine learning methods to decipher the neural code that links perception with the firing of neurons in the cerebral cortex. We propose novel mathematical models for holistic neuron data analysis that provide a framework for understanding the neural circuitry, which is unattainable with current single neuron methods. The proposed models are data-driven and capture the probabilistic conditional dependencies between the neural activity and the visual stimuli. We have conducted targeted neurophysiological experiments that interrogate the operation of mesoscale cortical computing circuits in awake behaving mice using two-photon calcium imaging. We record spontaneous activity and activity evoked by a database of visual stimuli ranging from drifting gratings, wavelets, composite textures and complex scenes. Using this neurophysiology data we train Bayesian graphical models to capture the spatio-temporal functional dependencies between neurons. The result is a compact representation that links visual stimuli to neural activity. We validate the models in the tasks of encoding (predicting) the neural activity and decoding (classifying) the visual stimuli. This work contributes novel machine learning tools for analyzing the functioning of neural circuits that are critical to advancing our understanding of the primary visual cortex. Discovering how the neural circuitry involved in visual perception works is an essential step toward understanding central visual pathologies and developing treatments. Furthermore, decoding the neural activity will bring us closer to bridging the gap between the firing of groups of neurons and perception, and, ultimately, cognition.

Title: Statistical estimates of neocortex semantical allocation breakdown

Authors: *L. SEYMOUR;
Persinvitro, LLC, Lake Barrington, IL

Abstract: Providing quantified statistical estimates of the semantical allocation of the neural microcircuit network in the neocortex have not been explored in the past. These statistics would unquestionably support both neuroscience research and commercial, information technology developments in personalizing products. A method and process are described in this presentation based on an integrated R&D landscape of the current state-of-the-art in computational neuroscience, big data analytics, artificial general intelligence, digital biomedical diagnosis repositories and pervasive multimedia and sensory data aggregation. The method is driven by an agreed upon and real-time updated ontology of concepts, the hierarchy of the concepts, the evolution of the configuration of the concept allocation in the neuronal network during the lifetime of the subjects, the aggregation of crowdsourced concept allocation statistics across a reference group of subjects, the contextual correlation between the lifetime use of the concepts and the multiple instantiation of any single concept across a number of physically different neural microcircuits. Initial estimates show that using several different alternative approaches of the aggregation processes and algorithms would lead to a consistent variance range in microcircuit capacity allocation needs for a specific portfolio of concepts. The variance improves as the solutions are enhanced for broader coverage. These results indicate that building software tools for scalable commercial strength coverage of the concept ontology and the entire neocortex capacity is feasible at the current state of the art in the underlying domains characterized here in the interdisciplinary landscape analysis.

Title: Understanding the structure and origin of transcranial magnetic stimulation artifacts in electroencephalographic signals

Authors: D. FRECHE[1], N. LEVIT-BINNUN[1], J. NAIM-FEIL[2,1], M. RUBINSON[2], *E. MOSES[2];
[1]Interdisciplinary Ctr. (IDC), Herzliya, Israel; [2]Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The concurrent use of transcranial magnetic stimulation (TMS) and electroencephalography (EEG) is emerging as a powerful tool to directly probe cortical excitability and connectivity of the brain. Currently, a critical limitation for the field of TMS-EEG research is the strong artifact evoked by the TMS pulses in the EEG recordings which may persist up to a hundred milliseconds after the pulse and mask underlying neural activity. Despite the developments of new hardware solutions, improved EEG amplifier technology and application of various artifact removal methods (ICA and PCA), the artifact may be suppressed but cannot be completely removed from the recordings. Insufficient artifact removal may hinder interpretation of cortical responses and especially prevent analysis of TMS-EEG data with network-based analysis tools. To address these limitations, we provide a description of the TMS-evoked artifact and clarify its main origin. A quantitative model is constructed, capable of generating and reproducing the TMS artifact. The dominant contribution to the artifact comes from the charge distribution on the electrodes and the structure of the scalp. While puncturing the skin and using abrasive electrode gel can reduce the artifact, this does not completely suppress it. Our Scalp Artifact Model can be used to subtract and correct for the dominant TMS-evoked scalp-related artifact in the EEG recordings. We demonstrate that the Scalp Artifact Model should be applied prior to other physiological artifact removal methods (e.g. ICA or PCA for eye blinks or muscle movement) and that it greatly advances our ability to index cortical excitability and connectivity of the brain with TMS-EEG. This novel artifact model opens the possibility to apply graph-theory analysis tools to investigate network dynamics and stability of the brain using TMS-EEG.

Title: Bringing knowledge to data: Visualizing coverage of the neuroscience data space in the Neuroscience Information Framework

Authors: ***T. GILLESPIE**[1], A. E. BANDROWSKI[1], J. S. GRETHE[1], M. E. MARTONE[2]; [1]Neurosci., UCSD, LA Jolla, CA; [2]Neurosciences, UCSD, La Jolla, CA

Abstract: What do we known about the brain? Currently, we cannot answer this question in a meaningful and concise way because much of information that we have is in a form that is inaccessible and difficult to digest algorithmically, i.e., the published literature. Since 2008, the Neuroscience Information Framework (http://neuinfo.org) has been aggregating data collected about the brain that is scattered across hundreds of different websites and databases and now searches across 200 databases comprising over 800 million records. The richness of the aggregated dataset allows us to ask more global questions about the state of neuroscience information. Here we use NIF's aggregate data and knowledge sources to reveal knowledge gaps and biases in the neuroscience dataspace. We use the NIF semantic framework, a collection of community-based ontologies covering the major domains of neuroscience, e.g. neuroanatomy, to tag the aggregate data sources. A Python-based workflow was developed to replace a prototype built in Kepler that queries for each term in the ontology across all data sources. These queries are used to produce semantically-enhanced "heatmaps" indicating the frequency with which terms do or do not appear in the dataspace. These heatmaps provide a unique overview of representation of neuroscience concepts within and between sources. Because the ontologies are relatively well populated, they represent a proxy for the state of knowledge within any one subdomain, e.g., brain anatomy, or disease. A comparison of the representation of neuroscience concepts across all sources shows that these entities are not uniformly studied; rather, we have over-representation of some entities and under-representation of others. For example, brain

structures in the forebrain tend to be more heavily represented than those in the midbrain and hindbrain. Further we show where and at what level of granularity concepts cross between different data types and sources. These heatmaps provide a unique opportunity to represent what we are calling the “neuroscience data space”, that is, data that is easily accessed by machine. We are currently exploring reasons for under- and over-representation through comparison with the literature and data sources like the NIH RePORTER for funded grants. We are also examining possible sources of experimental bias, particularly within the neuroimaging domain. The heatmap generation workflow is currently being ported to a web interface so that anyone can generate heatmaps for their domain.

Title: High performance computing web service for the analysis of local field potentials

Authors: *S. MACKESEY[1], M. PRABHAT[2], G. BUZSÁKI[3], A. KHOSROWSHAHI[4], F. SOMMER[1];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]New York Univ., New York, NY; [4]Nervana, San Diego, CA

Abstract: High-density multielectrode recordings of neural activity offer unprecedented opportunities to understand the function of the brain. However, the dimension of the data often prevents the broad mining of the signal structure. For example, the multi-site local field potential (LFP) is still a largely unexplored frontier in neural coding. Successful recent approaches to extract information from the LFP combined unsupervised and supervised learning methods, e.g., Agarwal et al 2014. We propose to create a community web service offering the computing resources and the software framework for processing large neurophysiological datasets. The resource will use the Lawrence Berkeley National Labs' NERSC (National Energy Research

Scientific Computer Center) supercomputing cluster, as well as the data format standard emerging from the Neurodata Without Borders (NWB) project. Here we present a proof-of-concept of this web service for a data analysis pipeline consisting of the following three steps: (1) filter to a band of interest; (2) apply unsupervised learning methods to the filtered data; (3) assess the correlation of learned features with stimulus, behavioral, or other physiological variables using supervised learning methods. A parallel implementation of convolutional sparse coding (CSC) for unsupervised learning was developed and optimized for running on the supercomputing cluster. The implementation plugs into a library that reads and writes dataset files structured according to the developing NWB data format standard. The features resulting from CSC, as well as their association with arbitrary behavioral, stimulus, or other physiological variables (e.g. position), may be visualized via a web interface. We demonstrate our toolset's utility using a 512-channel neurophysiology dataset captured via silicon probes embedded in the hippocampus of rats navigating a linear track. The raw LFPs were filtered into 4 frequency bands: 6-10 Hz (theta), 20-55 Hz (slow-gamma) , 60-100 Hz (fast-gamma), and 20-100 Hz (broadband gamma). Sparse dictionaries for the data were derived using our CSC implementation. We quantified the localization of the resulting sparse features and used generalized linear models to assess their correlation with position.

Title: Exploring data-driven techniques for visual representation of neuronal micro-connectomes

Authors: *L. MARENCO[1,2], R. WANG[1], R. A. MCDOUGAL[2], T. M. MORSE[2], N. T. CARNEVALE[2], P. MILLER[3,1], G. M. SHEPHERD[2];

Abstract: The connectivity between neurons in the brain, often referred to as connectomics, is driving much current research on fiber tracts between and interconnectivity within brain regions. This is creating the need for neuroinformatics support for databases for the neuronal data, and a

new generation of efficient digital representations of the interconnections and interactions underlying neuronal integration so that they can be both searchable by automatic search tools and extended as new data is obtained. SenseLab, an interoperable suite of databases dedicated to supporting research on dendritic properties and synaptic organization, is being adapted for these new connectomics challenges. Building on the SenseLab extensible data model, our group is increasingly incorporating new connectivity details at the neuronal compartment level. Part of this new information is currently described using new neuronal connectivity pages in NeuronDB. The complexity of this information poses challenges to creating new interfaces. Our solution to this problem has been to build an interface capable of exposing complex neuronal connectivity in a simple, yet extensible way, with the ability to accommodate new categories of data in the future. The new tool we are developing for this purpose uses data-driven techniques to render dynamic graphics via internet browsers. This application retrieves neuronal information from our soon to be released new versions of FunctionalConnectomesDB and NeuronDB. The categories of information used by this tool comprise: a) Microcircuit; b) Neuron: type (principal and interneurons), canonical form and compartments, and relative size; and c) Synapses: transmitter type released from a cell compartment (e.g. glutamate from an axon terminal) and receptor type activated from a cell compartment (e.g. NMDA receptor in a proximal dendrite). We are incorporating brain regions as well as region/layers in order to cluster these neuronal compartment connections. The tool is available at this URL http://ycmi.med.yale.edu/PubLinks/HBP/2015SfNConDiagram

Title: Representation of depth electrodes using parcellated cortical surface maps

Authors: *M. ROLLO[1], C. M. KADIPASAOGLU[1], N. TANDON[2];
[1]Neurosurg., Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX; [2]Mem. Hermann -TMC, Houston, TX

Abstract: The use of intracranial electroencephalography (icEEG) recordings in patients with pharmaco-resistant epilepsy is a common strategy in epilepsy surgery. This is generally conducted using subdural grid electrodes but the advent of neurosurgical robotic assistance has made stereotactic EEG (sEEG) using depth electrodes a broadly viable option. Currently, methods to localize the depth electrodes in imaging space are lacking. Precise localization is crucial when determining seizure foci and the representation of detected electrical fields is necessary to plan interventions after sEEG electrode placement. Here, we describe a novel method to precisely localize depth electrodes in patient specific imaging space. To localize the depth electrodes, the patient's Axial Bone CT is first aligned with their T-1 weighted image using AFNI. We then use FreeSurfer to processes the T-1 weighted image and create parcellated cortical surface maps (FreeSurfer software). The parcellated cortical surface maps are then converted into masks for the left and right hemisphere via AFNI. The masks are applied to the co-registered CT to remove the skull and any artifacts outside of the skull. The masked CT scan is also thresholded so that only the artifacts representing the depth electrodes remain. Regions of interest (ROIs) are then created around the artifacts using AFNI's 3dclust command, which determines the coordinates for the maximum intensity value in each volume cluster. These coordinates represent the center of each contact and are used to create a displayable object in SUMA. Thus, the depth electrodes are localized and can also be visualized in SUMA, along with the cortical surface reconstruction of the patient's brain. Additionally the prior cerebral parcellation can be used to isolate the gyral labels for each individual recording electrode as well as identify which electrodes are located in white matter, in semiautomatic fashion.

Title: Atomizing data to ensure that experimental, analytical and/or administrative data points, are: tangible, useable, fixed and federatable (TUFF-data)

Authors: *P. S. PENNEFATHER[1,2], W. SUHANIC[2];
[1]Univ. Toronto, Toronto, ON, Canada; [2]gDial Inc, Toronto, ON, Canada

Abstract: Neuroscience data now generally exist within digital formats. This makes it easier to transpose data points from one format to another, or one location to another. During initial creation of a data point or its subsequent transformation or translocation, key information about that data point can be lost. For example, information about data identity or context and process that led to its creation can be lost making it harder to determine if the data is what it is supposed to be. Even if that information can be recovered, that process can be costly. Here we discuss the feasibility of atomizing data at its point of creation through uniquely identifying instantiation of any particular data point. By atomized data, we mean that each data point is uniquely identified and recognized in a manner dependent on its elemental digital properties regardless of its information content. For that purpose, it is necessary to explicitly define the concept of a data point as being composed of: 1)the value returned by an query or probe within a predefined framework and 2)documentation of information necessary and sufficient for evaluating whether that value is accurate and replicable (i.e. reproducible). In that sense, the actual value is like an atomic nucleus and its reproducibility documentation acts like an atomic electron cloud. Together, they provide the data point with substance and chemistry allowing this elemental unit of data matter to interact and be combined into larger more complex data objects. That chemistry should occur without changing the identity and integrity of the objects atomic components and should remain unchanged during recording, archiving or retrieval processes. Unlike physical atoms, the periodic table of atomized data-points can consist of any arbitrarily large address space represented by any valid number system. This poster will describe a general method for atomizing data in a way that can be implemented with commodity instrument components and commodity software. The method is demonstrated using a computer controlled consumer camera sensor (a Canon DSLR). A data value generated by an area of interest on that sensor is bundled up with reproduction documentation and stored in a data point archive file format like ZIP. This data point is then uniquely identified in a way dependent of that value and that documentation within that archive using an algorithm. The identifier remains the same no matter how many times the value and its documentation are accessed and interrogated. The approach atomizes data-points and makes them: tangible, usable, fixed and federatable (TUFF-Data). It also enables an Ato-Publication strategy for promoting open science and replication.

Title: A new paradigm in accessing and analyzing big brain data

Authors: *J. KORICH[1], N. J. O'CONNOR[1], P. J. ANGSTMAN[1], B. S. EASTWOOD[1], M. J. FAY[1], J. O. BLAISDELL[1], S. J. TAPPAN[1], K. E. DAY[1], H. J. KARTEN[2], C. R. GERFEN[3], J. R. GLASER[1];
[1]MBF Biosci., Williston, VT; [2]Dept. of Neurosci., UCSD, San Diego, CA; [3]Lab. of Systems Neurosci., NIMH, Bethesda, MD

Abstract: Recent advances in slide scanning technologies and sample preparation have ushered in a new era of big data in microscopic brain imaging. Clearing techniques that allow deeper imaging into intact tissues, and fast high-resolution whole slide scanning technologies result in data sets that easily exceed tens of terabytes of image data per brain. These big image sets introduce new challenges in image storage, organization, viewing, and analysis. To overcome these hurdles we developed a platform for storing, serving, organizing, viewing, and analyzing large-scale image data. The platform consists of three networked components: 1. high-performance image server software and database (Biolucida), 2. an image storage device, and 3. a portable image analysis suite (BrainMaker, NL360). The image analysis software supports the alignment and compilation of 3D images from full resolution serial sections automatically delineated from whole slide images, neuronal reconstruction and connectivity analysis, and cellular population estimation. Together, these methods provide previously unavailable high resolution measurements from big data images with anatomical context provided by visualizing the aligned 3D images. Here, we present three sets of brightfield whole slide images containing Giemsa stained series through Nile rat brain residing on a server (wiley.biolucida.net/images)

and accessed by our remote analysis tools from MBF offices in Vermont. Serial sections were extracted, aligned, and compiled into 3D images and rendered. For these reconstructions, estimations of the volume of cholera toxin-B tracer tracts through the brains were generated. Also, previously aligned and compiled fluorescent 3D images of mouse brain were served from the GENSAT collection (GENSATcreBrains.biolucida.net) and rendered in 3D. Automated estimates of cellular population statistics are also reported. These examples present our platform's ability to remotely visualize and analyze whole slide image data in the forms of unprocessed serial sections and volumetric data. Increasingly large data sets from modern imaging methods (e.g., quantitative array tomography, light sheet microscopy, and clearing methods) necessitate a platform for managing, serving, and analyzing big data. Efficiently serving big neuroanatomic image data to remote analysis facilities alleviates the need to maintain and transfer multiple copies of image data that exceed typical storage, memory, and file format size limitations. It is our hope that it also opens the possibility of independent evaluation and open sharing of primary data by third-party observers.

Title: Unified real-time searching of keywords and attributes in ModelDB

Authors: *T. M. MORSE, R. A. MCDOUGAL;
Neurobio., Yale Univ. Sch. Med., New Haven, CT

Abstract: ModelDB is a public database that supports computational neuroscience by making models associated with publications available for download. Readily accessible model source code is critical for allowing simulation results to be verified and extended. By sharing code, ModelDB also acts as a common place to find examples of how to implement models for each of the approximately 70 different simulation environments represented in the database. ModelDB has grown to include the source code for approximately 1000 published computational neuroscience models. This large number of models has made it critical to provide search tools that assist researchers -- both experimentalists and modelers -- in finding models of interest. Previously we created a variety of search strategies (paper author name or model accession number, full text search, attribute (keyword) search, etc). Multiple search methods burdened the modeler with the decision of which search method to use. To simplify and accelerate searching, we (R.A.M.) replaced the multiple search fields on ModelDB's homepage with a single search box -- available at the upper left of every ModelDB page -- that combines full text, attribute, and model accession number searches. After a few characters are entered, the search box dynamically supplies possible completions and attribute search results with headers in a drop-down list. Attributes are considered to match if any part of the value matches the entered text; for example, a search for "memory" would suggest the model topic "working memory". Author suggestions include a secondary drop-down menu with each of that author's models; clicking on a model title opens the corresponding model. Full text suggestions list possible completions for the word being entered; if there are no completions shown for a 3+ letter word, then the entered characters do not begin a word in the repository, indicating a possible typo. The figure shows an example of the real-time search results. The new method greatly enhances the ability of researchers to find models directly relevant to their interests.

Title: Independent Component Analysis (ICA) for ocular artifact correction in EEG data is far from perfect: limitations and trade-offs

Authors: *J. DREO, B. PIKŠ, A. EMERŠIč, Z. PIRTOŠEK;
Lab. For Cognitive Neurosci., Ljubljana, Slovenia

Abstract: Among the common EEG artifacts blinks represent one of the biggest challenges to quantitative analysis. This is because they occur very frequently, have large amplitudes compared to background EEG and also contaminate all scalp channels -albeit to differing degrees. Their efficient correction is thus paramount to most QEEG analyses. Independent Component Analysis (ICA) is a mathematical method of generating components that are linear combinations of the original EEG channels. While the resulting components do not necessarily have any a priori relation to physical sources, it is often noticed that they are similar to known source signals (muscular, alpha wave, eye-movements···). Excluding components that likely contain blinks, before re-assembling the rest, effectively subtracts blinks from EEG data. But since no component is truly "clean" (free of any other type of source activity) removing blinking-related components will also remove at least some genuine EEG signals. We conducted a basic review of 147 recently published EEG papers (2015-2012) and found that of those using and adequately reporting on ocular artifact correction (OAC): 58% used ICA, 25% a regression method, 11% source analysis and 6% used other methods. Since ICA seems to be the most popular method of OAC, assessing how effective it is and also how might corrupt EEG data is crucial. We assessed the effect of A) two ICA algorithms (Infomax, FastICA), three input data lengths (300, 600, 900 sec) and C) 6 different levels of component exclusion (1, 2, 3, 4, 5 and an adaptive method) on the efficiency of OAC and EEG preservation. The former was quantified by averaging 1 sec segments surrounding blink peaks after their removal by ICA. The average amplitude remaining after ICA on frontal EEG channels in the interval [-150,+150] ms relative to blink peaks was used as a measure of remaining blink activity. We quantified the preservation of background EEG activity by the remaining P3 amplitude in an Oddball task after ICA. These analyses were performed on 37 healthy subjects using 64-channel EEG data sampled at 500 Hz. Our results show that even when rigorously selecting which components to exclude based on correlation analysis, ICA still leaves between 2-20 μV of blinking-related activity. Trying to reduce these residual artifacts by excluding more components (>3) seriously degrades EEG activity as measured by decreases of P3 amplitudes on the order of 10-50%. We thus conclude that ICA, while often employed, is far from a perfect method of OAC. It is a sub-optimal trade-

off between blink removal and EEG preservation and commonly leaves contamination comparable to ERP amplitudes on frontal and central channels.

Abstract: The application of 2-photon laser scanning microscopy (TPLSM) techniques to measure the dynamics of cellular calcium signals in populations of neurons is an extremely powerful technique for characterizing neural activity within the central nervous system. Moreover, the use of awake and behaving subjects is becoming necessary in order to understand how neural circuit elements cooperatively interact to form sensory perceptions and generate behavior. A major challenge in imaging such preparations is the relative motion between the imaging location and the microscope due to animal and tissue movement. Although there are surgical and technical approaches to minimize brain motion under these conditions, it is generally unavoidable. This relative movement creates presence of image jitter at different times within the acquired image sequence. The presence of image jitter, particularly in the Z-dimension, is highly problematic when trying to quantify fluorescence signals from small regions of interest (ROIs) within the image sequence. Here, we used TPLSM to image either a) static signals from fluorescent proteins expressed in subtypes of cortical neurons or b) dynamic signals from genetic encoded calcium indicators in the superficial layers of auditory cortex of anesthetized or awake mice. In addition, we imaged in single and across multiple focal planes (i.e., volumes) of cortical tissue. To address the problem of brain motion, we have developed a procedure of motion compensation that relies on locating neurons and tracking their positions

over time. Object tracking is accomplished using established techniques of image processing that we have adapted from the field of soft matter physics. We describe the performance of our techniques both for 2D (single plane) and 3D (volume) image sequences. For comparison, we also present the performance of widely used image registration techniques. Our analysis demonstrates the benefit of correcting for vertical motion across focal planes, as a means of suppressing false neural signals.

Title: A comparison of motion correction techniques applied to functional near-infrared spectroscopy data from children

Authors: ***X. HU**[1], M. M. ARREDONDO[2], N. CONFER[1], A. DASILVA[3,4,1], M. SHALINSKY[1], I. KOVELMAN[2,1];

Abstract: Functional near-infrared spectroscopy (fNIRS) is an emerging optical brain imaging technique, and is becoming an increasingly popular method for child brain imaging. fNIRS measures the hemodynamic changes that effectively reflect brain activities occurring while people perform a wide range of mental tasks; it can provide both topographic and tomographic brain images Motion artifacts are significant sources of noise in functional near-infrared spectroscopy (fNIRS) data, especially in studies with child and infant participants. In fact, motion artifacts are one of the most significant concerns in pediatric brain imaging designs and data analyses. Different methods have been developed to correct motion artifacts in fNIRS data, but the relatively effectiveness of these methods towards pediatric data_which is often found to be significantly noisier than adult data_remains largely unexplored. The issue is further complicated by the heterogeneity of fNIRS data artifacts. In the current study, we compared the efficacy of the six most prevalent motion artifact correction techniques with fNIRS data acquired from children participating in a language acquisition task, including wavelet, spline interpolation, principal component analysis (PCA), moving average (MA), correlation based signal

improvement (CBSI) and combination of wavelet and moving average. We evaluated five predefined metrics (including the motion artifact quantity variation, t-values and R-values of general linear model regression, the area under the hemodynamic curves from 0-1.5 seconds and 1.5-3.0 seconds) to quantitatively evaluate the performance of the different motion correction methods. The comparison results suggest that the moving average and wavelet methods yield the best outcomes. These findings elucidate the varied nature of fNIRS data artifacts, the efficacy of artifact correction methods with pediatric populations, and will help inform both the theory and practice of optical brain imaging.

Title: Informatics tools for mapping brain connectivity at meso- and micro-scale

Authors: ***L. FENG**[1], H. JEON[2], H. LEE[2], O. KWON[2], J. KIM[2];
[2]Ctr. for Functional Connectomics, [1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Comprehensive knowledge of how brain areas and neurons are connected at both meso- (region-by-region) and micro-scales (synapse-by-synapse) is essential for understanding brain functions. Guided by the established brain-wide online meso-scale connectome resources (www.mouseconnectome.org and http://connectivity.brain-map.org), we developed a platform for further detailed sub-region and synapse-level circuit mapping in basal ganglia circuitry. We obtained meso-scale dataset from injections and projections of fluorescent protein-expressing viral tracers and micro-scale dataset from mammalian GFP reconstitution across synaptic partners (mGRASP)-assisted circuit mapping (mGRASPing). We built a system that can reliably extract wiring information from digitized meso- and micro-scale images and reconcile these data into a hierarchical structure in a common 3D reference space. The system features 2D brain slices alignment, 3D registration or co-registration with reference atlas and proof editing. To achieve the high accuracy of registration required for sub-region connectivity mapping, anatomical annotations from registration were converted to splines and manually corrected if necessary. We believe that comprehensive cross-referencing of connectivity data from different scales into the same reference space will allow for exploring complex neuronal networks at multiple scales and will facilitate understanding circuit functions.

Title: M-sorter2015: enhanced automatic spike sorting

Authors: *S. WANG, W. MA, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: M-Sorter was first introduced in 2012 (Yuan et al., 2012) aiming at automatic sorting of action potentials (spikes) based on raw neural waveforms. Potential spike detection in M-Sorter was based on our own multiple correlation of wavelet coefficients (MCWC) algorithm (Yang et al., 2011), which was followed by a template matching for spike clustering. A major update took place in M-Sorter2014 where spike clustering was carried out by our new accurate and robust expectation-maximization (AREM) algorithm. In this study, we present the 3rd generation M-Sorter, or M-Sorter2015, which takes advantage of improved MCWC and AREM. Also in the new version, we developed an accurate and robust variational Bayesian (ARVB) approach for automated clustering as an alternative. The M-Sorter2015 consists of three major modules: 1) spike detection using improved MCWC; 2) feature extraction function by principle component analysis, independent component analysis, Wavelet-based analysis, Laplace Eigenvalue, or Relieff algorithm; and 3) automatic clustering by AREM or ARVB. Only two easy-to-choose free parameters, i.e. the noise floor level τ and the spike quality level S, need to be determined prior to using M-Sorter2015. The parameter τ for the namesake is the noise floor level from recorded signals. The spike quality level S reflects signal-to-noise ratio. Recommended S values are provided in the M-Sorters and were tested to show its robustness. The M-Sorter2015 was comprehensively tested and compared with M-Sorter2014, Klutakwik (Harris et al., 2000), Wave Clus (Quiroga et al., 2004) and Signal Energy detection plus T-Distribution EM clustering in Plexon's Offline Sorter (Plexon, Inc.). Sorting results from artificial datasets (Wave Clus software package) and labelled real datasets (Harris et al., 2000; Henze et al., 2000) demonstrated superior performance of M-Sorter2015 over all compared sorters. Results by M-Sorter2015 with AREM or ARVB had lower false alarm rates and higher accuracy than other sorters. The following measures were used in comparisons: 1) results consistency or repeatability, 2) accuracy in determining cluster numbers under conditions of poor SNR, high similarity among clusters, and overlapping spikes. Comparisons were also conducted using real datasets (Yuan et al., 2015; Mao et al., 2015). Sorter performance was examined by waveform shapes, spike counts, waveform variances of sorted spikes, and interspike intervals. Results showed that M-Sorter2015 was at least comparable to other sorters.

Title: Quantification of spatial gradients in cells and tissues

Authors: ***M. N. PAVELIEV**[1,4,2], N. LIPACHEV[2], N. ARNST[4], N. KULESSKAYA[2], M. SAARMA[3], H. RAUVALA[2];
[2]Neurosci. Ctr., [3]Inst. of Biotech., [1]Univ. of Helsinki, Helsinki, Finland; [4]Inst. of Fundamental Med. and Biol., Kazan Federal Univ., Kazan, Russian Federation

Abstract: Biochemical processes are spatially structured and compartmentalized both at the single cell and tissue levels. Tools are required for the quantification of the spatial distribution of biological molecules and cellular structures under normal and pathological conditions. Here we present two algorithms for the quantification of spatial gradients in single cells and in the spinal cord tissue. We propose a border-based contour segmentation method to quantify intracellular molecule distribution in cell microscopy images based on the distance from the plasma membrane. We use this method to quantify: 1) intracellular distribution of phosphorylated extracellular signal-regulated kinases 1/2 in confocal stacks in response to nerve growth factor and epidermal growth factor; 2) precursor form of glial cell line-derived neurotrophic factor in electron microscopy images; 3)spatio-temporal propagation of the intracellular Ca^{2+} response to glutamate in neurons. To quantify spatial gradients at the tissue level we propose an automated software tool measuring intensity and object size distribution around the hemisection injury site in the rodent spinal cord. We analyze the size and intensity of perineuronal nets (PNN) - the extracellular matrix structures that play an important role in the plasticity of the central nervous system. We demonstrate that the distribution of the PNN parameters is affected by the distance from the trauma epicenter and PNNs at the injury site differ from those in the uninjured tissue. Our results support the importance of the spatial distribution of biochemical processes at the cell and tissue levels under the normal and pathologic conditions.

Title: Live-cell high-content analysis of synapse loss and recovery during HIV-1 neurotoxicity

Authors: ***R. SPINDLER**, K. A. KROGH, S. A. THAYER;
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Here we describe a high-content analysis method that quantifies changes in excitatory synaptic connections between primary rat hippocampal neurons *in vitro*. A key feature of the assay is the ability to track synapses from the same neuron over time. Thus, the assay can quantify the formation of synapses during development of the neuronal network, loss of synapses during neurotoxic insult, and drug-induced recovery of synapses following loss. Primary hippocampal neurons were cultured in 96-well plates and transfected with plasmids that encode the fluorescent proteins tdTomato and PSD95-GFP. In each of the 96-wells, a stack of 8 confocal images was acquired in 5 fields per well using an automated spinning disk confocal microscope. The stage position of each stack was recorded, enabling return to the same positions at later times. Automated image analysis was developed using MetaMorph software that identified postsynaptic densities as green fluorescent puncta in contact with a binary mask created from the red fluorescence image. Cognitive decline correlates with synaptodendritic injury in many neurodegenerative diseases, including human immunodeficiency virus-1 (HIV-1)-associated neurocognitive disorders (HAND). Because HIV-1 does not infect neurons, synapse loss in HAND results from the release of neurotoxins from infected cells, such as the HIV-1 protein transactivator of transcription (Tat). Application of Tat produced significant synapse loss following 16 h exposure. Addition of an antagonist for GluN2B-containing NMDA receptors ifenprodil (at t=16 h), induced a significant recovery in the number of synapses by 24 h. Thus, the automated acquisition and analysis assay successfully quantified the neurotoxic loss and drug-induced recovery of synapses. This high-content analysis should prove useful for screening a library of pharmacologically active compounds that induce the recovery of synapses following neurotoxic loss.

Title: A voxel-based morphometry pipeline in a computer cluster environment

Authors: R. J. ANDERSON, J. J. COOK, J. C. NOULS, M. FOSTER, G. JOHNSON, *A. BADEA;
Radiology, Duke Univ. Med. Ctr., Durham, NC

Abstract: Introduction Anatomical phenotyping provides important biomarkers in mouse models of disease. Regional differences for anatomical regions defined in reference atlases (e.g. Waxholm) can be quantified after spatial normalization. Analyzing the deformation fields provides insight into morphometric change, and applying them to magnetic resonance diffusion tensor imaging (MR-DTI) parameters provides insight into microstructural changes. We present an efficient pipeline for regional and voxel based analysis, implemented in a high-performance computing environment. Methods The pipeline is scripted in Perl and runs on a cluster consisting of six nodes using the SLURM resource management software. We use MATLAB and Advanced Normalization Tools (ANTs) for data cleaning and registration to achieve a minimum deformation template (MDT). VBM analysis is performed using SurfStat. Label-based statistics are calculated via MATLAB. The primary functions of the pipeline have been validated using DTI images of the mouse brain, namely fractional isotropy (FA) and diffusion-weighted imaging (DWI). We assessed the ability of VBM in detecting known differences in FA and morphology through simulations. In select white matter structures FA values were reduced by ~12%. Morphologic changes in other regions were achieved by diffeomorphically registering a mask of a structure's label to a version of itself that has been dilated or eroded by 1 voxel. VBM analysis was performed for a simple cross-sectional analysis using the FA and the log Jacobian images. The results were evaluated for three different sets registration parameters. Results We have tested the pipeline using both simulations and a mouse model of epilepsy. We assessed accuracy against manual segmentation for a mouse injected with kainic acid exhibiting a large hippocampus deformation. Dice coefficients demonstrated good agreement with manual labels: 82.5 (corpus callosum), 85.0 (anterior commissure), 91.9 (hippocampus) and 94.7% (caudate putamen). Discussion A critical step in voxel-based morphometry (VBM) is the creation of a minimal deformation template (MDT). This computationally intensive task requires a large number of pairwise diffeomorphic registrations, and is usually the rate-limiting factor in VBM.

Using a study specific MDT as intermediary between each image and the atlas produces more accurate segmentations compared to labels generated by direct registration to the atlas. Moreover, our automated VBM processing pipeline takes advantage of the parallel nature of a computing cluster, reducing the computation time from 16 to 2 days for a study with 9 control and 6 treated subjects, for example.

Title: Web visualization of massive neuroscience datasets using the open connectome project

Authors: *A. D. BADEN[1], K. A. LILLANEY[1], W. GRAY RONCAL[3], J. T. VOGELSTEIN[2], R. BURNS[1];
[1]Computer Sci., [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [3]Applied Physics Lab. of Johns Hopkins Univ., Laurel, MD

Abstract: Advances in neuroimaging techniques such as serial electron microscopy (EM), array tomography (ATomo), optophysiology (e.g. calcium imaging), CLARITY, and multimodal magnetic resonance imaging can yield data sizes exceeding workstation storage and working memory. For example, the Open Synaptome Project (http://opensynapto.me) expects to generate 1 PB of data over 5 years (~650 GB per day) using an automated ATomo pipeline. Visualization of these datasets is important both for quality assurance (e.g. confirming registration of spatial data) and for analysis. However, the massive size of each dataset precludes researchers from simply downloading data to their computers and using existing visualization tools. We have built a web-based neuroimaging visualization tool, ocpviz, which runs in modern browsers on a wide

variety of devices and supports a range of viewing options to allow neuroscientists to browse massive datasets on demand without having to store data locally. We designed ocpviz to get data from the Open Connectome Project (OCP, http://openconnecto.me) leveraging OCP's RESTful web-based query system and cache hierarchy, which speeds up image load times. We support pan and zoom navigation, as well as keyboard shortcuts for zoom and for navigating between slices. Supported data types include 8, 16, 32, and 64 bit 2D, 3D, and 4D data, which collectively support raw images, segmentations (with false coloring), multi-channel datasets (e.g. ATomo), and time series datasets (e.g. calcium imaging). We will also support layering multiple data types with opacity controls for each layer. In addition to visualization of the raw image data, we provide query support for looking up metadata associated with visualized objects. For example, when viewing an annotated EM dataset (as in the figure below), the user can pull up a unique identifier for each annotation by clicking anywhere in the annotated region. This approach can be extended to any spatial queries supported by OCP, and allows us to integrate tools that operate on points in space.

Title: Automatic and accurate spike clustering based on robust variational Bayesian method

Authors: *W. MA, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: We introduce a new cluster number determination scheme that can be integrated into robust variational Bayesian (RVB) algorithm and other automatic clustering methods. As a result, we were able to develop an improved automatic neural action potential (spike) clustering algorithm, referred to as automatic RVB or ARVB, with good properties such as improved accuracy, robustness, and consistency. The ARVB is implemented by two interleaving steps: 1) optimization of clustering once given cluster number using the RVB (Takashi et al., 2009); 2) cancellation of spurious clusters by unlabeling a cluster with minimum impact on clustering performance. The ARVB is initialized by the K-means with larger cluster number than actual, and then reduced automatically according to the interleaving two-step approach until a negative change of the ensemble likelihood, or the clustering performance measure, is above a threshold. Four different types of neural spike datasets were used for performance evaluation of the ARVB: simulated dataset with t-distributed clusters, artificial dataset from Wave Clus software package (Quiroga et al., 2004), labelled real dataset from Buzsaki lab (Harris et al., 2000; Henze et al., 2000), as well as labelled and unlabeled real data from our lab (Yuan et al., 2015; Hongwei et al., 2015). First, our evaluation results by using simulated and artificial datasets show that the ARVB clustering results were consistent over a reasonably wide range of parameter values under various data conditions. We then conducted extensive comparisons of ARVB with our own accurate robust expectation-maximization (AREM) algorithm developed in 2013, and three other popular sorters: Klutakwik (Harris et al., 2000), Superparamagnetic Clustering in Wave Clus (Quiroga et al., 2004) and T-Distribution EM clustering in Plexon's Offline Sorter (Plexon, Inc.). AREM and ARVB provided comparable results to the three other algorithms measured by total classification accuracy and misclassification rate for datasets with high SNR and low similarity among clusters. But when comparing performance based on artificial datasets and labelled real datasets under challenging conditions (e.g. low SNR, high similarity), AREM and ARVB outperformed other classifiers. Furthermore, the ARVB at times outperformed our AREM. When evaluating classifier performance for real neural waveforms, four statistical measurements (J3, Pseudo-F, Davies-Bouldin and Dunn) and spike statistics were used. Both AREM and ARVB were at least comparable to, or sometimes subjectively better than the other three algorithms.

Title: ilastik - a software framework for interactive volume neuro-image analysis and for automatic calcium imaging analysis

Authors: ***S. PETER**[1], A. KRESHUK[1], S. BERG[1], M. SCHIEGG[1], T. BEIER[1], C. HAUBOLD[1], B. EROCAL[1], J. KIRKHAM[2], C. ZHANG[1], U. KOETHE[1], F. DIEGO[1], F. A. HAMPRECHT[1];
[1]Univ. of Heidelberg, Heidelberg, Germany; [2]HHMI Janelia Farm, Ashburn, VA

Abstract: The interactive learning and segmentation toolkit (ilastik) is a general purpose pipeline framework for building modular, user-friendly biological image analysis applications. Its ability to handle and visualize image data in up to 5D and to perform fast calculations makes it especially attractive for neuroscience applications dealing with very large and diverse data. We present the general architecture of ilastik and a few easy-to-use workflows which accomplish the following tasks: 1. Synapse and membrane detection in Electron Microscopy (EM) volume images by interactively trained classification. For these workflows the user defines a set of possible semantic categories, such as synapses, membranes, or mitochondria and ilastik tries to predict the best matching category for each pixel or object in the volume. As soon as the user provides the first labels ilastik starts predicting the categories allowing fast interactive refinement of the classification results. The classification can be based on: 1.1 pixel-level labels and features [1, 4], 1.2 labels given to entire objects, as opposed to single pixels, and object-level properties such as shape. We show an application of this workflow to synapse and membrane detection in mammalian neural tissue volumes obtained by FIB/SEM and ssTEM microscopy. 2. Semi-automatic extraction of single processes in EM and LM volume images [3] based on inside-outside user annotations and segmentation uncertainty feedback. We show an application of this workflow to FIB/SEM volume image segmentation. 3. Automated Calcium Imaging analysis [5] allowing end-users to conveniently analyze their data with minimal manual effort. Its automated detection of cell centroids relies on a flexible matrix factorization that exploits the sparseness of neuronal activity in space and time. For CI analysis we also provide a new algorithm as an external package for ROI detection and spike train inference in a unified formulation. It allows finding an extremely sparse representation for sequences in terms of cell locations, cell shapes, spike timings and impulse responses [6]. Solving a single optimization problem yields cell segmentations and activity estimates without the need for heuristic pre- or postprocessing. Applications are composed of re-usable building blocks merged into workflows. For the GUI ilastik provides a flexible volume viewer component which supports pixel and object labeling. ilastik is available as open source software at www.ilastik.org. Abstract: Purpose: Intracranial ERPs from epilepsy patients are a great opportunity to study the brain activity of cognitive processes with a unique spatial and temporal resolution. In this cases is of critical importance to know the exact localization of the electrodes. Here we present an open source Matlab toolbox (https://sourceforge.net/projects/ielectrodes/) to obtain the coordinates and anatomical labels of each electrode in a semiautomatic way with minimal user intervention. Method: Six patients implanted with grids and depth electrodes were studied. Post implantation T1 MRI and CT were coregistered using an affine transformation with SPM8 toolbox. Subject-specific cortical segmentation labels were obtained using Freesurfer software. Brain masks were obtained using FSL-BET software. T1 MRI and CT were coregistered to the MNI-152 space using a brain mask and nonlinear warping deformations with SPM8. Images were then processed in the toolbox (see figure). Electrode voxels were detected by using a dilated brain mask and thresholding high intensity CT voxels in a 3D reconstruction [1]. User intervention was needed to determine the threshold and dilation levels. Then, these voxels were

automatically clustered and the electrode coordinates were obtained. Electrodes were numbered and an anatomical label was assigned automatically to each one. A 3D view of electrodes over a semitransparent brain was shown for visual interpretation. CT and MRI sagittal, coronal, and axial views of electrode coordinates were visually checked by an expert. Electrode coordinates are finally exported to EEGLAB. Results: Six patients were studied with 104/332 SEEG/ECoG electrodes. In all cases, electrode coordinates were successfully located within visualized electrodes artifact in CT and MRI images. Conclusions: The proposed tool is a useful instrument to achieve a fast and robust localization and labeling of electrodes. [1] Blenkmann et. al. Title: Current source density method for single neurons

Authors: ***D. CSERPAN**[1], Z. SOMOGYVARI[1,2], D. WOJCIK[3], H. GLABSKA[3]; [1]Dept. of Theory, Wigner RCP, Budapest, Hungary; [2]Natl. Inst. of Clin. Neurosciences, Budapest, Hungary; [3]Nencki Inst. of Exptl. Biol., Warsaw, Poland

Abstract: The recent blooming of multi-electrode array (MEA) technology made it possible to measure extracellular electric potential with spatial and temporal resolution of tens of micrometers and several tens of kHZ in thousands of points simultaneously. So far, however, these advancements seem to have mainly quantitative impact, no significant qualitative changes in experimental or analytical methodology have occurred, except for higher density of probing for spiking cells. Here we present two methods of data analysis utilizing these high density extracellular recordings for estimating detailed spatio-temporal description of electrophysiological processes on single cell level. These methods differ in their requirements and predictive power. If just the recordings of extracellular potential are available, spike Current Source Density (sCSD) method [Somogyvári et al. , 2012] allows one to estimate profile of current sources from spike-triggered averages of measured potentials. If in addition morphology of the cell is available, which is viable in combination of MEA electrophysiology, patch-clamping and optical imaging, single cell kernel CSD (skCSD) method, an application of kernel CSD method [Potworowski et al., 2012] to this situation, allows one to reconstruct detailed spatio-temporal distribution of current sources along the cell at any moment in time. By applying these methods to simulated and experimental data we demonstrate their utility, study their limitations and applicability on several examples.

Abstract: Granger causality methods analyze the flow of information between time series. The Geweke measure of Granger causality (GG-causality) has been widely applied in neuroscience because its frequency-domain and conditional forms appear well-suited to highly-multivariate

oscillatory data. Here, we analyze the statistical and structural properties of GG-causality in the context of neuroscience data analysis. We analyzed simulated examples and derived analytical expressions to demonstrate how computational problems arise in current methods of estimating conditional GG-causality. We found that the use of separate full and reduced models leads to either large biases or large uncertainties in the causality estimates, and high sensitivity to uncertainties in model parameter estimates, producing spurious peaks, valleys, and even negative values in the frequency domain. We also analyzed how the generative system's properties and frequency structure relate to the structure of GG-causality estimates. We used simulated examples and derived analytical expressions to show that GG-causality is independent of the receiver dynamics, i.e. the dynamics of the effect node that "receives" the input of the putatively causal node. In particular, the magnitude of the receiver response is ignored by GG-causality. This is potentially misleading in many neuroscience applications, where often the "cause" of a particular "effect" is being sought—for example, the foci of epileptic seizures—because from the perspective of GG-causality, the magnitude of the effect response is irrelevant. In addition, we found that GG-causality combines transmitter and channel dynamics in a way that cannot be disentangled without evaluating the component dynamics of the full model estimate. The separate-model fit computation in GG-causality leads to either large bias or large uncertainties that make the interpretation of frequency-domain structure highly problematic. Even if these computational issues are overcome, correct interpretation of GG-causality values is challenging, since GG-causality ignores receiver dynamics and is not informative of the system dynamics without consideration of the full model estimate. Our work suggests that GG-causality analyses could be easily misinterpreted without careful consideration of these factors. Through this work we hope to provide conceptual clarification of GG-causality and place it in the broader framework of modeling and system analysis, which may enable investigators to better assess the utility and interpretation of such methods.
