Title: Neuronal polarization and morphogenesis are disrupted by mutation of Kinesin-6 family member Kif20b

Authors: *N. DWYER, T. D. CUPP, T. L. ARNELL, A. SHRESTHA, K. M. JANISCH; Cell Biol, Univ. Virginia, Charlottesvle, VA

Abstract: Neurons must polarize and adopt complex morphologies in order to perform their functions. The mechanisms underlying these processes remain poorly understood. Recent evidence suggests that cytokinesis structures and proteins may be involved in neuronal polarization. A mouse mutant in the cytokinetic kinesin Kif20b may provide insights into mechanisms of neural stem cell division and neuronal morphogenesis, and possible relationships between the two. We previously reported that a loss-of-function mutation in the vertebrate-specific Kinesin-6 gene, *Kif20b*, disrupts growth of the cerebral cortex and causes microcephaly and perinatal lethality. Loss of Kif20b disrupts late cytokinesis (abscission) of cortical neural stem cells, reduces production of progenitors and neurons, and increases apoptosis in the embryonic cortex. The *Kif20b*^{magoo} mutant cortex has thinner neuronal layers, but they are properly ordered. Here we show that the cortical neurons that are produced in the *Kif20b* mutants display robust morphological differences from control neurons in dissociated cultures. Mutant neurons show reduced polarization at both 2 and 4 days *in vitro*. Among mutant neurons that do polarize, their axons have increased branching, their dendrites are longer, and both appear thicker. In addition, growth cone filopodia are longer, while growth cone areas are not different from controls. These morphological differences are not due to fate changes in cell or neuron types. They could arise from abnormalities in the cytokinesis events at the birth of these neurons, and/or from post-division requirements for this kinesin in regulating the neuronal cytoskeleton. We are addressing these possibilities, roles of Kif20b in cytoskeleton regulation, and candidate downstream effectors. We are also testing whether these *in vitro* abnormalities in neuronal polarization and morphogenesis are also found *in vivo* in *Kif20b* mutant mice.

Title: Spectrin cytoskeleton orchestrates peripheral nervous system node of Ranvier assembly and axon integrity

Authors: *Y. HUANG, C. ZHANG, D. ZOLLINGER, M. RASBAND;
Baylor Col. of Med., Houston, TX

Abstract: Spectrins are a family of cytoskeletal proteins, that provide structural support of the cell membrane, link membrane-associated proteins to actin and serve as platforms for cell signaling. Spectrins consist of α and β subunits, forming heterotetramers to function as a complex. Among the spectrins, αII-spectrin is the only α-spectrin expressed in the nervous system. αII-spectrin is also implicated in neurological disorders, including traumatic brain injury, spinal cord injury, neurodegenerative diseases and West syndrome. Moreover, embryonic lethality of constitutive knockout mice with nervous system malformation highlights the importance of αII-spectrin in the nervous system. To investigate the potential function of αII-spectrin in the brain, we generated αII-spectrin conditional knockout (cko) mice. Using Nestin-cre mice, we generated αII-spectrin cko mice to examine the function of αII-spectrin in the central nervous system (CNS). Mutant animals had profound neurological phenotypes and died perinatally. Loss of αII-spectrin results in dramatic reduction in all brain β-spectrins. To specifically interrogate the spectrin function in neurons and to bypass the perinatal lethality observed in Nestin-cre; αII-spectrin cko mice, we generated sensory neuron specific αII-spectrin cko mice using advillin-cre. Peripheral sensory neuron KO mice had abnormal gait and motor incoordination while nociception remained intact. We found that dorsal root nerve conduction was significantly reduced in cko mice. Immunohistochemistry showed that mutant mice had fewer nodes of Ranvier. Moreover, paranodal junctions, flanking nodes, were extensively disrupted. We also found widespread axon degeneration in advillin-cre cko mice. Consistent with axonal injury, we observed ATF3 in cko dorsal root ganglia (DRG) neurons beginning at P10 and increasing with age. Remarkably, ATF3+ neurons are mostly large diameter neurons; small

TRPV1+ neurons did not have the injury marker. This difference could account for the motor coordination defects caused by deficits in proprioception while nociception remains unaffected.

Title: DTPPP, a novel microtubule polymerizing protein, is essential for proper *Drosophila* embryonic CNS organization

Authors: ***R. E. MINO**[1], A. L. RISINGER[2], S. BANERJEE[1], S. L. ROGERS[3], C. ROHENA[2], M. A. BHAT[1];
[1]physiology, [2]pharmacology, UTHSCSA, San Antonio, TX; [3]Biol., UNC-Chapel Hill, Chapel Hill, NC

Abstract: The cytoskeleton is an essential cellular structure that helps in providing shape, support and movement. In the nervous system, the microtubule cytoskeleton has specific characteristics that allow it to play important roles in the development and function of its constituent cells. Through a genomic deficiency screen, aimed at the identification and characterization of novel molecular players involved in the development of the embryonic *Drosophila* midline, we discovered an uncharacterized cytoskeleton-associated protein which we have named DTPPP (*Drosophila* Tubulin Polymerization-Promoting Protein). DTPPP displays high structural similarity to its mammalian counterpart, Tubulin Polymerization-Promoting Protein (TPPP), suggesting a conserved role across species. TPPP has been implicated in severe pathologies such as Multiple Sclerosis and Parkinson's disease; however, no mutational analysis of the *tppp* locus had been carried out in any species. In *Drosophila*, immunohistochemical analyses indicate that DTPPP is temporally and spatially regulated in the embryonic nervous system. To further understand its role in the development of the embryonic CNS, we generated a *dtppp* null mutation through transposon mobilization strategies. In-depth *in vivo* analyses on *dtppp* null and overexpressing embryos reveal that changes in DTPPP expression result in

neuronal phenotypes, including cell misplacement as well as axon targeting and projection extension defects. Further work uncovered that these developmental defects, observed in the absence or with increased levels of DTPPP, are the result of its effects on microtubules. Biochemical microtubule polymerization assays show that DTPPP can directly interact with purified tubulin to increase microtubule polymerization and bundling. Ongoing studies are aimed at the identification of other DTPPP interacting partners in defining the mechanism of microtubule polymerization in cells. Overall, these studies advance our understanding of the molecular details of DTPPP function during development, and may offer a molecular basis to identify mechanisms involved in precipitating neuronal dysfunction at later developmental stages that may involve cytoskeletal proteins.

Title: N-terminal and central domains of APC differentially and cooperatively sculpt optic axon growth cones, arbors and targets *in vivo*

Authors: *T. M. ELUL, G. PENG, J. PINZIOTTO, A. SOHAL;
Touro Univ., Vallejo, CA

Abstract: APC is a target of Wnt ligands that regulates microtubule organization, β-catenin stability and other key cellular activities. Here, we studied how the N-terminal and central domains of APC, that are important for indirect cytoskeletal regulation, and for modulating the stability of β-catenin, cooperatively shape optic axons, their growth cones and their arbors in tectal midbrains of intact, living Xenopus tadpoles. Overexpression of the N-terminal domain of APC caused disorganization of optic axons, whereas overexpression of the central domain of APC both dispersed and disorganized optic axons in the optic tract. APCNTER expressing optic axons also formed growth cones that were abnormally wide with long filopodia while optic axons expressing APCβ-cat developed more elongated growth cones with no filopodia in the dorsal optic tract. At a later stage, APCNTER optic axons elaborated arbors that had longer branches but targeted to the appropriate region of the optic tectum. In contrast, optic axons that expressed the APCβ-cat mutant formed arbors that had fewer branches and were frequently

mistargeted within the tectum *in vivo*. These data suggest that the N-terminal and central domains of APC differentially and cooperatively regulate growth cones, arbors and target locations of optic axons *in vivo*.

Title: Collapsin response mediator protein 1 (CRMP1) and CRMP2 mediate Semaphorin3A signaling, but through distinct pathway to regulate dendritic spine maturation and patterning

Authors: *Y. GOSHIMA[1], H. MAKIHARA[2], S. NAKAI[3], N. YAMASHITA[4,6], H. NAKAMURA[5,3], F. TANAKA[5], F. NAKAMURA[3];

Pharmacol. & Neurobio., [5]Neurol., Yokohama City Univ. Grad. school of Med., Yokohama, Japan; [6]Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: Collapsin response mediator protein2 (CRMP2), originally identified as an intracellular molecule that mediates Semaphorin3A (Sema3A) signaling, has been implicated in a variety of neurological and psychiatric disorders. CRMP2 also plays an important role in axon elongation and neuronal polarization. However, physiological roles of CRMP2 *in vivo* remain unknown. We previously reported that CRMP1, close homologue to CRMP2, is involved in Sema3A-induced spine maturation. To elucidate physiological roles of CRMP2, we generated CRMP2 gene-deficient mice (crmp2-/-) and performed phenotypic analysis. The crmp2-/- mice had no apparent phenotype and demonstrated normal development and survival. We focused on morphological analysis of the layer V pyramidal neurons in the cerebral cortex using the Golgi - impregnation method. The density of dendritic spines was reduced in the cortical layer V pyramidal neurons of crmp2-/- mice as well as crmp1 -/- mice. We next examined phenotype of double heterozygous mice, crmp2 and sema3A (crmp2+/-;sama3A+/-), crmp1 and sema3A (crmp1+/-;sama3A+/-) , and crmp2 and crmp1 (crmp2+/-;crmp1+/-). The dendritic spine density and branching were significantly reduced in crmp2+/-;sema3A+/- mice as well as crmp1+/-

;sema3A+/- mice. These phenotypes had no genetic interaction between crmp1 and crmp2, although crmp2+/-;crmp1+/- mice showed aberrant morphology of basal dendrites that was distinct from that observed in crmp1 -/- or crmp2-/- mice. These findings suggest that both CRMP1 and CRMP2 mediate Sema3A signaling and regulate dendritic spine maturation and patterning, but through distinct signaling pathways *in vivo*.

Title: RACK1 is necessary for the formation of point contacts and axon growth

Authors: *L. J. KERSHNER[1], K. WELSHHANS[2];
[1]Dept. of Biol. Sci., [2]Dept. of Biol. Sciences, Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: The formation of appropriate connectivity in the developing nervous system is dependent on the process of local translation. In developing neurons, select mRNAs are transported to and locally translated within growth cones, the pathfinding structures at the tip of extending axons. However, the specific substructural locations in which local translation takes place and the molecular mechanisms underlying this process are not well understood. Local translation of β-actin mRNA within growth cones is necessary for appropriate axon guidance and requires receptor for activated C kinase (RACK1), a ribosomal scaffolding protein. We have previously demonstrated that the local translation of β-actin mRNA is dependent on the phosphorylation of RACK1 and zipcode binding protein 1 (ZBP1), an mRNA binding protein. ZBP1 binds to the 3'UTR of β-actin mRNA, represses its translation, and localizes it to growth cones. RACK1 then binds the ZBP1/β-actin mRNA complex on ribosomes. In response to stimulation with brain-derived neurotrophic factor (BDNF), phosphorylation of RACK1 facilitates both the release of β-actin mRNA from ZBP1 and the translation of β-actin mRNA. Here, we investigate whether local translation occurs at point contacts, adhesion sites important for axonal pathfinding, and examine the role of RACK1 in axon growth and guidance. Interestingly, we have now found that RACK1 is localized to point contacts, which led us to hypothesize that point contacts might be a site of local translation in growth cones. Thus, we examined the location of components of the local translation complex relative to point contacts

under both basal and growth factor stimulated conditions in cortical neurons of embryonic day 17 C57BL/6J mice. β-actin mRNA, RACK1, ZBP1 and ribosomes colocalize with paxillin, a marker of point contacts in growth cones. BDNF stimulation increases the colocalization of β-actin mRNA and RACK1 with paxillin. Additionally, the density of point contacts within growth cones increases following BDNF stimulation in a RACK1 and ZBP1 dependent manner. Finally, RACK1 expression and phosphorylation is required for axonal growth. Taken together, these data suggest that RACK1 expression and phosphorylation is critical to the formation of point contacts, the local translation process, and appropriate neuronal development. Furthermore, these data suggest that point contacts are a strategic location for targeted local translation, and critical signaling centers. This research provides insight into how and where local translation is regulated within growth cones, and thereby leads to appropriate connectivity formation in the developing nervous system.

Title: FMRP is involved in the NGF-induced axon elongation by locally regulating Map1b and Calm1 translation

Authors: *L. BAO, B. WANG, L. PAN, M. WEI;
Inst. of Biochem. and Cell Biology, Chinese Acad. of Sci., Shanghai, China

Abstract: Objective Previous studies have shown that FMRP is a repressor of its binding transcripts and their association can be affected by extrinsic signaling. Our previous data showed that FMRP mediated axon delivery of *Map1b* and *Calm1*, we next ask if any signals regulate their association in FMRP granules. Nerve growth factor (NGF) plays a critical role in the axon growth in the development of primary sensory neuron. However, the relationship of FMRP with NGF signaling is not identified. **Methods** Microfluidic cultured E13.5 DRG neurons were sampled to detect axon growth rate, the protein and mRNA level of MAP1B and calmodulin

induced by 100 ng/ml NGF. Immunoblotting and quantitative real-time PCR were used to respectively examine the protein and mRNA level of MAP1B and calmodulin. Co-immunoprecipitation experiment was performed to detect the association of FMRP with *Map1b* and *Calm1* respond to NGF in PC12 cells. Loss of FMRP was achieved by AAV-shFMRP-GFP infection and *Fmr1*^{I304N} mutant mice. **Results** (1) Treatment with 100 ng/ml NGF for 2 h in the axon compartment significantly increased the protein level of MAP1B and calmodulin in axons without affecting that in the cell bodies of microfluidic cultured E13.5 DRG neurons. This increase was blocked by co-treatment in the axon compartment with cycloheximide (CHX), an inhibitor of protein synthesis, or K252a, an antagonist of TrkA receptor. Neutrotrophin-3 (NT-3) was unable to induce axonal translation of MAP1B and calmodulin. (2) *Map1b* and *Calm1* remained unchanged both in the cell bodies and axons after NGF treatment in the axon compartment. (3) In PC12 cells endogenously expressing high level of TrkA receptor and exogenously expressing FMRP-GFP-Flag, the co-immunoprecipitated level of *Map1b* and *Calm1* by Flag antibody was significantly decreased after 100 ng/ml NGF treatment for 2 h, whereas that of *Fmr1* was not changed. (4) In the microfluidic cultured E13.5 DRG neurons infected with AAV-shFMRP-GFP, knockdown of FMRP significantly decreased the axon growth rate induced by 100 ng/ml NGF for 1 h and 24 h. Meanwhile, the NGF-induced local translation of MAP1B and calmodulin in axons was totally abolished in the microfluidic culture of E13.5 DRG neurons infected with AAV-shFMRP-GFP. (5) In presence of 100 ng/ml NGF, the axon elongation was significantly decreased in the cultured P14 DRG neurons of *Fmr1*^{I304N} mice compared with WT mice, whereas overexpression of FMRP-GFP completely rescued this defect in the *Fmr1*^{I304N} mice. **Conclusion** These data suggest that NGF triggers release of *Map1b* and *Calm1* from FMRP granules, leading to the escape of MAP1B and calmodulin from translational inhibition of FMRP.

Title: Formin-2 in neuronal development

Authors: *K. V. GHATE, A. SAHASRABUDHE, A. JACOB, A. GHOSE;
Indian Inst. of Sci. and Research, Pune, Pune, India

Abstract: Precise functioning of nervous system requires establishment of accurate neuronal connections which is tightly regulated by guidance cues during early embryonic development. The exploring growth cone steers in response to these cues to find its synaptic target. This motility is achieved by cue-dependent remodelling of the underlying cytoskeleton that regulates polarity, protrusion and generation of coordinated traction forces. We have screened actin nucleators in developing chick nervous system and have identified Formin 2 (Fmn-2) as a potential candidate, expression of which coincides with the spinal commissural outgrowth and floor plate crossing. Using cultured primary neurons, we show that depletion of Fmn-2 affects filopodial stability and growth cone morphology. Additionally *in vivo* knockdown of Fmn-2 results in defective midline crossing by the commissural interneurons. Taken together our study identifies Fmn-2 as central regulator of growth cone dynamics central to axonal outgrowth and pathfinding.

Title: Ran-dependent control of axon elongation

Authors: *D. M. WATT, V. CAVALLI;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Axon growth is a critical feature of both neural development and repair. Microtubule dynamics are essential for axon growth; however the molecular mechanisms governing microtubule dynamics in developing axons are complex and not fully understood. The activity of many cytoskeletal regulatory proteins must be carefully controlled to properly coordinate axon growth. Therefore upstream regulators of cytoskeletal remodeling cascades are particularly important to our understanding of axon growth. The small GTPase Ran, originally characterized as a nucleocytoplasmic trafficking protein, was recently demonstrated to also function in ciliary

transport. Furthermore, Ran function is regulated temporally, acting, for example, as a nucleocytoplasmic transport protein during interphase but as a microtubule regulatory protein during mitosis. Several Ran-dependent cytoskeletal remodelers active during mitotic spindle formation are also known to control axon cytoskeletal dynamics. Since Ran is present in developing and adult axons, we explored the possibility that Ran regulates axon growth by controlling microtubule dynamics. Here we present evidence that neuronal Ran levels are precisely tuned to promote axon growth. Both overexpression and knockdown of Ran dramatically reduces axon elongation of sensory neurons plated on laminin, a permissive substrate. Furthermore, we show that Ran promotes axon growth by controlling cytoskeletal dynamics in filipodia. Interestingly, we found that Ran knockdown in sensory neurons plated on chondroitin sulfate proteoglycan, a substrate that mimics the inhibitory environment of the injured central nervous system, promotes axon elongation, in contrast to its effect on permissive substrates. We also investigated proteins that might modulate Ran function in the axon, focusing particularly on the only known cytoplasmic Ran guanine exchange factor, RanBP10. We demonstrate that RanBP10 is enriched in growing axon tips and interacts with Ran in neurons. RanBP10 knockdown significantly reduces axon elongation, an effect that is rescued by expression of Ran, suggesting that RanBP10 promotes axon elongation in a Ran-dependent manner. These results indicate that Ran is a key player in the modulation of axon elongation and might differentially affect axon growth in the peripheral and central nervous systems.

Title: Microtubule plus-end-binding protein, TACC3, promotes axon outgrowth and guidance *in vivo*

Authors: *L. A. LOWERY, B. ERDOGAN, G. CAMMARATA, M. EVANS;
Boston Col., Chestnut Hill, MA

Abstract: Proper neural connections, essential to nervous system function, depend upon precise navigation by the growth cone during development. A fundamental problem in growth cone

biology is how guidance pathways are integrated to coordinate cytoskeletal dynamics and drive accurate axonal navigation. To address this question, we focus on the plus-ends of microtubules (MTs), which explore the growth cone and play a key role in growth cone steering. MT plus-end dynamics are regulated by a conserved family of proteins called 'plus-end-tracking proteins' (+TIPs). Yet, it is unclear how +TIPs interact with each other and with plus-ends to control MT behavior, and how signaling mechanisms downstream of extracellular cues coordinate +TIPs to guide the growth cone in the right direction. We recently determined that the centrosome adaptor, TACC3, is a MT plus-end tracking protein that promotes MT polymerization and axon outgrowth. We predict that guidance cue regulation of TACC3 function in order to spatially restrict MT polymerization within the growth cone may represent a critical mechanism for directing axon guidance *in vivo*. We have begun to test this hypothesis using a combination of high-resolution live imaging of Xenopus laevis axons *in vivo* and *ex vivo*. By examining spinal cord at high resolution, we demonstrate that TACC3-depleted motor neurons and commissural neurons exhibit defects in normal axon outgrowth. We also performed *in vitro* guidance assays and investigated the TACC3-manipulated spinal cord neurons' pathfinding behavior in response to ephrin-A repellent guidance cues. We found that axons overexpressing TACC3 showed less avoidance to ephrin-A repellent signals. Together, our findings reveal that TACC3 functions as an axon outgrowth promoting factor *in vivo* in embryonic spinal cord neurons and in proper axonal navigation during neuronal development.

Title: The role of tau phosphorylation and its 3R and 4R isoforms in regulating microtubule dynamics in living cortical growth cones

Authors: *S. BISWAS, L. GORAL, Q. GAN, K. KALIL;
Dept. of Neurosci., Univ. of Wisconsin, Madison, WI

Abstract: Tau is a phosphorylated microtubule associated protein (MAP) that binds to microtubules (MTs) and regulates their dynamics, essential for growth cone function. The role of tau and its phosphorylation in regulating MT dynamics has been little studied in living neurons. To explore how modifying tau phosphorylation can affect MT dynamics in hamster cortical growth cones, we constructed mutations of the entire tau microtubule- binding domain (MBD) and each of the four repeat regions within the MBD. We first transfected a mutant tau in which Ser262 was changed to non-phosphorylatable Ser262Ala. Although previous work has shown that in cell-free systems this mutated tau prevents tau binding to MTs, our results in HEK cells revealed no changes in tau binding to MTs, suggesting that in a complex cellular environment, mutations at several tau phosphorylation sites may be required to affect tau MT binding. Next, we investigated how each of the Tau phospho mutants affects MT polymerization in growing cortical axons. We transfected hamster cortical neurons with GFP labeled human tau constructs along with the +TIP protein EB3 tagged with td Tomato to label the dynamic plus ends of MTs. Using live cell imaging with TIRF microscopy, we measured the velocities of EB3 comets to determine rates of MT polymerization in growing cortical axons and growth cones. Comparisons among neurons overexpressing full length human tau, vs phospho-mimetic 262D or phospho-deficient S262A human Tau suggested that expression of mutant tau in cortical neurons decreased EB3 comet velocities. To detect effects of different phospho mutants of human tau on MT polymerization, we are knocking down endogenous hamster tau. Different isoforms of human tau are differentially expressed in the developing and mature CNS. In humans and rodent species only the 3R tau isoform, which has three MT-binding sequences is expressed in early development but later in development 4R isoforms, which has four MT-binding repeat sequences, become dominant. However, the functional significance of expression of different tau isoforms during development is not well understood. To determine possible differential effects of the shortest (3RS) and the longest tau isoform (4RL) on MT polymerization, we expressed human GFP-3RS or human GFP-4RL isoforms in hamster cortical neurons. We are co-transfecting with EB3-tdT to compare rates of MT polymerization in growth cones of neurons transfected with different tau isoforms. Our preliminary results suggest that the ability of tau to regulate MT polymerization is dependent not only on its phosphorylation states but also on the specific tau isoform.

Title: Dissociation of netrin-1 receptor UNC5C with TUBB3 is involved in netrin-1-mediated axonal repulsion

Authors: *Q. SHAO, G. LIU;
Biol. Sci., Univ. of Toledo, Toledo, OH

Abstract: The modulation of MT (Microtubule) dynamics is a key event of cytoskeleton remodeling in the growth cone during axon pathfinding. Our previous study has shown that direct interaction of TUBB3, a neuron-specific MT subunit, with DCC (Deleted in Colorectal Cancer) is required for netrin-1-mediated axonal attraction. Here, we propose that the dissociation of polymerized TUBB3 with netrin-1 repulsive receptor UNC5C is involved in netrin-1-mediated axonal repulsion. TUBB3 directly binds to UNC5C and colocalizes with UNC5C in the peripheral area of the axon growth cone. Interestingly, netrin-1 reduces the interaction and the colocalization of TUBB3 and UNC5C. Results from the *in vitro* co-sedimentation assay indicated that the netrin-1 induces dissociation of polymerized TUBB3 with UNC5C. Knockdown of either TUBB3 or UNC5C results in neuronal axon turning defects *in vitro* and misguidance of the DRG (Dorsal root ganglion) axon projection into the spinal cord *in vivo*. These results suggest that the disengagement of netrin-1 receptor UNC5C with polymerized TUBB3 may play an essential role in netrin-1-mediated axon repulsion.

Title: Subcortical cytoskeleton periodicity in the nervous system

Authors: E. D'ESTE, *D. KAMIN, F. GÖTTFERT, S. W. HELL;
Max Planck Inst. for Biophysical Chem., Göttingen, Germany

Abstract: Recently, far-field optical nanoscopy revealed a periodic cytoskeleton lattice underneath the membrane of axons in fixed hippocampal neurons consisting of actin and spectrin (Xu et al., Science 2013). This lattice has a periodicity of ~190 nm and consists of parallel actin rings spaced apart with spectrin tetramers. By combining live-cell stimulated emission depletion (STED) nanoscopy and the fluorescent probe SiR-Actin, we show that a periodic subcortical actin structure is in fact present in both axons and a subset of dendrites (D'Este et al., Cell Rep. 2015). Beside actin-binding proteins, the periodic arrangement of the subcortical cytoskeleton involves also cell adhesion proteins. For instance, nrCAM and neurofascin are enriched in the axon initial segment (AIS) and they both intercalate with the actin lattice. The periodicity of the subcortical cytoskeleton may be therefore transferred to the extracellular matrix through these adhesion molecules. So far the subcortical cytoskeletal periodicity was proven in unmyelinated cultured hippocampal neurons. In myelinated cells, nodes of Ranvier and AIS share a similar molecular composition. We found the cytoskeletal periodicity also at nodes of Ranvier of mouse sciatic nerve fibers belonging to the peripheral nervous system. In conclusion, we demonstrate that the periodic organization of the subcortical cytoskeleton is in reality not a unique feature of axons of hippocampal neurons, but it is a more general feature of the nervous system.

Title: Calsyntenin-1, a kinesin adaptor, regulates microtubule polarity and dynamics during sensory axon arbor development

Authors: ***T. J. LEE**[1], K. ELICEIRI[2], M. HALLORAN[3];
[1]Neurosci. Training Program, [2]LOCI, [3]Departments of Zoology and Neurosci., Univ. of Wisconsin, Madison, WI

Abstract: Axon growth and branching, as well as motor driven axonal transport, are critically dependent on proper organization and dynamics of the microtubule (MT) cytoskeleton. MTs

must organize with correct polarity for delivery of diverse cargos to appropriate subcellular locations, yet the molecular mechanisms regulating MT polarity remain poorly understood. Moreover, how an actively branching axon organizes MT polarity at branch points is unknown. Here we show that Calsyntenin-1 (Clstn-1), a kinesin adaptor required for sensory axon branching, is a crucial regulator of MT polarity and dynamics in developing vertebrate sensory axon arbors. We use high-speed, *in vivo* imaging of polymerizing MT plus-tips to characterize MT dynamics as sensory axon arbors develop in zebrafish. In wildtype embryos the vast majority of MTs are directed in the correct plus-end-distal orientation from early stages of development. Knockdown of Clstn-1 causes an increase in retrograde MT growth. Moreover, these aberrant retrograde MTs most often originate near branch points, suggesting Clstn-1 organizes MT polarity at branch points. Additionally, Clstn-1 knockdown causes both anterograde and retrograde MTs to polymerize for shorter times and distances, implying a role for Clstn-1 in maintaining MT stability. Furthermore, we found that loss of Clstn-1 caused reduced rates of MT polymerization. Together, our results suggest that Clstn-1, in addition to regulating kinesin-mediated cargo transport, also organizes the underlying MT highway during axon arbor development. We are currently investigating potential mechanisms of how Clstn-1 regulates MTs during development by targeting its potential cargos.

Title: The development of the corpus callosum is dependent on fibroblast growth factor 8 signaling

Authors: ***C. E. STEWART**, W. C. J. CHUNG;
Biol. Sci., Kent State Univ., Kent, OH

Abstract: Agenesis of the corpus callosum (ACC) is one of the more common clinical brain malformations found in patients with mental retardation, seizures, visual problems, and in more severe cases, holoprosencephaly. Yet, there is still little known about the underlying cause of ACC in these patients. Here, we explored whether fibroblast growth factor (FGF) signaling plays

a role in the development of the corpus callosum. Specifically, FGF8 has been shown to be especially important for normal embryonic development of the corpus callosum. Indeed, *Fgf8* hypomorphic mice not only exhibited severe morphological defects in developing neocortical-related structures, such as cortical thinning, but also ACC. Previously, we presented data showing that ACC in newborn homozygous ($^{neo/neo}$) *Fgf8* hypomorphic mice coincided with a major reduction in the anterior brain midline glial fibrillary acidic protein (GFAP)-expressing astrocytes. A similar, but smaller reduction in GFAP+ astrocytes was also detected in the anterior brain midline region of newborn heterozygous ($^{+/neo}$) mice. In our current studies, we found that these genotype-dependent differences in GFAP astrocytes did not persist into adulthood. Furthermore, using Sholl analysis we showed that the arborization complexity of these astrocytes did not differ between adult wildtype (WT) and heterozygous ($^{+/neo}$) hypomorphic mice. In a subsequent, anatomical study we used neuropilin (NP)-1 immunocytochemistry to examine the morphological organization of the corpus callosum in newborn *Fgf8* hypomorphic mice. These studies showed that NP1-immunoreactive (IR) fibers were dramatically reduced in the newborn indusium griseum, dorsal aspect of the corpus callosum, and midline zipper of $Fgf8^{+/neo}$ and $Fgf8^{neo/neo}$ hypomorphic mice when compared to their WT litter mates. These results suggest that a deficit in FGF8 signaling does not eliminate anterior brain midline astrocytes, but rather delays their maturation (i.e., GFAP expression) until a later postnatal time point. Furthermore, the dramatic genotype-dependent reduction in NP-1-IR fibers suggests that the *Fgf8* hypomorphy also affects the development of the callosal projecting neurons in the neocortical regions.

Title: The role of Transient Receptor Potential Melastatin 7 (TRPM7) channels in neuronal development under normal and hypoxia-induced stress conditions

Authors: *E. TURLOVA[1], C. BAE[1], M. DEURLOO[1], W. CHEN[1], A. BARSZCZYK[1], D. HORGEN[2], A. FLEIG[3], Z.-P. FENG[1], H.-S. SUN[1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Hawaii Pacific Univ., Kaneohe, HI; [3]Queen's Med. Ctr., Honolulu, HI

Abstract: Transient Receptor Potential Melastatin 7 (TRPM7) is a calcium-permeable, non-selective cation channel that has been implicated in biological processes such as cell adhesion, migration, cytoskeleton regulation and survival. As these processes are necessary for neurite outgrowth during neuronal development, we investigated whether TRPM7 is involved in regulation of neurite outgrowth. In this study we demonstrate that TRPM7 is highly expressed in the growth cones of mouse cultured hippocampal neurons, and that both viral knockdown and pharmacological inhibition of TRPM7 preferentially enhanced axonal outgrowth of hippocampal neurons at multiple time points during development. We also showed that pharmacological inhibition of TRPM7 accelerated the progression of neurons into a higher developmental stage, as was evident by the formation of morphologically distinct axons and dendrites. Moreover, we found that TRPM7 co-immunoprecipitated and co-localized with F-actin and α-actinin-1, two major cytoskeletal proteins involved in actin-based growth cone protrusion. Based on these findings we proposed a model of TRPM7-mediated calcium-dependent cytoskeletal dynamics at the neuronal growth cone. We also showed the involvement of TRPM7 in axonal outgrowth under the conditions of hypoxic stress and in neuroprotection against hypoxic-ischemic neuronal injury in the developing brain. Our findings highlight the importance of TRPM7 during neuronal development and suggest a therapeutic potential of TRPM7 blockers in neurodegenerative and neurodevelopmental disease.

Title: Activity-dependent regulation of the cisternal organelle in the axon initial segment during murine visual system development

Authors: *A. SCHLUETER[1], S. ROSSBERGER[2], C. SCHULTZ[3], M. ENGELHARDT[3]; [1]CBTM, Inst. of Neuroanatomy, Heidelberg University, Med. Fac. Mannheim, Mannheim, Germany; [2]Kirchhoff-Institute for Physics, Heidelberg, Germany; [3]Inst. of Neuroanatomy, Med. Fac. Mannheim, Heidelberg, Germany

Abstract: The cisternal organelle (CO) is a calcium storing compartment localized in the axon initial segment (AIS) of cortical principal and hippocampal neurons. The CO shows structural and functional similarities to the spine apparatus in dendritic spines. Both spine apparatus and CO formation are dependent on the expression of the actin-associated protein synaptopodin (synpo). The CO is composed of stacked smooth endoplasmic reticulum and interdigitating plates of electron dense material. It might play a functional role in the temporal and spatial regulation of calcium currents in the AIS and therefore in the generation and timing of action potentials. So far, it is unknown whether synpo/CO expression is activity-regulated during brain development. Moreover, the effect of CO presence and absence on AIS morphological and functional maturation has not been investigated. Here, we examined the impact of synpo expression on the morphological maturation of AIS during murine visual system development and whether morphological maturation of COs occurs in an activity-dependent manner. AIS were investigated in synpo knockout (KO) mice and a subset of synpo-expressing AIS were analyzed in wildtype mice, respectively. Visual deprivation was utilized to study the effect of altered visual input on CO expression and AIS maturation. Dark rearing of mice for 28 and 35 days resulted in significant increases of cluster sizes of synpo in AIS and in length of synpo-bearing AIS in the visual cortex. Interestingly, these light-regulated modifications are irreversible after mice reach postnatal day (P) 28 since light exposure of P28 dark-reared mice for further 7 days did not revoke synpo cluster size elongation and AIS lengthening. In addition, AIS length maturation during visual cortex development is affected by synpo expression. A recently described tri-phasic length maturation is hindered by both, synpo presence or absence. Strikingly, in synpo KO mice visual deprivation leads to AIS length shortening. Taken together, these findings indicate that morphological maturation of COs is subject to activity-dependent dynamic regulation and that CO presence shapes AIS morphological maturation in a subset of visual cortex neurons during visual system development.

Title: Period of axonal exuberance of corpus callosum in rat extends into the first two postnatal weeks

Authors: *M. CULJAT[1,2,3], J. M. JURASKA[2];
[1]Pediatrics, Hawaii Residency Programs, Honolulu, HI; [2]Dept. of Psychology and Program in Neurosci., Univ. of Illinois, Champaign, Urbana/Champaign, IL; [3]Sch. of medicine, Croatian Inst. for Brain Res., Univ. of Zagreb, Zagreb, Croatia

Abstract: INTRODUCTION: Fiber tracts of the mammalian central nervous system undergo axonal overproduction in the perinatal period, followed by a dramatic level of axonal pruning. This has been described in the corpus callosum (CC) in cats (Koppel, Innocenti , 1983) and rhesus monkeys (LaMantia , Rakic, 1990). In rats, pruning has been demonstrated after postnatal days (P) 15 (Kim, Juraska, 1997), but earlier ages are unexplored. MATERIALS AND METHODS: Thirty five Wistar albino rats were perfused at P0, 3, 5, 7, 12, 21 and adult. Midsagittal CC area and length were measured. Additionally, CC at ages P0, P7 and P12 were processed for electron microscopy, and were used for axon and growth cone counts. RESULTS: There is a 1.4x increase of CC midsagittal area between P0 and P3, followed by a plateau between P3 and 21. The midsagittal CC length showed a continuous increase of 1.9x from P0 to P12, followed by a plateau between P12 and P21. The total number of axons linearly increases between P0, P7 and P12 (4.9, 7.9 and 10.8 million, respectively). In all ages analyzed, the dorsal aspect of CC had the highest density. There was no statistical difference in the density of axonal elements between P0 and P7. The CC at P12 had the highest density. The ratio of growth cones to axons significantly increased between P0 and P7, and decreased between P7 and P12 (8.2%, 10% and 5.7%, respectively). CONCLUSIONS: Overproduction of axons in rat CC extends into the first two postnatal weeks. There is continuous increase of CC length during the initial plateau in surface. This coupled with a high ratio of growth cones and increasing density of callosal elements, indicates a high level of internal structural reorganization. Studies of cortical origins of callosal axons in rat showed there is a change in distribution of their neuronal bodies between

P0-P4 and P15 (Olavarria et al. 1984, Ivy et al. 1984), which fits with our interpretation of the callosal changes noted in this study. The higher ratio of growth cones at P7 might indicate an existence of a growth front, supporting the idea of growth in waves of callosal axons instead of continuous growth.

Title: Gtf2i regulates neuronal maturation and cognition

Authors: ***M. DEURLOO-STMICHAEL**[1], W. CHEN[1], M. YANG[2], Y. LIN[1], E. TAM[1], M. WU[1], F. LEWIS[2], G. FOLEY[2], J. CRAWLEY[2], H.-S. SUN[1], L. OSBORNE[1], Z.-P. FENG[1]; [1]Univ. of Toronto, Toronto, ON, Canada; [2]MIND institute, Sacramento, CA

Abstract: General Transcription Factor 2I (Gtf2i) has been implicated in the neurodevelopmental phenotypes associated with deletion (Williams syndrome) and duplication (7q11.23 duplication syndrome) of chromosome 7q11.23, primarily in its role as a transcription factor. Here, we show that copy number alterations in Gtf2i have reciprocal effects on cortical neuron maturation. Alteration of Gtf2i copy number in mice regulated axonal outgrowth and branching, and muscarinic M1 receptor-activated calcium signals. Mice with duplication of Gtf2i also show deficits in novel object recognition, in the absence of problems with hippocampal dependent learning and memory. Together, our results provide the first functional insight into the cellular mechanisms that underlie the 7q11.23 disorders.

Title: Structural changes of the axon initial segment in neurons derived from spectrin mutant qv3J

Authors: *M. DANNEMEYER[1], E. LAZAROV[2], F. WOLF[3], J. ENDERLEIN[1], A. NEEF[3]; [1]Georg August Univ. Goettingen, Goettingen, Germany; [2]Koret Sch. of Vet. Med., Hebrew Univ. Jerusalem, Israel, Goettingen, Germany; [3]Bernstein Ctr. for Computional Neurosci., MPI for Dynamics and Self-Organization, Goettingen, Germany

Abstract: The distribution and density of neuronal voltage-gated sodium channels (VGSC) is important for neuronal excitability, development and plasticity. High density of VGSCs at the axon initial segment (AIS) depends on the cytoskeletal proteins βIV-spectrin and ankyrin-G (ankG). The mouse mutant *qv^{3J}* has a mutation close to the C-terminus of βIV-spectrin sequence, which shifts the reading frame. [01] We studied the influence on the distribution of βII-spectrin, βIV-spectrin, ankG and VGSCs at the AIS. Neuronal cultures were prepared from hippocampus and immuno-fluorescence was imaged between *7* and *21 days in vitro* with conventional wide-field and stochastic optical reconstruction microscopy (STORM). [02] In wildtype βII- and βIV-spectrin are arranged in the AIS on a very regular structure already at *DIV 7*. During development βII-spectrin density decreases slightly, while the density of βIV-spectrin, ankG and VGSCs increases in the AIS. AnkG is periodically, whereas VGSCs-staining appears semi-periodic. At *DIV 7* wildtype and mutant neurons are very similar with respect to density and periodicity of ankG, VGSCs and βII-spectrin. However, only very little βIV-spectrin is observed in mutant *qv^{3J}* at *DIV 7* and it is completely lost at *DIV 14*. The density and regularity of βII-spectrin is not influenced. In contrast to the development in wildtype almost no increase in ankG and VGSCs is observed in *qv^{3J}*. The ankG which is still present is arranged periodically. The VGSC density in mutant *qv^{3J}* decreases strongly and progressively in the few neurons, that still show a comparably high staining intensity, some periodicity can still be observed. We conclude that βIV-spectrin is incorporated in the existing βII-spectrin grid. The ring-like organization of proteins along the AIS does not depend on βIV-spectrin. The C-terminal mutation *qv^{3J}* causes a complete loss of βIV-spectrin, but some ankG and VGSCs are retained. Remaining ankG is periodic. The remaining VGSCs are so sparse that it is not clear whether they are positioned in

the regular grid. Title: Map7 regulates the development of sensory axon collateral branches via its microtubule bundling activity

Authors: S. TYMANSKYJ[1], *L. MA[2];
[1]Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [2]Neurosci., Dept. of Neurosci., Philadelphia, PA

Abstract: During spinal cord development, sensory neurons in the dorsal root ganglion (DRG) extend both peripheral and central axons which allow connectivity of multiple targets. Centrally, axons form collateral branches, which originate from the axonal shaft, to generate local reflexes. Collateral branch formation is in part regulated by microtubule dynamics and transport, however the precise mechanism microtubules contribute to branching is not clear. Microtubules are known to be regulated by several microtubule associated proteins (MAPs), and here we report a novel function of MAP7, a lesser known MAP previously identified in *Drosophila*. MAP7 has been linked to kinesin functions, but its function in neurons has not been established. We report a novel function of MAP7 in collateral development of DRG sensory neurons. MAP7 expression in DRGs starts at the time of collateral formation. Precocious over-expression or knockdown of MAP7 in culture leads to effects consistent with its branching function during DRG development. This function is mediated primarily by the amino-terminal microtubule binding domain and the central phosphorylation domain, which together create stable, long and curly

microtubule bundles. Time-lapse imaging shows that the bundling activity enters nascent branches and accumulates in the base after branch initiation, suggesting a role in branch maturation. Furthermore, both microtubule bundling and axon branching can be regulated by phosphorylation at a specific site. Finally, the mshi mouse expressing a truncated form of MAP7 has excessive collateral invasion into the spinal cord. Overall we have identified a novel intrinsic mechanism regulating axon collateral development by MAP7. This mechanism is mediated by the ability of MAP7 to bundle microtubules that lead to the stabilization of newly formed collaterals.

Title: Identifying signaling cascades involved in growth and cell clustering of functional, non-prenylatable RhoA and Rac1

Authors: ***N. G. RAUT**, J. M. REDDY, K. RODEN, D. L. HYNDS;
Biol., Texas Women's Univ., Denton, TX

Abstract: The Rho guanine triphosphatase (GTPase) are highly characterized and GTPase proteins that act as molecular switches operating between an active GTP-bound state and an inactive GDP-bound state. These proteins play a pivotal role in neuronal differentiation and affect neurite outgrowth, axonal guidance, cell migration, cytokinesis and endocytosis. RhoA promotes assembly of focal adhesion complexes and formation of stress fibers. RhoA regulates the organization of actin cytoskeleton and several other cellular functions in response to the extracellular signals. On the other hand, Rac1 stimulates assembly of multimolecular focal complexes at plasma membrane, induces the peripheral actin accumulations, regulates membrane protrusions, membrane ruffling and formation of lamellipodia and filopodia. The interaction between RhoA and Rac1 is not well explored, though they are thought to be antagonist to each

other. Both require prenylation for membrane localization, though active forms of both have been found in other cellular compartments (GTP-bound Rac1 in the cytosol and GTP-RhoA primarily in the cytosol and nucleus). We designed non-prenylatable Rac1 and RhoA constructs to test how inhibiting prenylation affects morphology and the location of active RhoA and Rac1. Western blot analysis suggested that an increase in ARP2/3-WAVE complexing led to the increase in cell clustering after transfection of the non-prenylatable Rac1 construct and decrease in the prenylatable RhoA construct. An increase in cofilin was observed in after transfection with the wild-type RhoA construct leading to neurite outgrowth and ERK and JNK phosphorylation was increased when cells were transfected with non-prenylatable RhoA or Rac1. We have found transfection of these constructs in rat cortical neurons increase neurite outgrowth (for non-prenylatable RhoA) and neurite formation (for non-prenylatable Rac1). Both retained the ability to be made active independent of membrane targeting by prenylation. With emerging evidence of differential activation of these Rho GTPases based on their subcellular localization, elucidating the signaling cascades of the active GTPases may identify novel targets to facilitate axon regeneration in traumatic or degenerative neurological conditions. This research was supported by the TWU Department of Biology, Undergraduate Microgrant programs . We would like to thank Dr. DiAnna Hynds and laboratory associates for their guidance and collaboration.

Title: Correlation analysis of ATP levels and morphological change during neurite extension

Authors: *R. SUZUKI, F. NAGASE, K. HOTTA, K. OKA;
Keio Univ., Kouhoku-Ku, Yokohama, Japan

Abstract: Adenosine triphosphate (ATP) is a major energy source for cells and plays important roles in various physiological phenomena. In neurons, ATP depletion suppresses actin turn-over and long-term ATP depletion causes changes in cellular shape. Furthermore, it is known that

neuronal branching occurs at sites populated by stalled mitochondria. Though these previous researches indicate variation in ATP levels is related to cellular morphological changes, such relationships have never been directly demonstrated under physiological conditions, because simultaneous observation and spatiotemporal quantification of cellular morphology and ATP levels are difficult. In this study, a combination of simultaneous imaging and image processing analysis allowed us to observe and quantify these relationships under physiological conditions in growth cones (GCs) of dorsal root ganglion (DRG) neurons. We classified neurons into two groups according to their behaviors: 'elongating neurons' and 'other neurons', and quantified morphological parameters and ATP levels. GC has two domains: actin-rich 'peripheral domain (P-domain)' and microtubule-rich 'central domain (C-domain)'. ATP levels in P-domain and C-domain had positive correlations between newly generated area and gross size of the domains. Especially, these positive correlations in C-domains were more remarkable in elongating neurons. Also, ATP levels in elongating neurons were higher at C-domain, whereas the other neurons showed the reverse tendency. This trend is also true for newly generated areas. Moreover, Latrunculin A, an inhibitor of actin polymerization, diminished size and motility of P-domain, but not that of C-domain. On the other hands, GCs treated with Oligomycin A which inhibits ATP synthase showed not only decrease in ATP levels, size, and motility at P-domain, but also retraction of C-domain. Therefore, neuronal elongation would needs ATP but not actin polymerizations in P-domain. From the above, our research revealed that ATP levels in GCs are related to its morphological change, and the relationships in C-domain plays grate role in neurite extension.

Title: Regulation of retrograde mitochondrial transport in axons

Authors: *K. DRERUP, S. LUSK, A. NECHIPORUK;
Cell, Developmental and Cancer Biol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The cytoplasmic dynein motor is the primary motor protein complex responsible for retrograde cargo transport in axons. How this single motor moves disparate cargo in a regulated fashion remains largely unknown. We have utilized forward genetics, live imaging and biochemistry to identify a role for a dynein associated protein, Actr10, in the selective retrograde transport of mitochondria. In a forward genetic screen, we isolated a zebrafish mutant with mitochondria rich, swollen axon terminals. Using RNA-seq based analysis, we identified the causative mutation as a T to G change in the start site of the gene encoding Actr10. Actr10 is a component of the dynactin, a large accessory complex oftentimes associated with the cytoplasmic dynein. Actr10 is situated in a "pointed end" region of dynactin which is postulated to function as an adaptor for cargo transport; however, a specific role for Actr10 in retrograde cargo movement in axons has not been elucidated. Using *in vivo* analysis of mitochondrial motility, we found that the mitochondrial accumulation in *actr10* mutant axon terminals was due to a selective defect in the retrograde transport of this organelle. The localization of dynein-dynactin components and other cargos, such as lysosomes, autophagosomes, and activated JNK (c-Jun N-terminal Kinase) was normal in the *actr10* mutants. Additionally, *in vivo* analysis of dynein motility demonstrated that movement of this motor is unaffected with loss of Actr10, arguing for a specific role for Actr10 in mitochondria retrograde movement. Finally, using mitochondrial fractionation and immunoprecipitation, we have shown that loss of Actr10 results in failed dynactin-mitochondrial coupling further supporting a role for this protein in attaching mitochondria to the retrograde motor complex. Together, our data support a model in which Actr10 serves as a unique adaptor which links mitochondria to the retrograde motor complex for retrograde transport and proper positioning in axons.

Abstract: Carboxypeptidase E (CPE) is a member of carboxypeptidase family that processes various proteins. However, CPE has functions in addition to its carboxypeptidase activity. CPE knockout mice have neurobehavioral deficits, including deficits in learning and memory. They exhibit aberrant neurotransmission and dendritic architecture. Previously, we identified a role for CPE in mediating the effects of nitric oxide synthase 1 adaptor protein (NOS1AP) action on dendritogenesis. It was previously reported that $p150^{Glued}$ and CPE exist in a complex in cultured cells; we now confirm this interaction in mouse brain. Our current study identifies the region in $p150^{Glued}$ that is responsible for CPE binding. In addition, our studies in COS-7 cells suggest that CPE overexpression redistributes endogenous $p150^{Glued}$ from the centrosome and disrupts microtubule organization. As $p150^{Glued}$ is the largest subunit of the Dynactin complex, which is indispensible for the functional motor activity of dynein, we hypothesized that CPE exerts its effect on the cytoskeleton through its interaction with motor protein complexes and/or other microtubule binding proteins. Thus, we extended our studies to assess the role of CPE *in vivo* during the time of cortical neuron migration since this process relies heavily on motor protein complexes and the cytoskeleton. Preliminary data show that knockdown of CPE protein results in disrupted neuronal migration and altered cell morphology in neurons in the cortical plate. Together, our studies provide new evidence for the role of CPE and its interactor, $p150^{Glued}$, in regulating the neuronal cytoskeleton, dendrite morphology, and cortical cell migration.

Title: Regulation of hindbrain spontaneous activity by K2P channels

Authors: *K. DUONG[1], H. WATARI[2], A. TOSE[1], J. GILE[1], M. BOSMA[1];
[1]Univ. of Washington, Seattle, WA; [2]George Washington Univ., District of Columbia, DC

Abstract: The developing brain experiences endogenous electrical activity in the absence of any sensory input. This spontaneous activity (SA) has been shown to drive neuronal and circuit development in many areas of the brain. We have reported that in mouse embryonic hindbrain, SA is regulated spatially and temporally. SA initiates from a region along the midline, spreads across hindbrain in the form of propagating waves at E11.5, and retracts back to the initiation zone by E13.5. The mechanism of this retraction is the hyperpolarization of resting membrane potential and concomitant increase in conductance between E10.5-E15.5. Together, these changes decrease cellular excitability, resulting in the cessation of SA by E15.5. We found that membrane hyperpolarization is correlated with the upregulation of a class of resting potassium channels, the two-pore domain potassium channel (K2P). Three types of K2P channels are found in the developing hindbrain: KCNK2, KCNK9, KCNK10. At least 2 of the 3 channels (KCNK2 and KCNK9) are upregulated between E11.5 and E15.5, and KCNK9 is spatially expressed to mediate lateral hyperpolarization. These channels could play the appropriate role of increasing resting conductance and decreasing cellular excitability.

Title: An auditory hair cell-specific inducible gene expression system to suppress spontaneous activity in hair cells

Authors: *Y. ASAI[1,2], G. G. S. GÉLÉOC[1,2], J. R. HOLT[1,2];

Abstract: Cell type-specific, tightly-regulated, reversible gene expression systems are valuable for interpretation of gene/cell function. We designed a system that allows precise spatiotemporal control of gene expression in hair cells. In the *lac* regulatory system, gene expression is regulated by binding of LacI protein to *lac* operator sequences in promoter regions that flank the transcriptional start site. The regulation is reversible, as addition or removal of the inducer, Isopropyl β-D-1-thiogalactopyranoside (IPTG), which turns on or off gene expression at any point during the animal's life. We engineered this system for use with a modified Myosin7a (*Myo7a**) promoter, whose activity in the inner ear is restricted to hair cells. We tested *lac* operators placed at various positions within the *Myo7a** promoter for regulatability of luciferase gene expression in HeLa cells. After the initial screen, we prepared adenoviral vectors with the optimized *Myo7a** promoter and the coding sequence for GFP and transfected inner ear tissue that expressed LacI. GFP expression was restricted to hair cells and was tightly regulated by IPTG induction. Inner hair cells have spontaneous activity prior to the onset of hearing but the role of the activity is unknown. We hypothesis that spontaneous activity in hair cells may contribute to synaptogenesis and maturation of the peripheral auditory system. To investigate this hypothesis, we generated a transgenic mouse that expressed TREK1 K^+ channels regulated by the *Myo7a** promoter. We found that IPTG induction drove expression of TREK1 potassium currents and clamped the hair cell resting potential near E_{K+}, which effectively silenced the cells. To assay for behavioral consequences of TREK1 expression we measured acoustic startle responses. Administration of IPTG for 3 days, from postnatal day 21 to 24 completely abolished startle responses in TREK1 mice. These results indicate induced expression of TREK1 effectively silenced hair cell electrical activity. This novel mouse model will be used to investigate the role of hair cell activity during inner ear development. Conclusions: 1) The *Myo7a** promoter was regulatable using *lac* operators and IPTG induction. 2) Hair cell expression was confirmed *in vitro* via adenoviral transfection. 3) The *Myo7a** promoter drives TREK1 expression in hair cells of transgenic mice and successfully silenced the cells. We suspect our inducible hair cell-specific promoter and the TREK1 mouse developed for this study will be valuable genetic tools to regulate gene expression and hair cell function *in vivo*.

Abstract: In our previous study (Sato et al., 2007), we applied a multiple-site optical recording technique with a voltage-sensitive dye to the embryonic chick olfactory system and showed that functional synaptic transmission in the olfactory bulb was expressed at around E7. It is known that odor stimuli elicit oscillatory events in the olfactory bulb in various species. In the present study, we found that oscillatory activity was also generated in the chick olfactory bulb during embryogenesis. At the early stages of development (E7-E8), postsynaptic response-related optical signals evoked by olfactory nerve stimulation exhibited a simple monophasic waveform that lasted a few seconds. At the E9 stage, the postsynaptic response-related optical signals became multi-phasic, and these neural responses developed into oscillatory activity around the E10 stage. As development proceeded, the pattern of the oscillatory activity became complicated and long-lasting. The oscillatory activity was restricted to the olfactory bulb, and its spatial pattern was different from that of the propagating wave activity termed the depolarization wave. We examined fundamental characteristics of the oscillatory activity and their developmental dynamics.

Title: Leptin guides chloride homeostasis in the developing rodent hippocampus

Authors: *C. DUMON[1], D. DIABIRA[1], C. PORCHER[1], G. A. WAYMAN[2], I. MEDYNA[1], J.-L. GAIARSA[1];

Abstract: γ-aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the adult brain. GABA controls neuronal excitability, network oscillations dynamic and synaptic plasticity, thereby playing a crucial role in brain functioning. However, at fetal and early postnatal stages, GABA depolarizes and often excites neurons due to an elevated intracellular chloride concentration, and this depolarizing effect is believed to support its multiple neurotrophic actions during development. The sequential expression of two major chloride co-transporters, Na+-K+-Cl- type 1 cotransporter (NKCC1) and K+-Cl- type 2 cotransporter (KCC2) drives the shift of GABAergic responses from depolarizing to hyperpolarizing (D/H) in the developing CNS. But if this sequential expression is crucial for brain functioning, factors that control it remains largely unknown. Leptin is an adipocyte-derived hormone acting on the hypothalamus to reduce food intake and enhance energy expenditure. But there is a growing number of evidences showing that leptin action is not only restricted to metabolism, but also implies a key neurotrophic role in different brain areas. Based on the fact that circulating levels of leptin are developmentally regulated and parallel the D/H shift of GABA, we hypothesized that leptin could be one factor controlling chloride homeostasis in the brain. Here we show that the developmental D/H sequence of GABA is abolished in leptin- (ob/ob) and leptin receptor- (db/db) deficient mice hippocampi. Thus, the reversal potential of GABAA receptor-mediated synaptic currents (EGABA) remains hyperpolarizing throughout postnatal development (from P3 to P15) in db/db and ob/ob mice. Moreover, a brief (2min) application of the specific GABAA receptor agonist isoguvacine (3μM) decreases spiking activity of hippocampal neurons in newborn db/db and ob/ob, while the same application increases spiking activity in WT. We further show that acute administration of leptin induces a depolarizing shift of EGABA. Finally, we also provide data showing that this effect involve a down-regulation of KCC2 activity. These results indicate that high leptin levels controls chloride homeostasis in neonatal neurons and that the decrease to adult leptin level underlies the physiological developmental switch of GABAergic responses.

Title: Development of functional synaptic networks in the mouse vagal pathway revealed by voltage-sensitive dye imaging

Authors: *Y. MOMOSE-SATO[1], K. SATO[2];
[1]Dept. of Nutr. and Dietetics, Kanto Gakuin University, Col. of Nutr., Yokohama, Japan;
[2]Komazawa Women's Univ, Fac. of Human Hlth., Tokyo, Japan

Abstract: The vagus nerve (N.X) transfers autonomic input and output information to and from the brainstem, and analysis of the N.X-related brainstem nuclei is the first step to understand the functional organization of the autonomic neuronal circuits. Investigations of the neural network organization have been hampered because conventional electrophysiological means have some technical limitations. In the present study, the multiple-site optical recording technique with a voltage-sensitive dye was used to survey the functional organization of the vagal system in a mouse embryo. Stimulation of the N.X in E11 to E14 mouse embryos elicited optical responses in areas corresponding to the vagal sensory and motor nuclei. Postsynaptic responses in the first-order sensory nucleus, the nucleus of the tractus solitarius (NTS), were identified from E11-E12, suggesting that sensory information was transferred to the brain by this stage. In addition to the NTS, optical responses were identified in the rostral and contralateral brainstem regions, which appeared to correspond to second/higher-order nuclei of the vagus nerve. Postsynaptic responses in the second/higher-order nuclei were detected from E12, suggesting that polysynaptic pathways were functional by this stage. We discuss the results of optical mapping, comparing them with previous findings obtained in chick and rat embryos.

Title: Spontaneous emergence of neuronal groups and attractor dynamics in a spiking model of developing primary sensory cortex

Authors: *T. MICONI, J. MCKINSTRY, G. M. EDELMAN;
Neurosciences Inst., La Jolla, CA

Abstract: A long-standing proposal suggests that sensory neurons organize into coherent, competitive groups, which emerge from attractor dynamics supported by reciprocal connections, and represent stimuli by their collective activity (rather than through the responses of individual cells). Recent observations from multiple sources have provided tantalizing support for this hypothesis. However, whether (and how) neurons develop attractor dynamics remains controversial. Here we describe a computational model of a small patch of primary visual cortex, composed of 100 spiking neurons endowed with spike timing dependent plasticity for lateral and feedforward connections, and all-to-all mutual inhibition. We use state-of-the-art models for neural dynamics (Adaptive-Exponential neurons) and synaptic plasticity (Clopath-Gerstner voltage-based spike timing dependent plasticity). We expose this model to natural images, processed to emulate the operation of retinal cells. We find that the model spontaneously arranges into competitive groups of reciprocally-connected, similarly-tuned neurons, while developing realistic, orientation-selective receptive fields for each individual cell. Neural groups respond in a competitive, all-or-nothing manner, in accordance with experimental data. Crucially, the same groups are observed in both stimulus-evoked and spontaneous (stimulus-absent) activity, confirming the role of internal dynamics in their formation and replicating physiological observations. Mutual connections exhibit the experimentally observed properties of symmetry, sparsity and cliquishness. The final self-organized network is inhibition-stabilized and exhibits attractor dynamics without slowing down network dynamics. Importantly, the development of coherent neural ensembles requires naturalistic stimuli: randomized stimuli (with identical distribution of intensities but no spatial correlations) do not give rise to group formation or attractor dynamics. Our results support the hypothesis that local cortical microcircuits organize into attractor networks that support discrete response patterns (i.e., neuronal groups), and show that known properties of developing cortex, together with exposure to natural stimuli, suffice to explain the emergence of these dynamics.

Title: Functional serotonin signaling in the hippocampus prior to dorsal raphe maturation in neonatal mice

Authors: *R. A. MORTON[1], Y. YANAGAWA[2], C. VALENZUELA[1];
[1]Neurosciences, Univ. of New Mexico, Albuquerque, NM; [2]Genet. and Behavioral Neurosci., Gunma Univ. Grad. Sch. of Med., Maebashi, Japan

Abstract: During brain development serotonin (5-hydroxytryptamine (5-HT)) plays a major role in cell proliferation, migration, axonal guidance, and circuit wiring. In rodents the first two weeks of postnatal life are developmentally equivalent to the third trimester of human development. Previous studies have shown that serotonin plays a critical role in dendritic development, dendritic length, branching, and spine formation in the hippocampus. Serotonin is produced by neurons located within the raphe nucleus that are highly regulated by local GABA interneurons. The goal of these studies is to characterize the electrophysiological properties of both local GABA and putative serotonin neurons within the dorsal raphe and the functionality of serotonin synapses in the CA1 hippocampal region during the third trimester-equivalent period (post-natal days (P) P5 - P17). To identify GABA neurons, we used a transgenic mouse that expresses the Venus fluorescent protein (developed by Dr. Atsushi Miyawaki at RIKEN, Wako, Japan) driven by the vesicular GABA transporter (VGAT) promoter (Wang et al. 2009). Putative serotonin neurons were identified by their anatomical location and the lack of Venus expression. P5-P7 and P15-P17 pups were used to represent early and late stages of the third trimester equivalent period, respectively. GABA neurons displayed a lower threshold for action potential firing (P5-P7 = 20 pA vs P15-P17 = 50 pA, n=11) and a higher firing rate with a 100 pA current injection (P5-P7 = 17.28 Hz vs P15-P17 = 9.46 Hz, n=11). Spontaneous excitatory post-synaptic currents (sEPSCs) had a frequency of ~1 Hz and a peak amplitude of ~50 pA in both cell types at both ages (n=10 for each). Putative serotonin neurons displayed an increase in the frequency of spontaneous inhibitory post-synaptic currents (sIPSCs) (P5-P7 = 0.9 Hz vs P15-P17 = 4.16 Hz). To test for functional serotonin synapse in the CA1 region of the hippocampus, we utilized another transgenic mouse that expresses channel rhodopsin 2 under the control of the tryptophan hydroxylase 2 (TpH2) promoter, restricting the expression to serotonin neurons only. In the CA1 region of the hippocampus, serotonin is known to potentiate sIPSCs in CA1 pyramidal neurons.

Light induced serotonin release increased the sIPSC frequency by ~2 fold (P5-P7 = 2.4x, P15-P17 = 1.76x, n=7), and induced a tonic current of ~18 pA (P5-P7 = 15.8 pA, P15-P17 = 20.4 pA, n=7) at both ages. Our studies suggest that both GABA and serotonin neurons undergo electrophysiological and synaptic changes during the third trimester equivalent, but serotonin signaling in the CA1 region is functional as early as P5.

Title: Functional dynamics of developing newborn neurons

Authors: ***J. BOULANGER-WEILL**, G. SUMBRE;
IBENS INSERM U1024, Paris, France

Abstract: During vertebrate embryogenesis and up to adulthood, newborn neurons are continuously added to the existing circuitry. A major challenge in neurosciences is to understand how newborn neurons functionally incorporate into mature neuronal circuits. To this end, we have used the retino-tectal system of the zebrafish larva to monitor the developing activity of newborn neurons and the surrounding matured network. Due to the zebrafish larva's small size, transparency, rapid external development and the genetic advantages that the model presents, it was possible to label both newborn and matured circuit tectal neurons, and monitor their developing activity dynamics by means of two-photon calcium imaging and optogenetics, in an intact non-anesthetized and non-paralyzed vertebrate, during four consecutive days after the neurons were born. At the onset of labeling (day 1), labeled newborn neurons displayed an undeveloped dendritic arbor and their cell identity was not yet established (excitatory or inhibitory). Within a 4-days period their dendritic arborization increased by ten-fold and matched described mature morphological subtypes (Nevin et al., BMC Biology, 2010). Rapidly (day1) newborn neurons exhibited spontaneous activity events although robust correlated activity with their matured surrounding neighbors emerged 2 days later (day3). Certain newborn neurons progressively incorporated into local assemblies forming part of the retinotopic map of the optic tectum (Romano et al, Neuron 2015), while others incorporated into spatially sparse circuits.

Interestingly newborn neurons already displayed visually induced responses from the onset of labeling. These responses became more robust and neuronal tuning became sharper (receptive field and direction selectivity) matching those of the matured population after four days. Overall, our results suggest that newborn neurons first choose pre-synaptic partners before integrating into tectal micro-circuits. We are now investigating whether newborn neurons first establish their functional identity and then choose their tectal partners accordingly, or whether they incorporate within a tectal circuit later adopting a functional identity matching the matured recruiting circuit. Understanding the functional dialogue between newborn and matured neurons may open the way for the development of novel techniques for stem-cell brain repair.

Title: Spontaneous neuronal activity is required for dendrite pruning of olfactory mitral cells in early postnatal development

Authors: *S. FUJIMOTO[1], Y. MUROYAMA[2], T. SAITO[2], T. IMAI[1];
[1]Lab. for Sensory Circuit Formation, RIKEN CDB, Kobe-Shi, Japan; [2]Dept of Developmental Biology, Grad. Sch. of Med., Chiba Univ., Chiba, Japan

Abstract: Neuronal circuits are sculpted by pruning excessive axons and dendrites of neurons in early postnatal stages. In the olfactory system, each mitral cell initially connects multiple primary dendrites to multiple glomeruli, and then eliminates all but one primary dendrite during the first postnatal week, eventually forming a single primary dendrite which connects to a single

glomerulus. This observation indicates that the wiring specificity of primary dendrite is established by a postnatal pruning process. However, the mechanisms of selective dendrite pruning remain largely unknown. Here we investigated the involvement of neuronal activity by overexpressing Kir2.1 to silence neuronal excitability in mitral cells. We found that overexpression of Kir2.1 severely perturbed the pruning of primary dendrites as well as the extension of lateral dendrites. In contrast, mice expressing tetanus toxin in all olfactory sensory neurons showed only minor delays in the pruning process, which is most likely due to an indirect consequence of poor suckling. These results suggest that olfactory sensory neuron-independent spontaneous neuronal activity regulates selective dendrite pruning in mitral cells. We next performed two-photon calcium imaging of acute olfactory bulb slices to clarify the nature of spontaneous activity during development. We observed propagating waves of activity across glomeruli before and during dendrite pruning process (P0-3). Pharmacological experiments revealed that gap junctions are required to propagate the spontaneous activity in the olfactory bulb. The pattern of spontaneous activity gradually became decorrelated after the pruning period. Taken together, our data suggest that sensory stimuli-independent spontaneous activity regulates precise dendritic connections. This propagating spontaneous activity may have an instructive role in the dendrite pruning process.

Title: Developmental changes in spontaneous activity in the neonatal mouse olfactory bulb *in vivo*

Authors: ***M. N. LEIWE**, T. IMAI;
Lab. For Sensory Circuit Formation, Kobe, Japan

Abstract: The correct formation of neural circuits is vital for the function of the brain, this is achieved by both the correct outgrowth and pruning of neurites (axons and dendrites). In the mouse olfactory bulb (OB), Mitral and Tufted cells (M/T cells) are the principal output neurons, receiving input from Olfactory Sensory Neurons (OSNs) in the glomerular layer of the OB, and projecting axons to the olfactory cortex. During postnatal development, M/T cells refine their dendrites from connecting to multiple glomeruli (Postnatal days 0-4/5) to a single primary dendrite connecting to a single glomerulus ≥P6). Genetic experiments in our lab uncovered a critical role for non-sensory (spontaneous) activity in shaping this refinement. However, the nature of this spontaneous activity is unknown. Therefore our aim was to uncover the nature, source, and role of spontaneous OB activity and to provide insight into the rules that regulate M/T dendrite refinement, i.e. how M/T cells determine the winning (surviving) dendrite. To this end, we directly recorded spontaneous activity in the neonatal mouse OB using 2-Photon *in vivo* Ca2+ imaging with the genetically encoded calcium indicators GCaMP3/6f expressed in either M/T cells or OSNs across the early postnatal days (up to P10). We detected spontaneous activity in M/T cells in awake mice, but not in OSNs, suggesting that it is intrinsic to the OB, consistent with our previous genetic experiments. We also observed a change from a correlated wave-like pattern (P2-3), to random decorrelated activity patterns (P4-10) within M/T cells. This was quantified with Spike Time Tiling Co-efficient (STTC) analysis which demonstrated a distance dependent correlation pattern at P2-3, an intermediate stage at P4-5, and a purely random pattern at P10. These results suggest that the wave-like spatiotemporal patterns of spontaneous activity in early postnatal period (P2-3) may be important in shaping the innervation patterns of the dendrites of M/T cells.

Title: *In vivo* expression of Pro-Brain-Derived Neurotrophic Factor (proBDNF) alters Glutamate/GABA balance and increases seizure susceptibilty

Authors: *B. RIFFAULT, C. DUMON, N. KOURDOUGLI, N. FERRAND, J.-L. GAIARSA, C. PORCHER;
INMED, Marseille, France

Abstract: The Brain Derived Neurotrophic Factor (BDNF) is synthesized as a precursor, namely proBDNF, which can be processed into mature BDNF (mBDNF). ProBDNF, signaling through p75NTR is biologically active and are assumed to produce opposing physiological responses to mBDNF. Accumulating evidences indicate that impairment of proBDNF proteolysis may account for the emergence of neurological disorders. These findings support the view that the relative availability of mBDNF and proBDNF forms is an important mechanism underlying brain circuit formation and cognitive functions. Here we show that *in vivo* cortical expression of a cleavage resistant proBDNF isoform (CR-proBDNF) results in aberrant dendritic complexity in cortical pyramidal neurons, impaired excitatory/inhibitory balance that in turn leads to cortical network hyper excitability *in vitro*. The latter was confirmed *in vivo* as we find that CR-proBDNF rats are highly susceptible to epileptic seizure. Altogether these results suggest that neuronal disorders triggered by alterations in BDNF processing play a key role in cortical network wiring and shed light on the involvement of proBDNF/p75NTR signaling in the development of epilepsy.

Title: Calcium binding to Synaptotagmin III regulates patterned spontaneous activity during visual circuit development

Authors: *W.-C. SHU[1], Y.-T. HUANG[1], S.-Y. KAO[1], Y.-T. HSIAO[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., [4]Genome and Systems Biol. Program, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Patterned spontaneous activity in the developing retina, termed retinal waves, appears during the critical period of visual circuit refinement. Stage II retinal waves (P0-P9 in rats), essential for eye-specific segregation of retinogeniculate projection, are initiated by starburst amacrine cells (SACs) releasing neurotransmitters to other SACs and retinal ganglion cells (RGCs). Our previous studies found that the expression level of Synaptotagmin III (Syt III) was significantly increased in the RGCs during P4 to P6, i.e., the critical period of eye-specific segregation. We also found that Syt III regulates the kinetics of calcium-dependent exocytosis through calcium binding to the C2A and C2B domains. However, how calcium binding to Syt III plays a role in regulating stage II waves remains unknown. In this study, we combined molecular perturbation and live calcium imaging to detect the function of Syt III-calcium binding sites in regulating stage II waves. By using the cell-type specific promoters (pBrn3b for RGCs and pmGluR2 for SACs), we overexpressed Syt III or its mutant with the abolished calcium binding sites in the C2AB domains (Syt III-D386,520N). We found that overexpressing wild-type Syt III in RGCs increased the frequency of wave-associated spontaneous calcium transients compared to the control. By contrast, overexpressing Syt III-D386,520N in either SACs or RGCs decreased calcium transient frequency compared to wild-type Syt III. These results suggest that Syt III may regulate the kinetics of retinal waves through calcium binding to its C2AB domains.

Title: Phosphorylation of cysteine string protein-alpha regulates retinal waves during development

Authors: C.-F. CHEN[1], Y.-T. HSIAO[1], T.-Y. WO[1], *C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., [4]Genome and Systems Biol. Program, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: During a developmental critical period, the binocular visual system displays a robust patterned spontaneous activity termed “retinal waves”, which are shown essential for visual

circuit refinement. These waves are initiated by presynaptic starburst amacrine cells (SACs) releasing neurotransmitters onto other SACs and retinal ganglion cells (RGCs) through calcium-regulated exocytosis. Cysteine string protein (CSP) is found to ensure correct folding of the exocytotic machinery and can be phosphorylated by protein kinase A (PKA), whose activity demonstrates correlated oscillations with retinal waves. However, it is unknown whether retinal waves can be regulated by PKA-mediated CSP phosphorylation in SACs. In this study, we combined molecular perturbation, exo vivo transfection, and live imaging to investigate how CSP phosphorylation in SACs regulates the spatiotemporal properties of retinal waves. We found that CSP was expressed in the inner plexiform layer (IPL) of the neonatal rat retina and the dominant isoform in the developing rat retina was CSPα. Further immunostaining of dissociated retinal cells confirmed that the expression of CSP was localized to presynaptic SACs, suggesting that CSP involves in regulating neurotransmitter release from SACs. To investigate whether phosphorylation of CSPα in presynaptic SACs affects retinal waves, we targeted gene expression to SACs by the metabotropic glutamate receptor type II promoter. After overexpression of CSP or its phosphomutants in SACs, subsequent calcium imaging was performed in the RGC layer to detect the spatiotemporal properties of wave-associated spontaneous calcium transients. We found that the frequency of calcium transients was significantly decreased by the phosphodeficient mutant (CSPα-S10A), but not by the wild-type CSPα (CSPα-WT) or the phosphomimetic mutants (CSPα-S10D and CSPα-S10E) compared to the control. These CSPα phosphomutants had a relatively minor effect on the spatial correlation of spontaneous calcium transients. Therefore, our results suggest that phosphorylation of CSPα may play an important role in regulating the temporal properties of retinal waves.

Abstract: Spontaneous activity patterns emerge in neurons during maturation process in several central nervous system regions. In the course of postnatal development of hippocampus, a number of neurons display spontaneous activity characterized by increased of calcium dynamics and voltage changes. These events present characteristics such as coherent and recurrent electrical activity among hippocampal neurons (synchronous plateau assemblies, SPAs, and giant depolarizing potential, GDPs). The spontaneous activity of hippocampal neurons modulates the proper conduct of neuronal connections during local network shaping. Thus, some studies have been demonstrated that gap junction (GJ) is essential for SPAs generation and propagation. GJ allow the passage of small molecules up to 1 kDa. GJ channels are made of protein subunits called connexins (Cx). Our previews results demonstrated the dynamics changes of transcript and protein of Cx36 and Cx45 during postnatal development. Interesting, Cx36 expression was higher in hippocampus at P5 (2^1.96= 3.89 fold-expression, P<0.001) and P10 (2^1.71= 3.27 fold-expression, P<0.01) when compared with adult animal (P60). Similarly, our results indicated that Cx45 is highly expressed during all analyzed postnatal periods of hippocampus (P0:2^2.74= 6.7 fold-expression, P<0.0001; P5: 2^2.73= 6.63 fold-expression, P<0.0001; P10: 2^2.25= 4.75 fold-expression, P<0.0001). Likewise, Cx36 protein levels are found highly concentrated during early postnatal periods (P0:553%, P<0.01; P5:447%, P<0.05) when compared with P60. Nevertheless, Cx45 protein levels are found less concentrated during this period (P5:55%, P<0.01; P10:60%, P<0.05). Taking these results into account, neuronal GJ made by Cx36 can be important modulators of spontaneous activity propagation during activity-dependent period of hippocampus development.

Title: Odor activation domains of inhibitory neurons expand with neuronal maturation

Authors: *K. B. QUAST[1], I. GARCIA[2], B. R. ARENKIEL[3];
[1]Mol. & Human Genet., [2]Developmental Biol., [3]Mol. & Human Genet. and Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Sensory maps are created by neuronal responses that vary with their anatomical position, so that representations of the external world are systematically organized within the structure of the brain. Current understanding of cortical sensory maps is that they are sculpted and refined throughout development and/or sensory experience. However, this model is largely derived from investigations into patterns of excitatory cell responses. Taking advantage of the mouse olfactory bulb, where ongoing neurogenesis supplies new inhibitory granule cells into existing circuitry, we isolated the development of sensory evoked activation domains of an inhibitory network. Using *in vivo* calcium imaging of odor responses of the entire dorsal olfactory bulb, we compared functional responses of genetically defined populations of both maturing and established granule cells. We found that in contrast to the activity-dependent refinement and pruning observed for excitatory maps, we see an expansion in the odorant specific activated domains of inhibitory neurons. These data describe the development of an inhibitory sensory map, highlighting the differences between previously described excitatory maps.

Abstract: Coordinated neuronal activity is essential for the development of cortical circuits. GABAergic hub neurons that function in orchestrating early neuronal activity through a widespread net of postsynaptic partners are therefore most likely critical players in the establishment of functional networks. So far, evidence for hub neurons has been achieved in the hippocampus where an early birthdate delineates a subgroup of hub cells. Whether hub cells also exist in the neocortex remains unknown. This is an important issue given that both structures share common developmental programs including a similar sequence for the emergence of population coherence, but also since recent evidence indicates important differences especially regarding the origin of GABAergic neuron diversity. We decided to examine this issue in the entorhinal cortex, the major input region to the hippocampus. To this aim, we used an unbiased approach that identifies operational hub neurons through targeted patch-clamp recordings of high functional connectivity degree neurons in living slices. Further, as spatial origin is a determinant hallmark of selective differentiation for cortical interneurons, we also used the *5-HT3aR-BAC*^{EGFP} and *Lhx6Cre::RCE* mice to differentiate among caudal and medial ganglionic eminences-derivate interneurons, to characterize whether or not spatial origin is critical in the generation of cortical hub cells. Similarly as in the hippocampus, developing entorhinal cortex displays a scale-free organization with hub neurons being GABAergic cells that often display characteristic morphophysiological properties.

Title: Depolarizing $GABA_A$ transmission restrains excitatory synapse formation in the developing hippocampus

Authors: *C. K. SALMON[1], H. PRIBIAG[2], S. CAMERON[3], V. MAHADEVAN[4], D. STELLWAGEN[2], M. WOODIN[4], K. MURAI[2];
[1]Ctr. For Res. In Neurosci., Montreal, QC, Canada; [2]McGill, Montreal, QC, Canada; [3]UC Davis, Davis, CA; [4]Univ. of Toronto, Toronto, ON, Canada

Abstract: GABA is the main inhibitory neurotransmitter in the mature brain, but has the distinct property of depolarizing neurons in the immature brain. Depolarizing $GABA_A$ transmission is implicated in glutamatergic synapse formation, however due to GABA's many roles in central nervous system development, its precise role in glutamatergic synapse formation remains to be fully delineated. Here we addressed the importance of depolarizing $GABA_A$ transmission for glutamatergic synapse development in hippocampal CA1 pyramidal neurons. Based on the expression profile of K^+-Cl^- co-transporter 2 and changes in GABA reversal potential, we pinpointed the timing of the switch from depolarizing to hyperpolarizing $GABA_A$ transmission in CA1 neurons in organotypic hippocampal slice culture. Remarkably, prior to the switch, pharmacological blockade of depolarizing $GABA_A$ transmission increased spine density, whereas promoting depolarizing $GABA_A$ transmission decreased spine density. The increase in spine density corresponded to increased mESPC frequency. Interestingly, when slices were allowed to recover from the pharmacological manipulations, the changes in excitatory synapses were sustained for more than a week. Together, these findings suggest that depolarizing $GABA_A$ transmission plays a critical role in shaping connectivity during postnatal hippocampal development by restraining gluatmatergic synapse formation. To determine whether this is the case *in vivo,* we have developed tools to disrupt $GABA_A$ transmission with temporal precision in the living brain during development. We placed a dominant negative Gamma 2 $GABA_A$ receptor subunit under control of the TetOn tetracycline transactivator system for use with *in utero* electroportation. This approach provides tightly controlled expression of dominant negative Gamma 2 in neurons. Furthermore, we designed and screened 6 artificial micro RNAs targeting the Gamma 2 subunit and found that all of these decreased the number of Gamma 2 puncta as well as Beta 3 $GABA_A$ receptor subunit puncta. Moving forward, we will use these tools to inhibit depolarizing $GABA_A$ transmission *in vivo* to assess its role in glutamatergic synapse formation in a temporally specific manner.

Title: NMDA receptor-based template networks of the developing neocortex

Authors: *M. C. ASHBY, S. R. HULME, J. L. ROZAS;
Univ. of Bristol, Bristol, United Kingdom

Abstract: Experience-dependent synaptic plasticity drives the functional maturation of the mammalian neocortex. This type of plasticity usually requires activity of, and often modifies, existing synaptic partners within a pre-existing neuronal network. As such, the earliest-emerging neuronal networks can be thought of as a template that is subsequently modified by experience-dependent plasticity. The properties of these template networks will therefore constrain, or at least strongly influence, the possible effects of subsequent experience-dependent processes. There is significant evidence that NMDA receptors (NMDARs) play a prominent role in the early postnatal development of synapses. In particular, silent, NMDAR-containing synapses are known to be converted to functional, AMPA receptor-containing synapses in an experience-dependent manner. Here, to investigate the properties of emergent template networks, we have analysed the development of NMDAR-based synaptic connectivity in the early stages of postnatal development in the barrel cortex. Using two-photon glutamate uncaging to photostimulate individual neurons, we assessed the of rate of NMDAR-based synaptic connectivity, and the characteristics of those synapses, between layer 4 neurons in acutely-prepared slices from 4 to 10 day old mice. We found that, on top of slowly developing increase in connectivity over the postnatal period, there is a transient burst of NMDAR-based synapses that precedes the normal time window for classical synaptic unsilencing. Unexpectedly, the emergence of this burst of NMDAR-containing synapses is dependent on sensory experience through the whiskers. In contrast, we found that sensory experience has no effect on the postnatal development of passive electrical properties and excitability of the neurons. At these early developmental stages, the layer 4 neurons, which are stellate cells, almost completely lack dendritic spines. Therefore, to assess the role of NMDAR location in driving early synapse formation, we mapped the distribution of NMDARs on the dendritic branches of layer 4 neurons using brief two-photon glutamate uncaging to replicate synaptic events. The emergence of silent and functional synapses on dendritic shafts and on newly-formed spines was shows highly non-random spatial and temporal bias that likely contributes to the maturation of the earliest template networks.

Title: Neurogenin brings about photoreceptor-like cells in chick Müller glial cell culture

Authors: R.-T. YAN, L. HE, *S.-Z. WANG;
Univ. Alabama, Birmingham, Birmingham, AL

Abstract: Restoring vision through regeneration of the retina is hampered by the lack of means to activate endogenous progenitor cells to produce a sufficient number of photoreceptors. Recent advances in research of retinal regeneration in fish and of adult neurogenesis in the mammalian brain have heightened the expectation of Müller glia as potential endogenous progenitors for photoreceptors. A critical barrier persists. Thus far, Müller glia of high vertebrates have been largely unresponsive to various experimental manipulations, with few, in any, photoreceptor cells being generated. This study tested whether photoreceptor-like cells would be generated in chick Müller glia cell culture reprogrammed with proneural gene neurogenin. Müller glia cell culture was established with functionally mature retina isolated from day 19 chick embryos. During dissection, the peripheral region of the retina was removed to minimize potential contamination by progenitor cells at the ciliary margin. Passage one culture was infected with RCAS retroviruses expressing neurongenin1 (ngn1), ngn3, or GFP as control. Analysis with immunocytochemistry and cell morphology showed cells positive for visinin, a calcium-binding protein of photoreceptor cells, in cultures infected with RCAS-ngn1 or RCAS-ngn3, but not in the control. Visinin+ cells exhibited morphologies typical of young photoreceptor cells - a compact cell body with a thin process on one side and a short, inner-segment-like compartment on the other. The cultures were also examined with RA4 antibody, which labels retinal ganglion cells and some unidentified progenitor/precursor cells. While RA4+ cells were present in all cultures, RA4+ cells with neuronal morphologies were only present in cultures infected with

RCAS-ngn1 or RCAS-ngn3, with those in the control culture overtly maintaining morphology of Müller glia. Our data show that photoreceptor-like cells could rise de novo in Müller glia cell cultures when reprogrammed with ngn1 or ngn3 and suggest a possibility of using ngn1 or ngn3 to guide Müller glia towards the regeneration of photoreceptors and ganglion cells as well.

Title: Presynaptic zinc regulates optic nerve regeneration: role of ZnT-3 and nNOS

Authors: ***Y. LI**[1,2], K. YUKI[1], L. ANDEREGGEN[1], M. ASDOURIAN[1], M. HERSHFINKEL[3], S. J. LIPPARD[4], P. A. ROSENBERG[1], L. I. BENOWITZ[1];

Abstract: Retinal ganglion cells (RGCs), the projection neurons of the eye, cannot regenerate their axons following damage to the optic nerve and undergo delayed cell death. Consequently, victims of traumatic or ischemic nerve damage or individuals with degenerative diseases such as glaucoma suffer lifelong visual losses. Zinc is essential for many cellular functions but also

contributes to neuronal death in hypoxic-ischemic injury and other conditions. We reported previously that, shortly after injury to the optic nerve (nerve crush, NC), levels of free zinc (Zn2+) increase rapidly in synapses of the inner plexiform layer (IPL) of the retina, with amounts within RGCs increasing more slowly. Chelating Zn2+ leads to enduring survival of many RGCs as well as extensive axon regeneration (Li et al., SfN Abstract 399.19, 2014). The present experiments explored the mechanisms underlying presynaptic Zn2+ accumulation. We found that levels of the vesicular Zn2+ transporter ZnT-3 increase greatly in terminals of retinal interneurons within a day after NC in a laminar pattern similar to that of Zn2+ itself. Deletion of slc30ac, the gene encoding ZnT-3, nearly eliminated Zn2+ accumulation in the IPL and in RGCs, and promoted both RGC survival and axon regeneration. Because reactive nitrogen species can liberate Zn2+ from metallothioneins, we also investigated the role of nitric oxide (NO) in presynaptic Zn2+ accumulation. Deletion of nos1, the gene encoding neuronal NO synthase (nNOS), eliminated the Zn2+ signal in the mouse retina after NC. Similar results were obtained with the NO scavenger PTIO (2-phenyl-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide) or the nNOS-selective inhibitor L-NPA (Nω-propyl-L-arginine). Conversely, the NO donor DETA-NONOate ((Z)-1-[N-(2-aminoethyl)-N-(2-ammonioethyl)amino]diazen-1-ium-1,2-diolate) caused Zn2+ to accumulate in the retina in the absence of NC. Combined with our previous results, these findings show that ZnT-3 and nNOS are required for presynaptic accumulation of Zn2+ in the retina after optic nerve injury, a key step in the suppression of RGC survival and axon regeneration.

Title: Cadherin expression in normal and regenerating adult zebrafish retinas

Authors: S. BHATTARAI[1], A. SOCHACKA-MARLOWE[1], N. WANG[1], K. FORKAPA[1], R. LONDRAVILLE[1], *Q. LIU[2];
[1]Biol., [2]Univ. Akron, Akron, OH

Abstract: We examined mRNA expression of two classical cadherins (*cadherin-6*, *cadherin-7*) and two delta protocadherins (*protocadherin-17* and *protocadherin-19*) in normal and regenerating (1 day to 3 weeks post optic nerve injuries) adult zebrafish retinas using *in situ* hybridization and qPCR methods. Cadherins are calcium-dependent cell adhesion molecules that play important roles in eye development in both invertebrate and vertebrate species. Our knowledge of cadherins expression and function in developing vertebrate retinas is extensive, but little is known about their expression in normal and regenerating retinas of adult organisms. We found that all four cadherins are mainly expressed in the retinal ganglion cell layer (GCL) and/or inner nuclear layer (INL) of the normal retinas. Following optic nerve crush, expression of these four cadherins showed distinct and time-dependent changes in the regenerating retinas. Increased expression of *cadherin-6* (in the GCL) and *cadherin-7* (in the inner most portion of the INL) in a subset of cells became obvious 1 week after the optic nerve lesion, and the increased expression lasted for another week before returning to control levels 3 weeks following the optic nerve crush. Expression of *protocadherin-17* and *protocadherin-19* in the GCL was apparently decreased after the optic nerve lesion. The decrease in their expression became detectable 1 day after the injury, and became more pronounced in retinas harvested 3 days to 2 weeks post optic nerve crush. Expression of both *protocadherins* returned to control levels 3 weeks after the optic nerve crush. Our results suggest that cadherins may play differential roles in the regeneration of the zebrafish retina. *Bhattarai and Sochacka-Marlowe contributed equally to this project. Title: After spinal cord injury extracellular cues affect the dynamics of local protein synthesis machinery in regenerating central nervous system axons

Authors: *R. SACHDEVA[1], M.-K. MCMULLEN[1], J. L. TWISS[2], J. D. HOULÉ[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: Peripheral nerve grafts (PNGs) support significant regeneration of central nervous system (CNS) axons after spinal cord injury (SCI) in rats, yet most axons fail to leave the PNG when reapposed to spinal cord tissue across a lesion site. Intra-axonal localization of mRNAs and protein synthesis machinery (PSM) generates proteins locally, which the regenerating axons likely use to fine tune the spatiotemporal response to extracellular stimuli. Here we examine regenerating CNS axons for the presence of several key components of PSM and whether their levels change when axons are exposed to the injured spinal cord. Ascending sensory axons after lower thoracic spinal cord transection regenerated into PNGs for different timepoints: Group 1 rats were euthanized at 3 weeks and Group 2 rats at 7 weeks post grafting to compare axons when they are actively growing vs. when they are stalled at the distal end of the PNG, respectively. To analyze whether a second injury to axons elevates levels of PSM, the distal PNG end was cut at 7 weeks (in Group 3 rats). To analyze effects of the injured spinal cord environment, the distal end of PNGs was cut at week 7 and reapposed to spinal cord treated with ChondroitinaseABC or Penicillinase (control) in Groups 4 and 5 respectively. Using immunofluorescence and confocal microscopy, we analyzed the intra-axonal levels of eIF4E-binding protein-1 (4EBP1), phospho-4EBP1, eIF2α, phospho-eIF2α, and phospho-ribosomal protein S6 within neurofilament positive axons. We report that regenerating axons contain PSM components during growth, but the PSM levels are reduced when axons stop growing at the distal end of the PNG. Re-injury of these stalled axons increases axonal localization of the PSM proteins. Preliminary results suggest that re-apposition of the PNG to the injured CNS environment affects the levels of PSM. Our results suggest that CNS axons are capable of local translation to modulate their local protein repertoire during regeneration. This response could be shaped by local extracellular cues that can ultimately promote or inhibit regeneration. A better understanding of these mechanisms may provide future targets to prevent regeneration failure and improve recovery after SCI.

Title: E6020 as a modulator of immune-mediated gliogenesis

Authors: *L. M. MILICH[1], J. S. CHURCH[2], P. POPOVICH[2], D. M. MCTIGUE[2]; [1]Neurosci., The Ohio State Univ. Wexner Med. Ctr., Norton, OH; [2]Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Oligodendrocytes (OLs), the myelinating cells of the CNS, are vital to axon conductance and integrity but can become damaged during CNS injury and disease. As post-mitotic cells, OLs in the adult CNS are replaced by an endogenous population of oligodendrocyte progenitor cells (OPCs). Following injury or disease in the CNS, various inflammatory mechanisms have been shown to influence OPC and OL responses. Our lab has previously investigated activation of innate immune Toll-like Receptors (TLRs) in the healthy adult rat spinal cord and found that activation of TLR4 by intraspinal microinjection of lipopolysaccharide (LPS) induced robust OPC proliferation and oligodendrogenesis. LPS treatment also induced microglial activation and damaged gray and white matter around the injection site. However, due to its pathogenic nature, the use of LPS (endotoxin) as an oligogenic therapeutic will likely never be approved for use in humans. Therefore, in the current study, we investigated the oligogenic potential of E6020; a less potent, synthetic (non-pathogenic) TLR4 agonist. We hypothesized that E6020 activates microglia/macrophages and induces OPC proliferation and oligodendrogenesis. E6020 treatment of bone marrow derived macrophages and RAW-Blue™ cells *in vitro* elicited an increase in proinflammatory cytokine production and NF-κB activation similar to LPS. Intraspinal E6020 microinjection in adult Sprague-Dawley rats induced microglia/macrophage activation by 24 hours that increased through 7 days. A robust increase in proliferating OPCs was also observed at 7 days with E6020 treatment. E6020 induced significantly less axon/myelin damage than LPS, demonstrating its reduced pathogenic nature. Ongoing studies are investigating the oligogenic potential of intraspinal E6020 treatment after lysolecithin administration to determine E6020s effect on a demyelinating lesion. The results of this study may help elucidate a novel method of promoting oligodendrogenesis within the CNS, which could be used to promote oligodendrocyte replacement and recovery following trauma or demyelinating disease.

Title: Structural regeneration and functional restoration of the adult dentate gyrus after catastrophic granule cells death

Authors: *T. LICHT[1], T. KREISEL[2], B. WOLF[2], G. ROTHE[2], E. KESHET[2];
[1]Developmental biology and cancer research, The Hebrew Univ. of Jerusalem, Jerusalem, Israel;
[2]Developmental Biol. and Cancer Res., The Hebrew Univ., Jerusalem, Israel

Abstract: The adult hippocampus maintains the capacity to generate new neurons throughout life but its normal neurogenic output is rather low and progressively declines with age. The issue whether this neurogenic potential may suffice for recovery from a catastrophic damage associated with massive neuronal loss has not been adequately challenged. Here we addressed this issue with the aid of a VEGF-based conditional transgenic system in which months-long exposure to VEGF leading to continual elevation of synaptic plasticity and markedly enhanced neurogenesis, eventually culminates in granule cell apoptosis and greatly reduced DG cellularity. This experimental platform of a DG-restricted cellular damage has provided a unique opportunity to follow DG regeneration initiated upon VEGF de-induction. The DG was efficiently re-built with locally generated new neurons (with proper axonal and dendritic growth) and even an extreme cellular deficit of up to 90 percent was fully restored within a period of 12 weeks. Remarkably, impaired DG-dependent memory evident in the distracted DG was fully rectified following regeneration. Together, these results uncovered a yet unappreciated regeneration potential of adult DG neurogenesis.

Title: Genetic lineage tracing of Müller glia-derived progenitors in the mouse retina *in vivo*

Authors: *C. BOUDREAU-PINSONNEAULT[1,3], M. CAYOUETTE[2,3];
[2]Cell. Neurobio. Res. Unit, [1]Inst. De Recherche Clinique De Montréal, Montreal, QC, Canada;
[3]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: The mammalian retina is incapable of regeneration after neuronal cell loss caused by injury or disease, leading to irreversible blindness. In contrast, most fishes and amphibians have the capacity to regenerate their retina through the reprogramming of Müller glia into progenitor-like cells that are able to proliferate and differentiate into all retinal cell types. Recent studies have demonstrated that Müller glia reprogramming is also possible, at least to some extent, in mammals. After artificial retinal injury and injection of growth factors in the mouse eye, some Müller glia re-entered the cell cycle and BrdU-labelled neurons were observed 5 days after growth factor treatment. Although promising, these studies did not provide direct evidence that Müller glia actually generated new neurons, as genetic lineage tracing was not performed. Here we used a Glast-CreERT2;RosaYFP mouse line to study this question *in vivo*. We have shown that the RosaYFP reporter is specifically expressed in adult Müller glia 4 days after 4 intraperitoneal injections of tamoxifen, providing a highly specific and efficient genetic lineage tracing tool. To reprogram the Müller glia in a progenitor state and stimulate proliferation, we injected NMDA and epidermal growth factor (EGF) in the eyes of Glast-CreERT2;RosaYFP mice that were previously injected with tamoxifen. Müller glia-derived progenitors and their descendants will then be followed using expression of the RosaYFP reporter. Results from these ongoing studies will be presented. We next plan to manipulate gene expression in Müller glia-derived progenitors using *in vivo* electroporation of a Cre-inducible expression vector. This work may lead to novel therapies for blindness by promoting endogenous Müller glia to regenerate retinal cell types lost after injury or disease.

Title: A challenge to induce retinal regeneration in mouse retina

Authors: *Y. BABA, S. WATANABE;
Univ. of Tokyo, Minato-Ku, Japan

Abstract: Backgound: Adult mammalian retina is incapable of regeneration after traumatic injury, which results in retinal degeneration and permanent vision loss. In lower vertebrates, zebrafish retina can be repaired after traumatic injury through Müller glia proliferation and neural differentiation. In contrast, few Müller glia in mouse retina enter the cell cycle after the injury, and several transcription factors, including Ascl1, related with retinal regeneration failed to be expressed in the damaged retina. These findings raise the possibility that transducing transcription factors could fully reprogram Müller glia, allowing Müller glia to proliferate in the mouse retina. To date, I found that Ascl1-NICD3 cotransfection induced cell proliferation of Müller glia in ICR mice retinal explants. Purpose: To reveal the mechanism of Müller glia proliferation by Ascl1-NICD3 and characterize the biological significance of Ascl1-NICD3 inducing proliferation, gain-of-function analysis was performed under various conditions. Results: Gain-of-function analysis using Müller glia specific promoter Hes5 showed that Ascl1-NICD3 induces Müller glia proliferation cell-autonomously *in vitro*. In the marker expression analysis, NICD3 and Ascl1-NICD3 enhanced Nestin expression, and Ascl1-NICD3 induced retinal progenitor cell marker Chx10 expression *in vitro*. In addition, cell proliferation of Müller glia at P9 (n = 3) and P20 (n = 1) was elicited by Ascl1-NICD3 transfection *in vivo*. Furthermore, Ascl1-NICD3 inducing proliferation was occurred in C57/BL6 mice retinal explants which were previously reported to be difficult to induce cell proliferation.

Title: Hedgehog signaling regulates tissue regeneration in Xenopus laevis tadpoles

Authors: *A. M. HAMILTON[1], L. N. BORODINSKY[2];
[1]Shriners Hosp. For Children, Northern Californi, Sacramento, CA; [2]Physiol. and Membrane Biol., Univ. of California Davis Sch. of Med., Sacramento, CA

Abstract: Hedgehog signaling regulates tissue regeneration in *Xenopus laevis* tadpoles The Hedgehog signaling pathway regulates a wide variety of biological processes, including cellular proliferation, migration and stem cell differentiation and specification. Recent studies have also demonstrated that enhancing Hedgehog signaling following neural injury improves regeneration in the peripheral and central nervous system. It should be noted, however, that runaway Hedgehog signaling is a common feature in a number of cancers, making it imperative to future therapeutics that the exact mechanisms underlying Hedgehog's pro-regenerative capacity be characterized in detail to allow for targeted clinical manipulation. Using the *Xenopus laevis* tadpole as a model, we find that pharmacological manipulation of the Hedgehog co-receptor Smoothened (Smo) following tail amputation significantly alters regeneration of spinal cord, notochord and muscle in a tissue-specific manner, while perturbing Hedgehog signaling in intact tadpoles does not affect ongoing tissue development. Enhancing Hedgehog signaling by incubating amputated tadpoles with SAG, a Smo agonist, prevents the outgrowth of the spinal cord, whereas muscle regeneration remains normal. In contrast, inhibiting Hedgehog signaling with cyclopamine leads to the outgrowth of a normally elongated spinal cord, whereas muscle regeneration is blocked. Furthermore, we find that perturbing Hedgehog signaling for only the first 24 hours post amputation is sufficient to induce the effects on spinal cord and muscle regeneration observed after 72 full hours of treatment, suggesting that regulation of Hedgehog signaling is critical during the first stages post injury. In addition, we find that within 36 hours of amputation, continuous exposure to SAG or cyclopamine induces increased and decreased numbers of Sox2-positive neural progenitor cells in the regenerating tissue, respectively. These results suggest that a delicate balance of neural progenitor production, migration and differentiation is necessary to achieve successful tissue regeneration, and that Hedgehog plays different roles in the regeneration of different tissues, emphasizing the importance of targeting Hedgehog manipulation in a spatially and temporally restricted fashion. Title: CNS regeneration: investigating the transcriptional combinatorial logic underlying successful regeneration in zebrafish

Authors: *A. J. UDVADIA[1], I. VENKATESH[2];
[1]Biol. Sci., Univ. of Wisconsin Milwaukee, Milwaukee, WI; [2]Marquette Univ., Milwaukee, WI

Abstract: CNS injury in adult mammals fails to stimulate a regenerative response and usually results permanent disability. In contrast, CNS injury in fish elicits a robust regenerative response often leading to almost full recovery of function. Since the basic machinery regulating the wiring of the nervous system is well conserved across vertebrate species, the underlying difference stems from the relative abilities to restart the axon growth machinery in response to CNS injury. Our work is focused on discovering the gene regulatory network underlying successful CNS regeneration in zebrafish. We have discovered a combination of three transcription factors from the bZIP and bHLH transcription factor families that are essential for regeneration-associated expression of GAP-43 and successful target reinnervation in a zebrafish optic nerve transection injury model. We are now investing the mechanisms underlying the synergistic activities of this critical combination. One possibility is that they regulate overlapping, but distinct transcriptional networks, which together are necessary for successful regeneration. A second possibility is that they physically and/or functionally act together to regulate a common regeneration-associated gene regulatory network. Our current work investigates protein-protein and protein-gene interactions involving these transcription factors to understand the transcriptional combinatorial logic underlying successful vertebrate CNS regeneration.

Title: GDNF-secreting Schwann cells in multichannel OPF+ hydrogel scaffolds promote ascending axonal regeneration, remyelination, and partial locomotor recovery following complete spinal cord transection in rats

Authors: *B. K. CHEN, N. N. MADIGAN, J. S. HAKIM, A. M. SCHMEICHEL, A. M. KNIGHT, S. ZHANG, J. J. NESBITT, M. DADSETAN, M. DADSETAN, T. CHIANG, M. J. YASZEMSKI, A. J. WINDEBANK;
Neurol., Mayo Clin. Rochester, Rochester, MN

Abstract: Positively-charged oligo [poly (ethylene glycol) fumarate] (OPF+) is a biodegradable hydrogel with biomechanical properties similar to spinal cord tissue. In this study, OPF+ is used in a combinational tissue engineering approach for the investigation and in the treatment of spinal cord injury. Multichannel OPF+ scaffolds loaded with primary Schwann cells (SCs) or genetically-modified Schwann cells secreting glial cell-derived neurotrophic factor (GDNF-SCs) were implanted into completely transected rat spinal cords at the T9/10 level. GDNF-SCs promoted regeneration of higher numbers of axons (2773.0 ± 396.0, mean ± SEM) into OPF+ scaffolds than primary SCs (1666.0± 352.2) ($p<0.05$) (n=10 animals). A central and ventral midline orientation of axonal growth was observed. The number of neurons projecting caudally through the scaffold was significantly higher in GDNF-SC scaffolds as identified by retrograde fast blue (FB) tracing. The majority of FB-labelled ascending axons were intraspinal motor neurons. GDNF-SC implantation enhanced the remyelination of regenerating axons. The numbers of unmyelinated and myelinated axons, and the percentage of axons that were myelinated were each higher in the GDNF-SC OPF+ group. Myelinating cells in the tissue engineered spinal cord were demonstrated to be Schwann cells from the host animal. p75+ cell density increased in direct proportion to increasing axonal density in SC and GDNF-SC channels with strongly positive correlation coefficients (Pearson $r=0.8995$, $p<0.0001$ in SC channels, and Pearson $r=0.7665$, $p<0.0001$ for GDNF-SC channels). Axons were observed to associate with p75+ cells as premyelinated complexes, and myelinating axon bundles. Transected animals transplanted with GDNF-SC OPF+ scaffolds demonstrated partial hindlimb locomotor recovery at weeks 3 and 4 following surgery.

Title: The tumor suppressor HHEX restricts axon growth in central nervous system neurons

Authors: *M. SIMPSON[1], I. VENKATESH[1], B. CALLIF[1], L. THIEL[1], D. COLEY[1], K. WINSOR[1], Z. WANG[1], J. LERCH[2], M. G. BLACKMORE[1];

Abstract: Neurons in the peripheral nervous system respond to injury by activating transcriptional programs supportive of axon growth, ultimately resulting in functional recovery. In contrast, neurons in the adult central nervous system (CNS) possess a limited capacity to regenerate axons after injury, fundamentally constraining repair. We and others have shown previously that activating pro-regenerative gene expression in CNS neurons is a promising therapeutic approach, but progress is hampered by incomplete knowledge of the underlying transcription factors. In order to identify novel regulators of axon regeneration, we employed high content assays of neurite outgrowth, testing sixty-nine transcription factors that have been previously associated with cellular growth and motility in non-neuronal systems. This screen revealed two novel transcription factors (E2F1 and YAP1) as growth promoting, and four (PITX1, RBM14, ZBTB16, and HHEX) as growth inhibiting. Follow-up experiments focused on HHEX, the most potent and consistent growth inhibitor. Immunohistochemistry with axon-specific Tau1 antibodies showed that HHEX overexpression in cortical neurons reduced both initial axonogenesis and the rate of axon elongation, and domain deletion analysis strongly implicated transcriptional repression as the underlying mechanism. Although HHEX is unstudied in the CNS, we used immunohistochemistry and western blotting to show that HHEX is widely expressed in CNS neurons, including corticospinal tract neurons after spinal injury. Intriguingly, peripheral neurons lack native HHEX, and forced overexpression of native HHEX restricted axon growth potential in DRG neurons. These findings suggest a role for HHEX in limiting the regenerative capacity of mature CNS neurons.

Title: Strategies to generate migratory precursors for cortical projection neuron replacement

Authors: *M. GRONSKA, H. BELALCAZAR, N. MCKEEHAN, J. HEBERT;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The human neocortex is subject to many insults such as neurodegeneration to which there is no cure. Previous attempts to replace lost cortical projection neurons failed because the cells did not migrate outside the injection site. We propose an alternative approach where we take advantage of highly migratory medial ganglionic eminence (MGE) cells that have been shown to migrate long distances upon transplantation into the neocortex of rats and mice. Yet, MGEs give rise primarily to inhibitory GABAergic interneurons. Using recent developments in cell reprogramming, we seek to determine the transcription factor and chromatin remodeling factor combinations that would reprogram MGE precursors into cortical projection neurons. We designed a doxycycline inducible system, that allows for a temporal control of gene expression using lentiviruses carrying the genes of interest and Cre recombinase, TRE-GeneX-IRES-Cre. Thus, we will infect embryonic day 12.5 donor mice MGE cells that carry doxycycline responsive Rosa26rtTA and TauloxP-STOP-loxP-mGFP-IRES-LacZ reporter constructs, with various combinations of the lentiviral constructs. We will test for *in vivo* and *in vitro* reprogramming using cell cultures and stereotaxic injections into the adult mouse cortex. Reprogrammed cells will be tested for marker expression and electrophysiological properties. We are currently in the process of screening over 31 possible gene candidates. Our preliminary results suggest that Brn2 and NeuroD genes may be involved in the MGE to cortical projection neuron cell fate conversion.

Title: Combinatorial expression of transcription factors to promote axon regeneration

Authors: *C. L. ATTWELL[1], N. FAGOE[1], R. E. VAN KESTEREN[2], A. B. SMIT[2], J. VERHAAGEN[1], M. R. J. MASON[1];
[1]Neuroregeneration, Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands; [2]Dept of Mol. and Cell. Neurobio., Ctr. for Neurogenomics and Cognitive Res., Amsterdam, Netherlands

Abstract: Objective. Dorsal root ganglia (DRG) neurons are ideal for research into the intrinsic regeneration associated gene (RAG) program. Injury to the central projection of these neurons in the spinal cord does not result in regeneration, but after a lesion to the peripheral projection an increase in growth of the central projection is observed. We hypothesised that the RAG program is coordinated by combinations of transcription factors (TFs) that act synergistically or in a complementary fashion. This hypothesis was tested in two approaches: 1. *In vivo* AAV vector-mediated simultaneous overexpression of ATF3, c-Jun, STAT3 and Smad1, four TFs in injured DRG neurons which have been functionally linked to axon regeneration and are known to physically and functionally interact. 2. Promoter analysis of the RAG program which resulted in the identification of nine key TF families, some of which were previously linked to regeneration (AP1, ATF, KLF) and some of which are not (e.g. the MEF family). We systematically screened combinations of these TFs *in vitro*. **Methods**: 1. ATF3 alone or the combination of ATF3, c-Jun, STAT3 and Smad1 were over expressed in the left L4/L5 DRG of rats using an AAV5-dual vector[1,2] that also expresses GFP. The L4, L5 dorsal roots were transected and repaired. Axonal regeneration was assessed histologically and sensory recovery tested functionally. 2. Nine TFs identified by promoter analysis of the RAG program were screened in various combinations in the F11 neuronal cell line with Cellomics neurite length analysis. All single TFs, all possible pairs, and selected combinations of 3 and 4 TFs were tested. **Results**: 1. Over-expression of ATF3 or the combination of ATF3, c-Jun, STAT3 and Smad1 together resulted in faster axonal growth after dorsal root injury, but no additional benefits of the combination over ATF3 alone were observed. No sensory recovery was observed. 2. Of the nine selected TFs screened in F11 cells several combinations of transcription factors promoted synergistic increases in neurite growth, which included combinations of TFs of the ATF, KLF, MEF and STAT families. **Conclusion**: We successfully delivered multiple TFs to DRG neurons *in vivo*. Simultaneous overexpression of four known pro-regenerative TFs promoted faster axon regeneration in the dorsal root *in vivo*, but without apparent synergistic effects. Identification of key TFs by RAG promoter analysis followed by systematic combinatorial screening has yielded several more promising combinations of TFs, which we are currently testing *in vivo* for effects on regeneration

and gene expression. 1.Fagoe et al *Gene Ther*. 2014 Mar;21(3):242-52 2. Mason et al *Mol Ther*. 2010 Apr;18(4):715-24

Title: Reestablishment of axonal subdomains in regenerating axons of the optic nerve

Authors: ***M. A. MARIN**[1], S. DE LIMA[2], H.-Y. GILBERT[3], A. MARTINEZ[2], L. BENOWITZ[3], M. RASBAND[1];
[1]Baylor Col. of Med., Houston, TX; [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [3]Boston Children's Hosp. and Harvard Med. Sch., Boston, MA

Abstract: Myelinated axons are divided into distinct excitable domains, including the axon initial segment (AIS) and nodes of Ranvier. The AIS serves as both a physical barrier between the axonal and somato-dendritic compartments of the neuron and as the site of action potential (AP) initiation. Nodes of Ranvier are responsible for the rapid and efficient propagation of APs along the axon. Disruption of the AIS or nodes of Ranvier by injury or disease has a dramatic impact on neuronal function. Thus, any therapeutic strategy aimed at nervous system repair or regeneration must include the reestablishment or maintenance of these excitable domains. Myelinated axons of the adult mammalian central nervous system are incapable of self-regeneration after injury. However, intravitreal administration of proinflammatory glucans as well as deletion of the PTEN gene in retinal ganglion cells (RGC) after injury to the optic nerve allows for substantial long distance growth of axons. When these treatments are combined with elevation of cAMP, some regenerating axons can grow past the optic chiasm and reinnervate the dorsal lateral geniculate, suprachiasmatic nucleus, and other central target areas. Using this model, we performed a detailed analysis of the dismantling and reorganization of the AIS and nodes of Ranvier. In the absence of any treatment, immunofluorescence reveals a dismantling of the excitable domains within 48 hours of the crush. Loss of nodes of Ranvier is detectable by 6 hours after crush in the immediate vicinity of the crush site, and across the entire optic nerve

within a week of the crush. Analysis of the PTEN$^{f/f}$+Zymosan+cAMP regeneration model by both immunofluorescence and electron microscopy (EM) demonstrates the reestablishment of excitable domains and remyelination of regenerating axons in the optic nerve. Analysis by immunofluorescence revealed the reestablishment of RGC-AIS in the retina 6 weeks after crush. We also observed growth of axons and reestablishment of nodes of Ranvier proximal, distal and within the crush site of the optic nerve 6-12 weeks after crush. Furthermore, EM analysis of regions close to the chiasm shows remyelination of regenerating axons 12 weeks after lesion. Thus, regenerating axons are capable of reestablishing excitable domains and undergoing remyelination, supporting the possibility of efficient signal conduction.

Title: Dephosphorylation of CRMP2 enhances recovery after spinal cord injury

Authors: *J. NAGAI[1], Y. KITAMURA[1], K. OWADA[1], Y. GOSHIMA[2], T. OHSHIMA[1]; [1]Waseda Univ., Tokyo, Japan; [2]Yokohama City Univ., Yokohama, Japan

Abstract: The presence of inhibitory molecules and the lack of neurotrophic factor are two major difficulties to central nervous system (CNS) regeneration. Common mediator of these two has been not found yet. Collapsin response mediator protein 2 (CRMP2) was originally identified as a mediator of Semaphorin3A-induced repulsive response. CRMP2 directly binds and stabilizes cytoskeletal microtubule polymerization and transport tyrosine kinase B (TrkB) to axonal tip, the receptor for brain-derived neurotrophic factor (BDNF), to promote axonal elongation. Meanwhile, inhibitory molecules-induced signals phosphorylate CRMP2 to decrease its affinity to cytoskeleton proteins, leading to axonal growth inhibition. However, the role of CRMP2 phosphorylation after CNS injury *in vivo* remains unknown. Here we investigate the role

of CRMP2 phosphorylation after spinal cord injury (SCI) using CRMP2 knock-in (KI) mouse where CRMP2 phosphorylations by Cdk5 and GSK3beta are eliminated by replacing serine522 with alanine residue. Elevated level of pCRMP2 was observed in injured spinal cord. Inhibition of CRMP2 phosphorylation exhibited neuroprotective effect against SCI by suppressing depolymerization of microtubules and fibrous scar formation. This permissive environment for enhanced axon growth of 5-HT-positive raphe-spinal tract induced locomotor recovery in CRMP2KI mice. To examine the signaling cascades involving CRMP2 phosphorylation, we cultured dorsal root ganglion (DRG) neurons. Suppressed axonal growth inhibition by chondroitin sulfate proteoglycan (CSPG) and enhanced axonal elongation with BDNF were observed in CRMP2KI neurons. Therefore, dephosphorylation of CRMP2 could be a unique approach to repair injured CNS by reduced inhibitory responses and enhanced sensitivity to neurotrophin.

Title: A role of autophagy in microtubule assembly and axon regeneration

Authors: ***M. HE**, Y. DING, Z.-G. LUO;
Inst. of Neurosci., Shanghai, China

Abstract: Limited axon regeneration after spinal cord injury (SCI) results in lots of structural and functional deficits. Minimal intrinsic axon growth capacity and extracellular inhibitory factors are major obstacles for spinal cord repair. Before a lesioned axon attempts to pass through the inhibitory environment, the primary and crucial step is to assemble a new growth cone. However, mammalian CNS axons after injury usually form retraction bulbs, which impede the growth cone re-assembly. Microtubule stabilization prevents the formation of retraction bulbs and promotes axon regeneration. Here, we report a novel role of autophagy in neuronal microtubule assembly and axon regeneration. We found that treatment of cultured rat cortical neurons with a membrane-permeable peptide TAT-Beclin, which was used to specifically induce autophagy, increased microtubule stability and promoted its bundling. Furthermore, TAT-Beclin-enhanced microtubule stability was through specific degradation of a microtubule destabilizing

protein SCG10. Interestingly, TAT-Beclin treatment dampened the inhibitory effect of myelin on cultured neurons, and prevented the formation of retraction bulbs during axon degeneration after injury in cultured neurons and sensory neurons in spinal cord. Finally, application of TAT-Beclin attenuated axon retraction of corticospinal tract in mice subjected to dorsal spinal cord hemi-section and promoted its locomotor function recovery. This study indicates a potential role of manipulation of autophagy activity in axon regeneration after injury.

Title: Epigenetic profiling reveals a developmental decrease in promoter accessibility of regeneration associated genes in CNS neurons

Authors: *I. VENKATESH, M. SIMPSON, B. CALLIF, M. BLACKMORE;
Dept. of Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Embryonic neurons and peripheral neurons respond to axonal injury with activation of transcriptional programs conducive to regrowth. In contrast, mature CNS neurons fail to reactivate expression of crucial regeneration associated genes (RAGs) in response to injury, resulting in failed axon growth and permanent loss of function. Forced re-expression of key RAGs in mature CNS neurons is a promising strategy for therapeutic intervention. We and others have previously shown that ectopic expression of pro-regenerative factors such as KLF7 and Sox11 promotes axon regeneration in CNS neurons. Growth is incomplete however hinting that additional factors limit the cell intrinsic ability to promote growth. One reason could be restricted DNA accessibility due to a closed chromatin conformation in genomic loci corresponding to key RAGs in CNS neurons. We hypothesized that the developmental decline in regenerative ability is accompanied by a corresponding decrease in RAG promoter accessibility for pro-regenerative transcription factors. To test this, we profiled the epigenetic landscape surrounding promoters of select RAGs across development for changes in histone modifications indicative of DNA

accessibility. We observed that RAGs including KLF7, Sox11, cJUN and GAP-43 switch from a relaxed chromatin environment to a restricted chromatin state as CNS neurons age. We are currently combining pro-regenerative TFs along with treatments that relax chromatin in assays of axon outgrowth. Overall, understanding changes in the chromatin landscape as CNS neurons mature, opens up the possibility of manipulating epigenetic modifications to promote axon outgrowth after injury.

Abstract: Grafting of induced pluripotent stem cells (iPSCs)-derived NPCs has shown promise in promoting functional recovery in animal models of spinal cord injury (SCI), but the contribution of different neuronal and glial cell populations to morphological and functional improvements remains poorly understood. To better define the role of astrocytic subtypes, we have generated patterned NPCs and glia with specific phenotypes from human embryonic stem cells (ESCs) and iPSCs. Caudalized pure astrocytic lines were generated following standard neural induction protocols, followed by a long expansion phase of neurospheres in low attachment conditions. Prior to terminal differentiation, dissociated neurospheres cultivated on poly-L-ornithin/laminin consist of a homogeneous population of vimentin-expressing precursors, resembling early spinal glial progenitors present during CNS development. The characteristics of maturing, differentially patterned human ESC- and iPSC-derived astrocytes were examined *in vitro* and their pro-regenerative capacity *in vivo*. Terminal differentiation was induced by

treatment with BMPs, FGF1, CNTF or mere growth factor withdrawal for at least 2 weeks. While no obvious differences could be observed between the latter two groups, BMP-treated astrocytes were up to ten times larger and had larger nuclei, whereas FGF1-treated astrocytes displayed a smaller cell size. These differences were maintained after withdrawal of BMPs, FGF1 or CNTF and a 2-week exposure to pro-inflammatory factors.This indicates that functional differences might exist between differentiation groups, which might be maintained in a pro-inflammatory lesion-environment. We are currently analyzing the effect of specific astrocytic lines on neurite growth in co-cultures of rat primary DRG neurons on maturing astrocytes and potential mechanisms underlying these effects. In ongoing studies, cells have been grafted into the lesioned rat spinal cord to investigate *in vivo* differentiation, integration and host-graft interaction. Based on *in vitro* and *in vivo* data, we aim to determine whether iPS-derived glial progenitor cells integrate into the host spinal cord to form a conducive substrate for axonal growth and whether pre-differentiation can influence these process.

Title: Peripheral electrical stimulation to enhance the regenerative capacity of sensory axons after spinal cord injury

Authors: *I. GOGANAU[1], B. SANDNER[2], K. FOUAD[3], A. BLESCH[2];
[1]Neuroregeneration, Universitats Klinikum Heidelberg, Heidelberg, Germany; [2]Spinal Cord Injury Ctr., Heidelberg Univ. Hosp., Heidelberg, Germany; [3]Fac. of Rehabil. Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Axotomy of peripheral nerves induces complex changes in gene expression of dorsal root ganglion (DRG) neurons contributing to successful regeneration after PNS or subsequent spinal cord lesions. We hypothesized that evoked neuronal activity by direct peripheral electrical stimulation (ES) can enhance regeneration-associated gene (RAG) expression in DRG neurons and support the growth of the central spinal cord branch. For ES, temporary or chronic, bipolar

cuff electrodes were placed around the sciatic nerve at mid-thigh level in adult female Fischer 344 rats. Sham animals received cuff electrodes, but no stimulation for the same duration; naïve animals and animals with PNS lesions served as additional controls. Basic ES parameters were 20Hz, 0.2ms square pulse, 5V with an intensity of 2x motor threshold. 7 days (7d) after cuff placement, DRG neurons were isolated, cultivated, and neurite length was quantified using ImageJ. Short ES for 1h enhanced neurite growth of DRG neurons isolated 7d post-stimulation and cultivated on 5µg/ml laminin, increasing the average longest neurite by 104% compared to naïve and sham animals (ANOVA $p<0.0001$; PLSD $p<0.01$), while CL increased growth by 382%. When DRGs were isolated 1 day after ES, no effect on neurite growth was observed. Repeated ES for 7d (1h/d) also increased the growth compared to sham animals ($p<0.01$), but no more than a single 1 h stimulation. However, a single ES applied for an increased duration (7h) seems to further increase the neurite growth-promoting effect compared to sham animals. Similar findings were obtained on less permissive substrate (0.5µg/ml laminin). The pattern of growth and the timeline were similar to a PNS lesion, suggesting a partial overlap in mechanisms. Current experiments analyze the expression of RAGs in DRGs, and dorsal column sensory axon regeneration *in vivo* after ES. Taken together, our results indicate that the growth capacity of DRG neurons can be modulated *in vivo* by externally-induced activity providing a therapeutic strategy to increase sensory axon regeneration in the injured spinal cord.

Title: The role of mitochondrial dynamics in CNS axon regeneration

Authors: *A. KREYMERMAN[1], M. B. STEKETEE[2], J. L. GOLDBERG[3];
[1]Shiley Eye Center, UCSD, La Jolla, CA; [2]Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA; [3]Univ. of California San Diego, San Diego, CA

Abstract: Central nervous system (CNS) disease or injury is often accompanied by progressive axon degeneration, leading to lost sensory, motor, or cognitive abilities. In search of factors to restore degenerated CNS axons, we identified a group of developmentally regulated transcription factors, the Krüppel-like transcription factors (KLFs), which differentially suppress or enhance retinal ganglion cell (RGC) axon growth. However, the downstream mechanisms by which KLFs regulate axon growth are unknown. Evidence suggests one downstream effector may be mitochondrial (Mt) fission/fusion dynamics. We recently showed that suppressing fission (increasing fusion) leads to a loss in RGC axon growth inhibition by chondroitin sulfate proteoglycans, presenting evidence of mechanism in which CNS axon growth and guidance responses can be regulated by Mt fission-fusion. Moreover, suggesting that suppressing fission is a potential therapeutic strategy for improving axon regeneration after CNS trauma. To identify whether Mt fission/fusion mechanisms also underlie the axon suppressing/enhancing activity of KLFs, we are investigating the potential ability for KLFs to critically regulate Mt genes. Pertinent to our previous findings, we found that axon growth suppressing KLFs increase the genetic expression of mitochondrial fission process 1,18 kDa (MTP18), a positive regulator of Mt fission, supporting the hypothesis that increased fission is inhibitory for axon growth in RGCs. We hypothesize that KLF-mediated regulation of the mitochondrial dynamics, in part through MTP18 expression, regulates intrinsic axon growth ability in CNS neurons. The overall goal is to improve our understanding of how Mt fission/fusion regulates axon regeneration and to use this understanding to identify strategies for restoring axon growth after CNS injury or disease.

Title: Whole transcriptome response to spinal injury in the regenerating spinal cord of the opossum, Monodelphis domestica

Authors: *B. J. WHEATON[1], P. UMALE[2], A. SUNDARARAJAN[2], S. GUIDA[2], J. SENA[2], F. SCHILKEY[2], K. M. DZIEGIELEWSKA[3], N. R. SAUNDERS[3], R. D. MILLER[1];

Abstract: When the spinal cord is injured during early development the axons have the capacity to grow across the injury site and form functional circuitry. As the spinal cord matures this ability is lost. This has been demonstrated extensively using the Grey short-tailed opossum, *Monodelphis domestica,* a South American marsupial whose young are born at an altricial stage of neural development. In these animals there is a pronounced growth of axons across an injury made at post-natal-day (P) 7, but no such regrowth following an injury at P28. The mechanisms underlying the increased regeneration of the immature cord and those controlling the switch to the non-regenerative state are not fully understood. Here we have investigated this by analyzing the spinal cord transcriptome as it responds to injury over time. Opossum spinal cords were completely transected in the mid-thoracic region at either P7 or P28; cords were collected for analysis after 1, 3 or 7 days. RNA was extracted from the segment of tissue containing the injury site (or equivalent areas from controls), processed for high throughput Illumina RNA sequencing and differentially expressed genes were identified between selected samples using standard algorithms. Two analyses were performed: Developmental analysis of control cords between the permissive and nonpermissive ages and injury progression analysis studying the time course of the response to injury. Several development-regulating genes were more highly expressed in the P7 animals. We found higher expression of homeodomain genes orthopedia homeobox (*Otp*) and ISL LIM homeobox genes (*Isl1*), which are involved in CNS and motor neuron development, respectively. Also higher at this age were the POU class 4 homeobox (*Pou4f1*), which is important in the developing sensory nervous system and the cadherin *Celsr3* which is involved in axon guidance. In the P28 animals several genes involved in axonal support were more highly expressed including myelin-associated genes myelin basic protein (*Mbp*), myelin-associated glycoprotein (*Mag*), myelin oligodendrocyte glycoprotein (*Mog*), oligodendroctye-lineage factor-1 & 2 (*Olig1 & 2*) along with glial fibrillary acidic protein (*Gfap*). Immune related genes including *Cd74, Cd200*, interleukin 1 receptor accessory protein (*Il1rap*) and chemokine ligand 14 (*Cxcl14*) were also more highly expressed at P28. The developmental state of the spinal cord changes considerably as it matures between the ages when axonal regrowth occurs and when it does not. Understanding how this changing internal environment affects the outcome after injury may be an important step in explaining the regenerative response.

Title: LPA pathway modulates intrinsic axon growth of intact CNS neurons after spinal cord injury

Authors: *K. FINK, S. STRITTMATTER, W. CAFFERTY;
Yale Univ., New Haven, CT

Abstract: Axons fail to regenerate in the adult central nervous system (CNS) after spinal cord injury (SCI) due to decreased growth capacity of adult neurons and an inhibitory growth environment. Myelin associated inhibitors (MAIs) prevent axon growth in the CNS by signaling through the neuronally expressed Nogo receptors (NgR) and PirB. Genetic and pharmacological targeting of the MAI axis modestly increases regeneration of damaged axons yet incompletely restores function after SCI. An additional strategy to enhance recovery would be to form *de novo* circuits through intact axons spared by lesion. Previous work from our laboratory has shown that after unilateral corticospinal tract (CST) injury (unilateral pyramidotomy, uPyX) the intact CST functionally sprouts into denervated spinal cord. After bilateral PyX a *de novo* intact functional circuit emerges between the red nucleus and the nucleus raphe magnus. Furthermore, plasticity within these intact circuits was significantly enhanced in nogo receptor-1 knockout mice (*ngr1-/-*). We sought to identify the mechanism underlying functional sprouting in intact neurons. To this end, we completed uPyX in μ-crystallin-GFP (expresses GFP in CST neurons) wild type (n=6) and *ngr1-/-* (n=6) mice. Two weeks post lesion mice received contralateral intraspinal injections of the retrograde tracer fast blue to label axons that had sprouted across the midline. Two weeks later mice were prepared for laser capture microdissection (LCM) and processed for RNAseq. Transcriptional analysis revealed 1174 genes were significantly differentially expressed between intact sprouting CST neurons and intact non-sprouting CST neurons. Ingenuity Pathway analysis revealed that a number of differentially expressed genes were enriched in the lysophosphatidic acid (LPA) pathway. Significantly, pro-growth genes were up regulated in sprouting neurons with simultaneous down regulation of growth inhibitors in the LPA pathway including LPA receptor 1 (*lpar1)*. Overexpressing the pro-growth genes in cortical neurons *in vitro* resulted in an increase in acute neurite outgrowth as well an increase in axon growth in an *in vitro* injury model. The role of the LPA pathway in modulating functional sprouting of intact neurons after SCI is underway using pharmacological inhibition of lpar1. Wild type mice have undergone unilateral PyX (n=24) or sham lesion (n=24) followed by 10 day treatment of either vehicle (n=12) or lpar1 inhibitor (n=12). Behavior is being assessed using the forelimb pellet retrieval

task and sprouting will be assessed histologically to determine if lpar1 inhibition results in an increase in functional recovery and sprouting after SCI.

Title: Biomimetic injectable 3D hydrogels with aligned topography for neural tissue engineering

Authors: C. P. HOFSTETTER[1], L. J. KOBELT[1], L. N. CATES[1], *Z. Z. KHAING[2];
[1]Neurolog. Surgery, [2]Biomed Engin., Univ. of Washington, Seattle, WA

Abstract: Hydrogels are soft materials with high water content that are widely used as scaffolds to interface with soft central nervous system tissue. Spinal cord trauma leads to destruction of a highly organized cytoarchitecture that carries information up and down the spinal column. Experimental therapeutic efforts aim to provide aligned topography to support anisotropic regeneration. Although a number of techniques have been developed for producing topography, current methods require complex methodology, and hence it remains challenging to introduce topography within soft 3D hydrogels with ease. Here we describe a simple and reproducible system that results in consistently aligned profiles within 3D matrices using thermally gelling biomimetic polymers that are biocompatible with neuronal cells. A collagen type I (Col)-based thermally gelling hydrogel system was used in combination with other native extracellular matrix proteins: laminin I (LN), hyaluronic acid (HA). Gelling kinetics for all gel types (Col, Col/LN, Col/HA) were examined. Alignment of fibers was obtained by aspirating gelled samples through different syringe gauges. The resulting hydrogels were dried and examined using scanning electron microscopy (SEM). Primary embryonic cell cultures (cortical neurons, spinal motor neurons and spinal interneurons) were first encapsulated in 3D hydrogel solutions, allowed to form gels, and then aligned. Samples were cultured for up to 14d *in vitro* and the resulting samples were fixed and examined using immunohistochemistry. Stained samples were examined and photomicrographs were obtained using an Olympus FV1000 MPE BX61 multi-photon laser. All three combinations of polymer formed consistent gels at 37°C. Col and Col/HA were faster to gel (20 - 22 min, n = 8 - 9 per gel type), while Col/LN took longer (26 - 28 min, n = 8). SEM

images confirmed successful alignment in all gel types using the aspiration and ejection method. We infer from the size of the fibers that the aligned fibers were collagen fibers (~250 nm in diameter). Next, we encapsulated all three neuron types (cortical, spinal motor and spinal interneurons) within the hydrogels and aligned. We found that the cells within the hydrogels survived, differentiated and neurons produced processes along the same direction as the aligned fibrils within the hydrogel. Our data indicate that thermally gelling biomimetic polymers can produce aligned matrices by aspiration and ejection method. This process and material are compatible with the survival of neuronal cells *in vitro* and may be a useful novel platform for regenerative therapies in the Central and Peripheral Nervous Systems.

Title: A single cell approach to defining the molecular recipe for successful regeneration of CNS neurons after spinal cord injury

Authors: *S. R. ALLEN[1], S. M. FOGERSON[2], S. A. BRYANT[3], O. E. BLOOM[4], J. J. SMITH[3], J. R. MORGAN[1];
[1]Eugene Bell Ctr. for Regenerative Biol. and Tissue Engin., Marine Biol. Lab., Woods Hole, MA; [2]Cell and Mol. Biol. Res., Manhasset, NY

Abstract: Spinal cord injury (SCI) elicits differential responses in injured neurons: some neurons die, while others survive and regenerate their axons. This phenomenon has been observed in vertebrates ranging from lampreys to mammals. Thus, there is a growing interest in identifying the key intrinsic factors that govern whether or not an injured neuron will regenerate.

Manipulations of single factors often improve axon regeneration, but the effects are modest or incomplete, suggesting that successful regeneration is driven by a more complex set of factors. To address this, we are using an unbiased single cell transcriptome approach, which is a powerful method for identifying the complete molecular profiles and gene networks that drive successful regeneration. This approach is not possible in most SCI models, because it is difficult to reliably distinguish neurons that regenerate from those that do not. Therefore, we are utilizing the lamprey giant reticulospinal (RS) neurons, because they are large, identifiable, and have known and varying regenerative capacities. After spinal cord transection, a reproducible subset of RS neurons survives and regenerates, while another subset dies and fails to regenerate (i.e. "good" and "poor" regenerators). Here, we describe our initial analyses of single cell transcriptome data for several RS neurons, including good and poor regenerators. Neurons were isolated using laser capture microdissection. cDNA libraries were sequenced using RNA-Seq. Resulting reads were mapped to the lamprey genome and quantified using RNA-Seq by Expectation Maximization. A Gene Ontology (GO) analysis of transcripts expressed in the uninjured neurons revealed that the good regenerator differentially expressed genes involved in axon guidance, regulation of intracellular protein transport, Golgi vesicle transport, and regulators of Wnt signaling, suggesting that regeneration-competent neurons express molecular profiles that selectively advantage them for growth even before injury. We then compared the transcriptomes of a poor regenerator before and at 3 days post injury. GO analysis revealed a significant upregulation of genes involved in glutamate receptor activity and calcium channel activity, while genes involved in axon guidance and microtubule-based processes were downregulated, suggesting that excitotoxicity and reduced axon growth contribute to a non-regenerative outcome. Taken together, this pilot study establishes the lamprey RS neurons as a robust model for identifying the complete set of intrinsic factors associated with successful regeneration of CNS axons after spinal injury.

Title: PTEN deletion and alpha9 integrin expression enhance adult corticospinal tract regeneration

Authors: *M. R. ANDREWS[1], K. ZUKOR[2], S. MORRIS[1], Z. HE[2], J. W. FAWCETT[3]; [1]Univ. of St Andrews, St Andrews, United Kingdom; [2]F. M. Kirby Program in Neuroscience, Children's Hosp. Boston, Harvard Med. Sch., Boston, MA; [3]Dept. of Clin. Neurosciences, Ctr. for Brain Repair, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Central nervous system (CNS) axons do not regenerate after injury although several experimental treatments have shown promise for nervous system repair. Contributing to the strong inhibition of regrowth is the extracellular matrix glycoprotein, tenascin-C, which is highly expressed after CNS injury without concomitant neuronal expression of its receptor, alpha9 integrin. To address this issue, we have previously demonstrated that reintroduction of the alpha9 integrin receptor promotes axonal regeneration after dorsal rhizotomy or dorsal column crush lesion to modest levels *in vivo*. Further ongoing studies have suggested that there is a defect in axonal localisation and transport of these integrins within the adult corticospinal tract (CST) using virally-expressed integrins in the CNS. This defect is not present in systems with a greater propensity for regeneration such as in the neonatal corticospinal tract, or in the peripheral nerve. From another perspective on CNS repair, studies evaluating the effects of either conditional deletion or suppression of the phosphatase and tensin homolog (Pten) gene have demonstrated significant levels of axonal regeneration in the CST and optic nerve. These studies showed an upregulation of mTOR (mammalian target of rapamycin) activity as a result of Pten deletion, generating an increased regenerative ability within the CNS. We therefore combined these two therapies of enhancing neuroprotection and intrinsic regenerative capacity by Pten deletion while promoting axonal growth with alpha9 integrin expression and assessed CST regeneration following a T8 spinal cord crush lesion in adult mice. We hypothesize these two therapies will promote significant levels of regeneration in the adult CST further than either treatment alone. Experiments consisted of conditional deletion of Pten in corticospinal neurons at birth and injection of AAV-alpha9integrin-V5 into corticospinal neurons at 8 weeks of age concurrent with spinal cord injury. CST regeneration was anatomically assessed by anterograde tracing with biotinylated dextran amine at 8 weeks post-injury. Our results suggest a strong combinatorial effect on CST axon regrowth following Pten deletion and overexpression of alpha9 integrin in corticospinal neurons.

Title: Demethylation of c-Myc gene triggers transcription of a group of regeneration-associated genes in DRG sensory neurons following conditioning peripheral nerve injury

Authors: *H. SHIN[1,2], K. KIM[3], M. KWON[2], B. KIM[2,4];
[1]Ajou University, Med. Sch., Suwon, Korea, Republic of; [2]Dept. of Biomed. Sciences, Ajou Univ. Grad. Sch. of Med., Suwon, Korea, Republic of; [3]Dept. of Med. Informatics, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [4]Dept. of Neurology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Conditioning injury (CI) to the peripheral branches of DRG sensory neurons can lead to robust upregulation of many regeneration-associated genes (RAGs), allowing axon regeneration of central branches beyond lesion site in the spinal cord. How the peripheral nerve injury can lead to the coordinated upregulation of RAGs is not fully understood. The current study was designed to examine changes in DNA methylation of RAGs after CI. Although CI induced DNA methylation changes in almost 10% of all genes, the majority of RAGs did not show significant changes in methylation level. Instead, we found methylation changes in several of the transcription factor genes that have known interactions with promoters of RAGs on the basis of bioinformatics analysis. Of these, we focused on c-Myc transcription factor of which demethylation was nicely correlated with increased mRNA expression. Chromatin immunoprecipitation assay showed increased binding of c-Myc after CI to the promoters of a group of RAGs such as c-Jun, Atf3, and Sprr1a, but not to those of Gap43, Npy, and Galanin. Demethylation of c-Myc was observed as early as 4 hours after CI, when apparent mRNA upregulation of the c-Myc-binding RAGs was not found. AAV-mediated overexpression of c-Myc resulted in an increase in the extent of c-Myc occupancy on the promoters of c-Jun, Atf3, and Sprr1a. Intraganglionic injection of AAV5-c-Myc enhanced neurite outgrowth compared to control AAV5-GFP injection when DRGs were freshly dissected and cultured on permissive substrate 4 weeks after injection. These results suggest that DNA methylation of c-Myc precedes and triggers transcription of a group of crucial RAGs for intrinsic regeneration capacity. Further studies will provide novel insights into upstream orchestration of the coordinated transcriptional activation of RAGs in DRG neurons following conditioning peripheral nerve injury.

Title: DNA methylation as a possible epigenetic barrier preventing Müller glia damage-induced dedifferentiation in mammals

Authors: *L. I. REYES-AGUIRRE[1], M. LAMAS[2];
[1]Farmacobiología, CINVESTAV, Mexico, Mexico; [2]Farmacobiología, CINVESTAV, Ciudad de Mexico, Mexico

Abstract: In response to retinal injury, Müller Glia (MG) can start a gliosis process or dedifferentiate, proliferate and replace dead neurons. This regenerative response occurs naturally in teleost fish but is absent in mammals, despite structural and functional similarities between their retinal cells. In past studies, we have been able to induce MG dedifferentiation in mammals. However, most cells fail to completely lose their glial phenotype and are unable to express photoreceptor markers after being treated with previously tested differentiation protocols. One, or several, kinetic barriers affecting all cells might explain this partial dedifferentiation. Epigenetic memory has been reported as one of such barriers, and is considered responsible for low efficiency in dedifferentiation studies. In order to understand its role on MG response to damage in mammals and to compare it with available information in fish, we analysed early gene expression in mice retina after NMDA-induced damage. Stem-related gene expression was analysed in samples extracted 4, 12, 18 and 24 hours post retinal injury (pi). Real-time PCR revealed a rapid induction of Oct4 and Nanog, which reached its peak at 18h pi. However, these genes were barely detectable shortly after (24h pi). This transient expression suggests a silencing mechanism preserving MG differentiated state. Thus, we analysed the expression of maintenance and *de novo* DNA-methyltransferases (DNMTs), as well as demethylation-related Tet proteins (1, 2, 3), and Gadd45 (a, b). At 4 and 12h pi, we observed a reduction in DNMT3b expression,

accompanied by an increase in Gadd45b relative level. This coincides with the Oct4 and Nanog expression peak, and indicates that an indirect demethylation process allows their transcription. DNMTs levels are restored after this temporal window. These results suggest that DNA methylation acts as an epigenetic memory mechanism and prevents further expression of Oct4 and Nanog, which have been described as necessary for an adequate regenerative response.

Title: Novel mouse models for elucidating the impact of alpha-tocopherol stereoisomers on neonatal brain development

Authors: *J. G. MUN[1], K. DU[1], C. RENDEIRO[1], D. S. MILLER[1], M. BARKER[1], P. KOZAK[1], T. BHATTACHARYA[1], S. RUBAKHIN[1], C.-S. LAI[2], K. MATTHEW[2], J. S. RHODES[1]; [1]Univ. of Illinois, Urbana, IL; [2]Abbott Nutr., Columbus, OH

Abstract: Vitamin E, as α-tocopherol, has long been touted as an antioxidant despite clear evidence for a role in embryogenesis and the maintenance of pregnancy in tocopherol-deficient animal models. Moreover, preferential sequestration of the RRR- stereoisomer of α-tocopherol by tissues including the brain, and recent evidence suggesting translocation into the nucleus of cells suggests that a specific, yet unknown function may exist. Uncovering a specific role for this stereoisomer has been met with the major obstacles of depleting vitamin E from tissues and discriminating the RRR- form from the other 7 stereoisomers. In the current work, we will present two models that address these challenges for studying α-tocopherol in neonatal brain development. In the first study, we paired 24 C57BL/6J mice to produce litters and assigned each pair to one of three AIN-93G-based diets, two of which were α-tocopherol deficient (32 IU RRR-α-tocopherol and 32 IU all-rac-α-tocopherol) and one that was α-tocopherol-adequate (75 IU all-rac-α-tocopherol) as a control. Pup body weights were recorded and on postnatal day 21 (PN21), pups were perfused with saline, tissue weights were recorded, half brains were stored in

paraformaldehyde for histological measures and the other halves were stored at -80 C for biochemical analyses. In the second study, we cross-fostered C57BL/6J pups (N=23) at birth with tocopherol transfer protein-knock out (TTP-/-) mouse dams fed a tocopherol-stripped diet. Mouse milk was shown to be deficient in α-tocopherol and pups within each litter were orally-supplemented daily for 21 days with either RRR-α-tocopherol (0.0010 IU/g body weight), all-rac-α-tocopherol (a synthetic mixture of 8 α-tocopherol stereoisomers; 0.0010 IU/g body weight), or medium chain triglycerides as a vehicle. Pups were perfused on PN21, tissue weights were recorded, and then stored as previously described. Pups from dams fed tocopherol-deficient diets were shown to have significantly reduced body, brain, and liver weights compared to control-fed dams and the 32 IU RRR- treatment showed protection against tissue weight loss compared to the all-rac-α-tocopherol treatment. Biochemical analyses showed that the neonatal brain discriminates between natural and synthetic forms of vitamin E. Furthermore, these methodologies have allowed us to demonstrate proof-of-concept that α-tocopherol stereoisomer profiles and concentrations in the neonatal brain could be feasibly manipulated through oral-supplementation of different vitamin E sources and that α-tocopherol stereoisomer source can significantly alter gross anatomy in the neonate.

Title: Witnessing social defeat stress mediates a depression-like phenotype in female c57BL/6 mice

Authors: F. J. FLORES-RAMIREZ[1], L. M. RIGGS[1], J. B. ALIPIO[1], M. A. HERNANDEZ[1], B. CRUZ[1], S. H. BRAREN[2], P. A. SERRANO[2], *S. D. INIGUEZ[3,1];

Abstract: Stress exposure is a prevailing risk factor for the development of mood-related illnesses, wherein women represent the majority of those afflicted with depression-, anxiety-, and posttraumatic stress disorder. Despite the growing literature suggesting that affective disorders can arise after a traumatic event is vicariously experienced, this relationship remains to be examined in females at the preclinical level. Thus, the objective of the current investigation is to assess whether the witness defeat stress (WDS) behavioral paradigm (Biol Psychiatry, 73[1], 7-14; 2013) - a model that dissociates emotional versus physical stress - induces a depression-like phenotype in female c57BL/6 mice. To do this, female mice witnessed the social defeat bout of a male conspecific, by a larger CD1 aggressor, for 10 consecutive days. Twenty-four hr after the last stress exposure, mice were tested in the social interaction, sucrose preference, and tail suspension tests. Our results show that when compared to non-stressed controls, female mice exposed to WDS display depressive-like behaviors, as inferred from decreases in social behavior, decreased sucrose preference, and increased immobility in the tail suspension test. Collectively, our data suggests that the WDS paradigm may be used to examine the etiology of vicarious stress-induced mood-related disorders in the female population.

Title: GABAergic disruption in the juvenile prefrontal cortex of Npas4 deficient mice

Authors: *L. COUTELLIER;
Dept. of Psychology, Ohio State Univ., Columbus, OH

Abstract: Disruption of juvenile GABAergic maturation of the prefrontal cortex (PFC) is associated with cognitive and emotional deficits that characterize psychopathologies including schizophrenia and mood disorders. Understanding these disorders implies the identification of juvenile factors contributing to such GABAergic maturation. Using molecular, pharmacological and behavioral methods in mice, we show that Npas4 could be a significant contributor to the postnatal development of the GABAergic system. We first show sex- and age-dependent Npas4 expression in the PFC of C57Bl/6 mice: males have a higher level of Npas4 mRNA than

females, and in males, Npas4 mRNA level doubles from postnatal day (PND) 21 (childhood) to PND35 (adolescence). We then show that transgenic Npas4 deficient mice display sex-dependent abnormal expression of several pre- and post-synaptic GABAergic markers in the PFC during the juvenile period. These prefrontal GABAergic abnormalities are associated with PFC-dependent cognitive function deficits in males and with depressive-like behavior in females. These behavioral abnormalities are rescued by a chronic treatment with a GABA enhancer during the juvenile period. This treatment also normalizes expression of most of the PFC GABAergic markers. Our data indicate for the first time that Npas4 could contribute significantly to the juvenile maturation of the prefrontal GABAergic system in a sex-dependent way. The study of Npas4 could help us understand susceptibilities to neuropsychiatric disorders that are characterized by prefrontal GABAergic dysfunctions (i.e. schizophrenia; mood disorders). Further analyses in tamoxifen-inducible conditional knockout mice will be conducted to verify the significant contribution of Npas4 during the juvenile period.

Title: Environmental enrichment during adolescence alters anxiety, cognitive functioning, and dendritic spine density in male and female rats

Authors: *R. E. BOWMAN[1], J. WAGENBLATT[1], K. BARATELI[2], V. LUINE[2], M. FRANKFURT[3];
[1]Sacred Heart Univ., Fairfield, CT; [2]CUNY - Hunter Col., New York, NY; [3]Hofstra North Shore - LIJ Sch. of Med., Hempstead, NY

Abstract: Exposure to environmental enrichment (EE) during times of organizational development are known to enhance performance on a variety of cognitive tasks and these behavioral enhancements are associated with morphological changes in the brain. Increasingly, the period of adolescent development is being recognized as a time of sensitivity and continued brain development; however, the effects of EE exposure during adolescence have not been extensively studied. In the current study, male (n=16) and female (n=16) Sprague-Dawley rats were weaned (post-natal day 21) and assigned to a control group or an enriched group. Experimental animals were exposed to 2hr/day of environmental enrichment during post-natal

days 24-42 while the control subjects remained in their home cages, but received equal amounts of daily handling. At 6 weeks of age, all subjects were tested for anxiety (elevated plus maze) and activity (open field), as well as spatial memory (object placement) and non-spatial working memory (object recognition) with inter-trial delays of 1 and 2 hrs. In addition, we measured dendritic spine density in the CA1 region of the hippocampus. Females, regardless of EE treatment, were less anxious than males on the elevated plus maze. However, on the open field, EE had a sexually-differentiated effect in which anxiety was decreased in females, but increased in males, following EE. All groups demonstrated intact spatial memory but performance was enhanced in EE females following a 1 hr inter-trial delay compared to all other groups. Interestingly, while performance was well-above chance for all groups on the object recognition task, both male and female EE groups spent significantly less time with the novel object than their control counterparts following a 2 hr inter-trial delay. Adolescent EE exposure increased dendritic spine density in CA1 basal dendrites in both males and females (20% increase). Together these results indicate that adolescent EE exposure alters both behavior and neuronal morphology, although some effects appear sex-dependent.

Title: Voluntary binge-level consumption of ethanol in adolescent rats and the consequences on adult social behavior

Authors: *D. HOSOVÁ, E. I. VARLINSKAYA, L. P. SPEAR;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Initiation of alcohol use occurs predominantly in early adolescence; episodic heavy drinking during this time has long-lasting detrimental consequences. Rat models assessing adolescent heavy drinking often employ intragastric, vapor or intraperitoneal (IP) routes of ethanol administration. Such methods enable precise dosage, but do not account for a realistic drinking pattern; the full dose is given at once, unlike a drinking session, and, in the case of the

IP or vapor route, ethanol does not enter via the gastrointestinal tract. Yet, most models of adolescent voluntary consumption in outbred rat strains rarely produce blood ethanol concentrations (BECs) in the binge range. To determine if there may be an effective method for inducing voluntary binge levels of ethanol consumption in adolescent Sprague-Dawley rats, the present study used a schedule induced polydipsia (SIP) protocol. Adolescent males and females were food deprived to 85% free-feeding body weights from postnatal day (P) 24, and placed into operant chambers for 30 minutes daily from P28-P41. There, pellets were dispensed on a fixed interval 1 minute schedule, with simultaneous free access to either: ethanol in chocolate Boost© (10%, v/v), Boost© alone, or water. Ethanol consumptions in these 30 minute sessions averaged in the binge range (mean BECs > 80 mg/dl) and varied across days, with high consumption days sometimes producing BECs approaching 200mg/dl, followed by several lower consumption days, in repeating cycles. From P77-P87, animals were tested for social interactions and intake of 20% ethanol in a social context, as well as intake when alone, in alternating every other day sessions. These were recorded and scored for time spent drinking and play fighting, an adolescent-typical form of social behavior. As expected, regardless of adolescent exposure condition, adult females consumed nearly twice as much ethanol as males. A significant interaction was found between adolescent exposure and drinking context: whereas adults in the control groups averaged similar intakes in both conditions, adolescent ethanol-exposed animals drank notably more when drinking socially than when alone, in both sexes. Also, intake of animals exposed to ethanol during adolescence (but not control animals) was significantly correlated with level of play fighting, revealing for the first time socially facilitating effects of ethanol in an adult social drinking context - social facilitation that was evident only after adolescent exposure. Current studies are exploring whether this induction of binge levels of ethanol consumption is a function of the schedule per se, and specific to adolescent access.

Title: Impact of gonadectomy within the Four Core Genotype mouse model: Evidence that sex steroids shape brain structures via activation as well as organization and that influences of sex chromosomes are independent of hormonal milieu

Authors: *C. CORRE[1], D. A. VOUSDEN[2], S. SPRING[2], E. COX[2], A. METCALF[1], L. R. QIU[1], M. R. PALMERT[1], J. P. LERCH[2];

Abstract: Understanding the basis of sexual dimorphisms in brain structure and function will likely inform our understanding of sexually dimorphic incidence rates for psychiatric disorders. Using the Four Core Genotype (4CG) mouse model, in which impacts of sex steroids and sex chromosomes are decoupled, we recently showed that steroids and chromosomes influence distinct regions in the mouse brain, and that sex steroids, but not chromosomes, affect learning in the radial arm maze (RAM). Here, we used pre-pubertal gonadectomy within the 4CG model to examine two additional influences on brain development: 1) the dependence of sexual dimorphisms in brain anatomy and behaviour on organizational vs. activational steroid effects; and 2) compensation (the masking of chromosome-dependent sexual dimorphisms by circulating steroids). **Methods** Intact or gonadectomized 4CG mice (XX F, XX M, XY F, XY M; n=9-26/group) were perfused on postnatal day 65 and the brains were scanned using MRI. Automated algorithms were used to compute the volume of 62 brain regions for each mouse, and ANOVAs were performed for each structure and at each voxel to assess effects of sex steroids, sex chromosomes, and gonadectomy. A subset of mice was trained on the RAM for 5 days. **Results** 1. Prepubertal gonadectomy reduced many previously observed sex steroid-dependent effects in brain structure volumes, including the hypothalamus, parieto-temporal lobe, and bed nucleus of the stria terminalis (Fig. 1). 2. Effects of sex chromosome complement in gonadectomized 4CG mice recapitulated those in intact mice: sex steroids did not influence chromosomal effects. 3. In both intact and gonadectomized mice, gonadal sex, but not chromosome complement, affected RAM learning. **Conclusion** While RAM learning depends on organizational effects of sex steroids, both organizational and activational effects influence sex-steroid dependent

dimorphisms in brain structure. No brain area displayed evidence of previously masked effects of sex chromosomes. These findings further our understanding of the shaping of the male and female brain.

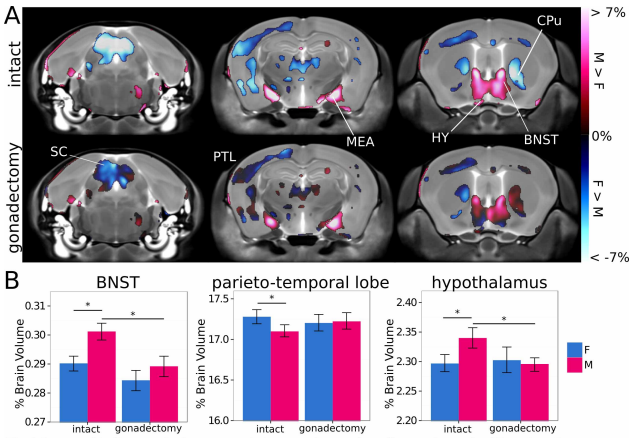

Fig. 1 Sex steroid effects on brain structure in intact and pre-pubertally gonadectomized Four Core Genotype mice. A: Voxel-wise analysis: An ANOVA was performed at each voxel to assess the effects of sex steroids, sex chromosomes, and gonadectomy on local volume. Multiple comparisons were accounted for using the false discovery rate (FDR). Representative coronal slices show areas in which there was a significant (10% FDR) effect of sex steroids on local volume. Slices depict the percent difference in voxel size between intact males and females (top row) or between gonadectomized males and females (bottom row). Gonadectomy reduces sex-steroid dependent effects in many brain structures. B: Volumetric analysis: Gonadectomy reduced or eliminated sex-steroid dependent differences in brain structure volume. SC: superior colliculus, PTL: parieto-temporal lobe; MEA: medial amygdalar nuclei; HY: hypothalamus; BNST: bed nuclei of the stria terminalis; CPu: caudoputamen; F: XX & XY Females; M: XX & XY Males. Error bars are 95% confidence intervals.

Title: Unpredictable chronic mild stress during adolescence shifts preference for nicotine and alters gene expression in the ventral tegmental area

Authors: *L. F. ALCANTARA, E. M. PARISE, O. K. SIAL, M. A. GREENWOOD, T. GNECCO, N. J. HARDIMAN, A. I. GONZALEZ, C. A. BOLAÑOS-GUZMÁN; Psychology, Florida State Univ., Tallahassee, FL

Abstract: Many adults report that their first encounter with drugs of abuse was during adolescence, and most common during this time is the initiation of tobacco use. This is troubling

because individuals who begin smoking at a young age have a much harder time trying to quit, suggesting that adolescents are particularly vulnerable to future nicotine dependence. Stress, an essential factor in precipitating mood-related disorders, has been shown to perpetuate nicotine use and change the rewarding properties of nicotine. Surprisingly, the neurobiological basis of this synergistic relationship has been largely understudied in young populations. To further examine the interaction(s) between stress, age and vulnerability to nicotine, adolescent (postnatal day 35) male Sprague Dawley rats were exposed to 4 weeks of unpredictable chronic mild stress (UCMS) and their behavioral reactivity to anxiety-provoking (i.e., elevated plus maze [EPM]), stress-eliciting situations (i.e., forced swim test [FST]), and reward (i.e., sucrose preference) was assessed. Changes in sensitivity to nicotine (0.08, 0.16, 0.24, 0.32 mg/kg) were also assessed using the conditioned place preference (CPP) paradigm. Brain tissue was collected from a separate group of UCMS-exposed rats and changes in gene expression within the ventral tegmental area (VTA) were examined. The VTA was chosen given its crucial role in mediating drug- and mood-related behaviors. Adolescent rats exposed to UCMS spent less time in the open arms of the EPM, displayed decreased latency to immobility and higher total immobility in the FST, and had a reduced preference for sucrose - all behavior outcomes indicative of a depression-like phenotype. Assessment of CPP scores showed that these rats also had a higher preference for the lowest dose (0.08 mg/kg), while showing no preference for the highest dose (0.32mg/kg) of nicotine, which non-stressed, control rats found rewarding. This indicates that stress changes sensitivity to nicotine. Gene expression was measured using rt-qPCR. UCMS-exposed rats showed dysregulation of genes implicated in mood disorders and drug abuse: Delta fos b (Dfosb), the extracellular signal-regulated kinase 1/2 (ERK 1/2), and the early growth response protein 1 (Zif268) were elevated in the VTA when compared to non-stressed controls. This data indicates that chronic stress during adolescence induces an anxiety- and depression-like phenotype while increasing sensitivity to nicotine. This work expands the current knowledge of the interaction between stress and nicotine reward and gives insight into better understanding the genes potentially mediating drug use driven by mood-related disorders.

Title: Repeated ketamine exposure during adolescence produces long-lasting changes in reward sensitivity to drugs of abuse and gene expression in the Nucleus accumbens in adulthood

Authors: *O. K. SIAL[1], E. M. PARISE[1], A. M. GANCARZ[2], L. F. ALCANTARA[1], A. I. GONZALEZ[1], T. GNECCO[1], D. M. DIETZ[2], C. A. BOLAÑOS-GUZMÁN[1];

Abstract: Major Depressive Disorder (MDD) is a highly prevalent and potentially debilitating psychiatric condition affecting approximately 20% of the global population. MDD afflicts up to 10% of adolescents, with nearly 50% of those afflicted considered non-responsive to available treatments. Ketamine (KET), a non-competitive N-methyl-D-aspartate receptor antagonist has shown potential as a rapid-acting and long-lasting treatment for MDD. Unfortunately, these effects are not permanent and it is conceivable that patients will require subsequent exposure to KET. We have recently shown that repeated exposure to KET in adolescent male rats produces behavioral adaptations indicative of a stress-resilient phenotype in adulthood. Given that adolescence is a critical developmental period and that KET has high abuse liability, the lasting neurobiological consequences of repeated KET treatment and its subsequent re-exposure must be characterized. Therefore, this study was designed to assess the effects of re-exposure to KET on behavioral reactivity to rewarding (i.e., drug self-administration, conditioned place preference [CPP]) and aversive stimuli (i.e., forced swim test [FST]) in adult rats pretreated with KET as adolescents. Adolescent male rats were treated with KET (0, 20 mg/kg, twice daily) for 15 consecutive days (postnatal days [PD] 35-49) and then left undisturbed until adulthood. On PD80, rats received a submaximal dose of KET (10 mg/kg) and tested in the FST or for locomotor activity. KET pretreated rats showed increased latency to immobility and decreased total immobility in the FST, and a robust KET-induced locomotor sensitization. Adult rats pretreated with KET as adolescents also showed increased sensitivity to the rewarding effects of KET (5, 10 mg/kg) as measured in the drug self-administration and CPP paradigms as compared to controls. These findings suggest that repeated exposure to KET during adolescence produces increased sensitivity to KET in adulthood. A separate group of adolescent rats were used for assessment of KET-induced biochemical changes in the nucleus accumbens (NAc). Rt-qPCR analysis revealed that pretreatment with KET modulates the expression of genes implicated in depression and drug-addiction. Rats pretreated with KET showed significant decreases in TrkB, BDNF, Akt, dFosB and ERK2 mRNA when compared to controls. Conversely, there was an increase in CREB, GSK3B, GluR2, and GluR3 mRNA expression. Together these findings indicate that repeated KET during adolescence increases sensitivity to subsequent KET in adulthood, and implicate the intracellular pathways mediating responsivity to stress and KET re-exposure.

Title: Repeated Ketamine treatment produces a stress-resistant phenotype in adolescent mice

Authors: ***E. M. PARISE**, L. F. ALCANTARA, O. K. SIAL, A. I. GONZALEZ, N. J. HARDIMAN, C. A. BOLAÑOS-GUZMÁN;
Dept. of Psychology and Neurosci. Program, Florida State Univ., Tallahassee, FL

Abstract: Major Depressive Disorder (MDD) is a leading cause of disability and among the top leading causes of disease burden in the world. MDD, also common in pediatric populations, affects about 10% of children and adolescents at any given time. Early life MDD can be highly debilitating, with lasting negative consequences extending into adulthood. Although available treatments are generally effective and safe, they are suboptimal. Recently, Ketamine (KET), a non-competitive N-methyl-D-aspartate receptor antagonist, has shown promise as a rapid acting and potentially long-lasting antidepressant in patients with MDD. Unfortunately, initial clinical assessments indicate that acute ketamine is not sufficient to produce lasting effects, and that repeated KET treatment may be more effective. Nevertheless, very little is known about the effects of KET treatment on subsequent stress responding, especially during adolescence. Therefore, this study was designed to assess the effects of KET treatment on behavioral reactivity to stress in adolescent (postnatal day [PD] 35) mice. An initial experiment was conducted to determine KET antidepressant activity in naïve male adolescent C57BL/6J. PD35 mice received an acute injection of KET (0, 5, 10, 20 mg/kg) and 24 h later their behavioral reactivity to anxiety- and stress-eliciting situations (i.e. social interaction test [SIT], and forced swim test [FST]) was assessed. KET significantly increased time spent with a social target in the SIT and decreased total immobility in the FST, responses indicative of an antidepressant-like response. Next, we assessed the ability of an acute dose of KET to reverse the effects of chronic social defeat stress (CSDS) during adolescence. PD35 mice were subjected to 10 days of CSDS, treated with a single dose of KET (0, 10, 20 mg/kg) 1 h after the last defeat and then tested in the

SIT and FST 24 h later. Although both doses of KET significantly reduced total immobility in the FST, only the 10mg/kg dose increased time spent in the interaction zone. Finally, we determined whether repeated KET during adolescence could block the effects of CSDS. Separate groups of adolescent male mice were treated once daily with KET (0 or 10 mg/kg) for 15 consecutive days (PD 35-49). After a 7 d washout period, mice were subjected to 10 d of CSDS and 24 h after the last stress session, exposed to the SIT and FST. KET significantly blocked the CSDS-induced deficits in the SIT and FST. Together, these findings indicate that KET produces a stress-resistant phenotype in adolescent male mice and support the notion that repeated KET treatment may provide superior efficacy as an antidepressant.

Title: Oxycodone exposure during adolescence and adulthood dysregulates striatal gene expression and facilitates hydrocodone-seeking in rats

Authors: *M. A. GREENWOOD[1], L. F. ALCANTARA[1], E. M. PARISE[1], C. PIEKARSKI[2], O. K. SIAL[1], J. BEVERLEY[2], H. STEINER[2], C. A. BOLAÑOS-GUZMÁN[1];
[1]Neuroscience, Psychology, Florida State Univ., Tallahassee, FL; [2]Dept. of Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., Chicago, IL

Abstract: Opiate drugs are prescribed for short-term treatment of mild to moderate pain. Due to the ease of access and availability of these medications, illicit use of prescription opiates has become a growing health concern in the United States. Nonmedical use of prescription opiates can facilitate transition to long-term opiate abuse and dependence. In spite of the high rates of medication abuse by adults and adolescents, the neurobiological changes that occur with chronic opiate exposure are poorly understood. Therefore, the purpose of this study was to characterize the biological consequences of chronic oxycodone exposure in adolescent and adult rats, namely in the striatum, a brain region implicated in habit formation and compulsive behaviors related to drug addiction. Adolescent (postnatal day [PD] 35) and adult (PD 65) male Sprague-Dawley rats were treated with once-daily subcutaneous injections of oxycodone on a schedule of escalating doses (10-70 mg/kg), over 7 consecutive days. Two hours after their final injection, rats were

sacrificed and tissue collected. Gene expression was measured by *in situ* hybridization in a total of 23 striatal sectors that represented all major functional domains of the striatum. Opioid peptide markers selectively expressed by direct (dynorphin, DYN) and indirect (enkephalin, ENK) striatal output pathways were assessed. Results indicate that chronic oxycodone treatment reduces ENK expression throughout the striatum regardless of age of exposure. No differences in expression of DYN (or substance P) as a function of age or pre-treatment were detected. Adolescents also displayed reduced expression of the immediate early gene Zif268 throughout the rostral striatum, while both adolescents and adults showed increased Zif268 expression in the lateral part of the caudal striatum. Given that ENK and Zif268 have been implicated in addiction-related behaviors, additional cohorts of rats were chronically treated with oxycodone and subsequently underwent place conditioning to 1 mg/kg hydrocodone. Post-conditioning, time to extinguish their place preference was measured. Adolescents developed a preference regardless of pretreatment, whereas only adults pretreated with oxycodone developed a preference for environments paired with hydrocodone. However, only adolescents pretreated with oxycodone required significantly more time to extinguish their established place preference. These findings suggest that chronic oxycodone exposure modulates drug-seeking behaviors in adolescent and adult rats possibly via differential gene regulation in striatal output pathways, including reduced ENK function in the indirect pathway.

Title: Pubertal timing depends on TRPC2 signaling in mice

Authors: ***D. R. PFAU**[1], S. M. BREEDLOVE[2], C. L. JORDAN[3];
[1]Michigan State Univ., Lansing, MI; [2]Neurosci. Program, Michigan State Univ., East Lansing, MI; [3]Neurosci. Program, Michigan State Univ., Lansing, MI

Abstract: Function of the vomeronasal organ is critically tied to the transient receptor potential cation channel, subfamily C, member 2 (TRPC2). There is evidence that a subpopulation of TRPC-expressing neurons in the vomeronasal organ (VMO) exert control over the timing of puberty in female mice (Oboti et al. 2014, BMC Biology 12: 31) but whether TRPC2 neurons in the VMO have the same role in male mice is not known. To address this question, we monitored pubertal timing in male and female mice that had the TRPC2 gene knocked out (KO; Jackson Laboratories Strain Name: B6;129S1-Trpc2tm1Dlc/J; Stock Number: 021208). TRPC2 KO mice were on a mixed 129S1 and C57BL/6 genetic background and compared to wildtype (WT) controls of the same mixed background. Pubertal onset was based on preputial separation in males and vaginal opening in females. Body weight was also measured at weaning. We found a significant delay in pubertal onset for both male ($F(1,31)=10.72$, $p=0.003$, $d=1.3$) and female ($F(1,44)=13.18$, $p=0.001$, $d=1.0$) KO mice. Puberty was delayed by about 2 days for KO males (KO = 29.560 ± 0.57 (Mean + SEM) vs. WT = 27.12 ± 0.57) and by about a day for KO females (KO = 29.545 ± 0.61 vs. WT = 28.059 ± 0.40). This is the first demonstration that TRPC2 plays a role in pubertal timing in male mice and confirms the previous finding of an effect of TRPC2 on pubertal timing in female mice. While body weights are reportedly higher in KO mice at birth and at six days postnatal, we find that body weight was significantly reduced at weaning for KO mice: KO females weighed almost 3 grams less than WT females ((13.268g ± 0.678) vs. 16.044g ± 0.655, respectively; $F(1,28)=6.38$, $p=0.018$, $d=0.86$)) at weaning (22 days postnatal) whereas KO males weighed around 1.5 grams less than WT males (14.005 ± 0.568 vs. 15.718 ± 0.765, respectively; $F(1,30)=4.846$, $p=0.036$, $d=0.78$) at weaning. This effect on body weight at weaning may reflect poor quality lactation seen in KO dams (Hasen and Gammie 2011, Behav Brain Res 217: 347). Future studies will examine the potential influence of TRPC2 signaling on the adult neural systems mediating aggression and sex-specific behaviors that depend on the detection and discrimination of sex-specific chemical cues.

Title: Development of dopaminergic fibers in the medial prefrontal cortex of male and female rats during adolescence

Authors: J. WILLING[1], J. M. BRODSKY[1], L. R. CORTES[1], T. KIM[1], *J. M. JURASKA[2]; [1]Psychology and Program in Neurosci., [2]Psychology, Univ. of Illinois, Champaign, IL

Abstract: Adolescence is a critical developmental period associated with neuroanatomical changes that are accompanied by improved cognitive performance. The medial prefrontal cortex (mPFC), a region that mediates executive function, undergoes extensive reorganization during the adolescent period. Data from our lab show that neuron number and the dendritic tree in the mPFC change from preadolescence to adulthood in a sex-specific manner. Less is known regarding the development of dopaminergic fibers innervating this region. Specifically, while it has been demonstrated that the density of dopaminergic fibers increases between adolescence to adulthood in male rats, the precise trajectory of these changes across adolescence, in both males and females, remains unexplored. In the present study, we track changes in the volume of tyrosine hydroxylase (TH) immunoreactive axons in distinct layers of the male and female mPFC at multiple time points from preadolescence to adulthood (P25, P35, P45, P60 and P90). The density of fibers was multiplied by the volume of the region for each animal to give the total amount (volume) of TH fibers. Both males and females gained TH fiber volume in layers 1 and 2/3, with significant increases early between P25 and P35. In layer 5, there was a gradual increase in TH fiber volume in both males and females, with a significant difference between P25 and P90 rats. Analysis of "skeletonized" images, measures fiber length (not width), yielded the same trends, suggesting that increases in TH fiber volume were the result of increased total length of fibers. In summary, dopaminergic innervation of the mPFC increases during adolescence with similar trajectories in male and female rats. Elucidation of the precise timing of dopaminergic innervation of the mPFC, along with other developmental changes, may help provide insight into mental illnesses characterized by mPFC dysfunction such as schizophrenia, depression and addiction that frequently manifest during adolescence.

Title: Environmental enrichment promotes adaptation to environment rearrangement in younger but not older adolescent rats

Authors: *D. E. COBB, K. L. PATTERSON, R. GUCWA, A. J. ROSSI, E. A. ARTZ, A. P. BRUNSON, M. C. ZRULL;
Appalachian State Univ., Boone, NC

Abstract: Experiences, such as environmental enrichment (EE), that allow for investigation and informal learning can lead to brain changes and alter novelty seeking and exploratory behaviors, and adolescence is a developmental period during which these behaviors are apt to change. We investigated the effect of EE during adolescence on preference for location of known objects (constant or rearranged) using an object-in-place (OiP) task. In addition, neural activation in the dentate gyrus (DG) and CA1 region of hippocampus, which is implicated in the detection of novel spatial relationships, was investigated using the neural activity marker c-fos. Adolescent Long-Evans rats (n=16) were exposed to EE between postnatal days (pnd) 25 and 48. Age-matched controls (n=16) experienced a non-enriched home-cage. Two-trial OiP testing occurred on pnd 36 and 50 with two delays (15 and 60 min) in an open field containing four objects. Exploration time and time in direct contact with the rearranged objects was measured at each delay. After testing, brain tissue was processed to examine levels of neural activity in DG and CA1 using immunohistochemistry for c-fos. At pnd 36, EE animals spent more time with all objects (M=45-s, SD=12.3) than no-EE animals (M=32-s, SD=13.1) across both delays ($p<.01$). EE rats spent about half their time exploring rearranged objects at both delays, which contrasted with no-EE controls spending more time (+23%) and less time (-32%) with the switched objects at the 15 and 30 min delays ($p<.05$). At pnd 50, EE rats spent less time on average with the objects (M=29-s, SD=15.1) than no-EE animals (M=41-s, SD=21.1) across both delays ($p<.05$). However, both EE and control rats spent similar proportions of time with rearranged objects at the 15 min (M=0.66, SD= 0.22) and 60 min (M=0.38, SD= 0.23) delays. Analysis of c-fos tissue showed 24.4% fewer active neurons in CA1 of EE rats than no-EE rats ($p<.05$) and no difference between groups in DG neural activation suggesting some impact of EE on hippocampal processing evoked by the OiP task. While neural data support the conclusion that EE animals recognize novelty, behavioral results indicate a decrease in novelty preference in younger, but not older adolescent animals, because of EE. EE promotes adaptation to novelty in younger but not older adolescent rats. These results indicate that adolescence may, in fact, be a critical period for the impact of EE and that EE that takes place earlier in adolescence is most effective at reducing risk-taking behaviors, such as novelty seeking or preference.

Title: Ketamine exposure during adolescence increases sensitivity to reward-related stimuli in adulthood

Authors: *L. M. RIGGS[1], J. B. ALIPIO[2], M. A. HERNANDEZ[2], K. L. SHAWHAN[2], B. CRUZ[1], D. SANCHEZ[2], A. R. ZAVALA[3], S. D. IÑIGUEZ[1];

Abstract: Pediatric depression was not well recognized until relatively recent. Today, however, major depressive disorder (MDD) is commonly diagnosed in children and adolescents, and when left untreated, may result in negative consequences that extend into adulthood. It is estimated that children and adolescents who suffer from MDD are likely to develop conduct and anxiety disorders, and that up to 25% eventually develop substance abuse disorder. Consequently, this has resulted in a disproportionate increase in the prevalence of antidepressants prescribed to populations below 20 years of age. Recently, the non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist, ketamine, has been shown to alleviate symptoms of MDD in individuals that suffer from treatment-resistant depression. However, little is known about the potential long-term consequences of exposure to ketamine during early development. This is particularly important to examine, given ketamine's abuse potential. To address this issue at the preclinical level, we examined whether ketamine exposure during adolescence results in long-lasting changes in sensitivity to the rewarding effects of sucrose (i.e., natural reward), as well as cocaine (i.e., drug reward). Specifically, male c57BL/6 mice were exposed to ketamine (0 or 20 mg/kg) during adolescence (postnatal days [PD] 35-49) and were later assessed in adulthood (PD 70+) on behavioral responsivity to a sucrose solution (1%), or cocaine (0, 5, 10, or 20 mg/kg) place conditioning (CPP). Here we show that adult mice pre-treated with ketamine during adolescence displayed enhanced preference for a sucrose solution, as well as environments previously paired with moderately low doses of cocaine, when compared to saline pre-treated controls. Together, our findings suggest that exposure to ketamine during adolescence increases sensitivity to both natural and drug-rewards, later in life.

Title: Effects of single bout of treadmill exercise on epigenetic parameters in hippocampus from adolescent female and male Wistar rats

Authors: *I. R. SIQUEIRA, L. C. F. MEIRELES, K. BERTOLDI, C. G. BASSO, L. R. CECHINEL, V. R. ELSNER;
Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: DNA methylation at promoters and histone acetylation have been linked to sex-specific responses, as well some proteins related to DNA methylation are related to sexual dimorphic in the rodent amygdala during the critical period for sexual differentiation. However there are no studies, to our knowledge, reporting DNA methylation and histone acetylation machineries in hippocampus of female and male adolescent rodents. Moreover it has been demonstrated that different exercise protocols are able to alter epigenetic marks, such as DNA methyltransferases (DNMTs) content and histone deacetylases (HDACs) activity in hippocampus of young adult and aged male Wistar rats. Interestingly, a decreased striatal HDAC activity was found at 1 h and 18 h after a single session of exercise in adolescent male Wistar rats. Our aim was to investigate HDAC activity and DNMT1 content in hippocampi of adolescent female and male Wistar rats submitted to a single session of treadmill exercise at different time-points after the exercise, 1 hour and 18 hours. The Local Committee (CEUA/UFRGS) approved all handling and experimental conditions (nr.21449). Male and female Wistar rats were maintained under standard conditions. The rats were submitted to a single session of treadmill (20 min). The samples were obtained from 39-day-old rats at different time-points after the exercise, 1 hour and 18 hours. Three-way ANOVA showed a significant effect of gender and time point after the single exercise session, since female had higher HDAC global activity than male Wistar rats. Moreover, a temporal pattern in HDAC activity was observed, given that this parameter was enhanced in the early morning (18 hours group) than the afternoon (1 hour group). Besides, there was a trend of interaction between gender and time point factors ($p=0.08$). Additionally, three-way ANOVA evidenced that hippocampi of female Wistar rats exhibited higher levels of DNMT1 than male. Our data can suggest that DNA

methylation and histone acetylation machineries, specifically the enzymes HDAC and DNMT1, can be related to sex-specific responses.

Title: Environmental enrichment reverses down-regulation of hippocampal brain-derived neurotrophic factor (BDNF) in male rats following early-life inflammatory challenge

Authors: A. KHOURY[1], M. MACRAE[2], *A. C. KENTNER[2];
[1]Sch. of Pharm., [2]Sch. of Arts and Sci., MCPHS Univ., Boston, MA

Abstract: In the laboratory, environmental enrichment (EE) is generally designed using a multifactorial approach incorporating novelty (i.e. alternating toys and their locations within an animal's cage) alongside opportunities for physical activity (i.e. increased cage space) and social engagement facilitated through group housing. This type of rearing is often utilized to evaluate its neuroprotective and rehabilitative potential as a translational intervention for complications associated with stroke, Huntington's disease, traumatic brain injury, and even psychological stressors. Typically the utility of EE is evaluated in response to challenges that occur in adulthood but another stream has focused this environmental intervention on pediatric and long-term consequences following early-life adversity. Stemming from evidence that EE can rescue the brain from early-life trauma we are interested in how the various components of enrichment (i.e. novelty, physical space, social engagement) may contribute to the reversal of the behavioral and neural disruptions that accompany maternal immune activation (MIA). In the present study, standard housed female Sprague-Dawley rats were administered either the inflammatory endotoxin lipopolysaccharide (LPS; 100ug/kg) or pyrogen-free saline (equivolume) on gestational day 15. Following weaning on postnatal day (P)22, male and female offspring remained in same-sex pair-housed standard cages until P50 at which point they were randomized into one of three conditions: EE (groups of 4-6 animals housed in a large multi-level cage with toys, tubes and ramps), Colony Nesting (CN; groups of 4 animals socially-housed in a larger style cage), or Standard Care (SC; animals pair-housed in standard cages). Six weeks later we collected hippocampus and prefrontal cortex (n = 7-9) and evaluated these structures for brain-

derived neurotrophic factor (BDNF) and TrkB receptor gene expression (normalized to GAPDH) using qPCR methods. Overall, MIA resulted in a sex-specific down-regulation of BDNF gene expression in the hippocampus of male rats, which was only rescued by EE housing. Our next step is to evaluate the accompanying social behavior data and follow up with further qPCR and protein quantification. Given concerns that behavioral and neural changes in offspring may be associated with inflammation (i.e. sickness) during pregnancy, this ongoing research offers some assurance that interactions between components of the environment (i.e. novelty, physical space, and social engagement) could offer rehabilitative options following early-life exposure to inflammation and other developmental adversities.

Title: The effects of voluntary exercise on oligodendrocyte development and myelin in juvenile mice and in cuprizone treated adult mice

Authors: *L. G. TOMLINSON, P. HUANG, H. COLOGNATO;
Stony Brook Univ., Stony Brook, NY

Abstract: Voluntary Exercise is known to promote adult hippocampal neurogenesis in rodents, while the extent to which exercise influences oligodendrocyte lineage development and myelination remains unclear. However, some studies have found that voluntary wheel running promotes oligodendrocyte precursor (OPC) differentiation in adult rodents, and a recent study has found that neuronal activity in the premotor cortex promotes oligodendrocyte differentiation and myelination. However, it remains unknown whether exercise can influence myelination during late juvenile development, and if so, whether a critical period for this effect exists, as has been shown for the negative effect of social isolation on myelination. In addition, while voluntary exercise has also been shown to delay symptom onset and reducing damage severity in

some demyelinating mouse models, the degree to which voluntary exercise influences OPC development and myelination dynamics remains unknown. To investigate the effects of voluntary exercise on oligodendrocyte development in juvenile mice, we used two approaches. First, mice at 4, 5, or 8 weeks of age were given free access to running wheels or not for 4 weeks, followed by an assessment of proliferating (Ki67+) OPCs and newly-born EdU+ OPCs (NG2+) and oligodendrocytes (CC1+) in several brain regions including the corpus callosum, prefrontal and motor cortices. Second, using a similar experimental design, we conditionally labeled OPCs with YFP in PDGFaR-CreERT:RosaYFP transgenic mice and analyzed the densities of newly-born YFP+ OPCs and oligodendrocytes. We observed both increased OPC proliferation and increased oligodendrocyte development, and noted an age-dependent decrease in some of the effects such that the more robust exercise-induced changes occurred selectively in younger mice, indicative of a critical window for optimal exercise-regulation of OPC development. To gain insight into exercise-regulated oligodendrocyte lineage dynamics during de- and remyelination, we fed both exercising and non-exercising adult mice cuprizone for 4.5 weeks, then assessed myelin (MBP) levels in the motor cortex. Our preliminary findings indicate an increase in MBP levels in the motor cortex of exercising cuprizone-treated mice relative to that in sedentary cuprizone-treated mice. Overall the results suggest that voluntary exercise influences oligodendrocyte development in juvenile mice, an effect that is attenuated as mice reach adulthood. However in adult mice following myelin damage, myelin is once again modulated by exercise, suggesting that exercise-regulated myelin plasticity can be reactivated following injury.

Title: Grooming as a de-arousal behavior underlying novelty habituation: An effect potentiated by environmental enrichment

Authors: *M. ROJAS[1,2], J. C. BRENES[2], J. FORNAGUERA[2], A. MORA-GALLEGOS[2];
[2]Neurosci. Res. Ctr., [1]Univ. of Costa Rica, San José, Costa Rica

Abstract: The open field test (OFT) has been extensively used for assessing exploratory behavior, memory, and anxiety-related traits in rodents. Previous evidence suggests that early environmental enrichment (EE) reduces psychomotor reactivity to novelty in the OFT, as compared with animals reared in standard housing (SH). A detailed analysis of OFT activity has shown that EE rats progressively increased self-grooming as locomotion reduced. A preliminary observation revealed that, among the different types of grooming, EE particularly increases the so-called sequential or type 3 grooming (i.e., snout-head-torso liking). Since grooming behavior has also been associated with pain, stress, and thermoregulation, the question of whether increases in grooming behavior can be taken as an indicator of novelty habituation potentiated by EE has not been fully elucidated. In the first experiment, we evaluate the effects of housing conditions on novelty habituation within a 10-min OFT and between two independent OFT conducted 30 days apart. After a baseline OFT, rats were housed either in SH or EE from post natal day (PND) 35, and were evaluated at PND65 and 95 in such a test. In a second experiment, we aimed to test whether grooming behavior, specifically the type 3, is related to novelty habituation independently from EE. Therefore, non-enriched rats were exposed to a 15-min OFT during four consecutive days, expecting that repeated exposition to the same environment increases familiarity and, in consequence, grooming behavior. In a final experiment, SH rats were i.p. treated with the glutamate receptor antagonist (MK-801) to test whether blocking the acquisition of OFT memory prevents grooming behavior to appear in further expositions to the same environment. Evidence will be provided about the putative role of grooming behavior in a non-associative learning process -namely novelty habituation in the OFT- following the assumption that grooming may be a de-arousal behavior belonging to the risk-assessment repertoire of the rat, which is affected by environmental enrichment.

Title: Juvenile amphetamine exposure does not induces long-term alterations in exploratory behavior and neural morphology of limbic regions in the rat

Authors: *H. TENDILLA, SR, L. ARROYO-GARCÍA, I. CAMACHO-ÁBREGO, G. FLORES;
Inst. De Fisiología, Benemérita Univ. Autónoma De Puebla, Puebla, Pue. CP 72570, Mexico

Abstract: Amphetamine (AMPH) is a psychostimulant widely used for therapeutic as well as recreational purposes. This substance is a treatment of choice for children with attention deficit hyperactivity disorder (ADHD) despite the lack of preclinical and clinical information about its long-term effects. The controversy surrounding the use of AMPH in children is, because it has been demonstrated that the psychostimulant exposure during the neurodevelopment significantly affects this process, which is essential to generate adequate neural networks for the optimum brain function in the individual. In addition, previous results of our group showed that AMPH exposure in pregnant rats induces physiological and behavioral changes in the offspring at prepuberal and postpuberal ages. On the other hand, several reports have proved that AMPH is capable to modify the morphology of neurons in some regions of the limbic system related to some psychiatric conditions such as substance abuse behavior, major depression and schizophreniform disorder. In this protocol we studied the influence of low dose AMPH exposure (similar to those used in children with ADHD) during juvenile age in healthy rats on exploratory behavior and neural morphology of limbic system areas at three ages: prepuberal, puberal and postpuberal. The behavioral test to evaluate the exploratory behavior was the locomotor activity protocol, in which AMPH alters locomotor activity in prepuberal rats, without changes at puberal and postpuberal age compared with controls. Besides Golgi-Cox staining method was used to describe the neural morphology of four limbic regions: prefrontal cortex, nucleus accumbens, hippocampus and amygdala, showing that AMPH induces changes at prepuberal and puberal ages on the arborization and spine density of these neurons, but interestingly these changes does not persist at postpuberal age. Our findings suggest that even the early-life AMPH exposure does not induces long-term behavioral and morphological changes, it causes alterations at puberal age in the limbic system networks, a stage of life strongly associated to the development of substance abuse behaviors.

Title: Learning, socioemotional behavior, and striatal dopamine D1 receptor expression after adolescent drug exposure

Authors: *A. IZQUIERDO, H. POZOS, A. DE LA TORRE, A. STOLYAROVA, S. DESHIELDS, J. CEVALLOS, J. RODRIGUEZ;
Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Adolescents, when diagnosed with ADHD or Major Depression, are frequently prescribed psychotropic medications. The introduction of methylphenidate (MPH) and fluoxetine (FLX) may impact brain development, potentially leading to long-lasting changes in behavior and cognition. These drugs have been studied for their effects on addiction vulnerability and emotion but not extensively for their enduring effects on cognitive flexibility. In Experiment 1, male and female adolescent Long Evans rats were treated with MPH or FLX for 15 days and compared to treatment with methamphetamine (mAMPH) and saline (SAL). On day 0, 7 and 15 of treatment, novel conspecifics were assessed for duration of social play and nonsocial behavior. Following drug washout, and now in adulthood, rats were tested on pairwise discrimination and reversal learning, a test of cognitive flexibility. We found sex differences in rates of initial discrimination learning, with males showing faster acquisition than females, but no sex by treatment interaction. MPH treatment impaired the accuracy of reversal learning performance (main effect of treatment and treatment group x session interaction). Analysis of reversal learning microstructure revealed the MPH group was faster to touch the stimulus and collect the reward on correct trials compared to SAL. There was also a significant sex by MPH treatment effect in the duration of both social and nonsocial behaviors on Day 7 and 15. In Experiment 2 we assessed activity on the elevated plus maze and sucrose preference in adulthood after adolescent MPH. There were sex, but not treatment group, differences in anxiety wherein females displayed anxiogenic responses. This anxiogenic response may explain the sex differences in learning in Experiment 1. We found no treatment or sex differences in sucrose preference. We then assessed expression of striatal dopamine D1 and D2 receptors via ELISA in tissue collected from animals in each experiment. We found significant elevations in striatal D1 expression in the MPH and mAMPH-treated animals and D2 in MPH-treated females in tissue collected after learning. No differences were found in expression levels from tissue collected within a week of treatment. Collectively these findings suggest that learning and MPH/mAMPH interact to prolong a window of enhanced striatal D1 expression, when otherwise these receptors

would be pruned. Ongoing analyses include measures of synaptic remodeling in both frontal cortex and amygdala in these animals.

Title: Repeated social defeat stress during adolescence impairs the maturation of GABAergic function in the adult prefrontal cortex

Authors: *E. FLORES-BARRERA[1], D. R. THOMASES[1], A. CABALLERO[1], J. S. CARTER[2], K. E. GRANT[2], J. A. ROSENKRANZ[1], K. Y. TSENG[1];
[1]Cell. and Mol. Pharmacol., Rosalind Franklin Univ., North Chicago, IL; [2]Dept. of Psychology, DePaul Univ., Chicago, IL

Abstract: Early life exposure to emotionally salient stressors is thought to contribute to the development of maladaptive behavioral patterns later in life, many of which are associated with aberrant functioning of prefrontal-mediated cognitive processing. However, the mechanisms underlying such developmental disruption remain unclear. Here we asked whether a disruption of prefrontal maturation could underlie the enduring cognitive impairments resulting from repeated social stress during adolescence (from postnatal day -P- 32 to P38). Using electrophysiological measures, we found that the normal inhibitory control of afferent drive is lacking in the adult prefrontal cortex (PFC) of rats that underwent adolescent social defeat. Results from local field potential recordings and ventral hippocampal stimulation revealed that the pattern of prefrontal response observed in the social defeat stress group resembles that seen in the immature PFC of naïve juvenile rats. At the cellular level, such inhibitory disruption in the PFC was associated with a state of increased AMPA/GABA ratio in layer V pyramidal neurons, mainly due to a selective downregulation of local GABAergic transmission. A similar dysregulation of prefrontal GABAergic function was observed in rats that underwent social defeat stress during the P42-48 adolescent period. However, no deficits in PFC inhibition were observed when the repeated social defeat stress was presented during late adolescence (i.e., P50-

55) or adulthood (P75-80). Collectively, these results indicate that social defeat stress during early and mid-adolescence had the most potent and enduring impact on PFC function and maturation, in particular at the level of local GABAergic function. As fine-tuning of PFC output and behavior are highly dependent on the activity of local inhibitory interneurons, impaired GABAergic maturation resulting from social defeat stress during adolescence is expected to elicit enduring deficits in prefrontal-dependent cognitive functions.

Title: Enduring effects of fluoxetine on spatial memory performance in adolescent and adult male c57bl/6 mice

Authors: *J. B. ALIPIO[1], L. M. RIGGS[2], L. F. ALCANTARA[3], S. D. INIGUEZ[1]; [1]Psychology, Univ. of Texas at El Paso, El Paso, TX; [2]Psychology, California State Univ., San Bernardino, CA; [3]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Epidemiological reports indicate that mood-related disorders are common in children and adolescents. The prevalence of adolescent clinical depression has resulted in parallel increases in the prescription of Fluoxetine (FLX) and related serotonin reuptake inhibitor antidepressants within this population. Although such treatments can last for years, very little is known about the long-term consequences of antidepressant exposure during developmental periods prior to adulthood on memory performance later in life. Thus, we exposed adolescent (postnatal day [PD] 35) and adult (PD65) male c57BL/6 mice to FLX (0 or 20 mg/kg) for 15 consecutive days. We then assessed animals' behavioral performance on the Morris Water Maze spatial memory task three-weeks after antidepressant exposure. Specifically, mice were trained to find the location of a submerged escape platform on a single day task (8 training trials), and memory for the platform location was re-tested after a 24 hr delay (distance traveled and velocity). To increase the demands of the spatial task, the mice returned to the spatial task once again 24 hr later, and completed a probe trial (escape platform absent), and time to reach the

quadrant of the target platform location, as well as total time spent in the quadrant were recorded. We found that FLX exposure, regardless of age, did not influence spatial memory acquisition on the training day. In addition, no differences between the groups were observed when spatial memory was examined 24 hr after training. Conversely, mice exposed to FLX during adolescence, but not adulthood, swam longer distances to reach the location of the missing platform, when tested 48 hr after training (probe trial). Together, our results suggest that as the demands of the spatial memory task increase, spatial memory deficiencies become apparent in adult mice exposed to FLX during adolescence.

Title: Enrichment of young adolescent rats promotes balanced exploration of a simple environment

Authors: *E. A. ARTZ, H. L. JOHNSON, S. J. SNOUSE, T. J. ARNOLD, Z. H. RICHARDSON-BULL, S. A. BLAKE, M. C. ZRULL;
Appalachian State Univ., Boone, NC

Abstract: For many mammals, adolescence is a time of development that features changes in sensation-seeking, response to novelty, and preference. Environmental enrichment (EE), such as an opportunity to interact with novel objects and conspecifics in a known or unknown environment, can influence exploration and novelty preference by affecting brain structures mediating these behaviors. We examined how EE affects features of exploratory behavior during an object in place (OiP) task in adolescent rats. Between postnatal days (pnd) 21 and 36, same-sex groups of Long-Evans rats (n = 8 each) experienced 9, 1.5-h EE sessions in cages containing a variety of objects, ramps, and platforms. Age-matched controls (8 female, 8 male) were not enriched. At pnd 36, an OiP task was performed, allowing assessment of field and object exploration and preference for objects in constant or new locations. There were 3 trials, sample and 15- and 60-min delays, that took place in a gridded, 1-m square open field. Time contacting each of 4 objects present on each trial was recorded, with the locations of two objects switched before Trial 2 and of the other two objects switched before Trial 3. After testing, brain tissue was

processed to neural activity in basolateral amygdala (BLA) using c-fos as a marker. Counts from sampling frames within BLA revealed similar numbers of activated neurons in EE and control brains. Across OiP trials, EE rats explored 43% more territory of the open field ($p<.05$) and spent 58% more time in the internal portions of the field ($p<.05$) than control rats. Controls decreased time spent exploring objects in the field from Trial 1 to 3 (54-s, 32-s, 32-s), and EE rats increased time spent with objects across the same baseline, 15-min and 60-min delays (38-s, 42-s, 49-s) ($p<.01$). While EE rats spent similar proportions of time with newly located objects on both delay trials (0.53 and 0.57, both SD=0.13), controls investigated the newly placed objects more at the 15-min (M=0.67, SD=0.17) than 60-min delay (M=0.36, SD=0.23) ($p<.01$). Behavioral data suggest that EE promotes fairly complete initial exploration of all areas of a simple environment. EE also increases exploration of a familiar but rearranged space upon re-introduction to that environment in young adolescent rats. Further, EE appears to promote balanced investigation of an environment diminishing any preference for familiarly or newly located features.

Title: Changes in the number of synapses in the medial prefrontal cortex across adolescence

Authors: *C. DRZEWIECKI, J. WILLING, J. M. JURASKA;
Univ. of Illinois, Champaign, IL

Abstract: Adolescence is marked by numerous neuroanatomical changes within the medial prefrontal cortex (mPFC), a brain region known to mediate executive function. In rats, these morphological changes include increases in white matter, as well neuron and dendritic losses between childhood and adulthood. Prior work from our laboratory has demonstrated that these neuron losses occur during the pubertal period and may be related to female sex hormones. However, less is known about the trajectory of synaptic losses across adolescence. Here, we track changes in the number of synapses labeled with synaptophysin in the male and female rat

mPFC across multiple time points from preadolescence into adulthood (P25, P30, P45, P60 and P90). Our results showed an overall significant post-pubertal drop between P35 and 45 in the number of synapses in the female mPFC. Although this pattern occurred in all of the layers, it was predominately driven by changes in layer I synapses, with a significant rise between P25 and 35. In male rats, there was a significant pre-pubertal rise in synapses between P35 and 45, followed by a post-pubertal decline between P45 and 60 in layer V/VI. This pattern also appeared over all layers but did not reach significance. As a whole, these results suggest a role for both male and female pubertal hormones in the trajectory of synaptic loss within the mPFC during adolescence. This may shed light onto why adolescents are notably susceptible to mental illnesses such as depression and schizophrenia, both of which are associated with prefrontal synaptic abnormalities.

Title: Perinatal SSRI exposure and social behaviors in juvenile offspring

Authors: *M. HAZLETT[1], M. GEMMEL[1], E. CSÁSZÁR[1,3], S. DE LACALLE[2], J. PAWLUSKI[1,4];
[1]Dept. of Biol. Sci., [2]Dept. of Biomed. Sci., Ohio Univ., Athens, OH; [3]Dept. of Reproductive Toxicology, Inst. of Exptl. Pharmacol. and Toxicology, Bratislava, Slovakia; [4]Irset-inserm u1085, Univ. of Rennes 1, Rennes Cedex, France

Abstract: Up to 20% of women experience depression during pregnancy or the postpartum period. Selective serotonin reuptake inhibitor (SSRI) medications are the most common antidepressant treatment for maternal mood disorders, being prescribed to up to 10% of women during this time. SSRI medications have been shown to cross the placental barrier; additionally, they are present in the breast milk of mothers taking these medications. Thus, there are concerns about the impact of SSRI exposure on offspring development. Previous research has shown a significant effect of early exposure to SSRI medications on juvenile play behavior and other aspects of social behavior; however, further work is needed to determine how perinatal exposure to SSRI medications, using a model of maternal adversity, may affect related neurodevelopmental outcomes in juvenile male and female offspring. The aim of the present

study was to examine how exposure to fluoxetine, a popular SSRI used during the perinatal period, affects social behavior in juvenile rat offspring, using a model of maternal adversity. To do this, Sprague-Dawley rat dams were subjected to chronic unpredictable stress prior to breeding and were treated with fluoxetine (10mg/kg/day) or vehicle via oral administration from gestational day 10 to postnatal day 21. Juvenile offspring from the following four groups were used: 1. Control+Vehicle, 2. Control+Fluoxetine, 3. Pregestational Maternal Stress+Vehicle, 4. Pregestational Maternal Stress+Fluoxetine. Offspring underwent a social interaction test one week after weaning. Preliminary results show that juvenile offspring perinatally exposed to fluoxetine spend less time pouncing on and crawling over or under a novel same-sex partner, as well as less time running away from a same sex partner. Further work will determine the impact of exposure to pregestational maternal stress on these outcomes as well as investigate how these changes in social behavior are related to neural plasticity in the hippocampus. Understanding the impact of perinatal exposure to SSRI medications on neurodevelopmental processes will further enhance our understanding of the benefits and risks of perinatal administration of these medications.

Title: Perinatal ssri exposure and social behaviors in adult offspring

Authors: ***M. GEMMEL**[1], E. CSASZAR[1,3], C. VESEL[1], S. DE LACALLE[2], J. PAWLUSKI[1,4]; [1]Dept. of Biol. Sci., [2]Biomed. Sci., Ohio Univ., Athens, OH; [3]Reproductive Toxicology, Inst. of Exptl. Pharmacol. and Toxicology, Slovak Acad. of Sci., Bratislava, Slovakia; [4]Univ. of Rennes, Rennes Cedex, France

Abstract: Selective serotonin reuptake inhibitor (SSRI) medications are the most frequently used antidepressant treatment for maternal mood disorders throughout pregnancy and in the postpartum period. Increased prevalence and duration of SSRI treatment, and the ability of antidepressant medications to cross the placental barrier, suggests possible impact on fetal neurobehavioral development. Furthermore, clinical research has shown that exposure to SSRIs during the perinatal period is associated with increased autistic traits in children and alterations

in social behaviors. Investigation of perinatal exposure to SSRIs and their effects on offspring brain and behavior are crucial in understanding the long-term effects of these medications on key aspects of development. The aim of this study was to determine the persisting effects of perinatal exposure to the SSRI medication, fluoxetine, on social behavior in adult offspring. Sprague-Dawley rat dams were treated during gestation until weaning with fluoxetine (10mg/kg/day), or vehicle, via oral administration. Half the dams were subject to chronic unpredictable stress prior to conception to model aspects of maternal depression during pregnancy and thus better mimic the clinical situation. Male and female offspring from the following four exposure groups were used: 1.Control+Vehicle (CV), 2.Control+Fluoxetine (CF), 3.Pregestational Maternal Stress+Vehicle (PMSV), 4.Pregestational Maternal Stress+Fluoxetine (PMSF). Play behavior in juvenile offspring and social interaction in adult offspring was assessed. In juvenile offspring, preliminary results show perinatal exposure to fluoxetine reverses the decrease in play behavior seen after exposure to dams who were pregestationally stressed. During adulthood, preliminary findings show that adult offspring perinatally exposed to fluoxetine spend more time interacting with a novel same-sex partner compared to controls. Specifically adult offspring exposed to fluoxetine spent more time performing peer-directed behaviors such as sniffing and following. In addition, adult male offspring spent more time engaging in these behaviors than adult female offspring. Further work will determine the long-term impact of exposure to pregestational maternal stress on these outcomes as well as investigate how these changes in social behavior are related to neural plasticity in the hippocampus and prefrontal cortex. Understanding the impact of perinatal exposure to SSRI medications on the neurodevelopmental processes related to social behaviors will further enhance our understanding of the benefits and risks of these medications during development.

Title: Magnetic resonance imaging and histology reveal adolescent binge ethanol-induced alterations in the developmental trajectory of the young adult rodent cerebral cortex

Authors: *F. T. CREWS[1], R. YAXLEY[2], B. PANIAGUA[2], A. G. JOHNSON[3], R. P. VETRENO[2];
[1]Prof Pharmacol & Psychiat, [2]Skipper Bowles Ctr. Alcohol, Chapel Hill, NC; [3]Dept. of Radiology, Duke Univ. Med. Ctr., Durham, NC

Abstract: Adolescence is a critical period of cortical maturation characterized by cortical expansion and thinning that parallels the development of adult behaviors. However, little is known regarding the trajectory of cortical development in the adult brain. Adolescent binge alcohol consumption is common and can exert deleterious effects on cortical refinement due to the heightened neuroplasticity that characterizes the adolescent brain. In the first series of experiments, we used magnetic resonance imaging (MRI) and histology to assess adult cortical thickness changes across aging on postnatal day (P)80 and P220 in the male Wistar rat brain. Magnetic resonance imaging revealed cortical expansion in the prefrontal cortex across aging, while cortical thinning occurred in both the cingulate and parietal cortices of adult P220 rats, relative to young adult P80 rats. In the second series of experiments, an animal model of adolescent intermittent ethanol (AIE; 5.0 g/kg, i.g., 20% ethanol w/v, 2-days on/2-days off from P25 to P55) was used to assess the effects of alcohol on the trajectory of cortical thickness refinement in young adult (P80) rats. Magnetic resonance imaging revealed that AIE treatment led to premature cortical thinning in the young adult prefrontal cortex as well as deficits in cortical thinning in the cingulate cortex, an effect that was replicated with histology. Thus, cortical refinement continues to occur throughout the aging rat brain and AIE treatment causes changes in the developmental trajectory of the young adult cortex that could contribute to behavioral dysfunction in adulthood. Title: Effect of sensory enrichment on perineuronal nets recovery following prolonged sensory deprivation

Authors: *P. CHU[1,2], S. FARAH[4], S. ALI[4], A. WAHID[4], J. C. BRUMBERG[3,5];
[1]Queens College, City Univ. of New York, Flushing, NY; [2]Neuropsychology Doctoral Subprogram, [3]Neuroscience-Biology Ph.D. Subprogram, The Grad. Center, CUNY, New York City, NY; [5]Psychology, [4]Queens College, CUNY, Flushing, NY

Abstract: Perineuronal nets (PNN's) are extracellular matrix aggregates in the central nervous system that are involved with regulating plasticity and protecting inhibitory interneurons from oxiditative stress. We have previously shown that one month of sensory deprivation via whisker trimming from the day of birth (P1) to 30 postnatal days (P30) reduces PNNs which do not recover following 30 days of whisker regrowth. In the current work, we used fluorescent labeling using FITC-Wisteria Floribunda, and unbiased stereology to determine whether the effects of critical period sensory deprivation on PNNs can be reversed with environmental enrichment. Sensory deprived regrow and enriched animals were both sensory deprived from P0 to P30 via bilateral whisker trimming. Sensory deprived regrow animals were allowed to subsequently regrow their whiskers for 30 days until P60 in standard housing conditions. Sensory enriched animals were allowed to regrow their whiskers in a sensory enriched cage which was larger and contained various sensory stimuli that were alternated every two days. Our data show that PNNs are reduced across layers 4 and 2/3 of the barrel cortex following early sensory deprivation, but are rescued following 30 days of sensory enrichment relative to control and sensory deprived regrow. Our results suggest that although early sensory input is important for the normal maturation of PNNs, a subsequent period of environmental enrichment in adolescents is sufficient to rescue their normal expression in adolescents.

Title: Sex differences in pubertally born cells persist in adult sexually dimorphic regions

Authors: *J. L. KIM[1], M. A. MOHR[2], L. L. DONCARLOS[3], S. BREEDLOVE[2], C. L. JORDAN[2], C. L. SISK[2];
[1]Psychology, [2]Neurosci., Michigan State Univ., East Lansing, MI; [3]Cell and Mol. Physiol., Loyola Univ. Chicago, Maywood, IL

Abstract: Many sexually dimorphic brain regions regulate sex-specific behaviors that emerge during puberty. Studies in rats and hamsters have established that new cells are added to these sexually dimorphic brain regions during puberty, and that a subset of these cells differentiates into mature neurons or glia. We have shown that pubertal cytogenesis occurs in the mouse brain, but whether pubertally born cells survive long enough to differentiate into mature neurons or glia is unknown. Because previous studies indicate that new cells in the mouse brain take ~3-4 weeks to mature, the current study aimed to examine long-term survival of pubertally born cells in mice. During puberty, male and female mice were given daily injections of cell birth date marker bromodeoxyuridine (BrdU; 200 mg/kg; ip) for 21 days (P28-49). All animals were sacrificed on P60 or P90. Brains were sectioned and stained for BrdU-immunoreactive (ir) cells. Quantitative analysis of BrdU-ir cell density (# BrdU-ir cells/mm2) revealed no significant difference in BrdU-ir cell density between P60 and P90 in four regions: the posterodorsal medial amygdala (MePD) and ventrolateral subdivision of the ventromedial hypothalamus (VMHvl), both male-biased neural structures, as well as the dorsomedial subdivision of the ventrolateral hypothalamus (VMHdm) and dentate gyrus (DG), both monomorphic neural structures. Moreover, males and females had the same density of BrdU-ir cells in the DG and VMHdm at each age whereas BrdU-ir cell density in MePD was ~1.5 times higher in males than females at both P60 ($t=2.96$, $p<0.02$) and P90 ($t=5.60$, $p<0.01$). Likewise, BrdU-ir cell density in the VMHvl was ~1.4 times higher in males compared to females at both P60 ($t=3.62$, $p<0.01$) and P90 ($t=2.65$, $p<0.03$). Thus, there is long-term survival of pubertally born cells in the mouse brain, and sex differences in pubertally born cells seen in young adulthood persist for at least a month. Because new cells take longer to mature in mice compared to other rodent species, these new findings demonstrate that there is sufficient time for pubertally born cells to differentiate into mature neurons or glia and to potentially contribute to the emergence of sex-specific adult behaviors. Ongoing work includes phenotyping these pubertally born cells to determine whether they become mature neurons or glia.

Title: Effects of testosterone on hypothalamic-pituitary-adrenal function before, during, and after puberty in male rats

Authors: ***M. GREEN**, M. MCLAREN, T. E. HODGES, C. M. MCCORMICK;
Brock Univ., St Catharines, ON, Canada

Abstract: The hypothalamic-pituitary-adrenal (HPA) axis responds differently to stressors before puberty than it does after puberty; exposure to a stressor before puberty causes a greater and a more prolonged release of corticosterone than it does in adulthood (rev in Romeo, 2013). In experiment 1, we replicated and expanded on previous work by examining the hormonal response to acute stress before, during, and after puberty in intact male rats (postnatal days 35, 45, and 75, respectively). In response to 30 mins of restraint stress, plasma concentrations of corticosterone and progesterone increased significantly, and this increase was more pronounced at PND 35 and 45 compared to PND 75. At baseline, testosterone concentrations were higher at PND 45 and 75 than at PND 35. In experiment 2, we investigated the effects of testosterone on HPA function at each of the three ages given that testosterone concentrations are low before puberty and testosterone is known to dampen HPA activity in adulthood but not pre-pubertally (Romeo et al., 2004). At PND 30, 40, or 70 male rats were orchiectomized (OCX) and given an implant (s.c.) that contained testosterone or was left empty. Five days after surgery rats were sacrificed directly from the home-cage (baseline), after 30 mins of restraint stress, or 45 mins after termination of the stressor to examine hormone concentrations in plasma as well as AVP and Fos-ir in the PVN of the hypothalamus. In response to restraint stress, testosterone tended to dampen corticosterone concentrations in adults (PND 75), but increased concentrations at puberty (PND 45) and had no effect on concentrations before puberty (PND 35). Among OCX rats that received testosterone replacement, stress-induced corticosterone was higher at PND 35 and 45 compared to PND 75, whereas among those without replacement, concentrations were higher at PND 35 compared to at PND 45 and 75. AVP-ir was dampened by testosterone and

Fos-ir was elevated after restraint stress, but these effects were consistent across all age groups. Thus, there is evidence of testosterone regulation of the HPA axis at all three ages, but in an age-specific manner. We are currently conducting studies to examine the potential targets of testosterone's actions at each age as well as examining glucocorticoid receptor signaling to try to explain the underlying cause of age-differences.

Title: Dietary DHA and the neural bases of risk taking: Implications for substance abuse

Authors: *V. L. DARCEY[1,2], B. W. STEVENS[1], M. F. AVALOS[2], M. JAWDAT[2], E. J. ROSE[3], D. H. FISHBEIN[3], J. W. VANMETER[2];
[1]Interdisc. Program in Neurosci., Georgetown Univ., Washington, DC; [2]Ctr. for Functional and Mol. Imaging, Georgetown Univ. Med. Ctr., Washington, DC; [3]Ctr. for Translational Res. on Adversity, Neurodevelopment, and Substance abuse (C-TRANS), Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The omega-3 fatty acid docosohexaenoic acid (DHA) is critical to neuronal function (Mitchell et al., 1998). Evidence supports its role the development of the prefrontal cortex (McNamara et al., 2010), a region implicated in both impulse control and regulating striatially-driven risk taking behavior. Previous research demonstrates low DHA status is related to impulsivity (e.g. Burgess et al., 2000; Conklin et al., 2007), however it is unknown whether DHA status is related to risk taking behavior. Thus, we sought to determine the relationship between DHA intake, risk taking, and the neural bases of risky decisions in drug and alcohol

naïve adolescents. Participants (N=81; age 12.6±0.8 y; 51% female) enrolled in a prospective longitudinal neuroimaging study of the risk for alcohol initiation and escalation (the Adolescent Development Study) completed a Harvard Food Frequency Questionnaire. Since long chain polyunsaturates compete for position within neuronal membranes, we examined the ratio of DHA to arachidonic acid (AA) (DHA:AA). Participants were ranked based on DHA:AA ratio and split into quartiles. We considered differences between highest ratio (HD; DHA:AA= 1.25±0.40 mg; N=21; age 12.6±0.8 y, 52.4% female) and lowest ratio (LD; DHA:AA = 0.07±0.07, N=20; age 12.8±0.9 y, 55.0% female). Groups were not different in race, socioeconomic status, pubertal stage, BMI, or IQ. Risk taking was assessed using the Wheel of Fortune game (Ernst et al., 2004) performed during functional MRI (3T BOLD EPI). Participants tried to maximize hypothetical monetary earnings over 99 total trials by choosing either a high risk/high reward or low risk/low reward (90%/10% risk paying out $9/$1, $18/$2 and 70%/30% risk paying out $7/$3, $21/$9). There were no significant behavioral differences between groups. In contrast, fMRI analyses focused on high > low risk selections revealed the LD group had greater BOLD activity in bilateral orbitofrontal cortex, right posterior cingulate cortex, and left temporoparietal junction (p_{uncorr} 0.001, cluster extent > $10mm^3$) compared to HD. There were no clusters where the opposite was true (i.e. HD > LD). These preliminary results suggest low DHA:AA intake is associated with heightened neural activation during risk taking in interconnected regions implicated in value- and risk-based decisions (Jarbo & Verstynen, 2015; Rodrigo et al. 2014). Low DHA status augments sensitivity to drug reward in rodents (Levant et al. 2004). Results suggest that adolescents with low DHA intake may exhibit heightened sensitivity to risk taking, which coupled with heightened reward sensitivity, may exacerbate later risk of drug and alcohol use.

Title: Prenatal stress exposure is associated with altered parietal gray matter volume in healthy adolescents

Authors: *M. AVALOS[1], V. L. DARCEY[1], B. W. STEVENS[1], E. J. ROSE[2], J. VANMETER[1], D. H. FISHBEIN[2];
[1]Ctr. for Functional and Mol. Imaging, Georgetown Univ. Med. Ctr., Washington, DC; [2]Ctr. for Translational Res. on Adversity, Neurodevelopment and Substance abuse (C-TRANS), Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Prenatal stress exposure (PSE) predicts several adverse outcomes, including working memory deficits (Entringer et al., 2009), impulsivity (Van den Bergh et al., 2005), symptoms of ADHD (Rodriguez & Bohlin, 2005), and decreased gray matter density in regions including the prefrontal cortex (Buss et al., 2010). As a region developing during adolescence and associated with impulsivity and addiction (Chambers et al., 2003), it is critical to explore how PSE may affect its development. We investigated the relationship between PSE, emotion regulation and gray matter volume (GMV) in a subset of healthy, drug/alcohol naïve adolescents (age 12.3±0.4 years) enrolled in the Adolescent Development Study, a prospective longitudinal neuroimaging study of alcohol initiation and escalation. PSE was measured using a questionnaire completed by biological mothers (N=117) assessing traumatic events such as relationship conflicts or death of someone close (Entringer et al., 2009). Those with in-utero tobacco use were excluded (n=5). Participants whose mothers experienced ≥ 1 traumatic events (Trauma; N= 29) were age-matched to those who reported 0 events (No-Trauma; N=38). Groups were similar in gender, race and intelligence (Trauma: 55.1% male, 55.1% Caucasian, IQ: 107.9±15.9; No-Trauma: 39.4% male, 60.5% Caucasian, IQ: 110.8±16.6). A T1-weighted (voxel size = 1mm3) MPRAGE was acquired on a Siemens 3T scanner. Independent raters verified image quality (ICC=0.91). GMV was assessed using VBM performed in SPM8. Statistical modeling compared the 2 groups and included gender as a covariate of no interest; multiple comparisons were addressed using Non-Stationary Cluster Correction. Affective function in adolescents was measured using a parental measure of emotional control (BRIEF) and an emotional counting Stroop task. Despite no behavioral differences in emotion regulation, whole brain analysis revealed greater GMV in the Trauma group in a cluster spanning the right superior and inferior parietal cortex (1470 voxels, p=0.026, peak 44, -43, 55). This region is implicated in empathetic judgments (Silani et al., 2013) and increased GMV here is associated with antisocial behavior (Aoki et al., 2014) and mood disorders (Adleman et al., 2012). Our preliminary findings suggest that PSE may be a factor contributing to long-term neurodevelopmental changes related to the ability to process emotions. The differences in GMV may at this relatively young age-range be a precursor of future behavioral manifestations of emotional reactivity that as of yet has not been identified in our Trauma cohort and possible future risk for addiction during adolescence (Steinberg, 2005).

Title: Associations between exposure to alcohol advertising and limbic-frontal activations during an Emotional Counting Stroop task in female adolescents at risk for alcohol misuse

Authors: *K. R. VIACAVA[1], B. W. STEVENS[2], I. M. PACHECO-COLON[2], T. N. CLARKE[2], D. MAYS[2], L. BIZARRO[3], D. H. FISHBEIN[4], J. W. VANMETER[2];
[1]Inst. of Psychology, UFRGS and Georgetown Univ., Washington, DC; [2]Georgetown Univ., Washington, DC, DC; [3]UFRGS, Porto Alegre, Brazil; [4]Univ. of Maryland, College Park, MD

Abstract: Exposure to alcohol advertising (AAds) is a risk factor for underage drinking (Fleming et al., 2004) as exposure to AAds increases the likelihood adolescents start drinking (Morgenstern et al., 2011) and predicts increased intake among alcohol consumers (Grenard et al., 2013). This study examined the relationship between AAds exposure and attentional bias (AB) for alcohol-related and emotional negative words during fMRI in female adolescents considered high risk for alcohol misuse. Participants were part of the Adolescent Development Study (ADS), a longitudinal neuroimaging study of alcohol initiation and escalation. A subset of 114 adolescents enrolled in the ADS performed an Emotional Counting Stroop (ecStroop) task during fMRI. Thirteen participants from this sample (mean age = 14.8 yrs.) completed the Media Exposure Questionnaire (MEQ; Collins et al., 2007). We performed whole brain fMRI analyses regressing the MEQ scores separately for emotional>neutral and alcohol>neutral, with results reported at $p < .001$ uncorrected. Lastly, we examined neuronal activations from the subjects not

included in this analysis (N = 101) to obtain a bias free set of region(s) of interest (ROIs) to determine whether AAds exposure mediates the relationship between neural activation and AB. Behavioral results revealed a main effect of ecStroop $F(2,24) = 15.999$, $p < .001$, and the Bonferroni post-hoc confirmed the difference between negative and neutral ($p = .002$) and between alcohol and neutral words ($p = .001$). There was a positive correlation between exposure to AAds on TV and AB for emotional negative words such that subjects exposed to AAds on sports ($r = .63$, $p = .02$) or non-sports TV channels ($r = .56$, $p = .04$) are more distracted by these words. fMRI results for alcohol>neutral showed a positive correlation between exposure to AAds and activity in limbic and frontal areas, suggesting higher exposure may be associated with greater AB for alcohol words. There was a negative correlation between exposure and fMRI activation in the orbitofrontal cortex for alcohol>neutral, which may reflect habituation to repeated AAds exposure. From the fMRI ROI's extracted, linear regression revealed the right inferior and medial frontal gyri for alcohol>neutral predicted AB for alcohol-related words ($B = .652$, $p = .03$). However, no mediation effects of exposure to AAds were found. For emotional>neutral, there was a negative correlation between AAds exposure and the insula and cingulate gyrus, implying lower emotional interference on those with higher AAds exposure. Altogether, these findings have implications for identifying risk factors for future alcohol misuse in female adolescents.

Title: Cortical and subcortical structural variability in drug naïve adolescents predicts subsequent alcohol use

Authors: *E. J. ROSE[1], V. DARCEY[2], T. CLARKE[2], D. ESTEFAN[2], J. VANMETER[2], D. FISHBEIN[1];
[1]Psychiatry, Univ. of Maryland Sch. of Med., Columbia, MD; [2]Georgetown Univ., Washington, DC

Abstract: Clinical models of alcohol misuse suggest a neurological profile characterized by dysfunction in multiple behavioral, cognitive and affective brain systems and abnormalities in the structures that support them. Yet, it remains to be established whether structural variability is an antecedent to or consequence of alcohol abuse. Moreover, although adolescence is seen as a period of heightened risk for alcohol use, to-date there has been no prospective exploration of the relationship between alcohol use onset in youth and variability in brain structure predating use. Here we considered aspects of brain structure (i.e. cortical thickness (CT), surface area (SA) and subcortical volume (SV)) in drug and alcohol naïve children (age 11-13 years) and their relationship to subsequent alcohol use in an 18 month follow up period. Individuals were recruited to a prospective, longitudinal study of neurodevelopmental trajectories in children at variable risk for alcohol misuse. The sub-sample in the current analysis (N=70; 41 female; mean age = 12.8 years) included 11 children who reported using alcohol at the 18 month study follow-up and 59 who remained alcohol naive. Distributions for gender, risk status and family history of substance abuse were matched between users and non-users ($p<0.05$). High-resolution T1-MPRGAGE images (voxel=1mm3) were collected in a Siemens TIM Trio 3T scanner. These scans were rated for quality and ratings were confirmed by independent raters. Data were preprocessed in Freesurfer using standard parameters and QC included visual inspection of cortical and subcortical segmentations and surface accuracy for white matter and pial surfaces. Data analysis consisted of general linear models, modeling differences between users and nonusers in CT, and SA and SV regions of interest. Covariates included total intracranial volume, gender and risk status. These analyses indicated that estimates of CT in the left cuneus and entorhinal cortex and SA in the left caudal middle frontal gyrus, right inferior temporal gyrus and right lateral occipital gyrus were all greater in users, compared to non-users. Similarly, users exhibited greater gray matter (GM) volume in the left putamen and right nucleus accumbens (NAcc). In light of other studies showing that increased GM in reward relevant areas is predictive of reward sensitivity, greater GM volume in the key reward regions (i.e., the putamen and NAcc) may suggest heightened reward sensitivity in those with a propensity to use alcohol in adolescence. While intriguing, these outcomes require replication in an extended sample and a determination of the functional and behavioral correlates of structural outcomes.

Title: Reductions in prefrontal cortex grey matter predict later initiation of alcohol use during adolescence

Authors: *B. W. STEVENS[1], V. L. DARCEY[1], T. N. CLARKE[1], D. L. ESTEFAN[1], E. J. ROSE[2], J. W. VANMETER[1], D. H. FISHBEIN[2];

Abstract: In a longitudinal study of neurodevelopmental precursors and consequences of alcohol misuse (i.e., the Adolescent Development Study) we used voxel-based morphometry (VBM) to consider the relationship between grey matter (GM) volume in drug and alcohol naïve adolescents (11-13 years old) and the subsequent initiation of alcohol use. At an 18 month follow up 12 adolescents (66% female) had initiated alcohol use. Alcohol users were matched for gender, race, SES and IQ with 12 adolescents who had not initiated alcohol or drug use. High resolution (voxel size=1mm^3) structural MRI scans (MPRAGE, 3T) from baseline visits were used for VBM analysis, which was carried out using the DARTEL toolbox in SPM8. Images were segmented into GM, white matter and CSF. A study specific template was used to co-register the GM images. Statistical models also included total intracranial brain volume and gender. Correction for multiple comparisons utilized the Non-Stationary Cluster Correction plugin and data were thresholded at an uncorrected $p \leq 0.005$ and minimum cluster size (K_E) of 50 voxels. In addition to imaging measures, we also considered whether the groups differed on baseline executive function measures using the Behavior Rating Inventory of Executive Function (BRIEF; Gioia et al., 2000). At baseline there were no behavioral differences between groups, yet participants who went on to drink alcohol by 18 months had reduced GM volume in clusters spanning the left middle and inferior frontal gyri (corrected $p = 0.043$, $K_E = 8821$) and right middle and superior frontal gyri (corrected $p = 0.066$, $K_E = 7018$). These PFC regions are well known to be associated with many functions such as working memory and inhibitory control (Collette et al., 2006; Simmonds et al., 2008), and while we found no behavioral executive function differences, possibly due to a lack of power resulting from the small number of adolescents that have begun to use alcohol, it is possible those that initiated alcohol use had baseline reductions in executive function. In addition, reduced PFC GM volume has been observed in alcohol naïve individuals with a family history of alcohol abuse (Benegal et al.,

2007). The current study extends these findings, suggesting such reductions in GM volume can serve as a risk factor predisposing individuals to initiate alcohol use.

Title: Weaker baseline fronto-amygdalar resting state functional connectivity in healthy adolescents who escalate in depression symptoms over time

Authors: *H. E. STEIN[1], G. ALARCÓN[2], D. V. DEMETER[2], E. EARL[2], D. FAIR[3], B. NAGEL[3];
[1]Developmental Brain Imaging Lab., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Dept. of Behavioral Neurosci., [3]Departments of Behavioral Neurosci. and Psychiatry, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Depression is a prominent mental health concern, with greater risk associated with child and adolescent onset. Emotional dysregulation is a key feature of depression. Previous work has shown aberrant resting state functional connectivity of the amygdala in depressed adolescents, compared with healthy controls, which may be a neural substrate of altered emotional processing. While these findings suggest abnormalities in the functional connectivity of the limbic system in depressed adolescents, no studies have examined whether these abnormalities may precede depressive symptom expression. This study used resting state functional connectivity magnetic resonance imaging (rs-fcMRI) to prospectively examine potential neurobiological markers of escalating depression symptom severity in an adolescent sample (n=37, female=21, ages 12-16 years and free from psychopathology at baseline). Of these 37 participants, 18 showed ≥ one standard deviation increase in depression t-scores over time, as assessed by the Children's Depression Inventory (CDI), administered at quarterly follow-up

interviews. These 18 youth were compared to 19 youth who showed stable CDI scores over time, matched on baseline CDI scores, age, sex, IQ, and baseline alcohol and drug use. Whole-brain analyses were conducted on baseline rs-fcMRI data (≥5 min. of data after motion scrubbing; collected with eyes open), using an atlas-based seed region-of-interest (ROI) that encompassed the whole amygdala bilaterally. Functional connectivity maps were compared with a two sample *t*-test assuming unequal variance ($Z>2.25$, $p<0.05$). Results indicated that those youth who demonstrated stable CDI score over time had increased rs-fc, relative to those whose CDI scores escalated, between the right amygdala and left inferior frontal and supramarginal gyrus and right cingulate cortex. Additionally, relative to youth who showed an escalation of self-reported depression symptoms, those with stable symptom presentations had decreased rs-fc between the left amygdala and the left cerebellar vermis. These findings suggest a possible neurobiological marker of increasing depressive symptoms during adolescence, characterized in part by reduced fronto-amygdalar connectivity, which may suggest a premorbid deficiency in top-down emotional regulation.

Title: EEG correlation in institutionalized adolescents: long term impact of adverse rearing

Authors: *J. C. HEVIA[1], A. SANZ-MARTÍN[2], M. GUEVARA[3], M. HERNÁNDEZ-GONZÁLEZ[4];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Lab. de psicofisiología de la memoria, [3]Lab. de correlación electroencefalográfica y conducta, [4]Neurofisiología de la conducta reproductiva, Inst. de Neurociencias, Guadalajara, Mexico

Abstract: In 1989 United Nations Convention of the Rights of the Child, pronounced that every child should group up in a family environment of trust, happiness and understanding. However, not every child has the opportunity to rise on this ideal family context. It has been showed that children grown up in institutional environments, where the quality of care presents some

deficiencies, manifest a deficient development of different brain areas. There is strong scientific evidence that support that while more time spent in institutional environment, more deficiency in the development of neuronal substrates children presents, mainly the prefrontal cortex. In this work was measured the electroencephalographic (EEG) correlation between prefrontal, temporal and parietal areas in 10 adolescents institutionalized that had lived in institutional environment since preschooler ages (more than 75% of their life time) and 10 that never had lived institutionalized. A higher EEG correlation between interhemispheric frontopolar areas and between intrahemispheric frontopolar-dorsolateral areas in slow bands of institutionalized adolescents was observed. Besides, a higher intrahemispheric EEG correlation between left dorsolateral-parietal areas in fast frequency bands was also obtained in never institutionalized children. These EEG changes shown that growing up in a institutional environment affect the degree of EEG coupling among cortices.

Title: Assessment of impulsivity, inhibitory control and alcohol use in preadolescents and adolescents: students from five schools in Porto Alegre, Brazil

Authors: *A. R. WILLHELM, J. C. C. CABRAL, L. M. UGARTE, R. M. M. DE ALMEIDA; Inst. de Psicologia, Univ. Federal Do Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: The periods of preadolescence and adolescence are characterized by maturation of emotional and cognitive skills that provide capabilities to the independent functioning in adulthood. The last area to develop in the central nervous system is the prefrontal cortex, the area also linked to the ability to control impulses, this suggests that preadolescents have less ability to control than adolescents and adolescents have less ability to inhibitory control than adults. The consumption of licit and illicit drugs are increasingly present in the lives of adolescents. The main aim was evaluate impulsivity, inhibitory control and alcohol use in preadolescents and adolescents age 10 to 16. The specific objectives were to compare impulsivity and inhibitory control among boys and girls and between three age groups (from 10 to 12, 13 and 14 years and 15 to 16 years old). The sample was composed for 190 individuals age 10 to 16, divide in three

age groups (from 10 to 12, composed of 52 participants, 13 and 14 years with 49 participants and 15 to 16 years with 89 participants) from private and public schools. The instruments used were: Questionário de Capacidades e Dificuldades, Questionário sobre o início do uso de drogas, Barratt impulsiveness scale-youth, Go/No-go task, Five Digits test e Escala de Inteligência Wechsler Abreviada (WASI). Statistically significant differences were observed ($p < 0,01$) in performance between the three age groups, showing a chronological increase in inhibitory control. For comparisons between types of school were significant statistical differences at all times of the task Go/No-go ($p < 0,05$) and in some subtests of the Five Digits Test, the better performance of students in private schools. Comparing the sexes was statistically significant difference of which variable, indicating a lower inhibitory control female. Approximately 60% of adolescents have tried alcohol and 17% with illicit drugs. It was observed that preadolescents are consuming alcohol ever earlier and in greater quantity. We can conclude that control the ability to inhibit increases through adolescence. In addition, public school students showed worse performance in inhibitory control and greater impulsivity, and it was suggested that perhaps the environment are related with this performance. Girls showed less inhibitory control than boys, committing more errors of omission in the Go/No-go task, suggesting that the sample, girls have higher attentional impulsivity than boys.

Title: Longitudinal sex differences in brain activity during spatial working memory in adolescents

Authors: *S. A. JONES[1], B. J. NAGEL[2];
[2]Behavioral Neurosci. & Psychiatry, [1]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: It is well established that adolescence is a time of numerous structural and functional changes in the brain, many of which may differ by sex. To that end, prior studies have documented sex differences in brain response during spatial working memory (SWM) across adolescence. However, to date, most of these findings have been observed using a cross-sectional design, which may not account for individual variability or accurately reveal developmental findings. The current study used functional magnetic resonance imaging to longitudinally investigate development and sex differences in brain response to SWM using an n-back task in healthy female (n=16) and male (n=16) adolescents (ages 12-16 at baseline). All participants underwent two scans, separated by a mean of 1.5 years (SD=0.67). Whole-brain repeated-measures ANOVA, examining main effects of sex, time, and their interaction, revealed that during SWM, at both time points, males showed significantly greater brain activation in task-related regions, such as the bilateral inferior parietal lobule (IPL) and lingual gyrus, as well as default mode network regions, such as precuneus and posterior cingulate cortex (voxel/cluster-wise corrected for multiple comparisons, $p<.05$). However, there were no regions that showed a significant developmental effect (main effect of time), or sex-by-time interaction. To investigate the possibility of non-linear developmental trends masked by the broad baseline age-range of the sample, we split the sample based on median age at baseline (14.8 years) to examine these effects in younger and older adolescents, separately. Again, repeated-measures ANOVAs found no significant main effect of time or sex-by-time interaction in either group; however, similar sex differences as those seen across the whole sample were evident in the left IPL in younger adolescents and in the precuneus and lingual gyrus in older adolescents, again with males showing greater activation than females in both age groups. These results suggest that compared to females, males require greater activation of task-related regions during SWM and may have greater difficulty suppressing default mode regions during the task, with the latter appearing particularly evident later in adolescence. These findings highlight the importance of considering sex differences in SWM-related brain response and suggest that a broader age range with multiple scans within-subject may be necessary to elucidate developmental effects longitudinally.

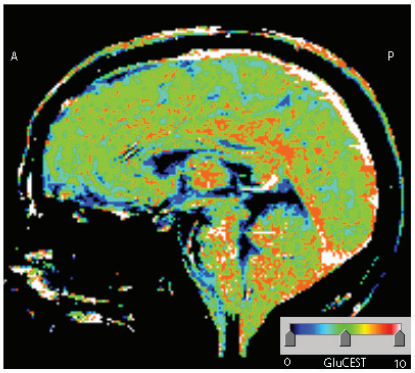
Title: *In vivo* mapping of cortical glutamate in early youth

Authors: *D. R. ROALF[1], M. QUARMLEY[2], R. REDDY NANGA[3], P. RUPERT[2], H. HARIHARAN[3], K. RUPAREL[2], J. BLAKE[2], M. A. ELIIOTT[3], R. REDDY[3], B. I. TURETSKY[2];
[1]Neuropsychiatry, [2]Psychiatry, Neuropsychiatry, [3]Radiology, Univ. of Pennsylvania, Philadelphia, PA

Abstract:



The cortex undergoes a protracted course of post-natal development during childhood and through young adulthood. In addition to allowing for expanded area, the brain's gyral structure allows enhanced computational efficiency within the gyral unit by speeding local information transfer and reducing wiring cost. In addition to progressive brain tissue changes, developmental changes in neurotransmitter availability likely precede or underlie these cortical changes. Here, we use a novel technique glutamate chemical exchange saturation transfer (GluCEST) to measure glutamate concentration, *in vivo*, across the entire cortex. We implemented an optimized

within-subject acquisition and analysis pipeline. Upon completion of 3T MRI scanning, each subject's whole-head structural image were segmented using FreeSurfer and ROIS were extracted and prepared for use with GluCEST data acquired at 7.0T. GluCEST, B0 map and B1 maps were collected and analyzed (Figure, from one individual). GluCEST data from 25 young healthy individuals and 25 individuals with clinical psychopathology were acquired. Our preliminary work indicates subtle, but significant changes in the distribution of GluCEST throughout the cerebrum that changes in a regionally dependent manner with age. In addition, the distribution of glutamate differed between the clinical sample and young healthy individuals (ps<.05). We suggest, that in addition to other metrics, GluCEST be considered as markers of brain development. Moreover, we believe that high-resolution GluCEST MRI could help elucidate subtle features of normal and abnormal brain. For example, hyperglutamatergic states within the brain are associated with schizophrenia and may aid in identifying individuals at risk for this disorder. Thus, the use of 7.0T GluCEST to map glutamate may yield improved quantification of brain neurochemistry and could improve diagnosis of brain disorders associated with alterations in glutamate.

Title: Neural control of social emotional actions in adolescence

Authors: *A. TYBOROWSKA[1,2], I. VOLMAN[1,2,3], S. SMEEKENS[2], I. TONI[1], K. ROELOFS[1,2];
[1]Donders Ctr. for Cognitive Neuroimaging, [2]Behavioural Sci. Inst., Radboud Univ. Nijmegen, Nijmegen, Netherlands; [3]Sobell Dept. of Motor Neurosci. and Movement Disorders, UCL Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Increased limbic and striatal activation in adolescence has been attributed to a relative delay in the maturation of prefrontal areas, resulting in the increase of impulsive reward-seeking

behaviors often observed during puberty. However, it remains unclear whether and how this general developmental pattern translates to the control of social emotional actions, a fundamental adult skill refined during adolescence. Using an fMRI-adapted social Approach-Avoidance (AA) Task, this study identifies how neural properties of emotional action control change as a function of pubertal development in 14-year-old adolescents (n=47; 21 males). During the AA-Task, participants had to evaluate the emotional expression (happy, angry) of faces and respond by either pulling a joystick toward (approach) or away (avoidance) from themselves. Affect-congruent conditions involved intuitive stimulus-response mappings (i.e. approach-happy and avoid-angry faces). In contrast, affect-incongruent conditions required participants to override these emotional action tendencies in order to meet task demands (i.e. approach-angry and avoid-happy faces). Pubertal maturation, indexed by testosterone levels, shifted the neural regulation of emotional actions from the pulvinar nucleus of the thalamus and the amygdala to the anterior prefrontal cortex (aPFC). Adolescents with more advanced pubertal maturation showed greater aPFC activity when controlling their emotional action tendencies, reproducing the same pattern previously observed in adults. In contrast, adolescents with less advanced pubertal maturation showed greater pulvinar and amygdala activity when exerting the same amount of control. These findings qualify the generic notion of a shift from subcortical to prefrontal processing during puberty, suggesting that the pulvinar and the amygdala are the ontogenetic precursors of the mature emotional control system centered on the anterior prefrontal cortex. The maturational shift of subcortical - prefrontal control is hypothesised to transition by late adolescence. We are currently testing this possibility by sampling the same participants later in their pubertal maturation.

Title: Associations between white matter microstructure and gonadal hormone levels are altered in youth with fetal alcohol spectrum disorders (FASD)

Authors: *K. A. UBAN[1], M. M. HERTING[1], J. R. WOZNIAK[2], E. R. SOWELL[1,3];
[1]Children's Hosp. Los Angeles, Los Angeles, CA; [2]Univ. of Minnesota, Minneapolis, MN;
[3]USC, Los Angeles, CA

Abstract: In animal models, prenatal alcohol exposure (PAE) results in endocrine dysregulation and sexually dimorphic brain alterations. However, very little is known about sex differences and hormone levels among youth with Fetal Alcohol Spectrum Disorder (FASD). The present study aimed to begin to fill this gap using diffusion tensor imaging (DTI) to assess how gonadal hormones relate to white matter microstructure in PAE youth. DTI measures restriction of water diffusion known as fractional anisotropy (FA). Previous studies suggest that PAE results in decreased FA, which may underlie common cognitive and behavioral deficits. Thus, we hypothesized that PAE would be associated with reduced FA, and hormone-FA associations would be altered by PAE in a sexually dimorphic manner. Sixty-one youth (8-20 yrs; 49% girls; 50% PAE) participated as part of the Collaborative Initiative on FASD (CIFASD). Participants completed a 30 directional DTI scan and a passive drool sample to examine FA-hormone associations with Testosterone (T), dehydroepiandrosterone (DHEA), and estradiol (E2). After standard preprocessing and motion correction, FSL's tract-based spatial statistics program was utilized to generate mean FA for 9 regions of interest (ROIs). In R, Group x Age interactions were analyzed separately for boys and girls, using linear regression for unilateral ROIs, and linear mixed effect modeling, including hemisphere, for bilateral ROIs. Compared to Control youth, FASD girls exhibited lower FA values in inferior fronto-occipital (IFO) and uncinate white matter tracts, but FASD boys exhibited higher FA values in the callosal body, cingulum, corticospinal, optic radiation and superior longitudinal fasciculus (SLF) white matter tracts (p's<0.05). These novel findings demonstrate sexually dimorphic effects of PAE on structural connectivity in youth. Positive associations between T and DHEA with FA were observed with the callosal body, optic radiation, and SLF in Control boys, but only with the SLF in FASD boys (p's$<.10$). A positive E2-FA association was observed with the IFO among Control girls ($p<.10$), while no hormone-FA associations were observed among FASD girls (p's$>.32$). These novel findings provide evidence that PAE results in a loss of typical hormone-FA associations observed among Control youth, particularly among boys with FASD. Importantly, the present results have implications for understanding sex differences in how PAE impacts hormone-brain associations, which may have implications for advancing our understanding of common cognitive, behavioral and mental health problems that occur at a high prevalence among individuals with an FASD.

Title: During the puberty morphological differences in autism are due to increased gyrification

Authors: *R. SIUGZDAITE, H. AERTS, D. MARINAZZO;
Data Analysis Department, Fac. of Psychology and Pedagogical Sci., Ghent Univ., Ghent, Belgium

Abstract: Social communication (SC) can be defined as "the synergistic emergence of social interaction, social cognition, pragmatics (verbal and nonverbal), and receptive and expressive language processing" (Adams, 2005). SC disorder can include problems with one or all the three components: social interaction, social cognition and pragmatics. To assess the disorder a lot of behavioral testings are performed including IQ, Social responsiveness scale (SRS), Social communication questionnaire (SCQ) and ect. But can we detect SC disorder from the structural differences in the brain between groups? Previous studies (Libero et al 2014, Valk et al 2015, Wallace et al 2013) showed distributed abnormalities in frontal and temporal brain areas. Inconsistencies come from different age groups and sample sizes (small groups within a specific age group or a huge heterogeneous age group), though in both cases the results were pointing to regions involved in social cognition. In this study we have picked age specific group of 103 children with ASD and 103 TD controls from the Autism Brain Imaging Data Exchange open-access database matched for age (average 10.5 ± 1.6 years). Groups were significantly different in social communication measures (VIQ, SRS and SCQ scores). We performed surface based morphological analysis using FreeSurfer (Fischl, 2012) to find properties of cortical regions involved in social communication disturbancies in children with autism spectrum disorder. We didn't find any grey matter differences in cortical volume or surface area between groups, but left inferior lateral ventricle and right choroid plexus were bigger in ASD than in controls. We also found smaller cortical thickness in left parahippocampal and in right middle frontal regions in ASD. Finally, folding measurements revealed differences in left hemisphere (fusiform, middle temporal areas, rostral middle frontal and lateral occipital gyri). We conclude that at age of puberty children brains do not differ in volume or surface area, though the only difference involves curvature of gyri, the way they are formed during the development of the brain. The gyrification in left rostral middle frontal area correlates with ADOS social scores and this could be a potential biomarker for social communication in ASD.

Abstract: Although numerous psychiatric disorders emerge as a result of abnormal brain development in adolescence, our understanding of normative maturation during this period remains limited. We apply the complex network framework to study the relationship between developmental trajectories of functional connectivity (FC) from 14 to 25 years and the architecture of FC in young adulthood. Anatomical and functional 3T scans were acquired from 97 healthy volunteers aged 14-25 (49M / 48F). The fMRI signal was de-noised using multi-echo ICA [1] and averaged over 272 cortical regions of interest. For each participant, weighted graphs were estimated where each node is a brain region and links correspond to correlations in fMRI signal. Nodal connectivity strength was calculated as the sum of the weights of each node's links to all other network nodes. The cross-sectional development of local strength as a smooth function of age was assessed using a generalized additive model. Pair-wise differences in

regional developmental trajectories were estimated by integrating over differences between the first derivatives of the smooth functions, and clustered using k-medoids clustering. An average adult FC matrix was created from subjects aged 22-25, which was partitioned into modules. A significant relationship between maturational similarity and adult FC was present, indicating that regions which follow more similar (less dissimilar) maturational trajectories in adolescence are more strongly connected in the adult brain. A subdivision of the maturational trajectories into five clusters yielded high overlap with a partition of adult FC into five modules. FC was significantly stronger within maturational clusters than within a set of randomized cluster partitions (preserving cluster size, spatial contiguity and hemispheric symmetry), particularly in parietal and occipital regions. Additionally, maturational trajectories were significantly more similar (less dissimilar) within FC modules than within randomized modular partitions. The strong correspondence between the adolescent maturation of functional connectivity and its architecture in the cortex of young adults could be explained by a network-level Hebbian mechanism. Such a mechanism was previously proposed to explain that resting-state networks result from the strengthening of connections due to task-based co-activations [2]. Our results provide a novel interpretation for the role of such a mechanism, indicating that high average FC between cortical regions might result from similarity in their developmental trajectories. Title: Birth weight predicts aberrant striatal intrinsic functional connectivity in preterm born adults

Authors: *J. G. BÄUML[1], M. AVRAM[1], C. MENG[1], M. DAAMEN[2], P. BARTMANN[3], D. WOLKE[4], A. WOHLSCHLÄGER[1], C. SORG[1];

Abstract: Background: Preterm birth constitutes a high risk for perinatal brain injury and adverse brain development. Both studies using animal models of premature delivery and neuroimaging studies in humans consistently point to the striatum as a structure to be particularly affected by preterm birth. Recently, we demonstrated aberrant intrinsic functional connectivity (iFC) of the basal ganglia network together with structural changes in underlying gray matter in preterm born young adults. Yet, little is known about the long-term consequences of preterm birth on the iFC of different striatal sub-regions at large-scale brain level. Method: Using resting-state functional magnetic resonance imaging we investigated seed-based intrinsic functional connectivity (iFC) of 12 striatal sub-regions (6 per hemisphere) in 91 preterm and 90 term born young adults (mean age 26 years). Voxel-wise statistical parametric maps quantified within-group striatal iFC and between-group differences for three caudate and three putamen seeds per hemisphere. Subsequently, prematurity-related variables (e.g. birth weight) were used to predict potential between-group iFC differences. Results: Across all subjects whole-brain voxel-wise one sample t-tests ($p<0.05$, FWE cluster corrected) for each of the 12 striatal sub-regions revealed distinct spatial maps highly consistent with the previously hypothesized sensorimotor, associative and limbic divisions among striatal sub-regions. Two sample t-tests ($p<0.05$, FWE cluster corrected) revealed that preterm born adults demonstrated a reduced iFC between ventral striatal seeds and both frontal cortex and caudate nucleus, and between dorsal striatal seeds and frontal, premotor, cingulate and insular cortices. Interestingly, between-group differences were almost exclusively found in seeds placed in the right hemisphere. Preterm born adults did not show increased iFC for any of the striatal seeds. Moreover, within the preterm group, birth weight significantly predicted the reduced iFC between the left ventral rostral putamen and the right caudate nucleus ($p<0.001$). Conclusion: Our data demonstrate the long-lasting effect of preterm birth on cortico-striatal and striatal-striatal connectivity into adulthood involving both the motor, cognitive and affective divisions among striatal sub-regions. The link between preterm born subjects' birth weight and aberrant iFC of striatal sub-regions in adulthood suggests striatal iFC to be a potential long-term biomarker of preterm birth.

Title: The age-effects on topological lateralization of hemispheric brain network from adolescence to adulthood

Authors: *S. ZHONG, Y. HE, G. GONG;
Beijing Normal Univ., Beijing, China

Abstract: Human brain is functionally and structurally lateralized and related to cognitive development across the life span. Brain functional lateralization may result from the difference of information processing between two hemispheres. Complex network analysis and graph theoretical approach can be used to study the efficiency of the information processing within the hemisphere. Here, we aim to spatially map the maturation of topological lateralization of the structural network from adolescence to adulthood, which might provide novel insights into brain functional lateralization and its developmental patterns. 106 adolescence and 98 adults were included. We first constructed two hemispheric structural networks for each subject. Then, the topological organization was quantified by the two network metrics (i.e. global efficiency and local efficiency) and one nodal metric (nodal efficiency). The degree of asymmetry of the network metrics was measured by LI=(Mr-Ml)/(Mr+Ml) . Finally, we applied paired t-test and a linear model were used to test if there is a topological lateralization in network metrics for either adolescent or adult group and the adolescent vs. adult group differences for the LI of network metrics, separately. There was significant rightward lateralization in the global efficiency for both adolescent and adult groups, while significant rightward lateralization in the local efficiency appeared only in adolescence. A significant group main effect on the LI was observed for both the local efficiency and global efficiency. For the nodal efficiency of the adolescence, the rightward lateralization regions were mainly located in the parietal lobe, temporal cortex, frontal cortex, and lateral inferior occipital regions, while this rightward lateralization became much less, with substantial leftward lateralization being found within temporal and occipital lobes in adulthood. The significant main group effect on the LI for the nodal efficiency (FDR corrected $p<0.05$) were mainly located around the posterior temporal cortex, temporal-parietal junction,

and inferior occipital cortex. These findings might provide new insights into brain structural and functional development.

Abstract: Adolescence is a time of increased risk-taking and reward sensitivity. Current models of human brain development posit that a functional imbalance between prefrontal cortex and subcortical regions contributes to these behaviors, due to the earlier development of limbic regions compared to the more protracted development of prefrontal cortex. Despite considerable evidence that hormones affect brain structure and function, nearly all neurodevelopmental studies of reward processing define childhood and adolescence based on age alone and do not consider measures of hormonal exposure such as Tanner Stage. Fifty typically developing children and adolescents underwent Tanner staging by a clinician and performed a monetary incentive delay task in a 3T fMRI scanner. Groups were defined based on both age and Tanner stage (Pre-pubertal: N=23, average age=8.6 years, age range 8.1-9.4, all Tanner stage 1, 11 females; Pubertal: N=27, average age=13.1, age range 12.1-14.6, Tanner stages 2-5, 12 females). Whole-brain voxel-wise data for reward anticipation and reward gain were analyzed in SPM5 to compare pre-pubertal children and pubertal adolescents, with sex added as a covariate of no interest. During reward anticipation, adolescents showed significantly greater activation in right orbitofrontal cortex and basolateral amygdala than pre-pubertal children ($p<0.001$, uncorrected)

with no differences observed in the opposite direction. During reward outcome, adolescents showed greater activation in right dorsolateral prefrontal cortex (DLPFC) and medial prefrontal cortex; pre-pubertal children, in contrast, had greater activation in right ventral striatum ($p<0.001$, uncorrected). In post hoc analyses, the predominance of DLPFC over ventral striatum (DLPFC - ventral striatum) during reward outcome was found to decrease with age in the pubertal group ($R=-0.43$; $p<0.03$), but was not correlated across the relatively restricted age range in the pre-pubertal group. These data provide evidence for greater recruitment of prefrontal cortex regions in pubertal adolescents compared to pre-pubertal children, consistent with studies of structural and functional development. The division of children into pre-pubertal and pubertal by clinical examination rather than by age alone provides confirmation that these groups are developmentally distinct. The Tanner scale defines development based on external sex characteristics that are dependent on pubertal timing and typically covary with age. Future longitudinal analyses will attempt to disentangle the roles of age, Tanner stage, and reproductive steroids in development of reward processing during adolescence.

Abstract: Vertical transmission of the human immunodeficiency virus (HIV) from mother to child is still a major public health problem in many countries. In the central nervous system, HIV can induce a variety of abnormalities such as thinning of the corpus callosum and cortical atrophy (Thompson et al., 2005). Infection in a developing brain may lead to even more devastating defects such as white matter lesions, calcifications, and degeneration as a result of HIV encephalopathy or other indirect consequences of the virus (George et al., 2009). We scanned 120 children in Thailand using diffusion tensor imaging (DTI) to study white matter structural differences in infected versus uninfected children. We further assessed white matter associations with a Processing Speed Index (PS-I) while controlling for age, sex, and imaging site (**Table 1**). FDR ($q<0.05$) was used to control for false discoveries in the multiple regions tested. Using the ENIGMA-DTI processing protocol, we found white matter diffusivity was significantly associated with HIV status, in many brain regions including the *corona radiata* ($P= 0.002$; $Beta= 1.4x10^{-5}$) for mean diffusivity, and the corpus callosum ($P= 4.0x10^{-5}$; $Beta= 3.2x10^{-5}$) for axial diffusivity. Similar trends were seen when also controlling for treatment status. White matter associations were also detected with PS-I in the full group when also controlling for infection status. When assessed separately, we found in HIV-uninfected children, the radial diffusivity in many brain regions was significantly associated with PS-I, including the superior fronto-occipital fasciculus ($P= 0.003$; $Beta=-4.8x10^{-7}$). For HIV-infected children, however, after multiple comparisons correction only non-significant trend associations remained. These results provide evidence of structural and cognitive changes during development with HIV infection.

Table 1- Demographic factors for all HIV uninfected and infected children. Mean and standard deviation of data is presented; percentage is presented where appropriate. 88 of the 120 scanned children also completed cognitive evaluations used for this study.

Variables	HIV uninfected (55)	HIV infected (33)	*p-value*

Title: Layer-specific comparison of high resolution MRI cortical thickness with the von Economo legacy

Authors: *L. H. SCHOLTENS, M. A. DE REUS, M. P. VAN DEN HEUVEL;
Brain Ctr. Rudolf Magnus, UMC Utrecht, Utrecht, Netherlands

Abstract: The human cortex harbors great spatial variety in cyto-, chemico- and myeloarchitecture. After detailed investigation of this rich variation in cortical cytoarchitectonics, pioneering anatomists von Economo and Koskinas published their monumental atlas (von Economo and Koskinas, 1925), reporting on a complete parcellation of the human cortex into 54 distinct cortical areas (and 107 detailed subregions) and quantitative data on cortical thickness and layer width (i.a.). Nowadays, Magnetic Resonance Imaging enables scientists to assess macroscale cortical thickness *in vivo*. Validating MRI cortical thickness measures by comparing von Economo whole-brain cytoarchitectural observations with MR-based cortical thickness estimates, we previously confirmed today's MRI technology as a good method for automated estimation of cortical thickness (Scholtens et al., in press). Extending these findings, we investigated the relation between regional von Economo individual cortical layer width and MR-based cortical thickness. The von Economo atlas includes a parcellation of the human cerebral cortex into 54 areas and regional cortical- and layer thickness data (von Economo and Koskinas, 1925). MR thickness estimates were derived from high-res MRI T1 data of 215+ subjects of the Human Connectome Project (Van Essen et al., 2013). Cross-technique analysis of cortical layer thickness was performed by correlation between mapped von Economo histological values and single hemisphere group-wise MR cortical thickness. MR-based total cortical thickness was associated with width of 5 out of 6 individual von Economo cortical layers (p=3.70x10-05, p=0.44 ns, p= 2.45x10-04, p=7.41x10-04, p=1.31x10-05, p=6.07x10-05, layer 1 to 6 resp.). Similar correlations were found within the von Economo data, where layer 3, 5 and 6 show a significant association with total cortical thickness, (p=2.84x10-14, p=8.11x10-13,

p=3.46x10-13). Examining the unique contribution of each layer to total MR thickness using multiple linear regression revealed the strongest unique contribution of layer 5 (β=0.742, p=0.0244), with layer 3 and 6 showing a trend-level effect, suggesting a unique contribution of these layers to the total cortical thickness, as derived by MR measurements. Comparing modern T1-weighted imaging to early histological findings of the von Economo atlas, we show von Economo individual cortical layer width to be associated with total cortical thickness as measured by MRI. Width of cortical layer 3, 5 and 6 shows the most consistent association, significantly contributing to total cortical width in both von Economo histological and MR-derived cortical thickness.

Title: Adolescent development of structural anterior cingulate cortex connectivity: meta-analysis of diffusion imaging studies

Authors: *S. D. LICHENSTEIN[1], E. E. FORBES[2], T. VERSTYNEN[3];
[1]Psychology, Univ. of Pittsburgh, Pittsburgh, PA; [2]Psychiatry, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [3]Psychology, Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Objective: The anterior cingulate cortex (ACC) has been implicated in a broad array of higher-order cognitive, affective and behavioral functions by virtue of its distributed connectivity with multiple neural networks. Protracted maturation of white matter pathways that facilitate ACC connectivity, including the cingulum and anterior thalamic radiations (ATR), may impact the course of psychosocial development across adolescence and into young adulthood. The aim of the current meta-analysis was to draw from existing studies of white matter development to establish whether maturation of structural ACC connectivity is ongoing throughout adolescence and thus represents a viable mechanism for the integration of cognitive, affective, and social neural networks that continues into young adulthood. Methods: Studies reporting linear, quadratic, or logarithmic relationships between age and fractional anisotropy

(FA) of the cingulum and/or ATR were selected for inclusion in the meta-analysis (cingulum: N=10 studies, N= 2067 total participants; ATR: N=7 studies, N=1633 total participants). Regression models reported for each pathway were used to simulate FA for each age within the range included in each study. FA values were then converted to z-scores in order to standardize across studies, producing estimates of the predicted direction and magnitude of change in FA at each age for each pathway. Simulated data from each regression model and each study were combined and linear and quadratic effects of age on FA across the lifespan (age 0-90) and within adolescence (age 10-20) were compared. Results: Significant quadratic effects of age on FA were found for the cingulum (age beta = 1.597, p = .000; age^2 beta = -2.096, p = .000) and ATR (age beta = .903, p = .000; age^2 beta = -1.616, p = .000) across the lifespan. Looking specifically at the adolescent period, a significant linear effect of age on FA was observed in both the cingulum (beta = .218, p = .000) and the ATR (beta = .168, p = .000), but no quadratic effects were observed. Conclusions: These results suggest that structural ACC connectivity continues to strengthen throughout adolescence, and may contribute to changes in functional connectivity and improvements in cognitive, affective, and social functioning during this period.

Title: Age of sign-speech bilingual language exposure and syntactic processing in deaf individuals with cochlear implants using functional near infrared spectroscopy (fnirs)

Authors: *L. PETITTO[1], A. STONE[2], D. ANDRIOLA[2], C. LANGDON[2];
[1]VL2, Galladet Univ., Washington, DC; [2]PHD PROGRAM IN EDUCATIONAL NEUROSCIENCE, GALLAUDET UNIVERSITY, WASHINGTON, DC

Abstract: Studies of bilinguals are a powerful tool for exploring language experience-dependent brain changes throughout the lifespan. While the age of first bilingual exposure correlates with a greater extent and variability in classic LH language tissue (Kovelman, Baker, & Petitto, 2008),

questions remain about the neural impact of different bilingual language experiences, including dual modality deaf bilinguals who learn a visual language and a spoken language via a cochlear implant (CI). Theories have been advanced that early visual language experience negatively alters classic LH spoken language sites. Here, we ask if early sign-speech bilingual exposure alters neural sites and systems associated with spoken language syntactic processing, testing two hypotheses: (1) Early sign-speech bilingual exposure renders typical neural development supporting syntactic processing. (2) Only early spoken language experience results in normal neural development; early sign-speech bilingualism disrupts typical LIFG recruitment for syntactic processing. Methods. Deaf CI adults (mean implantation age 3 yr) with early (0-4 yr) or late (4+ yr) ASL exposure performing an English (SO-OS) sentence judgment task while undergoing fNIRS neuroimaging. Like fMRI, fNIRS measures hemodynamic response, but has key advantages for studying language: good spatial/temporal resolution (SR 10x/sec); tolerates movement; safe for CI individuals (Shalinsky et al., 2009). Results. Behavioral data revealed similar group performance on measures of reaction time and accuracy. CI individuals with either early or late ASL exposure showed typical LIFG recruitment when reading English sentences. By contrast, late bilinguals showed a greater extent and variability in activation of LH language areas and bilateral inferior parietal lobules. Early sign-speech bilingualism did not disrupt typical development of LIFG tissue recruited for syntactic processing, findings that shed new light on how the age of sign-speech bilingual language experience can impact the development of language processing in deaf CI individuals. Early sign-speech bilingual exposure showed no negative impact on English syntactic processing. Yet, later sign-speech bilingual exposure was correlated with a greater extent and variability in LH neural recruitment, showing a similar "neural signature" observed in studies comparing early and late-exposed bilinguals using two spoken languages (Jasinska & Petitto, 2013; Kovelman et al., 2008). Of broad significance, early bilingualism, regardless of modality (signed or spoken), supports healthy neural development mediating language processing in all individuals.

Title: Exploring the anatomy and genetics of cortical asymmetries in surface area and thickness

Authors: *B. N. CIPOLLINI[1], H. BARTSCH[2], G. W. COTTRELL[1];
[1]Computer Sci., [2]Radiology, UC San Diego, La Jolla, CA

Abstract: We use MRI and genetic assessments from the cross-sectional PING study (Jernigan et al., 2015) to quantify and inter-relate cortical asymmetries during development, with over 1000 subjects in the 3-20 year old age range. These data include surface-based parcellations via FreeSurfer, with estimates of surface area and thickness per cortical region of interest. Ongoing work examines asymmetries in subcortical volume and fiber tract measures, as well as association with behavioral and familial background. We found that asymmetries are extremely consistent across age, gender, and handedness. Left hemisphere (LH) structure correlations was more similar to correlations amongst structure asymmetries than right hemisphere (RH), suggesting when structures are asymmetric, they covary more consistently in the LH. Multivariate analyses (PCA) showed little evidence of strong covariations across asymmetries, whether tested within a measure (surface area) or across all of them. Instead, the data indicate separable asymmetries for frontal pole, cingulate cortex, entorhinal cortex, and inferior frontal gyrus / superior temporal sulcus. We ran 8 preliminary genetic association studies; four with the top cortical area asymmetries, one summary statistic of brain-wide asymmetry, and one for each of the top component of the three PCA analysis we ran. Despite our modest sample size (~1200 subjects), in two of the analyses we found a significant association between our strongest asymmetry, in the cortical area of the frontal pole, and SNP rs17281622 ($p<3E-8$). This SNP resides closest to the STK31 gene on chromosome 7; the two other most significant SNPs (rs10278268 and rs6957300) also reside near or within STK31. STK31 has been associated with spermiogenesis, however it is expressed in the brain and its role in spermiogenesis is likely duplicated by other TDRD-family genes, leaving its functional role an open question. We validated our approach by replicating findings on cortical asymmetries from smaller MRI-based studies in both development and adulthood. We show small changes in thickness asymmetries over development, but an overall lack of change in cortical area asymmetry across the age range studied. We qualitatively match effect sizes of surface area asymmetries throughout the brain reported in adulthood. We also replicate the finding that a summary statistic of asymmetry across the brain correlates positively with brain size.

Abstract: Background: Neuropsychiatric disorders such as autism (ASD), ADHD, and schizophrenia (SCZ) share common symptomatic dimensions and evidence of concomitant neuroanatomical vulnerabilities may underlie joint clinical phenotypes. Here, we examined neuroimaging biomarkers under the hypothesis that convergence of diagnostic effects in select brain regions may indicate: 1. Involvement of the region in mediating specific neurocognitive functions, which are further; 2. Coincident with the common underlying deficit across disorders. **Methods**: Brain scans from 34 sites (N=2307; 1300/453/233/321, controls/ASD/ADHD/SCZ) were processed using the CIVET pipeline for cortical thickness (CT) estimation and the MAGeT Brain algorithm for subcortical surface area (SA). Effects of diagnosis on CT and SA were examined using mixed-model regression analysis, accounting for age, sex, intracranial volume as fixed, and site as the random effect. Peak regions were re-assessed by random effects meta-analysis. **Results**: Within individual disorders, we found both similar and distinct patterns of grey matter alterations: diffuse increases in CT along the left hemisphere in ASD, ADHD showed largely reductions, and SCZ with significant brain-wide decreases (Fig a, b). Once analyzed in conjunction, findings converged along the orbitofrontal cortex (OFC), and ventral striatum (VS), with consistent direction of effects across disorders (Fig c). **Conclusions**: We found common grey matter reductions in regions known to mediate multiple cognitive deficits across disorders, i.e. abnormal reward and emotion processing and social cognition (OFC, VS). Results suggest mutual structural anomalies, signifying shared deficits in symptom dimensions. Further, these regions are richly interconnected and indicate additional disruption of fronto-striatal circuitry apart from individual changes. These findings provide novel insights into shared patterns of altered neurodevelopment and aging across a large multi-site cohort, and illustrate potential for mutual biomarkers across multiple disorders.

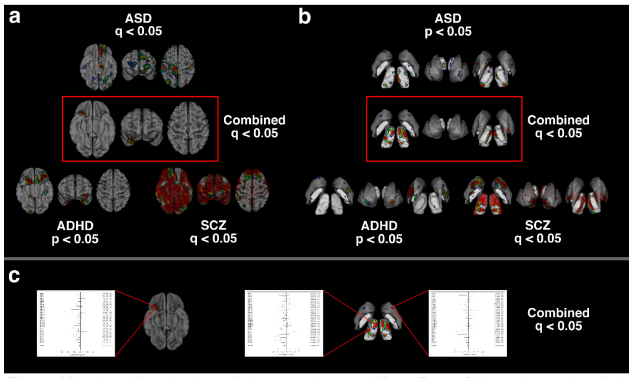

Figure. Mixed-model and meta-analysis regression, modelling effects of diagnosis on: a) cortical thickness and b) subcortical surface area. a, b) Within-disorder and combined mixed-model regression analysis. q < 0.05 indicates regions significant after FDR correction. Part of results in ASD and ADHD did not survive FDR correction. c) Meta-analysis within regions of peak significance for cortical thickness, thalamus, and striatum. Forest plots indicate magnitude and direction of disease-effects per site at the specified peak vertices.

Title: Individual structure-function relations within the default-mode network as a result of normal aging

Authors: ***M. AVRAM**[1], L. PASQUINI[2], J. BÄUML[2], V. RIEDL[3], C. SORG[4];
[1]Nuclear Medicine, Psychiatry, and TUM Neuroimaging Ctr., [2]Neuroradiology, TUM Neuroimaging Ctr., [3]Nuclear Medicine, Neuroradiology, TUM Neuroimaging Ctr., [4]Neuroradiology, Psychiatry, TUM Neuroimaging Ctr., Technische Univ. München, Muenchen, Germany

Abstract: Structure-function relationships, a pervasive topic in biology, are beginning to be well understood at the cellular level - for instance, different neuron types and their structural connections are intimately coupled with their function and correspondent activity (Honey et al., 2010). However, this correspondence remains unclear in neural systems, particularly at the level of macroscopic networks. In the present study we investigated whether structure-function

correspondence can be found in macroscopic networks in the individual brain, specifically in the default-mode network (DMN), and whether this correspondence is modulated by normal ageing. Resting state functional MRI data and structural MRI data was sampled for 23 young healthy subjects (mean age 26, 8 females) and 20 elderly healthy subjects (mean age 67, 13 females). We focused on two different measures, and their correspondence: (1) coherence of intrinsic activity - represented by functional connectivity (iFC) of ongoing blood oxygenation level dependent (BOLD) activity in selected intrinsic brain networks, and (2) brain structure - represented by cortical thickness. Independent component analysis was used to derive 25 components from iFC, reflecting a set of intrinsic brain networks and physiological noise. The component matching DMN was selected, and mapped via dual regression onto each subject's 4D dataset. Finally, individual DMN z-maps where projected into individual vertex-space. The output measure, structure-function correspondence (SFC), was determined by calculating the individual correlation coefficient (Spearman) of CT and iFC values within DMN. Results indicate positive SFC both at the individual and group level. In a second step, group differences were tested via an ANCOVA model using the number of vertices as a covariate of no interest. There was a significant effect of group (young > old) on SFC within DMN, $F(1, 161) = 6{,}86$, $p = .01$. The number of vertices had no effect on SFC, $p = .48$. We provide evidence that: (1) There is a positive relationship between iFC and CT in DMN in the individual brain, (2) SFC seems to be age dependent considering its decrease with normal ageing. These results are in line with previous work regarding the effects of ageing on the DMN measured either by iFC or CT (Damoiseaux et al., 2008; Kalpouzos et al., 2012). Thus, SFC could provide a valuable measure that may illustrate individual structure-function dynamics, and putative modulatory effects of biological processes such as ageing and pathology.

Title: Neurodevelopmental sex differences in response to emotional faces

Authors: J. C. SCOTT[1], K. RUPAREL[3], D. H. WOLF[2], T. SATTERTHWAITE[2], R. HOPSON[2], M. QUARMLEY[2], P. VILLA[2], R. E. GUR[2], *R. C. GUR[2];

Abstract: Background: Knowledge regarding developmental sex differences in affective processing across a broad age range is still limited, as most studies have had small samples or have focused on a narrow age range. Here, we aimed to examine developmental sex differences in affective processing in a large sample of children, adolescents, and young adults. Methods: From the Philadelphia Neurodevelopmental Cohort, 307 typically developing youths age 8-21 with no significant psychopathology underwent fMRI while performing a well-validated task of emotion identification. Sixty faces displaying neutral, happy, sad, angry, or fearful expressions were presented, and participants were asked to label the emotion presented. fMRI subject-level statistical analyses were conducted in FSL with motion correction parameters included as nuisance covariates. Voxelwise whole-brain analyses employed linear mixed-effects analysis (FLAME1). Task contrast maps were entered into second level analyses adjusted for task accuracy, participant race, and motion and with cluster correction for multiple voxelwise comparisons, and linear and nonlinear trends were tested. Results: Significant age by sex interactions in BOLD response were present in ventromedial and dorsolateral prefrontal cortex and the cuneus to all emotions versus baseline ($p<.05$). Follow-up analyses indicated that females evidenced linear increases in activation with increasing age in these regions, while males evidenced only slight decreases over time with increasing age. Conclusions: In a large sample of typically developing youth, we found developmental sex differences in response to emotional faces in ventromedial and dorsolateral prefrontal regions, such that females showed progressive increases in activation with age while males showed minimal age-related effects in these regions. These findings suggest maturational sex differences in circuitry responsible for the cognitive regulation of emotion. Notably, however, no significant age by sex interactions were found in the amygdala or other limbic circuitry. Nonetheless, longitudinal research is needed to more thoroughly probe developmental trajectories of brain response to affective processing.

Title: The influence of higher order regions on developing visual category specialization in children

Authors: *J. F. O'RAWE, A. HUANG, D. KLEIN, H.-C. LEUNG;
Stony Brook Univ., Stony Brook, NY

Abstract: Visual association areas along the ventral visual pathway exhibit selective activity in correspondence to different types of stimuli. This selectivity, however, seems to develop throughout childhood. Several neuroimaging studies have shown that face specific processing in the fusiform gyrus seems to emerge between the ages 8-15. Within this same time frame, brain regions which receive and send feedback projections to these visual association areas, such as the amygdala and posterior parietal cortex, are undergoing major developmental changes. To examine whether the development of these higher order regions influences the development of category specialization in visual association cortices, we collected both task and resting state fMRI data from a sample of 40 children (16 female) ages 9-12 (M = 10.4, SD = 0.93) using a 3T Siemens Trio System. The identity matching task was in a block design with 3 face conditions (happy, sad, and neutral faces) and a house condition as the control condition. The task blocks were intermixed in pseudorandom orders and separated by fixation blocks. Each participant performed one run, containing 3 blocks of each condition (12 total blocks; 6.2 minutes). In the resting state scan, we collected 11.7 minutes of fMRI data during which participants were instructed to fixate at a target of concentric circles. Univariate analysis of the task data revealed greater activity in response to faces than to houses in the typical nodes of the face processing network, including the fusiform gyrus, superior temporal sulcus, anterior temporal face patch, and the amygdala. The opposite comparison revealed activity in the typical nodes of the scene processing network, including the parahippocampal gyrus, retrosplenial cortex, transverse occipital sulcus, and posterior parietal areas. As shown in previous studies, we observed weaker activity in the face processing network compared to what has been observed for adults. Utilizing the resting state scans, we characterized the connectivity patterns of the amygdala and the superior parietal lobe, revealing substantial overlap in both the parahippocampal and fusiform gyri. Utilizing this region of overlap in the fusiform gyrus, we found that the variance in fMRI signal during the face blocks of our task could partly be explained by the interaction between activity in the amygdala and activity in the superior parietal lobe. Our results suggest that one possible contribution to the emergence of the specialization of visual association regions is the

recruitment of higher order brain regions that send feedback projections, presumably modulating activity in these regions.

Title: Reliability in engagement of maintenance and retrieval brain activation states underlies longitudinal improvements in working memory

Authors: ***D. F. MONTEZ**[1], D. SIMMONDS[1], B. LUNA[2];
[1]Neurosci., [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Working memory (WM) improves through adolescence largely due to age related decreases in the variability of responses. The neural basis for improvements in the reliability of WM performance is not well understood. The present study aimed to characterize trial-to-trial behavioral variability that can be attributed to variability occurring within purely motor or purely cognitive processes and to characterize the relative changes in their contribution to behavioral variability at different ages. We examined a mixed longitudinal cohort of subjects, between the ages of 8 and 30, as they performed a variant of the memory-guided saccade task during fMRI acquisition. We identified a set of canonical BOLD signal brain states, or whole-brain patterns of activity, that are associated with eye-movement motor responses, working memory maintenance, and memory-guided eye movements. We applied dimensionality reduction techniques to assess subject-level trial-to-trial variability of recruitment of networks supporting WM maintenance and retrieval as well as oculomotor performance. The results of our analyses demonstrate that performance of a spatial WM task relies on measurable independent contributions from motor and cognitive brain states. Variability in performance on individual trials is the result of differences in the degree to which motor and cognitive brain states are expressed on individual trials. We provide evidence that the magnitude of brain state variability in oculomotor systems is approximately fixed by late childhood but cognitive brain state variability _that variability associated with the maintenance and retrieval of spatial information_ continues to decrease during the same time. We therefore conclude that the primary driver of reduced behavioral

variability during adolescent development is the continued refinement of cognitive- and not occulomotor- related brain systems.

Title: Network modularity increases as the "social brain" matures: a gray matter covariance approach

Authors: *K. FETTICH[1], A. O. COHEN[2], K. S. BREINER[3], D. DELLARCO[2], A. GALVAN[3], B. J. CASEY[2], L. STEINBERG[1], J. M. CHEIN[1];
[1]Temple Univ., Philadelphia, PA; [2]Sackler Inst. for Developmental Psychobiology, Weill Med. Col. of Cornell Univ., New York, NY; [3]UCLA, Los Angeles, CA

Abstract: Adolescence is a sensitive period for social information processing, which is thought to rely on the functional and structural maturation of "the social brain" network (Blakemore, 2008). The maturation of this network, however, is not yet fully understood. The present study used gray matter covariance to characterize the modular architecture of the social brain network as it changes across development, from adolescence and adulthood, and investigated the hypothesis that the social brain network becomes more specialized (Bickart et al., 2014), and hence more modular with maturation. Subjects were 76 adolescents and 60 adults recruited through the MacArthur Foundation Research Network on Law and Neuroscience. Gray matter volumes were obtained for 15 structures bilaterally and entered into a symmetric covariance matrix that was binarized and FDR-thresholded (q=.01). The resulting matrix was then used to compute modularity, with significance testing implemented via Monte Carlo simulations with participant subsamples from each age group. For each subsample, an average cortical thickness score was also computed as an index of cortical maturation. Results indicate an inverse relationship between the structural modularity of the social brain network and global cortical thickness, r=-.412, p<.001. Networks derived from the adolescent subsamples had significantly thicker cortex means (M= 2.59, SD=.01; t(78) = 45.08, p<.001) and lower modularity (M=.66, SD=.18;t(57.38)=-3.71, p<.001) than did the networks derived from the adult subsamples

(thickness: M=2.49, SD=.01; modularity: M=.77, SD=.09). These findings suggest that, within the brain regions known to process social information, the relationships between regional volumes change with maturation, resulting in a more modular adult social brain architecture. Covariation in gray matter volume may result from functional specialization, and analyses of gray matter covariance could help advance our understanding of morphological maturation from a regional focus to a broader systems-level perspective.

Title: Effects of aging on T1, T2*, and QSM values in the subcortex using 7T MRI

Authors: *M. C. KEUKEN[1], A. SCHAFER[2], K. BACKHOUSE[1], S. BEEKHUIZEN[1], L. HIMMER[1], A. KANDOLA[1], J. LAFEBER[1], L. PROCHAZKOVA[1], A. TRUTTI[1], R. TURNER[2,1], B. FORSTMANN[1], P.-L. BAZIN[2];
[1]UvA, Amsterdam, Netherlands; [2]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Ultra-high field 7T MRI has made significant contributions over the last years in understanding the relationship between structure and function of the human brain. It allows the visualization of small subcortical structures with different tissue properties with tailored MRI sequences. However, the impact of structural changes associated with healthy aging on the visibility of such small subcortical structures remains largely unknown. In the present study, ultra-high field 7T MRI was used to segment the striatum, globus pallidus internal and external, subthalamic nucleus, substantia nigra, red nucleus, periaqueductal grey, as well as the lateral ventricles, 3th ventricle, aqueduct, and 4th ventricle in young (n: 30, mean age: 23.8, SD: 2.3), middle aged (n: 14, mean age: 52.5, SD: 6.6), and elderly healthy participants (n: 10, mean age: 69.6, SD: 4.6). The individual masks were used to extract the volume of the structure and the T_1, T_2^*, and quantitative susceptibility map (QSM) values. The volumetric measures generally showed a significant decrease with age in grey matter volume and an increase in ventricle

volume. The T1 values generally increased with age, likely reflecting a decrease in myelination, whereas the T2* and QSM values showed a more variable pattern reflecting the effect of increased iron deposition. In sum, the results of the present study indicate that structural changes in the subcortex associated with healthy aging influence the T_1, T_2^*, and QSM values differently, which may have an impact on structural delineations and volumetry. To characterise each subcortical structure better, it may be helpful to integrate multiple MR contrasts.

Title: How the inhibitory modulator GABA alters development, behavior and neuronal circuit function in *Drosophila*

Authors: *D. D MAHMOOD[1,2], N. DABBAIN[1], J. GRAFF[3], Z. MAJEED[1,4], R. L. COOPER[1]; [1]Biol., Univ. of Kentucky, Lexington, KY; [2]Biol., Univ. of Sulaimani, Sulaimani, Iraq; [3]Emory Univ., Atlanta, GA; [4]Biol., Univ. of Salahaddin, Erbil, Iraq

Abstract: *Drosophila* melanogaster is a simple model system that provides an advantage over vertebrates because of their less complex nervous system and the ability to make modifications genetically for studies on identifiable cells. Key questions in understanding the function of the central nervous system (CNS) in physiologic and pathologic conditions can be addressed in this system quickly and cheaply to develop a foundation which can be followed up in mammalian systems. Neuromodulators and neurotransmitters play a significant role in the activity of the CNS. Many studies address the effects of enhanced activity on synapse formation and axon growth but few address the effects of reducing activity or the effects of GABA, an inhibitor modulator in the brain. Our central research question is on the role of GABA, on the development and maintance of neural circuits and in relation to animal behavior. We examined the effects of administering varying levels of GABA to the organisms through tests on development, behaviors, olfaction, survival and physiology. The developmental time to pupation

and to eclosion as well as behavioral tests were also investigated. The larval development has been shown to be slowed in a dose-dependant manner with feeding GABA. Locomotive behavior was not altered, but mouth hook movements were reduced in the third instar larvae that were fed GABA. This study shows that GABA retarded larval development and altered behavior. We are now addressing GABA directly on the larval CNS and assessing neural activity as well as direct actions on the larval heart. Directly applying GABA onto exposed 3rd instar hearts unexpectedly increases the heart rate. This study has implications regarding dietary supplements and pharmacological agents used clinically that modify the GABAergic system in the CNS of humans. This multifaceted project is attempting to understand the effects of GABA on several levels from the exogenous aspects, to the altering of neuronal activity for the treatment of diseases. This study may help to address concerns of GABA being sold in common dietary supplements.

Title: Quantitative brain-wide mapping of GABAergic neuronal subtypes in mice

Authors: *Y. KIM[1], K. UMADEVI VENKATARAJU[1], K. PRADHAN[1], G. FITZGERALD[1], M. HE[2], J. LEVINE[1], Z. HUANG[1], P. OSTEN[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Inst. of brain science, Fudan university, Shanghai, China

Abstract: Recent advances in mouse genetic tools enable the identification and labeling of different neuronal subtypes, and promises to help in unraveling the cellular complexity of the mammalian brain. However, a lack of tools for quantitative brain-wide mapping of the genetically identified cell types has been a major constraint towards quantitative assessment of their distribution. Here, we use serial two-photon (STP) tomography and a data processing

pipeline, termed “qBrain” for quantitative brain-wide mapping, to provide the first whole brain quantification of three major cortical interneurons expressing parvalbumin (PV), somatostatin (SST) and vasoactive intestinal peptide (VIP). Our analysis reveals the numbers and densities of the three neuronal populations per anatomical regions of the Allen Mouse Brain Atlas and 3D sphere voxels. The three populations show distinct spatial patterns in cortical and subcortical regions. Furthermore, brain-wide statistical comparison between male and female brains revealed sexually dimorphic brain areas in SST neurons. In contrast to the relatively homogenous PV neurons, SST and VIP populations each contains subtypes. Thus, we used genetic intersectional approach to further distinguish SST subtypes co-expressing either calretinin (CR) or nitric oxide synthase (nNOS), and VIP subtypes co-expressing either CR or cholecystokinin (CCK). In the isocortex, both VIP/CCK and VIP/CR neurons are expressed mainly in the superficial layer. In SST intersection, SST/CR and SST/nNOS neurons are highly expressed in superficial and deep cortical layers, respectively. Our dataset provides a comprehensive resource for cell type-based manipulation experiments and *in silico* neuronal network modeling.

Title: SLC1A4 and SLC1A5 mediate transport of D-serine in brain

Authors: J. C. FARNSWORTH[1], G. E. LIND[1], B. R. LYDA[1], N. R. NATALE[2], *M. P. KAVANAUGH[3];
[1]Neurosci., [2]BMED Neurosci., [3]Univ. of Montana, Missoula, MT

Abstract: SLC1A4 and SLC1A5 constitute a subfamily of sodium-dependent amino acid exchangers within the SLC1 gene family that also contains the glutamate transporter subfamily. SLC1A4/A5 (ASCT1/2) are expressed in the CNS and they mediate transmembrane flux of many neutral amino acids including the eponymous substrates L-Ala, L-Ser, and L-Cys. SLC1A5/ASCT2 additionally displays selectivity for L-Gln. The functional roles of SLC1A4/A5 transporters in the brain remain largely unknown. D-serine is an endogenous co-agonist at

synaptic NMDA receptors and it plays critical roles in signaling and synaptic plasticity. The heteromeric sodium-independent amino acid transporter asc-1 (SLC7A10/SLC3A2) has been shown to mediate uptake of D-Ser, but many details of the homeostatic mechanisms controlling D-Ser levels in the CNS are not fully understood. As both L- and D-aspartate are recognized by homologous SLC1 glutamate transporter subfamily members, we examined D-Ser transport in Xenopus laevis oocytes expressing SLC1A4 and SLC1A5 and found that contrary to some reports in the literature, [3H] D-Ser was taken up by each and induced anion currents with Km values of 121 μM and 65 μM, respectively. We synthesized and characterized a novel molecule, (2S,3R,4R)-4-(biphenyl-4-ylmethoxy)-3-hydroxy-pyrrolidine-2-carboxylic acid (BOCA), that inhibited both SLC1A4/A5 transporters at nanomolar concentrations. Approximately one-half of [3H] D-Ser uptake in acute adult mouse brain slice was found to be Na-dependent and sensitive to block by BOCA, suggesting a critical role for SLC1A4/A5 transporters in the modulation of D-Ser levels in the brain. These results expand the repertoire of transport mechanisms in the brain for D-Ser. Importantly, as NMDAR dysfunction has been implicated in a number of neurodegenerative and psychiatric disorders, these transporters may become a critical therapeutic target, and blockers such as BOCA and its analogs could play a role in the treating these disorders.

Title: Role of ventral tegmental area glutamate neurons in behavioral reinforcement

Authors: *J.-H. YOO, V. ZELL, J. WU, A. JOHNSON, R. RESSLER, M. A. SHENASA, C. A. PUNTA, K. H. FIFE, N. A. GUTIERREZ-REED, T. S. HNASKO;
Neurosciences, UCSD, La Jolla, CA

Abstract: The ventral tegmental area (VTA) plays an important role in both positive and negative behavioral reinforcement. Recent physiological and neuroanatomical studies suggest that VTA glutamate neurons make functional synapses onto lateral habenula, ventral pallidum, nucleus accumbens and other limbic regions where they can co-release other transmitters, namely dopamine or GABA. Here we expand upon earlier physiological and anatomical studies and investigate whether selective optogenetic activation of VTA glutamate neurons promote behavioral reinforcement or avoidance. We find that photostimulation of VTA glutamate somata or terminals can lead to opposing and projection-target dependent effects on behavioral reinforcement. These results suggest that VTA glutamate neurons serve a unique and state-dependent roles in driving goal-directed behaviors

Title: Enzymatic biosensor measurements of dynamic, light-evoked release of the NMDA receptor coagonist D-serine in the retina

Authors: *E. C. GUSTAFSON[1], S. MARINESCO[2], R. F. MILLER[1];
[1]Neurosci., Univ. Minnesota, Minneapolis, MN; [2]Ctr. de Recherche en Neurosciences de Lyon, Univ. Lyon 1, Lyon, France

Abstract: D-serine is an essential co-agonist for activation of retinal ganglion cell NMDA receptors. The mechanisms that regulate D-serine availability to these receptors are poorly understood. To investigate these processes, we have utilized a biosensor that detects D-serine to nM levels. Biosensors were constructed by inserting a 25 μm diameter 90% Pt/ 10% Ir wire into a pulled glass capillary. A layer of m-phenylenediamine was place on the wire protruding from the glass to block non-specific oxidation. Then an enzymatic layer containing D-amino acid oxidase (DAAO) in a BSA solution was applied to the tip for D-serine sensitivity. Control electrodes were made by excluding DAAO from the final layer. We used a micromanipulator to manipulate the biosensors onto the surface of the retina in a mouse retina-eyecup preparation. Changes in electrode current, measured with a VA-10 amplifier (NPI Electronics), were monitored in response to light stimuli projected onto the retina as well as to responses during bath application of pharmaceutical agents. Biosensor currents showed a linear relationship with D-serine standards from 100 nM to 100 μM. A resting, background level of D-serine was determined by applying the D-serine degrading enzyme D-serine deaminase (DsdA). Following light simulation, a dynamic release of D-serine was measured. Application of pharmaceutical agents indicated that multiple mechanisms were involved in light-evoked D-serine release in the retina, including activation of glutamate receptors.

Title: Afferent inputs of transmitter-defined neuronal populations of the ventral tegmental area

Authors: *L. FAGET[1], J. DUAN[1], R. RESSLER[1], F. OSAKADA[2], E. M. CALLAWAY[2], T. S. HNASKO[1];

Abstract: The ventral tegmental area (VTA) has achieved a central status in the neural circuit control of behavioral reinforcement. Though generally considered a dopaminergic nucleus, the VTA contains substantial heterogeneity in neuron type, including both GABAergic and glutamatergic neurons. Understanding anatomical connectivity is essential to understanding how neural circuits control behavior. However little is known regarding how VTA neuron types, particularly VTA glutamate neurons, may be differentially regulated by distinct afferent inputs. We used a recently developed combinatorial viral approach using Glycoprotein-deleted Rabies virus (RVΔG) to transynaptically label afferent inputs to genetically identified dopamine, GABA, or glutamate neurons of the VTA. This approach enabled specific rabies virus replication and transynaptic transport in each of the VTA neuronal populations and the characterization of cell type-specific afferent inputs. We observed that nucleus accumbens, ventral pallidum, lateral habenula, hypothalamus, raphe nuclei, cortical and tegmental regions among others all send projections to each of the 3 transmitter-defined VTA cell types. Though afferent input is qualitatively similar, there appear to be quantitative differences suggesting specific inputs differentially target specific VTA cell types. Overall, these data shed important light on the organization of diverse inputs to VTA and to our understanding of the essential systems-level circuit structure of this important center in addictive behavior.

Title: A neurotensin-producing cell population of the subiculum forms glutamatergic synapses with both principal neurons of the entorhinal cortex and dentate gyrus

Authors: *N. I. CILZ, S. LEI;
Pharmacology, Physiology, & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: The perforant pathway is largely comprised of axons emanating from layer II stellate neurons of the entorhinal cortex (EC) that synapse on to granule cells of the dentate gyrus (DG). Previously, our lab has shown that exogenous application of neurotensin (NT) increases the excitability of layer II neurons in the EC and granule cells of the DG. These observations raise the question as to where endogenous NT may originate in order to influence this pathway. In an effort to address this question, we utilized a cre-lox genetic approach to selectively express channelrhodopsin-EYFP in NT-producing cell types. Consistent with previous NT expression studies, we found that EYFP expression is confined largely to the subiculum. Photostimulation of the local recording region elicits excitatory postsynaptic currents (EPSCs) in both EC and DG principal neurons. These EPSC's are completely blocked in the presence of tetrodotoxin (0.5 μM), confirming that photocurrents are generated in presynaptic neurons. Application of the AMPA receptor antagonist DNQX (10 μM) and NMDA receptor antagonist APV (50 μM) completely abolishes the EPSCs, indicating NT-producing neurons are glutamatergic. Prolonged stimulation hyperpolarizes postsynaptic EC neurons. These results offer preliminary functional insight into NT-producing neurons of the subiculum and this model will be used to further probe for endogenous actions of NT.

Title: The enzyme glutamate dehydrogenase is important for glutamate entrance in the tricarboxylic acid cycle in isolated nerve terminals

Authors: *M. C. HOHNHOLT, H. S. WAAGEPETERSEN;
Univ. of Copenhagen, Kobenhavn O, Denmark

Abstract: The enzyme glutamate dehydrogenase (GDH) catalyses the oxidative deamination of glutamate to alpha-ketoglutarate or the reverse reaction. This reaction connects major cellular pathways such as the tricarboxylic acid cycle and amino acid metabolism. Moreover, glutamate

is the most abundant excitatory amino acid in the brain and GDH might thus be important in neurotransmitter metabolism. To investigate the role of GDH in neuronal metabolism, nerve terminal endings (synaptosomes) were isolated from mice with a central nervous system specific deletion of glutamate dehydrogenase 1 (GDH1-deficient synaptosomes) or from control mice (control synaptosomes). The synaptosomes were incubated with 0.25 mM [U-13C]glutamate for 45 minutes and the occurrence of 13C-labelled metabolites was investigated by gas chromatography mass spectrometry. GDH1-deficient synaptosomes had a slightly higher cellular percent labelling of [U-13C]glutamate compared to control synaptosomes. But the first metabolite in the tricarboxylic acid (TCA) cycle generated directly from [U-13C]glutamate, [U-13C]alpha-ketoglutarate was significantly less labelled in GDH1-deficient synaptosomes compared to control. Other TCA cycle intermediates generated from [U-13C]glutamate, such as [U-13C]succinate, [U-13C]fumarate and [U-13C]malate were also less labelled in GDH1-deficient synaptosomes. In contrast, almost no differences in labelling in the isotopomers generated in the first turn of the TCA cycle, i.e. triple labelled alpha-ketoglutarate and double labelled succinate, fumarate and malate, were observed in GDH1-deficient synaptosomes compared to control synaptosomes. These data suggest that GDH plays an important role for the entrance of glutamate into the TCA cycle, but might not determine the subsequent cycling of glutamate-derived carbon in the TCA cycle.

Title: Actions of 3-hydroxykynurenine (3-HK), a tryptophan metabolite, on synaptic transmission in the mouse hippocampus and thalamus

Authors: *R. T. NGOMBA[1,2], S. A. NEALE[2,3], S. L. S. DUNN[2], R. SCHWARCZ[4], T. E. SALT[2];
[1]IRCCS Neuromed, Pozzilli 86077, Italy; [2]Visual Neurosci., UCL Inst. of Ophthalmology, London, United Kingdom; [3]Neurexpert Ltd, London, United Kingdom; [4]Maryland Psychiatric Res. Ctr., Dept. of Psychiatry, Univ. Maryland Sch. Med., Baltimore, MD

Abstract: The kynurenine pathway is a major route of tryptophan metabolism, and this pathway may be disturbed in several psychiatric and neurodegenerative disorders (Schwarcz *et al* 2012).

3-hydroxykynurenine (3-HK), a metabolite arising from tryptophan, is a precursor for several kynurenines, including xanthurenic acid (XA). We have previously shown that XA can reduce synaptic transmission in various brain areas, and that this may be related to inhibition of vesicular glutamate transport (VGluT) (Neale *et al* 2013, 2014). In order to investigate these pathways further, we studied the actions of 3-HK on synaptic transmission in the hippocampal dentate gyrus (DG) and the ventrobasal thalamus (VB), two brain areas that are involved in cognitive processes and psychiatric conditions. Either parasagittal (for DG) or horizontal (for VB) *in vitro* slice preparations were made from the brains of adult C57BL/6 mice. Recordings were made in an interface bath at ~33C. In the DG, stimulation of the perforant path with pairs of pulses (40 ms interval) resulted in excitatory post-synaptic field potentials (fEPSPs) that showed paired-pulse depression. Application of 3-HK (0.1-1 mM) resulted in a concentration-dependent depression of fEPSP amplitude (1 mM; 42 ± 11% depression), which reversed on washout. The paired-pulse ratio was unchanged by 3-HK. In comparison, we have shown that 10 mM XA was necessary to produce a comparable reduction of transmission in the DG (Neale *et al* 2013). In thalamic slices, extracellular multiunit spike recordings following stimulation of the internal capsule were made, revealing 86±3% of spikes occurring in bursts. Application of 1 mM 3-HK caused a reversible increase in the number of spikes recorded by 56±24%, however the proportion of spikes occurring in bursts did not change. Similarly, 1 mM XA caused a reversible increase in spikes by 53±40% with no change in the proportion of spikes in bursts. In summary, we have shown that 3-HK, the direct precursor of XA, has similar effects to XA in both hippocampus and thalamus. This finding is consistent with the idea that changes in 3-HK levels, either alone or by driving XA formation, produce effects on neuronal circuit function. This may be important in our understanding of how malfunction of tryptophan metabolism can cause neuropathological changes. Neale, SA *et al* (2013) Neuropsychopharmacol 38: 1060-1067. Title: High-throughput detection of Glycine in biological samples based on a novel enzymatic assay

Authors: G. E. CHAVARRIA, ***K. C. SCHMITT**, N. TIBREWAL, S. SADDAR, P. SAINI, G. TCHAGA, G. YAN;
Biovision, Milpitas, CA

Abstract: Glycine is the simplest of the twenty standard amino acids commonly found in proteins. Glycine functions as an important fast inhibitory neurotransmitter in the CNS, particularly in the spinal cord and brainstem. For example, spinal ionotropic glycine receptors regulate neuromotor function and skeletal muscle activity. Glycine also affects synaptic plasticity by acting as a co-agonist at NMDA receptors. Supplementation with exogenous glycine has been used in patients suffering from anemia, hypoglycemia, chronic fatigue, insomnia, obsessive compulsive disorder, epilepsy, memory disorders, and schizophrenia. Therefore, accurate and cost-effective detection methods are needed to validate the roles of glycine in neurological disorders. Traditionally, the concentration of glycine and other amino acids in clinical and non-clinical settings is determined by ELISA, NMR, HPLC, and Mass Spectrometry techniques, but these methods require expensive instruments and complex protocols that need to be performed by trained personnel. Enzymatic assays using one or more enzymes are routinely used for the detection of specific metabolites. Coupled-enzymatic assays are often preferred over complicated techniques due to the high specificity that enzymes show for their substrates, thus reducing potential interference. Additional advantages of enzymatic assays include superior reproducibility, high-throughput adaptability, and minimal sample requirement. BioVision, Inc. has developed the first Glycine Assay Kit using a coupled-enzymatic assay to detect this amino acid. The principle of the assay is based on the oxidation of glycine producing an intermediate that reacts with a fluorophore, producing a stable signal which is stoichiometrically proportional to the amount of glycine in the sample. The assay is glycine-specific and other standard and non-standard amino acids do not interfere with the assay. The assay is able to detect physiological concentration of glycine in a variety of biological samples utilizing 96-well plate and a microplate reader. Sample preparation is minimal and does not require laborious steps. In conclusion, BioVision's Glycine Assay Kit provides a unique, simple, sensitive, cost effective, and high-throughput assay for the detection of this amino acid.

Title: Molecular mechanisms of neuroprotection against hypoxia in a hyperglutamatergic state and the role of mitochondrial K+ channels and HIF1a

Authors: *E. K. MICHAELIS, D. HUI, R. PAL, M. L. MICHAELIS, X. WANG;
Dept Pharmacol & Toxicol, Univ. Kansas, Lawrence, KS

Abstract: Most investigations into the effects of glutamate (Glu) on neuronal survival have been focused on Glu-induced neurotoxicity. However, there is also evidence for the protection of neurons from stress following hyper-activation of Glu synaptic transmission. Such neuro-protection is mediated through synaptic Glu receptors and involves receptor-activated calcium signaling. However, the molecular pathways beyond the calcium-induced activation of transcription factors have yet to be fully defined. We observed [Badawi et al., Neurosci. Res. 2015, 93, 623-632] that hyper-glutamatergic synaptic activity in the brain of transgenic (Tg) mice that over-express glutamate dehydrogenase (Glud1) only in neurons [Bao et al., J. Neurosci. 2009, 29,13929-13944], can protect neurons following ischemia-reperfusion. To understand the molecular mechanisms for such neuroprotection, we probed for post-transcription mechanisms that might offer resistance to ischemia-reperfusion. We report that following ischemia the Tg mice have increased protein levels of the ATP-inhibited K+ channel (KCNJ1). Increases in the function of these channels in mitochondria protect cardiac and neuronal cells from ischemia/hypoxia. We identified a potential link to over-expression of KCNJ1 being the hypoxia-inducible factor 1a (HIF1a). Either induction of an hypoxia-like state or over-expression of HIF1a in cells in culture, led to increases in the expression of KCNJ1. We identified consensus sequences for HIF1a binding in the KCNJ1 promoter that are linked to the transcriptional activation by HIF1a. We recently also identified potential sites for epigenomic regulation of HIF1a and will continue to probe how these sites may be related to the effects of a hyper-glutamatergic state. Based on our observations, we advance the hypothesis that chronic increases in Glu synaptic transmission lead to increases in the expression of K+ channels in mitochondria and these increases are produced through upstream induction or stabilization of HIF1a, a transcription factor known to protect cells against many stresses. Title: Functions of novel RET isoforms in the nervous system

Authors: ***N. A. GABRESKI**[1], S. S. NOVAKOVA[2], J. VAGHASIA[2], B. A. PIERCHALA[1]; [1]Cell. and Mol. Biol. Grad. Program, [2]Biologic and Materials Sci., The Univ. of Michigan, Ann Arbor, MI

Abstract: Ret, a receptor tyrosine kinase that is activated by the glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs), plays a crucial role in the development and function of the nervous system, and additionally has important roles in kidney development and spermatogenesis. *RET* encodes a transmembrane receptor that is 20 exons long and produces two known protein isoforms differing in C-terminal amino acid composition, referred to as RET9 and RET51. Studies of human pheochromocytomas identified an additional two novel transcripts involving the skipping of exon 3 or exons 3, 4, and 5 and are referred to as $RET^{\Delta E3}$and $RET^{\Delta E345}$, respectively. Our analysis has revealed that these *RET* transcripts are also expressed in normal tissues of zebrafish, mice, rats and humans. Using reverse transcription PCR (RT-PCR) we have found that both splice variants are expressed in a wide array of tissues and at different ages in mice, and that these transcripts can have either a *Ret9* or *Ret51* c-terminal tail creating increased diversity of potential Ret proteins. The $RET^{\Delta E3}$ and $RET^{\Delta E345}$ isoforms are predicted to encode full-length Ret proteins with deletions in the extracellular domain, but their functional significance has not been established. Our *in vitro* analysis has shown that these proteins can interact with all four GFRα co-receptors, and that $RET51^{\Delta E3}$ can function as a GFL receptor while $RET51^{\Delta E345}$ can inhibit full-length RET51 activation. We are continuing experiments to identify the presence and the functions of these isoforms *in vivo*, particularly during development.

Title: TrkB modulates the function of Nav1.9 in activity-dependent axon growth in developing motoneurons

Authors: *R. BLUM, A. WETZEL, S. SAMTLEBEN, B. DOMBERT, S. JABLONKA, M. SENDTNER;
Univ. of Wuerzburg, Wuerzburg, Germany

Abstract: Embryonic motoneurons exhibit spontaneous electrical activity long before motor axons make synaptic contacts with the skeletal muscle. Spontaneous activity in cultured embryonic motoneurons is initiated by the voltage-gated sodium channel Nav1.9, providing an initial trigger signal for voltage-dependent calcium influx which then promotes activity-dependent axon growth. Several previous reports suggested that Nav1.9 opening may be promoted by the neurotrophin receptor TrkB, but evidence on direct interaction of these transmembrane proteins remained controversial. Here we studied the role of TrkB in spontaneous activity-dependent axon elongation in isolated motoneurons. In TrkB knockout motoneurons, BDNF effects on survival are reduced, but these cells can be supported by the neurotrophic factor CNTF. Interestingly, these TrkB-/- motoneurons exhibited a reduced frequency of spontaneous calcium transients in axons and growth cones, and this effect correlated with reduced axon growth. Similar observations were made with Nav1.9 deficient motoneurons. In order to study how TrkB modulates Nav1.9 in motoneurons, we developed a new mouse model for direct ER calcium imaging in motoneurons and hippocampal neurons. This mouse model should allow to investigate whether local calcium transients are initiated by TrkB signaling which then could lead to activation of Nav1.9 channels and subsequently to enhanced rates of spontaneous calcium influxes for regulation of axon growth, or whether Nav1.9 activation occurs in the absence of TrkB-mediated ER calcium release.

Title: Identification of nascent proteins synthesized locally in the axons of cultured rat cortical neurons

Authors: *C.-Y. WU;
Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Taipei, Taiwan

Abstract: Local protein synthesis has been proposed to play important roles in the growth, navigation and synaptogenesis of axons. More recently, it has been found that exposures to brain-derived neurotrophic factor (BDNF) and glutamate enhance local protein synthesis in the axons which have been severed from their cell bodies of rat cortical neurons in culture. Here, we

use MS spectrometric methodologies to identify the nascent proteins synthesized in axons without or with being subjected to glutamate or BNDF stimulation. We use bioorthogonal noncanonical amino acid tagging (BONCAT) method to label the nascent proteins in severed axons with biotin functional groups under various conditions. Proteins in the lysis of the axons are subjected to exhaustive trypsin digestion, and biotinylated peptides are pulled down by streptavidin beads. The collected peptides are then subjected to LC/MS/MS identification. A quantitative, comparative analysis among the nascent proteins locally synthesized in cortical axons without subjected to any stimulation and upon stimulation with glutamate and BDNF is also carried out. The above results will be presented in the poster. Our results will shed lights to how local protein synthesis may contribute to the various functions of axons at the basal level and upon exposure to stimulation with glutamate and BDNF.

Title: BDNF and TrkB are regulated by both pre- and postsynaptic activity and enhance presynaptic cPKC-betaI to modulate neuromuscular synaptic function

Authors: *M. A. LANUZA, E. HURTADO, L. NADAL, T. OBIS, A. SIMON, V. CILLEROS, N. GARCIA, M. M. SANTAFÉ, M. TOMÀS, J. TOMÀS;
Univ. Rovira i Virgili, Reus, Spain

Abstract: In the last few years, it has shown increasing evidence that one of the benefits of physical activity/exercise on the health of the CNS is to improve the synaptic function (Van Praag-H et al., 1999). Additionally, it is well accepted the preponderance of BDNF in mediating these benefits (reviewed by Gomez-Pinilla and Hillman, 2013). However, how an increase of synaptic activity-induced muscle contraction can modulate crucial aspects of neuromuscular synaptic function through BDNF and its receptor, TrkB, remains unknown. We have recently identified that PKC family is involved in neurotransmitter release when continuous electrical

stimulation imposes a moderate activity on the NMJ and that muscle contraction has an important impact on levels of presynaptic PKC isoforms, such as cPKCbetaI and nPKCepsilon (Besalduch et al., 2010; Obis et al., 2015). Accordingly, the present study is designed to test the hypothesis that muscle contraction is a key regulator of BDNF/TrkB signaling pathway activating presynaptic cPKC isoforms to modulate synaptic function. Results from ELISA and Western blotting techniques support that pre- and postsynaptic neuromuscular activity are both responsible for the increase of BDNF levels in the skeletal muscle (but not NT4) and that nerve induced-muscle contraction regulates TrkB-T1 without affecting TrkB-FL and p75 levels. Furthermore, our results show an involvement of BDNF induced by pre- and postsynaptic activity on regulation of the presynaptic classical cPKC isoforms (alpha and betaI) acting by a signaling pathway through TrkB. We use immunohistochemistry and confocal microscopy to demonstrate that cPKCbetaI is exclusively located in the motor nerve terminals on the NMJ. We also report by electrophysiological techniques and using a cPKCbetaI-specific translocation inhibitor peptide (betaI-V5-3) that cPKCbetaI is decisively involved in ACh release induced by electrical stimulation. Together, these results provide a mechanistic insight into how synaptic activity-induced muscle contraction could regulate the BDNF/TrkB signaling at the NMJ by enhancing BDNF production and decreasing the TrkB-T1 levels. It further suggests that this signalling pathway could increase presynaptic level of the cPKCbetaI isoform to affect neuromuscular neurotransmission.

Title: Dopamine function in ErbB4 mutant mice

Authors: ***M. SKIRZEWSKI**, I. KARAVANOVA, A. BUONANNO;
Section Mol. Neurobio., NIH/NICHD, Bethesda, MD

Abstract: Single nucleotide polymorphisms and a microdeletion in the genes encoding Neuregulin-1 (NRG1) and its receptor ErbB4, respectively, have been associated with schizophrenia (SZ), a neuropsychiatric disorder characterized by imbalances in brain dopamine (DA) function. Dysfunctional NRG1-ErbB4 signaling in brain areas such as hippocampus, pre-frontal cortex (PFC) and dorsal striatum may contribute to alterations in DA function, which in turn may explain several symptoms related to SZ. In addition, the number of parvalbumin (PV)-expressing fast-spiking basket cells, which also express ErbB4, are reduced in the postmortem dorsal PFC of schizophrenia patients and are implicated in the reduction of evoked gamma oscillations associated with cognitive deficits. We previously demonstrated that ErbB4 activation by NRG1 acutely increases extracellular DA levels in the rodent hippocampus, and regulates synaptic plasticity and local network activity by signaling through DA D4 and ErbB4 receptors (Kwon et al. (2008) PNAS 105:15587-92; Andersson et al. (2012) PNAS 109:13118-23). We also showed that NRG1 signals through a mechanism that requires both D4 and ErbB4 receptors to increase the power of kainate-induced gamma oscillations in hippocampal slices. Interestingly, both ErbB4 null and PV interneuron-restricted (PV-Cre;ErbB4f/f) mutant mice share several behavioral deficits with relevance to SCZ (Shamir et al. (2012) J Neurosci. 32:2988-97). The expression of ErbB4 in cortical interneurons and mesocortical/nigrostriatal tyrosine hydroxylase (TH) expressing DA neurons, which send efferent projections to the hippocampus, PFC and striatum, raises the question of the role NRG1/ErbB4 signaling in different neuronal sub-populations. Here we present preliminary experiments resolving behavioral and neurochemical differences between PV interneuron, TH-restricted or null ErbB4 mutant mice. This work was kindly supported by the Eunice Kennedy Shriver NICHD Intramural Research Program, NIH.

Title: Phenotypic assessment of mice with a loss of TrkB in serotonergic neurons

Authors: *A. STEINZEIG / SHTEINTCAIG, M. PRIYADARSHINI SAHU, E. CASTRÉN; Neurosci. Ctr., Neurosci. Center, Univ. of Helsinki, Helsinki, Finland

Abstract: Growing evidence indicates neurotrophins - factors providing neuronal growth and survival during development - are involved in pathophysiology of mood disorders (Nestler et al., 2002). Antidepressants, namely serotonin reuptake inhibitors increase brain level of brain-derived neurotrophic factor (BDNF) expression and the activation of its receptor TrkB, whereas altered BDNF level affect antidepressants action. Despite the evidence for interaction between BDNF-TrkB and serotonergic system (Martinowich&Lu, 2008), the mechanisms are poorly understood. To examine impact of TrkB receptor to the function of serotonergic system, we used the Cre/loxp system to delete TrkB from serotonergic neurons in a time-specific manner. We crossed two knockout mice strains: $Tph2^{CreERT2}$ and $TrkB^{loxP/loxP}$, to obtain $Tph2^{CreERT2}$:$TrkB^{loxP/loxP}$ mutants. In $Tph2^{CreERT2}$ strain, injections of tamoximen induce Cre-recombination selectively in serotonergic neurons. To induce Cre-mediated TrkB excision tamoxifen was administered 2 mg/mice daily for 5 days starting from PD42-45. Control group received similar course of corn oil injections. Group of $TrkB^{loxP/loxP}$ mice injected with tamoxifen served as an additional control. To confirm the specificity and efficacy of Cre-recombination we used $tdTomato^{loxP/loxP}$: $Tph2^{CreERT2}$ mice, expressing tdTomato fluorescent protein solely in the *Tph2*-positive serotonergic neurons in the raphe nuclei. Immunohistochemical staining revealed co-localization of Cre-positive and tdTomato-positive cells. Furthermore our results indicated that recombination was more efficient in males as compared to the females, therefore only males were used for our experiments. To study behavioral phenotype of the $Tph2^{CreERT2}$:$TrkB^{loxP/loxP}$ mice, we performed the tests for anxiety-like behavior: Light-dark, Forced swim test, Open field and Elevated plus maze after one month post tamoxifen injections. At the time-point investigated, mutant mice exhibit no remarkable behavioral differences as compared to the control animals. The weights of the animals were monitored before and after injections. There was no significant change between groups. Anxiety- and depression-like behaviors may not be triggered by deficits in BDNF/TrkB signaling alone, but rather, may require impairments in several other pathways. Our present model has no major behavioral effect, but a thorough study on other inter-related signaling pathways needs to be done. The interaction of these two major signaling pathway requires further investigation.

Title: A p75/Ret complex mediates programmed cell death in sympathetic neurons

Authors: *C. R. DONNELLY, N. A. GABRESKI, O. R. STEPHENS, M. A. CHOWDHURY, B. A. PIERCHALA;
Biologic and Materials Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: Target-derived neurotrophic factors, such as the neurotrophins and the glial cell-line derived neurotrophic factor (GDNF) family of ligands (GFLs) are crucial components aiding in the establishment of proper connections between neurons and their targets. In the peripheral nervous system (PNS), GFLs signal through their common receptor tyrosine kinase, Ret, to produce signals critical for neuronal survival, migration, and axonal growth. Recently, we have discovered that Ret associates with p75, a member of the tumor necrosis factor family of death receptors, in transfected cells *in vitro* and in brain, spinal cord, dorsal root ganglion sensory neurons, and superior cervical ganglion sympathetic neurons *in vivo*. This interaction is surprising because p75 is a critical mediator of apoptosis upon activation by proneurotrophins, while Ret is canonically involved in pro-survival signaling as a receptor for the GFLs. Interestingly, the interaction between p75 and Ret was increased upon stimulation of sympathetic neurons with brain-derived neurotrophic factor (BDNF) and proBDNF, both of which induce p75-dependent apoptosis in sympathetic neurons. These findings suggest a functional role of Ret in p75-mediated pro-apoptotic signaling. Consistent with this hypothesis, we find that knockdown of Ret in sympathetic neurons *in vitro* results in a reduction in BDNF-mediated apoptosis and a reduction in p75/BDNF-mediated activation of apoptotic effectors, including phospho-c-Jun and phospho-JNK. Furthermore, we find that genetic deletion of Ret results in a decrease in programmed cell death *in vivo*. Collectively, these data implicate Ret as a novel co-receptor for p75-mediated apoptosis. We suggest that these findings could have important implications for the mechanisms underlying the pathogenesis of gain-of-function mutations in RET resulting in Hirschsprung's disease in humans, and could more broadly have implications for the mechanisms governing apoptosis observed in many neurodegenerative disorders. Ongoing experiments are aimed at identifying the precise mechanism by which Ret is required for p75-mediated apoptosis, as well as the generalizability of this pro-apoptotic signaling complex in other neuronal populations.

Title: A time course of inflammation-driven changes in synaptic plasticity: the combined effects of aging and an immune challenge lead to long-lasting deficits in L-LTP in hippocampal area CA1

Authors: *N. TANAKA[1], G. P. CORTESE[2], R. M. BARRIENTOS[3], S. F. MAIER[3], S. L. PATTERSON[1];
[1]Biol., Temple Univ., Philadelphia, PA; [2]Dept. of Pathology and Cell Biol., Columbia Univ., New York, NY; [3]Dept. of Psychology and Neurosci., Unversity of Colorado, Boulder, CO

Abstract: Aging significantly increases brain vulnerability to negative life events. Cognitive function in older individuals often declines precipitously after events (surgery, infection, or injury) that trigger activation of the peripheral immune system. Even if the decline is temporary, its occurrence is associated with an increased probability of eventually developing dementia. Very little is known about the underlying mechanisms, but a rodent model offers some clues. Aged (24-month-old) Fischer Brown Norway (F344xBN) rats generally do not show significant physical or cognitive impairments. However, in response to signals triggered by a peripheral immune challenge (an intraperitoneal injection of E. coli), they mount an exaggerated inflammatory response in the brain. Their hippocampi produce more of the pro-inflammatory cytokine interleukin-1beta (IL-1β), and produce it longer than those of their younger (3-month-old) counterparts (Barrientos et al., 2009). In the aging animals, hippocampal IL-1β levels are significantly elevated 4 hours after infection and remain so for at least 8 days, but generally less than 14 days; in contrast, levels in young animals rise in response to infection but return to near basal levels within 24 hours. Interestingly, the prolonged elevation in IL-1β in aged animals is paralleled by prolonged, specific deficits in hippocampus-dependent long-term memory tasks. We have previously demonstrated that a memory related-form of long-lasting synaptic plasticity - theta burst-evoked late-phase long-term potentiation (L-LTP) - is reduced in the aged animals 4 days after the infection (Chapman et al., 2010). We have also reported that levels of the mature brain-derived neurotrophic factor (mBDNF) (the protein isoform thought to be required for long-term forms of memory and LTP) are reduced in aged rats at the same 4 day time point (Cortese et al., 2011). Here we extend these observations, and find that like the deficits in memory, the deficits in theta-burst L-LTP and mBDNF persist for the duration of the elevation in IL-1β.

These results are consistent with the hypothesis that an exaggerated brain inflammatory response, arising from aging and a secondary immune challenge, may be associated with a diminished capacity to provide the BDNF needed for stabilization of memory-related plasticity at synapses in the hippocampus. This also suggests the possibility that dysregulation of immune function may contribute to dysregulation of BDNF-dependent synaptic plasticity in a variety of conditions with an inflammatory component (Ex. autoimmune disorders, depression, PTSD, autism spectrum disorders).

Title: Stimulus-specific combinatorial functionality of neuronal c-fos enhancers

Authors: *J.-Y. JOO, T.-K. KIM;
Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The c-fos gene is induced by a broad range of stimuli, and has been commonly used as a reliable marker for neural activity. Its induction mechanism and available reporter mouse lines are exclusively based on the c-fos promoter activity. Here, we demonstrate that multiple enhancers surrounding the c-fos gene are critical for ensuring robust c-fos response to various stimuli. Membrane depolarization, brain-derived neurotrophic factor (BDNF), and Forskolin activate distinct subsets of the enhancers to induce c-fos transcription in neurons, suggesting that stimulus-specific combinatorial activation of multiple enhancers underlies the broad inducibility of the c-fos gene. Accordingly, the functional requirement of key transcription factors varies depending on the type of stimulation. Combinatorial enhancer activation also occurs in the brain. Providing a comprehensive picture of the c-fos induction mechanism beyond the minimal promoter, our study should help in understanding the physiological nature of c-fos induction in relation to neural activity and plasticity

Title: Inhibition of GABAregic synapses removes exercise-induced expression of nerotrophins in the motor cortex

Authors: *H. MAEJIMA[1], N. KANEMURA[2];
[1]Hokkaido Univ., Sapporo, Japan; [2]Dept. of Physical Therapy, Saitama Prefectural Univ., Koshigaya, Japan

Abstract: Neurotrophins positively modulate neuronal survival and plasticity in the brain. Physical exercise up-regulates the expression of neurotrophins including BDNF and NT-4 in the brain. GABAA is the most common neurotransmitter associated with IPSP in the brain. Recent reports indicate that the inhibition of GABAregic synapses in the hippocampus enhances neural plasticity associated with the increased expression of BDNF. The objective of the present study was to investigate the effects of exercise and the inhibition of GABAegic synapses on the expression of neurotrophins in the mouse motor cortex. ICR mice at 15 weeks of age were assigned to four groups based on two factors (exercise and the inhibition of GABAregic synapses). The mice in the exercise groups performed moderate treadmill exercise (15 m/min, 60 min) every day. The inhibition of GABAregic synapses was induced by intraperitoneal administration of GABAA receptor antagonist (picrotoxin, 1mg/kg). The intervention composed of exercise and picrotoxin administration was continued for 10 days. After the intervention, the motor cortex was deprived for quantitative PCR analyses. The mRNA expression of neurotrophins (BDNF and NT-4), and TrkB receptor of BDNF and NT-4 in motor cortex was measured based on real time PCR. Additionally, the expression of c-fos was measured as a maker of neural activity. All procedures were approved by the ethics committee for animal research of Saitama Prefectural University. After the intervention for 10 days, where exercise significantly increased the expression of BDNF and NT-4, picrotoxin administration to sedentary mice showed no effect on the expression of tneurotrophins. On the contrary, picrotoxin administration to exercised mice significantly decreased the expression of BDNF and NT-4 to the level of sedentary mice, indicating that picrotoxin administration removed the exercise-induced up-regulation of BDNF and NT-4. Interestingly, c-fos expression was also significantly decreased by picrotoxin administration in exercised mice. There was no effect of exercise and picrotoxin administration on the expression of TrkB. Taken together, the present study elucidated

that GABAA receptor blockade negatively modifies exercise-induced up-regulation of neurotrophins and neural activity in the motor cortex. It was suggested that, unlike the positive modification by GABAA receptor blockade in the hippocampus, exercise in the presence of regulated neuronal balance between EPSP and IPSP is crucial for the up-regulation of neural activity and the expression of neurotrophins in the motor cortex.

Title: Physical exercise-induced improvements of behavior and neuroplasticity are impaired in the BDNF Val66Met knock-in mice

Authors: A. IERACI[1], A. I. MADAIO[1], *A. MALLEI[1], F. S. LEE[2], M. POPOLI[1];
[1]Univ. degli Studi di Milano, Milano, Italy; [2]Dept. of Psychiatr, Cornell Univ., New York, NY

Abstract: Several lines of evidence suggest that physical exercise (PE) is an affordable and effective method to improve cognitive functions and mood at all ages, even in the elderly. Positive effects of PE have been associated with enhanced neuroplasticity, hippocampal neurogenesis and increased levels of brain-derived neurotrophic factor (BDNF). However, a considerable variability of individual responses to PE has been reported. The reason for this is not known, but may be accounted for by individual genetic variants. A common single nucleotide polymorphism (SNP) has been identified in the BDNF human gene (BDNF Val66Met) that leads to decreased BDNF secretion and has been associated with cognitive impairment and mood disorders. Recently, a knock-in mouse carrying BDNF Val66Met polymorphism, which reproduces core phenotypes identified in Val66Met human carriers, has been generated. Despite the well-documented role of BDNF as mediator of the beneficial effects of PE, it is presently unknown whether the BDNF Val66Met SNP influences the degree to which an individual may benefit from PE. To study whether and how the BDNF Val66Met polymorphism impacts the neurobiological effects induced by PE, we evaluated behavioral changes, hippocampal neurogenesis modifications and gene expression variations induced by 4 weeks of voluntary running in wild type ($BDNF^{Val/Val}$) and homozygous BDNF Val66Met

knock-in ($BDNF^{Met/Met}$) male mice. We found that PE decreased the latency to feed in the novelty suppressed feeding and the immobility time in the forced swimming test in $BDNF^{Val/Val}$ but not $BDNF^{Met/Met}$ mice. PE-induced hippocampal neurogenesis was reduced in $BDNF^{Met/Met}$ mice compare to $BDNF^{Val/Val}$ mice. PE significantly increased total BDNF mRNA, BDNF spliced variants 1, 2, 4, 6 and mGluR2 in the dentate gyrus of $BDNF^{Val/Val}$ but not in $BDNF^{Met/Met}$ mice. $BDNF^{Met/Met}$ mice had lower basal BDNF protein levels in the hippocampus that did not increase following PE treatment. Overall these results showed that the BDNF Val66Met polymorphism impairs the beneficial behavioral and neuroplasticity effects induced by PE in adult male mice.

Title: Probing the novel relationship between a transcriptional regulator of the cell cycle, Late Simian Virus 40 Factor, neurogenesis and epilepsy

Authors: *K. HOKENSON[1,2,3], U. HANSEN[4], A. R. BROOKS-KAYAL[5], S. J. RUSSEK[1,2,3]; [1]Pharmacol. and Exptl. Therapeut., [2]Program in Biomed. Neurosci., [3]Lab. of Translational Epilepsy, Boston Univ. Sch. of Med., Boston, MA; [4]Biol., Boston Univ., Boston, MA; [5]Pediatrics, Div. of Neurol., Univ. of Colorado Denver - Anschutz Med. Campus, Denver, CO

Abstract: Epilepsy is a neurological condition that causes recurrent, unprovoked seizures and is poorly understood. Our lab previously established a role for brain-derived neurotrophic factor (BDNF) in epilepsy, through regulation of GABAR subunits through activation of the Janus kinase (JAK)/Signal Transducer and Activators of Transcription (STAT) pathway. The pathophysiology of some types of epilepsy is thought to involve neurogenesis, the formation of new neurons from progenitor cells, in the dentate gyrus of the hippocampus. Late Simian Virus 40 Factor (LSF) is a transcription factor that plays a ubiquitous role in regulating cell cycle progression and cell survival and has been implicated in a number of diseases, including Alzheimer's disease (AD). The major site of phosphorylation by Erk on LSF is serine 291, while transient phosphorylation occurs at serine 309 by cyclin C/CDK2, in early G1. As cells progress through G1, LSF is dephosphorylated at both sites, and phosphorylation by Erk and cyclin

C/CDK2 at the G0/G1 transition down-modulates the activity of LSF during passage through G1. Our studies were designed to examine the role of LSF in neurons with the promise of learning more about neurogenesis and its role in epileptogenesis. We found that BDNF induced the phosphorylation of LSF at serine 291 in hippocampal and cortical primary neuron cultures, while levels of total LSF or p309 LSF did not change. *In vivo,* we found increased phosphorylation of p291 LSF in the hippocampus of rats with pilocarpine-inducted model of status epilepticus (SE), compared to control rats. Potassium chloride (KCl; 20mM for 2 hours) treatment did not affect phosphorylation of LSF at serine 291 LSF at days 7 or 14 *in vitro*. Using immunocytochemistry, we co-labeled with NeuN, a neuronal marker, and either total LSF, p291 LSF, or p309 LSF, and found that all forms of LSF are present in cortical and hippocampal neurons. Using Click-It EdU kit to label proliferating cells, we found decreased levels of p291 LSF within proliferating cells. EdU-positive neurons co-labeled for Nestin, but did not co-label for MAP2. Comparing protein levels of p291 LSF in adult brain regions that are relevant to neurogenesis, we found levels of p291 LSF differed significantly between the cortex, hippocampus, and olfactory bulb. Olfactory bulb had the highest levels, followed by hippocampus, while cortex had the lowest levels of p291 LSF. Cortex contained only one p291 LSF protein band, while hippocampus and olfactory bulb contained two p291 LSF protein bands near 63 kDa. Our results suggest that LSF phosphorylation may be mediated by BDNF signaling, which could potentially influence neurogenesis and epileptogenesis.

Title: Physiological role of TGF-β1 in hippocampal synaptic plasticity and memory

Authors: *D. PUZZO, W. GULISANO, C. A. GUIDA, A. A. R. IMPELLIZZERI, F. DRAGO, A. PALMERI, F. CARACI;
Univ. of Catania, Catania, Italy

Abstract: Transforming Growth Factor β1 (TGF-β1) is a cytokine involved in the control of cell growth, differentiation as well as immune suppression and repair after injury. In addition to its well-known neuroprotective and neurotrophic properties, it has been recently reported a possible role of TGF-β1 in synaptic transmission. However, its involvement in physiological mechanisms underlying synaptic plasticity and memory at hippocampal level has not been thoroughly investigated. Here, we aimed to examine the role of TGF-β1 in hippocampal long-term potentiation (LTP) and memory in adult wild type mice. For this purpose, we first performed electrophysiological studies to assess the effect of exogenous TGF-β1 on CA1 LTP and phosphorylation of the transcription factor cAMP-Responsive Element Binding protein (CREB). Then, we investigated the role of endogenous TGF-β1 in hippocampal synaptic plasticity, recognition memory and phospho-CREB levels by blocking its signaling pathway with SB431542, a selective inhibitor of the activin-like kinase (ALK) 5 TGF-β type I receptor. Finally, we examined the involvement of p-SMAD2, a TGF-β1 downstream pathway effector. We found that administration of exogenous TGF-β1 was able to convert early-phase-LTP into late-phase-LTP. Furthermore, the block of the endogenous TGF-β1 signaling pathway by SB431542, impaired LTP and object recognition memory. The latter impairment was rescued by administration of exogenous TGF-β1. TGF-β1 functional effects correlated with an increased expression of the phospho-CREB. Moreover, SB431542 selectively inhibited both the phosphorylation of SMAD2 and p-CREB, which was rescued by TGF-β1 treatment, thus suggesting a similar trend between p-SMAD2 and p-CREB levels. These findings suggest that endogenously produced TGF-β1 plays a key role in physiological mechanisms underlying LTP and memory.

Title: Generation and characterization of a brain derived neurotrophic factor (BDNF rs6265) knockin rat

Authors: *C. E. SORTWELL, C. J. KEMP, J. W. LIPTON, A. COLE-STRAUSS, F. P. MANFREDSSON, N. M. KANAAN, M. F. DUFFY, N. MARCKINI, T. J. COLLIER; Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI

Abstract: A highly prevalent variant in the brain derived neurotrophic factor (BDNF) gene exists in the general population (rs6265: val66met 35.4%, met66met 5.2%). Both the heterozygous major allele and homozygous minor allele of BDNF rs6265 result in a disruption of packaging and release of activity-dependent BDNF, whereas constitutive release of BDNF is unaffected. In humans, BDNF rs6265 variant status has previously been shown to impact grey matter volume during aging, memory performance, obesity, anxiety and depression as well as influence the therapeutic efficacy of antidepressants and antipsychotics. Further, we have previously shown that rs6265 allele status impacts rate of symptom progression in early, unmedicated Parkinson's disease subjects as well as response to anti-parkinsonian medication. Existing transgenic BDNF val66met and met66met mice recapitulate many of the human features associated with this variant however a rat model of BDNF rs6265 would offer distinct advantages. Rats have more complex cognitive and motor behaviors and are more similar to humans in their genetics and pharmacokinetics than mice, suggesting that results of therapeutics tested in rats would provide greater predictive validity than mice. The greater synaptic complexity observed in the rat brain compared to mice indicates that neural plasticity may be better modeled in the rat. On a practical level, the larger brain and body size of the rat allows researchers to harvest more tissue and fluid samples, enables neurosurgical interventions and *in vivo* electrophysiology, facilitates intrathecal drug delivery and can allow for neuroimaging procedures that can be more difficult in mice. With these advantages of the rat in mind, we generated a val68met BDNF knockin rat (corresponds to human val66met due to two additional Thr in rat Bdnf at positions 57 and 58) using nuclease-mediated genome editing technology (Cyagen). Two val68met founder females were generated on the Sprague Dawley background and have been successfully bred to homozygosity. BDNF val68val, val68met and met68met genotype has been verified via custom-designed TaqMan SNP genotyping assay. No breeding issues have arisen and both heterozygous and homozygous rat pups are viable and healthy for at least 6 months. Ongoing studies will examine the integrity of the nigrostriatal system as well as whole tissue and depolarization-dependent BDNF levels. This novel rat model can serve as a platform for studying the role of this prevalent BDNF rs6265 single nucleotide polymorphism in neurological disease and therapeutic mechanisms.

Title: Loss of brain-derived neurotrophic factor (BDNF) signalling in cortico-limbic interneurons contributes to synaptic imbalance and abnormal social behaviour in mice

Authors: *S. TAN[1,2,3], Y. XIAO[1], Y.-C. YEN[1], H. YIN[4], T. W. SOONG[3], H. S. JE[1,3];
[1]Duke-NUS Grad. Med. Sch., Singapore, Singapore; [2]NUS Grad. Sch. for Integrative Sci. and Engin., Singapore, Singapore; [3]Yong Loo Lin Sch. of Medicine, Natl. Univ. of Singapore, Singapore, Singapore; [4]Duke Inst. for Brain Sci., Durham, NC

Abstract: The execution of complex behaviour is dependent on the establishment of a tight balance between inhibition and excitation in cortico-limbic circuits of the mammalian brain. Developmental disruptions to either component have been implicated in neuropsychiatric disorders. BDNF is an important trophic factor for the developmental maturation of inhibitory neurons and their synaptic transmission. Due to the lack of genetic knockout mouse models, behavioural consequences of impaired BDNF signaling in cortico-limbic inhibitory neurons have not been elucidated. Therefore, we generated conditional knockout mice in which tropomyosin receptor kinase B (TrkB), the cognate receptor for BDNF, is ablated from a subset of cortico-limbic interneurons. Although their motor coordination and movement were not impaired, these mice exhibited abnormal social behaviour. Furthermore, electrophysiological analysis revealed an imbalance between excitatory and inhibitory neurotransmission within layer V local microcircuit of the prelimbic area in these mice. Taken together our results suggest a critical role of cortico-limbic interneuron BDNF-TrkB signalling in complex social behaviour. Disruptions to this pathway may underlie some of the abnormal behaviour present in neuropsychiatric disorders.

Title: BDNF levels mediate constitutive activity of ERα and ERβ, but not GPER in neuro-2A cells

Authors: *B. O. OGUNLADE[1], M. R. DESHOTELS[2], E. SPINU[2], A. G. ROBINSON[3], K. MANAYE[4], C. M. FILIPEANU[5];
[1]Howard Univeersity, Washington, DC; [2]Dept. of Pharmacol. and Exptl. Therapeut. and cardiovascular centre of excellence., Louisiana state Univ., New Orleans, LA; [4]Dept. of Physiol., [5]Dept. of Pharmacol., [3]Howard Univ., Washington, DC

Abstract: The neuroprotective effects of estrogens in CNS are well recognized but the receptors and the signaling pathways underlying these effects remain elusive. To start elucidating these aspects, in the present study we investigated the effects of exogenous expression of the estrogen receptors on neuronal differentiation and signaling of Neuro-2A cells. This cell line was selected because it retains the ability to differentiate toward a neuronal phenotype in presence of appropriate stimuli. Further, we found by both RT-PCR and western blot that Neuro-2A cells do not endogenously express either typical estrogen receptors ERα and ERβ, or the estrogen-related G-protein coupled receptor GPER. Transfection of neuro-2A cells with ERα, ERβ or GPER resulted in a marked increase of the number of cells bearing neuritis (25 ± 6.1%, 31± 8%, and 34±6% respectively, compared to control 15±4%). Surprisingly, treatment with the estrogen receptor ligands 17β-estradiol (100 nM, membrane permeable) and BSA-17β-estradiol (100 nM, membrane impermeable) did not further increase the number of differentiated cells. Also, the estrogen receptor ligand ICI-182,780 (100 nM) was without effect. The expression of ERα, ERβ or GPER was also accompanied by significant enhancement of basal cAMP cellular levels compared to cells transfected with empty vector. Brain derived neurotrophic factor (BDNF) mRNA levels were significantly enhanced by expression of ERα and ERβ, but not by expression of GPER. As in the case of neurite outgrowth experiments, 17β-estradiol, BSA-17β-estradiol and ICI-182,780 do not further change the responses observed after estrogen receptor expression. In conclusion, our results demonstrate that all three estrogen receptor subtypes are involved in neuronal differentiation of Neuro-2A cells. In addition ERα, ERβ and GPER appear to be constitutive active in this cell line, modulating cellular activity in absence of cognate ligands. BDNF is essential in responses induced by typical receptors ERα and ERβ, but not in the effects

of GPER. Supported by Latham Foundation and startup funds from Howard University (to CMF) and NIA/NIH HUADAR1R25AG047843-01 (to KM). Keywords: Estrogen Receptors, Neuronal Differentiation, and BDNF

Title: Endocannabinoid-BDNF interactions at cortical excitatory synapses

Authors: ***M. L.-W. YEH**, R. SELVAM, E. S. LEVINE;
Neurosci., Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Endocannabinoids (eCBs) and neurotrophins, particularly brain-derived neurotrophic factor (BDNF), are potent neuromodulators that are highly expressed throughout the mammalian neocortex. Both eCBs and BDNF play critical roles in many behavioral and neurophysiological processes and are primary targets for the development of novel therapeutics, specifically in relation to depression, anxiety and schizophrenia. In mammalian neocortex, eCBs and BDNF bind primarily to the type 1 cannabinoid receptor (CB1R) and the high affinity trkB tyrosine kinase receptor, respectively. These receptors are expressed throughout the cortical mantle, with the highest levels of both trkB and CB1Rs found in layers II/III and V. Our laboratory and others have previously established that at glutamatergic synapses in these cortical layers, BDNF rapidly potentiates excitatory transmission by enhancing presynaptic glutamate release and modulating NMDA receptors. In contrast, we have recently shown that BDNF attenuates inhibitory transmission by inducing postsynaptic release of eCBs that act retrogradely to suppress GABA release from presynaptic terminals. It is not known whether BDNF also induces release of eCBs at excitatory synapses, which could have a mitigating or opposing effect on the direct effects of BDNF at these synapses. Here, we investigate the physiological interactions between eCBs and BDNF at excitatory synapses in layer V using acute slices from mouse somatosensory cortex. Consistent with previous results, we observed an increase in the frequency but not amplitude of spontaneous AMPA-mediated miniature excitatory postsynaptic currents (mEPSCs) after bath

application of 0.2 nM BDNF. We also observed an increase in mEPSC frequency following exposure to the specific CB1R antagonist SR141716A, suggesting that tonic eCB signaling is present at these terminals. Bath perfusion of BDNF in the presence of SR141716A typically resulted in a greater increase in mEPSC frequency than BDNF alone, suggesting that BDNF-trkB signaling induced the release of eCBs at these excitatory synapses. We are also using immunohistochemistry to examine colocalization of trkB and CB1R at glutamatergic synapses. These observations bolster the growing evidence for cross-talk between eCB and BDNF signaling at cortical synapses.

Title: SNAREs mediate BDNF secretion essential for the development of callosal axons

Authors: *M. SHIMOJO[1,2], J. COURCHET[3], S. PIERAUT[2], N. TORABI-RANDER[2], M. HIGUCHI[1], F. POLLEUX[3], A. MAXIMOV[2];

Abstract: Neurons employ a diverse repertoire of trafficking organelles for the secretion of soluble cargo molecules and recycling of membrane constituents, and these mechanisms are essential for the circuit development and functional maintenance of the mammalian brain. Recent studies have identified core components of the secretory machinery that elicit the release of neurotransmitters from presynaptic terminals. Synaptic vesicle exocytosis is mediated by a ternary complex of SNARE (Soluble NSF Attachment Protein Receptor) proteins, represented by

a composition of synaptobrevin/VAMP2 (Syb2), SNAP25 and Syntaxin1, which facilitates membrane fusion. A variety of diffusible peptide cues also appear to be transported by dense core vesicles and undergo exocytosis, supporting the hypothesis that diverse SNAREs independently contribute to different types of membrane fusion. Among such peptide cues, the brain-derived neurotrophic factor (BDNF) is known to play critical roles in the development and homeostatic maintenance of the nervous system. However, the molecular mechanisms that control the secretion of BDNF and other diffusible protein cues remain largely unknown. Here, we demonstrate that, using total internal reflection fluorescence microscopy and BDNF fused to pH-sensitive GFP variant super-ecliptic pHluorin, activity-dependent exocytosis of BDNF from somatodendrites and axons of primary cortical neurons is mediated by SNARE proteins Syb2 and SNAP25, indicating that these SNAREs act in multiple secretory pathways. Importantly, axonal secretion of BDNF is also specifically regulated by SNAP47, one of the uncharacterized neuronal SNARE protein, suggesting this molecule plays as a part of unique SNARE complex fundamental to peptidergic vesicular release. Furthermore, during the development of mouse brain, shRNA mediated knockdown of SNAP47 in layer II/III pyramidal neurons of somatosensory cortex by *in utero* electroporation impairs the targeting and terminal branching of callosal commissure axons *in vivo* with cell-autonomous manner, similar to knockdown of BDNF and its receptor TrkB. Taken together, these novel combinatorial SNARE functions in BDNF secretion provide an important insight for neuronal circuit connectivity and brain development.

Title: Effects of BDNF, proBDNF and fluvoxamine on NO release from activated rodent microglial cells

Authors: ***Y. MIZOGUCHI**, Y. HARAGUCHI, H. NABETA, Y. IMAMURA, A. MONJI; Dept. Psychiatry, Fac. Medicine, Saga Univ., Saga, Japan

Abstract: Microglia are immune cells which release many factors, including proinflammatory cytokines, nitric oxide (NO) and neurotrophins, when they are activated after the disturbance in

the brain. There is increasing evidence suggesting that pathophysiology of neuropsychiatric disorders is related to the inflammatory responses mediated by microglia. Brain-derived neurotrophic factor (BDNF) is a neurotrophin well known for its roles in the activation of microglia as well as in the pathophysiology and/or the treatment of neuropsychiatric disorders. We have previously reported that pretreatment of BDNF significantly suppressed the release of NO from activated microglial cells, possibly mediated by sustained store-operated calcium entry (SOCE) induced by BDNF. Although BDNF is initially translated as the precursor proBDNF, which binds p75 neurotrophin receptor (NTR), it remains obscure whether proBDNF affects the release of NO from activated microglial cells. We observed that pretreatment of proBDNF significantly potentiated the release of NO from activated microglial cells. RT-PCR and immunocytochemical techniques revealed that p75NTR were highly expressed in rodent microglial cells. Opposite effects of BDNF and proBDNF on microglial function might contribute to the dichotomy of BDNF actions on neuroinflammation and also be involved in the pathophysiology and/or the treatment of neuropsychiatric disorders. In this study, we also tested the effect of fluvoxamine, a potent agonist of sigma-1 receptors, on the intracellular Ca2+ mobilization and function of rodent microglial cells.

Title: Mesocortical BDNF-mediated disinhibition of mPFC GABA neurons contributes to neuropathic pain

Authors: *F. FENG, W.-Y. SHI, X.-Y. HONG, Y.-Q. LI, J.-X. YANG, H.-R. WANG, L. WANG, X.-Y. WANG, H.-L. DING, H. ZHANG, J.-L. CAO;
Xuzhou Med. Col., Jiangsu, China

Abstract: Neuropathic pain has a 0.9%~17.9% of global prevalence, impairs the quality of life for millions of people. Only 1/3~2/3 of patients benefit from chronic use of currently available analgesics or antidepressants. Increasing evidence shown that neuropathic pain is a neural circuit disorder. The limited understanding of the neural circuitry in the brain involved in neuropathic pain is one of the key reasons for the lack of more effective treatments. mPFC has been implicated in chronic neuropathic pain, and receives heavy synaptic inputs from the ventral tegmental area (VTA), however the downstream cellular target of these synaptic inputs and the underlying molecular mechanisms remain largely unknown. Like most of the nucleus in the brain, medial prefrontal cortex (mPFC) is composed of principal neurons (pyramidal cells) that project to other areas and GABA-ergic interneurons that serve to integrate information among afferents. Here, focusing on mPFC GABA neurons, we first investigated the expression of inhibitory neurotransmitter GABA on day 7 following chronic constrictive injury (CCI) surgery in sciatic nerve, a widely used neuropathic pain model. Our enzyme-linked immunosorbent assay (ELISA) data found a significant decrease of GABA expression in the contralateral mPFC from CCI mice as compared to sham group. Interestingly, we observed that infusion of muscimol, a $GABA_A$ receptor agonist, evoked thermal hyperalgesia in the unaffected hindpaws of CCI mice, but not in sham mice. This result suggests that the contralateral mPFC of CCI mice is under a sub-activation state, and ready to be activated by intrinsic or extrinsic mechanisms that normally not sufficient to evoke behavioral effects. VTA dopamine neuron is a main source of BDNF in mPFC. To identify the role of BDNF in modulating CCI-induced disinhibition of mPFC GABA neurons, we injected AAV-GFP-BDNF to express BDNF in VTA neurons and observed overlap expression of BDNF and GAD65, a molecular mark of GABA neurons. This result built a direct link between VTA-derived BDNF and mPFC GABA neurons. Furthermore, on day 7 after CCI surgery, we infused BDNF into contralateral mPFC, and observed a significant decrease in paw withdrawal latency as well as a decreased expression of GABA and histone H3 acetylation (ACH3) in CCI mice, which could be reversed by pretreatment with Trichostatin A, a histone deacetylase inhibitor. Double immunofluorescent staining also confirmed an overlap expression of ACH3 and GAD. These studies unravel a novel neural circuit and its functional molecular mechanisms in neuropathic pain, and provide highly useful circuit and molecular targets to treat neuropathic pain.

Title: Novel pharmacological modulators of Arc/Arg3.1 protein stability

Authors: *J. LALONDE, S. A. REIS, S. J. HAGGARTY;
Ctr. for Human Genet. Res. (CHGR), Mass. Gen. Hosp. — Harvard Med. Sch., Boston, MA

Abstract: Accumulating evidence suggest that aberrant activity of specific molecular networks implicated in the control of actin cytoskeleton remodeling and synapse function contributes to the cognitive deficits associated with many neurodevelopmental, psychiatric and neurological disorders. The Activity-Regulated Cytoskeleton-associated protein (Arc, also known as Arg3.1) plays an important role in synaptic plasticity and memory formation. In recent years, different studies have suggested that defect in Arc biology may be contributing to the pathophysiology of Rett's and fragile X syndromes, Alzheimer's disease as well as schizophrenia. Reversing the imbalance in Arc abundance or activity could be a valid treatment option to help ameliorate the cognitive impairments associated with these serious brain disorders. Achieving this goal, however, will require a quasi-complete understanding of signal-dependent Arc expression in neurons and how different classes of pharmacology can influence this process. Currently, we know that Arc expression is concomitantly regulated by a multitude of signaling pathways at the transcriptional, translational and posttranslational levels. To begin understanding better whether and how various drugs available for the treatment of brain disorders are modulating Arc expression, we developed an image-based, high-throughput screening strategy to test systematically how different small-molecules with known or hypothesized CNS activity can influence BDNF-induced Arc protein expression in mouse primary cortical neurons. With this approach, we identified several molecules that strongly potentiate BDNF-induced Arc protein expression and others that completely block this process. Interestingly, most of the compounds in our library with neuroprotective and/or nootropic quality were found to increase levels of Arc protein, while the majority of the drugs with antidepressant and antipsychotic activity were more prone to limit Arc expression. To validate and expand our results, we selected three functionally related compounds that strongly potentiated Arc protein levels in our screen. Using a combination of experimental approaches, we found that these three small-molecules did not mediate their effect by promoting Arc transcription, as expected, but rather favored stability and accumulation of Arc protein. These striking and unpredicted results reveal a new facet about Arc

biology that may be exploitable for the development of novel pharmacological treatments of brain disorders.

Title: Expression of TRPV1 regulated by STAT5 in hippocampus

Authors: ***L. HUANG**, J. LIU, Y. WANG, H.-Y. YIN, C.-S. ZHANG, S.-G. YU, Y. TANG; Sch. of Acupuncture, Chengdu Univ. of Traditional Chinese Med., Sichuan, China

Abstract: Transient receptor potential vanilloid 1 (TRPV1) channel has been found to be expressed in hippocampus and contributed to synaptic plasticity,neurotransmitter release, etc. Signal transducers and activators of transduction 5 (STAT5), a transcription factor, has demonstrated to get involved in neuroprotective and neurotrophic effects in hippocampus.However, whether the function of STAT5 would exert impact on TRPV1 was unclear. To answer this question, we employed TRPV1 knockout mice to test the expression of STAT5 in hippocampus and then generated STAT5 conditional knockout mice through STAT5 flox and Nestin-cre system to measure the expression of TRPV1 in hippocampus. Our results indicated that in TRPV1-deficient mice, the expression of STAT5 did not show any significant changes while the expression of TRPV1 was raised in the absence of STAT5. Therefore, the current data suggests that the expression of TRPV1 in hippocampus is regulated by STAT5.

Title: Compensation for PKMζ function in spatial long-term memory in mutant mice

Authors: *C. HSIEH[1], P. TSOKAS[1,2], T. C. SACKTOR[1,3,2];
[1]Dept of Physiol. and Pharmacol., [2]Dept. of Anesthesiol., [3]Dept. of Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: PKMζ, a brain-specific, constitutively active, atypical protein kinase C isoform has been proposed to be crucial for the maintenance of late-LTP (L-LTP) and spatial long-term memory (LTM). Recent results from PKCζ/PKMζ null mice, however, have questioned this hypothesis. Using a pharmacogenetic approach (see Tsokas et al., SfN 2015), we showed that in PKMζ-null mice L-LTP is mediated by compensatory mechanisms, whereas in wild-type mice L-LTP is mediated by PKMζ. Here we show that similar to L-LTP, in PKMζ-null mice spatial LTM is mediated by compensatory mechanisms, and spatial LTM in wild-type mice by PKMζ. To determine the role of PKMζ in spatial LTM, we examined active place avoidance, a conditioned spatial behavior that is both rapidly learned and hippocampus-dependent. We found that 24 hr after active place avoidance training PKMζ protein levels are elevated in the dorsal hippocampus of adult mice. This suggests that similar to L-LTP, spatial LTM requires de novo synthesis of PKMζ. Using implanted guided cannulae targeting the dorsal hippocampus, we injected bilaterally the same PKMζ-antisense oligodeoxynucleotide (AS-ODN) construct we used in Tsokas et al., (SfN 2015) to block LTP in wild-type mice, or its scrambled control (SCR-ODN). We injected 2 nmol/µl ODN in PBS (0.5 µl/side) 20 min before each of three 30-min training sessions, spaced 2 hours apart. Antisense oligodeoxynucleotides injected in this manner into the hippocampus last at least 2 hours. We found that the PKMζ-antisense disrupts 1-day LTM in wild-type mice, but not in the PKMζ-null. Thus, spatial LTM, like L-LTP, is mediated by compensatory mechanisms in mutant mice, and by PKMζ in wild-type mice.

Title: miR-204 regulates surface expression of NMDA receptor through repressing EphB2 in mouse hippocampal neurons

Authors: *K. KIM, H. NAM, C. DANKA, K. KIM;
DGIST, Daegu, Korea, Republic of

Abstract: In order to gain an insight into how changes in miRNAs expression affect hippocampal function during aging, we performed small RNA profiling at seven different life stages of mouse hippocampus. Bioinformatical analysis of these small RNAs indicate that 55 miRNAs are differentially expressed showing more than two fold change between young (2M) and old (18M) mouse hippocampus and that their potential target mRNAs are important components in neuronal regulation pathways including axon guidance. Here we report that Eph-ephrin signaling pathway is significantly downregulated in aged hippocampus. mRNA levels of ephrin signaling molecule EphB2 decreased and its inhibitory molecule RhoA increased between young (2M) and old (18M) stages. We found that miR-204 is upregulated in old hippocampus and targets EphB2 in a dose dependent manner in neurons. Importantly, miR-204 regulates NMDA receptor trafficking by specifically inhibiting surface expression of NR1 subunit in neurons whereas inhibition of miR-204 promotes its surface expression. These findings indicate miR-204 is an important regulator of synaptic plasticity and NMDAR function that have association with age dependent decline in cognition.

Title: An NMDA receptor S1166A KI mouse exhibits impaired synaptic plasticity at CA1 synapses

Authors: *M. W. PORCH[1,2], J.-Y. HWANG[2], R. S. ZUKIN[2], A. E. CHÁVEZ[2];
[2]Neurosci., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: NMDARs are glutamate-gated ion channels and are enriched at excitatory synapses, where they are strategically positioned to play a crucial role in regulation of synaptic function. A unique feature of NMDARs is their high permeability to Ca2+. Ca2+ influx through NMDARs is essential for synaptogenesis, plasticity of neural circuitry, and higher cognitive functions, such as learning and memory. Emerging evidence reveals that PKA signaling represents a fundamental mechanism by which NMDAR-mediated Ca2+ influx is modulated in neurons. Direct activation of PKA promotes NMDAR Ca2+ permeability, Ca2+ signaling in dendritic spines, and induction of LTP at Schaffer collateral to CA1 pyramidal cell synapses. Consistent with this, extracellular signals that modulate cAMP bidirectionally regulate Ca2+ permeation through NMDARs and Ca2+ transients in spines in a PKA-dependent manner. We recently identified phosphorylation of GluN2B at Ser1166 to be the molecular target of PKA relevant to NMDAR Ca2+ permeability. Whereas the impact of PKA induced phosphorylation of Ser1166 on NMDAR Ca2+ permeability is well-established, its impact on NMDAR-dependent synaptic plasticity is unclear. To address this issue, we generated a mouse with a S1166A mutation knocked-in by means of the CRISPR method. These mice developed and bred normally and did not exhibit any gross morphological phenotypes. We first assessed basal synaptic transmission by monitoring the input/output relation at Schaffer collateral to CA1 synapses. The S1166A mutation does not alter basal transmission relative to wild-type controls. Next we investigated presynaptic function by means of paired-pulse facilitation at CA1 synapses. Paired-pulse facilitation was not altered in these mice relative to wild-type controls. We next examined the impact of the S1166A mutation on synaptic plasticity at CA1 synapses. Whereas theta-burst stimulation LTP was greatly diminished, high frequency stimulation at CA1 synapses exhibited little or no change relative to that of wild-type mice. These findings indicate a novel and previously unappreciated role for PKA phosphorylation of the NMDA receptor subunit GluN2B at Ser1166 on specific forms of synaptic plasticity at hippocampal synapses.

Title: Methylphenidate enhance long-term potentiation in CA3-CA1 hippocampal synapse involving insertion of functional AMPA receptors

Authors: G. UGARTE, C. CARVALLO, C. ROZAS, D. CONTRERAS, R. FARÍAS, R. DELGADO, M. ZEISE, *B. E. MORALES;
Univ. of Santiago, Santiago, Chile

Abstract: Methylphenidate (MPH, Ritalin©) is used in the treatment of Attention Deficit Hyperactivity Disorder and recently as abuse drug. Although it is known that MPH increases the TBS-dependent Long Term Potentiation (LTP) in hippocampus, the cellular and molecular mechanisms involved in this process are unknown. Using electrophysiological approaches and Western blot analysis we investigated the effect of MPH on LTP in hippocampal slices obtained from young rats (3-4 weeks). LTP in CA3-CA1 were induced by applying theta burst stimulation (TBS, 5 trains, 100 Hz). Superfusion with MPH during 20 min, significantly increased the magnitude of hippocampal LTP in a dose-dependent manner with a EC50 of 73.44 ± 6.32 nM. Paired-pulse facilitation curves remained unchanged after perfusion with MPH, suggesting that the effect of MPH does not involve presynaptic components. The increase induced by MPH was inhibited by the β-adrenergic blocker timolol (5 μM), from 194.3±5.8% to 152.7±1.7% (n=4,4; $p<0.01$). We also evaluated the dopaminergic contribution in the effect of MPH. Interestingly, LTP increase was also inhibited by 5 μM of SCH23390, a D1/D5 receptors blocker, from 193.1 ± 8.0 % to 144.4 ± 3.2% (n = 5,7; $p < 0.001$). The inhibition of PKA by PKI suppresses the MPH-dependent enhancement of LTP, suggesting that downstream activation of cAMP/PKA-dependent cascade. To determine whether the facilitation of LTP induced by MPH involves the insertion of new AMPA receptors in the postsynaptic membrane, CA1 areas from hippocampal slices used in LTP experiments were collected and Western blot analysis for phosphosphorylations in GluR1 was performed. CA1 areas from slices showing an enhanced LTP after perfusion with 5 μM MPH exhibited a significant increase of 28 ± 6 % in

phosphorylation of Ser845 residues (n=9,9; $p<0.05$) compared to slices with TBS-dependent LTP without MPH. No significant change in the phosphorylation state of Ser831 was observed (n=9,9; $p > 0.05$). In addition, the phosphorylation of Ser845 induced by MPH was inhibited by SCH23390 (n=4,4; $p > 0.05$). Cross-linking experiments for membrane-associated AMPA receptors are being performed to confirm these results. Finally, using whole cell recordings in pyramidal cells of CA1 we found a significant increase in short term plasticity of AMPA-dependent postsynaptic currents after perfusion with 5 μM MPH. No changes were observed in NMDA-dependent currents. Altogether, these results suggest that the increase of CA3-CA1 LTP induced by MPH involve β-adrenergic and dopaminergic components promoting the insertion of new AMPA receptors in the postsynaptic membrane through phosphorylation of Ser845 residues in GluR1 subunits.

Title: Regulation of NMDA receptor 2B expression in layer IV barrel cortex by CaMKII

Authors: *S. KO, S. CHUNG;
Yonsei Univ., Seoul, Korea, Republic of

Abstract: Regulation of NMDA receptor 2B expression in layer IV barrel cortex by CaMKII
Glutamate (Glutamic acid) is an essential excitatory neurotransmitter in mammalian central nervous system and acts on both metabotropic and ionotropic glutamate receptors (iGluRs). The iGluRs are divided into three groups according to their agonist selectivity: NMDA, AMPA and kinate receptors. Ionotropic glutamate receptors are ligand-gated ion channels that mediate the major excitatory neurotransmission. NMDA receptors are widely expressed in the central nervous system that play key role in excitatory synaptic transmission. Among the NMDA receptor subunits, NR2B is highly expressed in the hippocampus and cerebral cortex and plays important roles in synaptic plasticity, learning and memory. NR2B expression peaks in the hippocampus and cortex during the third postnatal week and then declines to moderate/low adult levels. However, the regulatory mechanisms of NR2B expression in developmental stage in layer IV barrel cortex are not clear. Recent study showed that in developmental stages, NMDA

receptor expression in barrel cortex is control the process of thalamocortical afferent innervation, segregation, and plasticity. In addition, NR2B have been reported to interact with several proteins such as Ca^{2+}/calmodulin-dependent kinase II (CaMKII), small GTPases, Homer. In the present study, we find that in adult whisker nerve injury model rat, NR2B protein expression levels were increased like NR1A protein expression and it regulated by CaMKII activities. These finding support the better understanding the regulatory mechanism of NR2B protein in the layer IV barrel cortex.

Title: Stimulus parameters determine the role of PKA, protein synthesis and CP-AMPARs in LTP at hippocampal CA1 synapses

Authors: *P. PARK[1,2], B.-K. KAANG[2], G. L. COLLINGRIDGE[1,2,3];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Long-term potentiation (LTP) has been considered to be the best cellular correlate of learning and memory. In the hippocampal CA1 synapses, two different forms of LTP have been reported in terms of underlying cellular mechanisms, as early LTP (E-LTP) and late LTP (L-LTP). L-LTP requires the process of PKA and protein synthesis, and is maintained as long as experiments are continued, while E-LTP only lasts for a few hours. However, this LTP dichotomy has been controversial because of its vague criteria and inconsistent results. Our previous report (Park et al., 2014) suggested that long-lasting LTP exists as two distinct forms following synaptic mechanisms and the requirement of certain stimulus parameters; which we referred to as LTPb and LTPc (sparing LTPa to presynaptic short-term potentiation). LTPb was induced by a single high-frequency stimulation (HFS) or compressed multiple HFSs (e.g. 3 HFS at 10 sec interval), and did not require the process of PKA and protein synthesis. On the other

hand, LTPc was induced when the same number of HFSs given at longer interval (e.g. 3 HFS at 10 min interval), and mediated by PKA and protein synthesis dependent mechanism. In this study, we used simultaneous field and patch electrophysiology to further understand the mechanism of these two forms of LTP. Theta-burst stimulation (TBS) was used, rather than HFS, for its induction protocol (we couldn't find any differential effect of TBS and HFS on LTPb/LTPc mechanism), and various drug combinations were applied to specifically antagonise the molecules of interest in the acute slices. Here, we show a line of evidence suggesting that calcium-permeable AMPA receptors (CP-AMPARs) are transiently recruited on the synaptic surface by LTPc induction, and are required for its expression. LTPc, but not LTPb, was time-dependently sensitive to three different types of CP-AMPAR blockers, philanthotoxin 433 (5 - 10 μM), NASPM (30 μM) and IEM 1460 (30 μM) in the extracellular recording. This transient CP-AMPAR expression was also confirmed by AMPAR inward-rectification via whole cell recording. Moreover, a weak TBS-induced LTP was significantly enhanced in the presence of rolipram (100 nM, PDE4 inhibitor) via a PKA dependent mechanism. This effect was completely reversed by IEM 1460 (30 μM), suggesting PKA-dependent LTP is mediated by CP-AMPARs. In conclusion, LTP can be maintained for a long time via two disparate cellular mechanisms whether or not PKA, protein synthesis and CP-AMPARs are involved. This is determined by the time interval afforded between multiple LTP inductions. And importantly, PKA-dependent LTP in our study is mediated by CP-AMPARs.

Title: Modeling the signaling mode of calcium influx through L-type calcium channels to the nucleus

Authors: *X. LI[1], W. HOLMES[2];
[1]Ohio Univ., Athens, OH; [2]Ohio, Athens, OH

Abstract: Calcium signals are important for learning and memory at the cellular level. Calcium can enter the cell body from L-type channels, triggering a series of downstream cascades, including the phosphorylation of CREB in the nucleus. How calcium carries out the journey from the membrane to the nucleus is debated. One line of studies has suggested that calcium ions

are taken to the nucleus by carrier proteins including calmodulin (CaM) and CaMKII gathered around the nanodomain of L-channels. This is known as a local signaling mode. Other studies have indicated that Ca2+ influx increases the overall bulk concentration in the cytosol and then diffuses into the nucleus. This is known as a global signaling mode. To test the signaling modes, we built a biophysically realistic computational model. A chunk of the cell body was modeled in a pyramid shape, with the apex toward the nucleus and the base as the membrane. The model includes three compartments: the shell, the cytosol and the nucleus. Molecule positions and reactions were tracked in these compartments. Molecules included in the model are Ca2+, CaM, βCaMKII and γCaMKII. The signaling cascade is modeled as follows: Ca2+ is taken up by CaM and together is bound by CaMKII. βCaMKII facilitates the phosphorylation of γCaMKII. γCamKII then carries the Ca2+/CaM to the nucleus. The reaction and diffusion process was modeled stochastically with Smoldyn. The reaction network was generated using BioNetGen. We examined the distribution of Ca2+ in terms of free Ca2+ ions or Ca2+ bound to CaM or CaMKII under different stimulation patterns and distributions of CaM. At early times the majority of Ca2+ in the shell and cytosol is bound to either CaM or CaMKII rather than staying free. This is consistent with the local signaling mode. The proportion of Ca2+ being bound varies with the Ca2+ input pattern. A steady influx of Ca2+ allows more Ca2+ bound to CaM but less bound to CaMKII. In contrast, burst influx (3 Ca2+ spikes) allows more Ca2+ to be bound to CaMKII but less to CaM. The distribution of CaM also plays a role. Compared with the uniform distribution of CaM in the cytosol and the shell, a nonuniform distribution of CaM (1 mM in the shell and 10 uM in the cytosol) leads to less Ca2+ bound to CaMKII and more bound to CaM. In summary, the preliminary data generated by the model suggests that in a short time scale the majority of Ca2+ binds to the carrier proteins (CaMs and CaMKIIs) before entering the nucleus and therefore supports a local signaling mode. However, it is unknown whether the global signaling mode may coexist in a longer time scale. Our future work will include the downstream cascades in the nucleus and examine the long term effect of Ca2+ signaling.

Title: Exploring Arc protein complexes in SH-SY5Y neuroblastoma cells

Authors: O. NIKOLAIENKO, *C. R. BRAMHAM;
Univ. of Bergen, N-5009 Bergen, Norway

Abstract: The immediate early gene ARC (also known as ARG3.1) encodes a synaptic protein that functions in multiple forms of neuronal plasticity (long-term potentiation, long-term depression, and homeostatic plasticity). Its expression is tightly controlled by a unique combination of molecular mechanisms - fast activity-induced mRNA synthesis by poised RNA polymerase followed by dendritic transport, translation, nonsense-mediated RNA decay and rapid degradation of the protein. Arc multiple functions within distinct subcellular compartments suggests the existence of different protein complexes, which composition is potentially regulated by Arc post-translational modifications (PTMs). To date, little information on Arc PTMs and their functional significance is available, and it is still not known if they influence the Arc interaction interface and trigger/block the binding to other proteins. To address this question we developed a procedure for two-step affinity purification of Arc protein complexes from SH-SY5Y neuroblastoma cells. Followed by tandem mass spectrometry it allowed the identification of previously unknown Arc protein partners and a number of new Arc PTMs. Our results show that Arc is extensively regulated by phosphorylation in neuroblastoma cells. Further experiments are needed to determine the effect of these modifications.

Title: Dopaminergic signalling regulates synaptic cooperation and competition of associative plasticity through differential activation of extracellular signal-regulated kinases (ERK1/2)

Authors: *M. S. SHETTY[1,2], S. GOPINADHAN[1,2], S. SAJIKUMAR[1,2];
[1]Dept. of Physiology, Yong Loo Lin Sch. of Med., Natl. Univ. of Singapore, Singapore, Singapore; [2]Neurobiology/Aging Program, Level-4, Life Sci. Inst. (LSI), Singapore, Singapore

Abstract: Role of dopaminergic mechanisms in hippocampal long-term plasticity and memory is well established. Altered dopaminergic signalling and modulation in the hippocampal circuits has been implicated in the pathophysiology of many neuropsychiatric disorders, and also in the age-associated memory deficits. Consequently, administration of dopamine agonists has been reported in many cases to alleviate or restore the alterations. Though dose-dependent differences in the dopamine-mediated mechanisms are reported in certain brain regions, similar effects in hippocampus have not been investigated. Here, using acute hippocampal slices from rats, we have performed long-term plasticity experiments under the conceptual framework of synaptic tagging and capture hypothesis. Our results demonstrate that D1/D5-receptor-mediated potentiation at the CA3-CA1 Schaffer collateral synapses differentially regulates synaptic co-operation and competition to establish long-term plasticity in a dose-dependent manner. Further investigating the molecular players involved, we reveal an important role for extracellular signal-regulated kinases-1 and 2 (ERK1/2) as signal integrators and dose-sensors. The concentration-dependent effects of the modulatory transmitter, as demonstrated for dopaminergic signalling in the present study, might offer additional computational power by fine tuning synaptic co-operation and competition for establishing long-term associative memory in neural networks. Our study provides important insights into how the changes in the extracellular dopamine concentrations influence the ongoing information processing and affect the encoding and maintenance of memories. These findings are significant in the context of learning-induced and drug-induced changes in hippocampal dopamine.

Title: CaMKII is required for long-term memory of conditioned taste aversion and its modulation of neocortical LTP

Authors: *Y. JUAREZ MUÑOZ, M. L. ESCOBAR;
Div. de Estudios de Posgrado, Facultad De Psicologia, UNAM, Distrito Federal, Mexico

Abstract: A central question in the field of cognitive neuroscience refers to the maintenance of long-term memory. Among the proposed molecules required for memory persistence, calcium/calmodulin-dependent protein kinase II (CaMKII) is a suitable candidate since it has the ability to remain active, through intersubunit autophosphorylation, even when the initial calcium stimulus has decayed. Previous work from our laboratory showed that training in conditioned taste aversion (CTA), an insular cortex (IC) dependent task, prevents the induction of long-term potentiation (LTP) in the basolateral amygdaloid nucleus (Bla)-IC projection, producing a metaplastic effect, i.e. a change in the ability to induce subsequent synaptic plasticity. In order to explore the molecular mechanisms that underlie memory persistence, we evaluated the effect of local IC microinfusion of a selective inhibitor of CaMKII in the maintenance of CTA memory as well as in the metaplastic effect produced by CTA over the subsequent induction of LTP. Our results show that CaMKII is required for CTA long-term memory and modifies the ability for subsequent induction of synaptic plasticity in the Bla-IC pathway. These results indicate that CaMKII is a central key component for long-term memory storage of aversive tasks as well as for the homeostatic plasticity processing. Supported by PAPIIT IN212013

Title: The role of autophosphorylation at Thr286 of CaMKII in single dendritic spines during long-term potentiation

Authors: *J.-Y. CHANG[1,2], P. PARRA-BUENO[1], R. YASUDA[1];
[1]Max Planck Florida Inst., Jupiter, FL; [2]Duke Univ., Durham, NC

Abstract: Ca^{2+}/CaM -dependent protein kinase II (CaMKII) has a central role in long-term potentiation (LTP), which is believed to be a cellular form of learning and memory. Despite the great number of the signaling molecules that are required for LTP, little is known about how the initial NMDA-receptor mediated Ca^{2+} transients transduces into the long-lasting modification of cellular process in supporting LTP. The initial influx of Ca^{2+} relays the extracellular signaling to LTP by activating calmodulin (Ca^{2+}/CaM), which in turn activates several downstream signaling molecules including CaMKII. Activation of CaMKII depends both on the binding of Ca^{2+}/CaM, and on the autophosphorylation at Thr286. Phosphorylation at T286 generates Ca^{2+}/CaM independent (autonomous) activity of CaMKII, and this prolonged activity is required for LTP, spatial learning and memory. However, it remains uncertain about the temporal requirement of CaMKII T286 phosphorylation during LTP. Here, by using CaMKII FRET sensor (camuiα) combined with ultra-fast temporal resolution (8Hz) of two-photon fluorescence lifetime imaging microscopy (FLIM), we showed that 1) CaMKII functions as a biochemical integrator of multiple Ca^{2+} pulses during LTP induction and autophosphorylation at T286 is required to efficiently integrate Ca^{2+} pulses. 2) During LTP induction, Ca^{2+}/CaM binds persistently to a fraction of activated CaMKII and autophosphorylation at T286 is required for the persistent binding of Ca^{2+}/CaM. 3) Phosphorylation at T286 is only required during LTP induction. Together, these findings elucidate the critical role of CaMKII T286 phosphorylation during the initial Ca^{2+} signaling steps in LTP.

Title: Hebbian long-term potentiation in feed-forward hippocampal interneurons

Authors: *M. MERCIER, D. KULLMANN;
Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Long-term potentiation (LTP) of excitatory transmission in hippocampal principal cells is thought to play an important role in memory encoding. Within area CA1, LTP in pyramidal cells depends on Ca^{2+} influx through postsynaptic *N*-methyl-D-aspartate (NMDA) receptors, and the subsequent phosphorylation of the α isoform of Ca^{2+}/calmodulin-dependent kinase type II (αCaMKII). Interestingly, a similar form of Hebbian LTP has been described in

CA1 feed-forward inhibitory interneurons, located in stratum radiatum, which serves to maintain the temporal fidelity of synaptic integration in pyramidal cells[1]. Unlike pyramidal cell LTP, however, this form of plasticity is only observed in ~50% of interneurons, and depends on a non-α isoform of CaMKII[2]. The perforated-patch clamp technique is necessary to observe interneuron LTP, as whole-cell recordings have been found to induce rapid run-down of NMDA receptor-mediated signaling in these cells[1]. Alternatively, feed-forward interneuron LTP can also be detected indirectly using whole-cell recordings from pyramidal cells, where an increase in disynaptic inhibition can be seen. In order to evoke and record such disynaptic responses, acute mouse hippocampal slices were taken and whole-cell voltage clamp recordings made from CA1 pyramidal cells, located distant (>1 mm) from the stimulation site at the Schaffer collateral pathway; cells were held close to the reversal potential for glutamate receptors in order to selectively detect inhibitory postsynaptic currents (IPSCs). In line with previous work, a pairing protocol designed to induce Hebbian LTP in local stratum radiatum interneurons led to a persistent increase in disynaptic IPSC amplitude in pyramidal cells. This enhancement of inhibition was blocked by D-(-)-2-amino-5-phosphonopentanoic acid (AP5), importantly confirming its dependence on NMDA receptor signaling. Interestingly, the potentiation was only evident in mice aged P20 or older, suggesting that the expression of Hebbian LTP in feed-forward interneurons may be developmentally regulated. Further experiments employing the perforated-patch clamp technique will seek to corroborate these findings and further probe the signaling pathways and mechanisms involved in this relatively unknown form of hippocampal plasticity. Title: CaMK2G, an intellectual disability candidate gene, is critical for spatial learning by controlling activity-dependent BDNF synthesis in the hippocampus

Authors: *H. MA, S. SANCHEZ, I. KATS, B. SUUTARI, R. TSIEN;
Neurosci., New York Univ., New York, NY

Abstract: Intellectual disability (ID) is characterized by significant limitations in both intellectual functioning and adaptive behavior. We have identified γCaMKII, encoded by an ID candidate gene, as a Ca2+/CaM shuttle protein to support membrane signaling to nucleus for excitation-transcription (E-T) coupling. Interestingly, various players in this pathway (CaV1 channels, γCaMKII, βCaMKII, calcineurin and CaMKIV) are encoded by genes associated with several neuropsychiatric disorders including autism spectrum disorder, schizophrenia and major depression disorder. Since these disorders often share certain ID symptoms, it is intriguing that many of the associated genes also functionally converge on a common cellular pathway. To test whether there is a link between this pathway and ID as well as other neuronal disorders, we probed γCaMKII mediated E-T coupling and its consequences in mice lacking γCaMKII. The CaMK2G KO mice were normal in general health and basic behavior. No change in anxiety was found in open field test or elevated zero maze. However, in the marble bury test CaMK2G KO mice buried marbles fourfold more than their WT littermates, which suggests a repetitive perseverative behavior phenotype. In the forced swim test, a test developed for screening potential antidepressant drugs, CaMK2G KO mice showed a markedly increased immobility. Thus, in addition to having repetitive behavior often found in animal models of autism, CaMK2G KO mice also showed depression-like behavior. In people with ID, the intellectual functioning is often limited. To assess the learning ability of CaMK2G KO mice, spatial memory acquisition and retrieval were tested in Morris water maze (MWM). Strikingly, CaMK2G KO mice show limited learning to find a hidden platform, as well as inability to recall that location after platform removal. To further validate this, we tested mice in a radial arm maze, which invokes different motivations and motor systems. Consistent with our findings in MWM, CaMK2G KO mice also showed significantly impaired reference memory in radial arm maze. Since CREB-dependent gene expression is critical for neuronal plasticity, we asked whether activity-dependent gene expression and protein synthesis in γCaMKII KO mice are defective. No significant change was found for activity-related proteins such as receptors for GABA, NMDA and AMPA. However, BDNF, a CREB-targeted gene, increased more than 2 fold with MWM training, which was strikingly prevented in CaMK2G KO mice. Interestingly, the inhibition of BDNF expression was not caused by a prevention for MAPK pathway, suggesting a specific and critical role of γCaMKII-mediated E-T coupling in spatial learning.

Title: Role and regulation of CRTC1 phosphorylation during activity-dependent synaptic plasticity

Authors: ***M. DESALVO**[1], T. CH'NG[2,3], A. VASHISHT[1], J. WOHLSCHLEGEL[1], K. MARTIN[1,4];
[1]UCLA Biol. Chem., UCLA, Los Angeles, CA; [2]Lee Kong Chian Sch. of Med., [3]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore; [4]Integrative Ctr. for Learning and Memory, UCLA Brain Res. Inst., Los Angeles, CA

Abstract: Previous studies have shown that CREB Regulated Transcriptional Co-activator 1 (CRTC1) plays a critical role in learning and memory by regulating gene expression in neurons. Our lab has shown that CRTC1 localizes at synapses and undergoes activity-regulated translocation to the nucleus where it interacts with CREB and other transcription factors to trigger changes important for the late phase of long-term potentiation (L-LTP). CRTC1 is heavily phosphorylated and its phosphorylation state changes dramatically upon stimulation. We have identified 50 phosphorylation sites in CRTC1 and are currently characterizing key sites that could be important not only in synapse to nuclear transport, but also for CRTC1's transcriptional role in the nucleus. We have created several phospho-incompetent mutants and are currently testing their effects in cultured cortical neurons. We hypothesize that different stimulation conditions cause distinct phosphorylation changes that inform both the trafficking and transcriptional role of CRTC1. We are using affinity purification and mass spectrometry to identify phosphorylation sites that are specifically affected during activity. To look at the effects of these mutants on transcription, we are using chromatin immunoprecipitation (ChIP) sequencing to identify genes that are differentially transcribed. De-coding the role of phosphorylation in the synapse to nuclear transport and transcriptional activity of CRTC1 is crucial to understand the complex regulation of plasticity in neurons.

Title: Compensation for PKMζ function in late-LTP in mutant mice

Authors: *P. TSOKAS[1], T. C. SACKTOR[2,3,4];
[1]Furchgott Ctr. for Neural & Behav. Sci., Physiol. & Pharmacol., Anesthesiol., SUNY Downstate Med. Center, Brooklyn, NY, Brooklyn, NY; [2]Furchgott Ctr. for Neural & Behav. Sci., Physiol. & Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY, NY; [3]Dept. of Neurol., [4]Dept. of Anesthesiol., SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: PKMζ is a persistently active kinase proposed to mediate late-LTP (L-LTP) and long-term memory. But these functions seem unaffected in PKMζ-null mice. We devised a pharmacogenetic approach to test whether compensatory mechanisms mediate LTP in PKMζ-null mice. PKMζ is generated by a dedicated PKMζ mRNA that encodes an independent PKCζ catalytic domain without a regulatory domain. Under basal conditions in neurons the PKMζ mRNA is translationally repressed, but LTP induction derepresses it, resulting in increased do novo PKMζ synthesis. Thus, if PKMζ-null mice produce L-LTP by a compensatory mechanism--and wild-type mice by synthesis of PKMζ--then PKMζ-antisense oligodeoxynucleotides (AS-ODN) will have no effect on LTP in the PKMζ-nulls, but block L-LTP in the wild-types. We first confirmed that bath application of AS-ODN to hippocampal slices selectively blocks de novo synthesis of PKMζ in wild-type mice during LTP, without affecting other activity-dependent gene products. We applied AS-ODN complementary to the PKMζ mRNA translation start site or a scrambled control oligodeoxynucleotides (SCR-ODN) to hippocampal slices for 2 hours prior to afferent tetanic stimulation of Schaeffer collateral/commissural-CA1 synapses.

Thirty min after tetanization, we measured protein levels in CA1 when the tetanic stimulation increases the expression of multiple activity-dependent gene products. We found that the PKMζ-antisense blocks the activity-dependent formation of PKMζ, but not that of the other atypical PKC, PKCι/λ, or the translation factor eEF1A. We then tested the effect of the drug on L-LTP in wild-type mice and PKMζ-null mice. Consistent with previous results, we found that L-LTP appears similar in PKMζ-null and wild-type mice. But the underlying molecular mechanisms for L-LTP in the two genotypes are different--the PKMζ AS-ODN has no effect on LTP in the PKMζ-null-mutant without the target PKMζ mRNA, but blocks L-LTP in wild-type mice. Thus, PKMζ-null mice mediate L-LTP by compensatory mechanisms, and wild-type mice by PKMζ.

Title: Proteasome inhibition lowers the threshold for CREB phosphorylation and L-LTP induction

Authors: *S. V. BACH, A. VASHISHT, J. W. MORGAN, T. K. SMITH, A. N. HEGDE; Wake Forest Univ., Winston Salem, NC

Abstract: The ubiquitin-proteasome pathway (UPP) plays a role in both induction and maintenance of the late phase of long-term potentiation (L-LTP). Previously we showed that inhibition of the proteasome with a specific and irreversible inhibitor, clasto-lactacystin β-lactone, enhances the induction of L-LTP but blocks its maintenance in the CA1 region of the murine hippocampus. We showed that proteasome inhibition enhances L-LTP induction by stabilizing the translational activators and inhibits maintenance of L-LTP by stabilizing the translational as well as transcriptional repressors. In this study, we examined whether proteasome inhibition affects the phosphorylation of the cAMP response element-binding protein (CREB), a key step in the induction of gene expression in L-LTP. Previous work showed that three- or four-train of high frequency (100Hz) tetanization results in the upregulation of phospho-CREB

(pCREB) and the induction of L-LTP. To investigate the effects of proteasome inhibition on signaling leading to the phosphorylation of CREB we used a subthreshold L-LTP induction protocol of two-train stimulation with 100Hz, fixed hippocampal slices 1 min after the treatment, stained slices with an anti-pCREB (Ser-133) antibody and imaged using a confocal microscope. We found that the two-train stimulation protocol alone is insufficient to upregulate pCREB levels. In combination with β-lactone treatment, however, pCREB levels were significantly upregulated compared to untreated slices. Treatment of slices with β-lactone alone did not change pCREB levels as compared to untreated controls. We hypothesized that proteasome inhibition lowers the threshold for L-LTP induction via enhanced kinase activity. Therefore, we examined the role of proteasome inhibition on the activity of several known kinases that contribute to CREB phosphorylation in L-LTP. The application of specific inhibitors for protein kinase A, protein kinase G, and MAP kinase, in combination with β-lactone, blocked the proteasome inhibition-mediated enhancement of pCREB after the two-train tetanization protocol. These findings suggest that proteasome inhibition reduces the threshold for phosphorylation of CREB and L-LTP induction by enhancing general kinase activity. In combination with our previous findings that proteasome inhibition blocks proteolytic degradation of translational activators, it is possible that β-lactone treatment augments local translation of kinases (or of some other factor that positively affects kinase signaling) at stimulated synapses to promote cytoplasm-to-nucleus signaling and to enhance the induction of L-LTP.

Title: Abnormal mTOR signaling contributes to Ube3A deficiency-induced impairment in hippocampal synaptic plasticity and hippocampus-dependent memory

Authors: ***J. SUN**, Y. LIU, J. TRAN, P. O'NEAL, X. HAO, M. BAUDRY, X. BI;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Angelman syndrome (AS) is a neurogenetic disorder caused by deficiency of maternally expressed UBE3A. Previous research has shown that both long-term potentiation (LTP) and learning and memory are impaired in AS mice. We previously reported that semi-chronic rapamycin treatment not only improved motor performance but also normalized mTORC1 and mTORC2 signaling in the cerebellum of AS mice. We showed that enhanced mTORC1 activation, due to the release of TSC2-imposed inhibition, was responsible for mTORC2 inhibition. We report here that a similar abnormal mTORC1 and mTORC2 signaling also exists in hippocampus of AS mice. We found that TSC2 inhibition was associated with increased mTORC1 activity as evidenced by increased S6K1 and S6 phosphorylation but decreased mTORC2 activity with reduced PKCα levels. mTORC2 inhibition was linked to S6K1-mediated inhibitory phosphorylation of its regulator, rictor. Immunostaining results confirmed that phosphorylation of S6K1 was increased while that of AKT was decreased in hippocampal CA1 region of AS mice. Semi-chronic treatment of AS mice with rapamycin normalized mTORC1 and mTORC2 signaling. These results support the notion that overactivation of mTORC1 as a consequence of TSC2 inhibition, suppresses mTORC2 via S6K1-mediated rictor phosphorylation. Furthermore, both rapamycin and the S6K1 inhibitor PF4708671 normalized LTP in hippocampal CA1 region in AS mice. More importantly, Ube3A deficiency-induced increase in Arc expression was markedly reduced by treatment with both rapamycin and PF4708671 in CA1 dendritic field of hippocampal slices. These results indicate a critical role for mTOR signaling pathway in regulating dendritic Arc protein synthesis in hippocampus. Finally, rapamycin treatment also improved dendritic spine morphology of CA1 pyramidal neurons and contextual memory in a fear-conditioning paradigm in AS mice, possibly through suppressing mTORC1-dependent dendritic Arc synthesis and increasing mTORC2-mediated regulation of synaptic cytoskeletal elements. Collectively, our results indicate that abnormal mTOR signaling may contribute to synaptic plasticity and learning and memory impairments in AS mice.

Title: An Arc-regulating chromatin modifying complex controls neuronal activity-dependent gene expression

Authors: *N. E. OEY, H. LEUNG, H. M. A. VANDONGEN, A. M. J. VANDONGEN; Duke-Nus Grad. Med. Sch., Singapore, Singapore

Abstract: Long-term memory formation is highly complex and likely requires the dynamic regulation of hundreds of neuronal activity-dependent genes. We have recently characterized a nuclear epigenetic complex that regulates the activity-dependent transcription of Arc, an immediate early gene that is important for memory consolidation1. This dual-function chromatin-modifying complex contains the X-linked Mental Retardation histone demethylase PHF8 and the Alzheimer's Disease-associated histone acetyltransferase TIP60, which act to modify chromatin at the H3K9S10P locus, enabling rapid activity-dependent gene transcription. While the transcriptional regulation is important for neuroplasticity, it is ultimately the expression of downstream effector genes that initiate the cascade of events leading to more permanent changes at the level of neuronal proteins. To demonstrate this, we developed a novel proteome-wide mass spectrometric quantitative assay to show that the expression of hundreds of neuroplasticity-related proteins change dramatically in response to neural network activity. However, inhibiting the function of the Arc-regulating epigenetic complex using either RNA interference or transfection of enzymatically inactive PHF8 causes massive downregulation of Arc and the activity-dependent proteome. These results suggest that the chromatin-modifying complex containing PHF8 may be important for the expression of many neuronal activity-dependent genes.

Title: Kappa opioid receptor signaling in hippocampal gain control and temporal lobe epilepsy

Authors: *R. L. DUNN[1], B. N. QUEENAN[2], P. A. FORCELLI[1], D. T. S. PAK[1]; [1]Pharmacology/Physiology, Georgetown Univ., Washington, DC; [2]Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Neurons form signaling networks via synapses, sites of contact between neurons. The strength of synapses can be modulated to encode information (Hebb 1949; Magee & Johnston 1997 Science) or stabilize networks (Turrigiano 1998 Nature; O'Brien 1998 Neuron; Turrigiano 2008). In cases of chronic neuronal hyperactivity, there is broad compensatory downregulation of synaptic strength (Pak 2003 Science), which may be a protective mechanism against toxic runaway excitation. The epilepsies are characterized by recurrent seizures, periods of excessive synchronized neural activity. In mesial temporal lope epilepsy (mTLE), seizures originate in or around the hippocampus, and subsequently propagate throughout the brain. The process by which epilepsy develops (epileptogenesis) is thought to involve alterations in hippocampal synaptic function. There are currently no treatments that clearly prevent epileptogenesis. Within the hippocampus, synapses between the dentate gyrus (DG) axons (mossy fibers, MF) and proximal CA3 dendritic spines (thorny excrescences, TE) serve as a checkpoint for information entering the hippocampus (Lee and Queenan 2013 Neuron), acting as homeostatic "gain control" (Chater & Goda 2013 Neuron). Recently, we have observed that kappa opioid receptor (KOR) activity bidirectionally regulates the strength of these gain control synapses in neuronal cultures. Here, we hypothesized that a failure to engage homeostatic DG-CA3 checkpoints is a contributing factor in the development of TLE. To test this hypothesis, we used the amygdala-kindling model of epileptogenesis, in which repeated subconvulsive shocks elicit gradually more severe seizures. While kindling seizures, we systemically administered mice saline, the KOR agonist U50488, or antagonist norBNI. We found that the KOR activation exacerbated seizure progression, while KOR inhibition attenuated seizure progression and severity. Taken together these results suggest that KOR signaling, perhaps due to modulation of MF-TE homeostasis, can be a novel target for combatting mTLE, the most common form of adult acquired epilepsy.

Title: Dynamic gap junction networks regulate ipRGC intra-retinal signaling in the developing retina

Authors: *D. ARROYO[1], M. B. FELLER[2];
[2]Mol. and Cell Biol., [1]Univ. of California Berkeley, Berkeley, CA

Abstract: Prior to photoreceptor maturation, intrinsically photosensitive retinal ganglion cells (ipRGCs) provide a robust light response that drives early visually-guided behaviors. Here, we demonstrate that the ipRGC-mediated light response of the developing mouse retina is dependent on extensive electrical coupling of ipRGCs. First, we found that ipRGCs are electrically coupled not only to other ipRGCs but also to non-intrinsically-photosensitive retinal neurons (non-ipRGCs). Second, ipRGC photocurrents are effectively propagated through gap junctions. Third, blocking gap junctions reduces the number of cells that respond to light. Finally, the extent of coupling was dynamically regulated by spontaneous synaptic activity, such that pharmacological blockade of cholinergic waves of activity led to an increase in the number of both coupled cells and light-responsive cells. This increase in coupling was phenocopied by blocking D1-type dopamine receptors, suggesting that waves lead to dopaminergic modulation of ipRGC gap junctions. In conclusion, the gap junction network of ipRGC and its activity dependent modulation allows for a dynamic light response in the developing retina.

Abstract: Transcranial magnetic stimulation (TMS) is a promising brain stimulation technique to induce cortical synaptic plasticity for scientific and therapeutic purposes. However, TMS-induced plasticity exhibit many nonlinearities and variabilities, and we have little understanding of the underlying mechanism of TMS. Here we present a mean field synaptic plasticity theory, based on well established neural field theory and synaptic plasticity theory. This theory reproduces experimental results and phenomena, including rTMS of constant frequency, continuous and intermittent theta burst stimulation (cTBS and iTBS), paired associative stimulation (PAS), TMS dosage dependency and inter-subject variability. Thus, we gain insights on the underlying mechanisms of TMS and cortical plasticity, and make recommendations on TMS protocols.

Title: Modulating hippocampal plasticity with *in vivo* brain stimulation

Authors: *R. JANKORD[1], J. ROHAN[2];
[1]Air Force Res. Lab., WPAFB, OH; [2]NAMRU-D, WPAFB, OH

Abstract: Investigations into the use of transcranial direct current stimulation (tDCS) in relieving symptoms of neurological disorders and enhancing cognitive or motor performance have exhibited promising results. However, the mechanisms by which tDCS impacts brain function remain under scrutiny. We have demonstrated that *in vivo* tDCS in rats produced a lasting effect on hippocampal synaptic plasticity, as measured using extracellular recordings. *Ex vivo* preparations of hippocampal slices from rats that have been subjected to tDCS of 0.10 mA or 0.25 mA for 30 minutes followed by 30 minutes of recovery time displayed a robust 2-fold enhancement in long term potentiation (LTP) induction accompanied by a 30% increase in paired pulse facilitation (PPF). The magnitude of the LTP effect was greater with 0.25 mA

compared to 0.10 mA stimulations, suggesting a dose-dependent relationship between tDCS intensity and its effect on synaptic plasticity. To test the persistence of these observed effects, animals were stimulated *in vivo* for 30 min at 0.25 mA then allowed to return to their home cage for 24 hours. Observation of the enhanced LTP induction, but not the enhanced PPF, continued 24 hours following completion of 0.25 mA of tDCS. Addition of the NMDA blocker AP-5 abolished LTP in both control and stimulated rats but maintained the PPF enhancement in stimulated rats. The observation of enhanced LTP and PPF following tDCS demonstrates that non-invasive electrical stimulation is capable of modifying synaptic plasticity.

Title: Neurons that innervate a single target adopt a different strategy for maintaining synaptic strength than those neurons that innervate multiple targets

Authors: *Z. LU[1], J. BORYCZ[3], A. CHOUHAN[4], Z. LU[3], I. MEINERTZHAGEN[3], G. MACLEOD[2];

Abstract: Synaptic strength sub-serves the plasticity of neural circuits and is highly plastic. Homeostatic mechanisms normally introduce a measure of stability by acting to maintain the strength of some synapses within a narrow range. However, whether all neurons adopt the same mechanisms for maintaining their output is not known, and little is known about the mechanisms for that maintenance. In a field of *Drosophila* larval muscle fibers that are stereotypically innervated by motor neurons we investigated whether neurons that innervate a single muscle fiber (e.g. MN12-Ib) manifest the same homeostatic changes as those that innervate several muscle fibers (e.g. MNSNb/d-Is). For this, we chronically induced synaptic homeostasis in synapses formed by two different motor neurons on the same muscle fiber (number 12), and found that terminals from the two different neurons adopt different strategies for maintaining their output. Terminals of MN12-Ib show an increase in calcium influx sufficient to generate the

observed increase in neurotransmitter release. In contrast, terminals of MNSNb/d-Is show morphological changes such as an increase in total active zone number, total number of mitochondria as well as increase in terminal volume not seen in MN12-Ib terminals. These changes appear to be sufficient to generate the observed increase in neurotransmission. Interestingly, the morphological changes show subcellular specificity, because terminals of the same neuron on other muscle fibers fail to show such morphological changes. This difference suggests that local rather than global signaling is adequate to enact synaptic homeostasis. Although chronic induction of synaptic homeostasis provides ample time for changes in morphology we are not aware of such morphological forms of synaptic homeostasis being described previously.

Title: Continuously recorded neurons reveal sleep/wake dynamics of firing rate homeostasis in freely behaving animals

Authors: ***K. B. HENGEN**[1], J. N. MCGREGOR[1], S. D. VAN HOOSER[1], D. B. KATZ[2], G. G. TURRIGIANO[1];
[1]Biol., [2]Psychology, Brandeis Univ., Waltham, MA

Abstract: We have developed tools to continuously record extracellular signals from ensembles of single neurons in freely behaving rats for hundreds of hours during the critical period for ocular dominance plasticity. This approach allows us to examine the same cells across many iterations of naturally occurring activities and arousal states, as well as during developmental and plasticity induced changes that occur on slower time scales than were formerly addressable. Previously, we demonstrated that activity in ensembles of cortical neurons is regulated homeostatically in the freely behaving animal around a firing rate set point. However, without

the ability track the same individual units across many days, we were unable to determine whether firing rate set-points were implemented at the level of individual neurons or only at the level of the network. Here we employ our system to address two open questions in neuroscience. First, we ask whether individual neurons in the freely behaving animal exhibit a firing rate set point. Second, we examine the role of sleep and wake cycles in the expression of firing rate homeostasis in the freely behaving animal. We recorded activity from ensembles of cortical single units in juvenile rats (postnatal days 24-34) continuously for 10 days during a monocular deprivation (MD) paradigm. When examining neurons that were "online" for the entire recording, firing rates dropped during early MD and then rebounded to baseline levels despite continued deprivation. These data suggest that neocortical neurons regulate their firing around an individual set point. We then examined the dynamics of the homeostatic rebound of spontaneous activity (during prolonged MD) as a function of sleeping and waking states. Our data indicate that homeostatic plasticity in the neocortex emerges during bouts of waking and not sleep. These results raise the possibility of unanticipated interactions between animal behavior and the expression of homeostatic plasticity mechanisms.

Title: Sleep disruption alters hippocampal filtering dynamics

Authors: *E. WALLACE[1], R. K. MAGANTI[2], M. V. JONES[3];
[1]Neurosci., Univ. of Wisconsin - Madison, Madison, WI; [2]Neurol., [3]Neurosci., Univ. of Wisconsin, Madison, WI

Abstract: Sleep is a function with vast consequences for physiological homeostasis. Perturbations in sleep patterns can disrupt neurological function, as evidenced by the strong interactions between sleep and epilepsy (Semin Neurol. 29:419). The mechanism of seizure propagation and transition from simple to complex seizures, and how this mechanism interacts with sleep patterns remains largely unknown. One possible contributor to this mechanism lies in

the hippocampal formation. The synapses mediating flow of signals through the dentate gyrus (DG), cornu ammonis (CA) 1 and 3 exhibit distinct frequency-dependent modulation of somatic output (Hippocampus. 22:2184). The hypothesis that sleep serves to down-regulate synaptic connections formed and strengthened during waking (Neuron. 81:12-34) suggests that sleep deprivation may impair synaptic homeostasis and result in hyperexcitability. Integrity of frequency-dependent signal modulation in the hippocampus may be important for suppressing seizures, and sleep disruption may deteriorate such filtering, thus allowing propagation of epileptiform activity. Brief sleep deprivation has been shown to temporarily increase slow-wave activity of rebound sleep, a metric of sleep intensity thought to be associated with synaptic pruning (Brain Sci. 3:318). Here, we evaluated synaptic frequency response dynamics in hippocampal slices from C57bl/6 mice, aged P40 ± 3, after a 1 hour novel object sleep disruption (n = 6 slices; 4 animals) and compared to age matched, treatment-naïve controls (n = 3 slices; 3 animals). Population spikes in the CA1 pyramidal layer were recorded in response to 500 ms trains (100 μs, <250 μA) of sequentially increasing frequencies (2-77 Hz) of stimulation of the Schaffer collaterals. Between groups, firing responses showed similar properties at low frequency stimulation, however divergent patterns were observed in response to frequencies greater than 40 Hz, where treated animals had increased spike facilitation at the two highest frequencies tested (60 and 77 Hz; $F(1, 210) = 45.39$ and $F(1, 273) = 35.00$, respectively; $p < 0.0001$) and a delayed onset of spike depression. It remains to be determined if this increase in high frequency facilitation in the CA1 region of non-epileptic animals in response to brief sleep disruption parallels those of epileptic animals, whereby concomitant sleep disruption may underlie the associated increase in epileptiform activity. Future experiments will be directed to further evaluate filtering properties of CA1 and other synaptic fields of the hippocampal formation with regard to conditions of sleep disruption and epilepsy.

Title: Mechanisms underlying the reversibility of synaptic homeostasis

Authors: *C. J. NEFF[1], C. FRANK[2];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA

Abstract: The ability of a synapse to maintain a physiologically appropriate output is necessary for all modalities of neurological function. Forms of homeostatic plasticity allow synapses to navigate normal processes of development and aging as well as respond to challenges such as disease. Failure to regulate neuronal output could contribute to a number of disease states including ataxia, migraine, and epilepsy. Yet fundamental aspects of homeostatic plasticity remain poorly understood. In this study, we have shown that homeostatic modulation of neurotransmitter release is a reversible process, and we have examined the time course of this reversibility. The *Drosophila* neuromuscular junction (NMJ) is accessible to electrophysiological recording and has a well-established model of homeostatic plasticity. In this model, impairment of muscle sensitivity to glutamate induces a retrograde (muscle-to-nerve) signal that causes a corresponding increase in the amount of presynaptic glutamate released during evoked potentials. We have examined the reversibility of NMJ homeostatic plasticity by temporally controlling glutamate receptor function. For example, by expressing dominant negative glutamate receptors for discrete time periods, we can provide an initial impairment to muscle glutamate sensitivity, which is offset by an increase in glutamate release. When expression of the mutant glutamate receptors is ceased, we find that glutamate release returns to control levels. Interestingly, we also find that the amount of time necessary for glutamate release to return to control levels depends on the extent of the initial glutamate receptor impairment. The NMJ can execute a homeostatic modulation of neurotransmitter release in the opposite direction as well. When the *Drosophila* vesicular glutamate transporter (dVGlut) is overexpressed in neurons, there is an enhancement in quantal size and a compensatory homeostatic decrease in quantal content. We have begun to characterize the reversibility of dVGlut-induced decreases in quantal content. Finally, data will be shared from an ongoing genetic screen we are conducting to identify molecules that are necessary to bring vesicle release back to control levels once homeostatic challenges to NMJ function are removed.

Title: Nicotinic receptor modulation triggers bidirectional synaptic scaling in embryonic motoneurons *in vivo*

Authors: *C. E. GONZALEZ-ISLAS, M. GARCIA-BEREGUIAIN, P. A. WENNER; Emory Univ. Sch. Med., Atlanta, GA

Abstract: When external challenges modify baseline firing rate in a neuronal network, a set of mechanisms is prompted to restore spiking to its original rate. One of these homeostatic mechanisms is believed to be synaptic scaling, which consists of adjustments in the strength of all synapses onto a neuron in order to stabilize its firing rate. While changes in spike rate are thought to trigger synaptic scaling, an alternative possibility is that changes in neurotransmitter receptor activation could directly trigger this form of plasticity. Since spiking and transmission are necessarily coupled, it has been difficult to separate their independent roles in triggering the scaling process. Recently, we have reported findings that suggest reduced transmission directly triggered cell-wide synaptic upscaling in cortical neurons *in vitro* (Nat Commun 2015. 6:6339). The current study intended to test if alterations in neurotransmission, rather than spiking, could also trigger scaling in the living embryonic spinal network. Previously we have shown that blocking spiking or $GABA_A$ receptors ($GABA_ARs$) in ovo for two days triggered synaptic upscaling of both AMPA- and GABAergic synapses (PNAS. 2008. 105:32 11412-17). Both perturbations reduce spiking and GABAergic transmission, so either could trigger scaling. We therefore independently manipulated spiking activity and $GABA_AR$ activation *in ovo* to better identify the trigger for synaptic scaling. To do this we took advantage of our recent finding that nicotinic receptors (nAChRs) presynaptically modulate the release of GABA vesicles. Our results suggest that presynaptic modulation of GABA release by modulation of nAChR activation can trigger bidirectional synaptic scaling, while dramatic changes in spiking activity have little effect. Further, we find the striking result that scaling can be fully achieved by simply altering the frequency of spontaneous release events, which are not dependent on action potentials. If changes in $GABA_AR$ activation due to action potential-independent GABA release were the trigger, then scaling would have little to do with spiking, and would not serve as an effective feedback control for the maintenance of spike rate.

Title: Glutamatergic signaling regulates potentiation of specific GABAergic synapse

Authors: *C. Q. CHIU, M. J. HIGLEY;
Dept. of Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Although it is known that strong glutamatergic activity can modify the strength of GABAergic synaptic transmission, the underlying cellular mechanisms are not well understood. This question is complicated by the great diversity of GABAergic interneurons, which may exhibit heterogeneous rules for altering their synaptic weights. Here, we utilize cell type-specific optogenetic stimulation in mouse prefrontal cortical slices to study the capacity of GABAergic synapses formed by different interneuron subtypes to exhibit activity-dependent plasticity. We find that brief activation of NMDA-type glutamate receptors (NMDARs) increases dendritic inhibition mediated by somatostatin-expressing interneurons (SOM-INs) but does not alter perisomatic inhibition arising from parvalbumin-expressing interneurons (PV-INs). Potentiation of dendritic inhibition (SOM-iLTP) requires postsynaptic activation of NMDARs, a rise in intracellular calcium, and activation of CaMKIIa. Similar potentiation of dendritic inhibition evoked by optical uncaging of GABA indicates that SOM-iLTP is expressed postsynaptically. We further show that postsynaptic activation of CaMKIIa selectively modulates GABAergic synapses formed by SOM-INs while leaving PV-IN synapses unchanged. This specificity may be mediated by the selective expression of beta3-subunit-containing GABA-A receptors at SOM-IN synapses, as evidenced by their sensitivity to the anesthetic agent etomidate. Finally, we find that NMDAR signaling *in vivo* is required for the maintenance of dendritic inhibition. Our results indicate that the molecular differences between subpopulations of GABAergic synapses confer a differential capacity for glutamatergic regulation in the neocortex.

Title: Quantitative ultrastructural dissection of cryo-fixed synapses using high-resolution electron tomography

Authors: *C. TAO[1], Y. LIU[1], R. SUN[1], B. ZHANG[1], J. ZHANG[1], P. LAU[1], Z. ZHOU[2], G. BI[1]; [1]Univ. of Sci. and Technol. of China, Anhui, China; [2]UCLA, Los Angeles, CA

Abstract: Functional heterogeneity of neuronal synaptic transmission and plasticity must stem from diverse molecular architectures and subcellular organizations. Using cryo electron tomography (cryoET) capable of capturing three dimensional subcellular ultrastructures in their native state at nanometer resolution, we have visualized *in situ* organization of macromolecules and organelles of various synapses in intact hippocampal neurons grown in culture. Semi-automated segmentation and quantitative analysis revealed fine details of synaptic architecture, including vesicular populations in the presynaptic bouton, cell adhesion molecules in the synaptic cleft, as well as postsynaptic density, actin filaments and ribosomes in the postsynaptic compartment. In order to determine the identity of glutamatergic and GABAergic synapses, we developed a convenient cryo-stage and a high-precision algorithm for correlative light and electron microscopy (cLEM), which allowed us to determine distinct shapes of the postsynaptic densities corresponding to different synaptic types. Finally, we observed altered synaptic ultrastructure following chronic neuronal inactivation characterized by a marked increase in the number of presynaptic dense core vesicles, indicating a new structural mechanism that may underlie homeostatic synaptic plasticity.

Title: Excitability modulation of CA1 neuron by TRPV1 channels activation

Authors: *C. A. ROZAS[1], C. MAUREIRA[2], R. DELGADO[1], B. MORALES[1];
[1]Univ. of Santiago de Chile, Santiago, Chile; [2]Univ. de Chile, Santiago, Chile

Abstract: The functional properties of TRPV1 channels have been described mainly in the nocioceptive neurons of peripheral nervous system. TRPV1 channels are also present at central nervous system where the signaling and functional properties are less well known. At the hippocampus, TRPV1 channels regulate long-term plasticity (LTP and LTD) by modulating the GABAergic system. Moreover, several studies involve TRPV1 channels in network excitability. In the pilocarpine-induced model of epilepsy, TRPV1 protein levels increase in the dentate gyrus of hippocampus. TRPV1 agonists induce temporal lobe epilepsy in a mice model. Additionally, human patients of mesial temporal lobe epilepsy, also display increased expression of TRPV1 channels in temporal cortex and hippocampus. However TRPV1 channels role in CA1 excitability properties has not been addressed. Here, we evaluated the effect of pharmacological activation of TRPV1 channels on excitability of CA1 hippocampal neurons. We observed that TRPV1 channels agonists induces a threshold hyperpolarization and shortening of action potentials duration. This changes correlated with an increase on excitability on the f vs I transfer function, as well as a broad network excitability increase; nevertheless this changes do not associate with changes in the input resistance of neurons.

Title: Homeostatic regulation of presynaptic neurotransmitter release in the vertebrate neuromuscular synapse

Authors: *A. E. HOMAN, G. E. RIBBLE, S. D. MERINEY;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Homeostatic synaptic plasticity is an essential process by which a synapse is able to regulate its excitability to compensate for perturbations to the system. Homeostatic changes to postsynaptic receptors following alterations in activity have been well studied at central nervous system synapses, however less attention has been paid to presynaptic effects. Presynaptic homeostatic plasticity centers on the mechanisms by which the nerve terminal alters neurotransmitter release in response to either reduced or enhanced postsynaptic activity. While presynaptic homeostatic plasticity has been well characterized in *drosophila*, this form of plasticity has not been well studied at vertebrate synapses. Here we explore homeostatic regulation of neurotransmitter release at the vertebrate neuromuscular junction synapse. Following acute partial block (30-60 minutes) of postsynaptic nicotinic acetylcholine receptors, we observed a compensatory increase in quantal content (QC). We did not observe an increase in quantal amplitude, suggesting a presynaptic locus for modulation. Additionally, we observed a dramatic increase in short-term depression during a 50 Hz stimulus train over 10 stimuli, further supporting the conclusion that short-term partial postsynaptic receptor blockade increases the probability of neurotransmitter release. These data provide evidence that presynaptic modulation of neurotransmitter release can occur on a brief time scale in a vertebrate neuromuscular junction. The mechanisms for such plasticity, and the retrograde signal that induces presynaptic change following a postsynaptic receptor blockade are currently being studied. These changes are reminiscent of what has previously been observed at the human neuromuscular junction where quantal content appears to be larger in neuromuscular junctions from myasthenia gravis patients (who have fewer postsynaptic receptors) as compared to healthy individuals (Cull-Candy et al., 1980, J. Physiol., 299: 621). Overall, presynaptic homeostatic plasticity is likely to be an important adaptation that contributes to physiological alterations in synaptic activity, disease adaptations, and treatment effects.

Title: Evidence that mctp is presynaptic calcium sensor necessary for robust homeostatic plasticity

Authors: O. GENC[1], D. K. DICKMAN[2], W. MA[2], A. TONG[1], *G. W. DAVIS[1];
[1]Dept Biochem & Biophysics, Univ. California-SF, San Francisco, CA; [2]Neurobio., USC, Los Angeles, CA

Abstract: Homeostatic signaling systems are believed to interface with the mechanisms of neural plasticity to ensure stable neural function throughout life. At the neuromuscular junction of organisms ranging from *Drosophila* to human, inhibition of postsynaptic neurotransmitter receptor function is offset by a compensatory increase in presynaptic neurotransmitter release, restoring normal muscle excitation. This is referred to a presynaptic homeostatic plasticity (PHP). It is widely speculated that impaired or maladaptive PHP will participate in the cause or progression of diverse neurological disease states. However, a clear link to disease will necessitate a molecular understanding of PHP. We are pursuing a forward genetic screen based on synaptic electrophysiology to identify genes that, when mutated, block PHP. In this screen, we identified mutations in the mctp gene (Multiple C2 Domain and Transmembrane Region Protein). MCTP is highly conserved from *Drosophila* to human and has a unique structure comprised of two transmembrane regions and three cytoplasmic C2 domains. We have identified multiple mutations in the *Drosophila* mctp gene, including molecular null mutations generated by CRISPR/Cas9-mediated mutagenesis. Loss of mctp causes a statistically significant decrease in presynaptic neurotransmitter release that is rescued by transgenic neuron-specific expression of UAS-mctp in the mctp mutant background. We then demonstrate that MCTP is necessary in motoneurons for both the rapid induction and sustained expression of PHP. An epitope-tagged MCTP transgene that is sufficient to rescue PHP in the mctp mutant background is found to localize on a highly reticulated system of membranes that extend continuously along the motoneuron axons and throughout the presynaptic nerve terminal. We speculate that MCTP is localized on the presynaptic endoplasmic reticulum where it functions as a calcium sensor and/or calcium buffer that is essential for normal neurotransmitter release and presynaptic homeostatic plasticity.

Title: Cocaine occludes bidirectional synaptic plasticity between medium-sized spiny neurons of the nucleus accumbens and ventral pallidum projection neurons

Authors: *M. CREED, C. LÜSCHER;
Univ. of Geneva, Geneva, Switzerland

Abstract: Meaghan Creed, Christian Lüscher The ventral pallidum (VP) is a structure critically involved in hedonic and motivational processing of both natural rewards and of drugs of abuse. It is the primary output of the nucleus accumbens (NAc), receiving projections from D1- and D2-dopamine receptor expressing medium sized spiny neurons (D1- D2-MSNs), and projecting on to other brain regions involved in reward processing, such as the ventral tegmental area (VTA). Our group has previously shown that D1 and D2 MSNs in the NAc undergo distinct forms of synaptic plasticity following cocaine exposure (Pascoli et al., Nature 2011, 2014). Classical pharmacology and ablation studies have implicated the NAc and the VP in both the liking and wanting of natural rewards; both of these phenomena are decreased following exposure to cocaine (Smith et al., Behav Brain Res, 2009). In this study, we used mutated channel rhodopsin (chETA; capable of following stimulation frequencies of up to 100 Hz) expressed selectively in D1- or D2-MSNs of the NAc shell to dissect the contribution of each of these projections to cocaine-evoked plasticity in the VP. Consistent with previous studies (Kupchik et al., J Neurosci, 2014), we found that following passive cocaine exposure, inhibitory tone onto VP neurons was increased and there was an occlusion of inhibitory long-term potentiation (iLTP) induced by electrical high-frequency stimulation. We report that D1- and D2-MSNs project to the VP in roughly equal proportion and we describe opposing forms of synaptic plasticity at synapses between D1- and D2-MSNs and VTA-projecting VP neurons. Specifically, and in agreement with previous work, high-frequency stimulation applied selectively at of D1-MSN inputs to the VP induces LTP of these inputs (Bocklisch et al., Science, 2013) whereas and the same stimulation protocol applied at D2-MSNs induced a long-term depression (iLTD) at the stimulated inputs. These two forms of activity-dependent plasticity were expressed by distinct mechanisms and, importantly, both forms of plasticity were occluded by cocaine treatment. Finally, by optogenetically manipulating D1- and D2-projections to VP neurons we explore the

causal role of each projection in the decreased hedonic impact and drive to obtain a natural reinforcer following cocaine treatment.

Title: Regulation of local calcium dynamics at a reciprocal synapse

Authors: *C.-T. JUAN, M. HENDRICKS;
Dept. of Biology, IPN, McGill Univ., Montreal, QC, Canada

Abstract: Calcium plays diverse roles in neuronal function, and calcium dynamics are under precise spatiotemporal control. We recently characterized complex calcium dynamics in a pair of interneurons called RIA in *C. elegans*. We observed overlapping calcium events comprising local mobilization of internal stores, regulated by metabotropic acetylcholine receptors, and whole-cell events resulting from depolarization. These two types of events represent motor and sensory circuit activity, respectively, and interact on behavioural time scales to contribute to the regulation of head movements and locomotion. We are now characterizing the molecular mechanisms for establishing and regulating the spatial and temporal properties of local calcium events and their affect on pre- and post-synaptic function. Our results suggest that RIA compartmentalized calcium dynamics share molecular mechanisms with the regulation of local calcium events and plasticity in dendritic spines in mammalian neurons, in particular the involvement of ryanodine-sensitive pools and the role of plasma membrane Ca^{2+} ATPases in regulating calcium dynamics.

Title: A possible role for REM sleep in synaptic plasticity: Opposed changes in the CA3-CA1 and hippocampus-to-Nucleus Accumbens connections during sleep states

Authors: *J. CARPONCY[1], N. FRAIZE[2], P.-A. LIBOUREL[2], G. MALLERET[2], P. SALIN[2], R. PARMENTIER[2];
[1]CRNL - UMR 5292, Equipe SLEEP, Lyon, France; [2]CRNL, Lyon, France

Abstract: Numerous theories have been elaborated to explain how different sleep stages and oscillations may regulate synaptic plasticity and memory. However, studies showing modulations of synaptic efficacy during sleep-wake cycles are scarce; especially at connections linking areas involved in memory. It has been proposed that a loop between the hippocampus (Hpc), the Ventral Tegmental Area (VTA), and the Nucleus Accumbens (NAc) could be crucial for the consolidation of salient memories (Lisman and Grace, 2005). Therefore, we decided to focus on the synaptic transmission within Hpc and between Hpc and NAc, during sleep. More precisely, we examined the dynamics of synaptic changes in the connections linking these areas during the three vigilance states: Waking (Wk), Slow-Wave Sleep (SWS), and Paradoxical Sleep (PS or REM sleep). We recorded Excitatory Post-Synaptic Potentials (fEPSP) at the Schaffer Collaterals of the Hpc (CA3-CA1) and in the NAc after stimulation of the fornix, in freely-moving rats during several days. CA3-CA1 and Hpc-NAc synapses were differently affected by the vigilance states. CA3-CA1 synaptic responses increased during SWS but decreased during PS, in comparison to Wk. In contrast, we found that Hpc-NAc fEPSP responses were significantly increased during PS compared to Wk and SWS. Thus, PS appears to be a privileged state for the information transfer between Hpc and NAc, although SWS may facilitate the intra-hippocampal communication. Altogether, these dissociations during different sleep stages may be crucial for the cognitive purposes sustained by the Hpc-NAc-VTA loop. Thus, these findings could help to decipher the functions that sleep could have in the information transfer during memory consolidation and in the reinforcement of salient memories.

Title: Differential effects on somatic and dendritic inhibition in PFC layer V pyramidal cells by emotional trauma

Authors: L. LIU, W. ITO, *A. Y. MOROZOV;
Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Stressful events increase susceptibility of developing psychiatric disorders such as PTSD. Previous studies have shown that mice exhibit enhanced contextual fear learning and passive avoidance learning, after they observe cagemates but not strangers receiving electric foot shocks in the observational fear paradigm. The forms of fear learning enhanced by observational fear require activity of the prefrontal cortex (PFC). However, it is unknown whether the PFC circuits undergo plastic changes, which could potentially be responsible for the behavioral changes. The aim of this study was to identify changes of glutamatergic and GABAergic synaptic transmissions in mouse PFC 12 hours after observational fear. Using whole-cell recording in brain slices from 60-80 day old mice, we found that EPSPs evoked in PFC layer V pyramidal cells by 5 Hz trains of electric stimulation of PFC layer I were facilitated more strongly along the train and that neurons fired more action potentials during the stimulation in emotionally traumatized mice. These differences were no longer detected in the presence of picrotoxin (100 μM), a GABAa receptor inhibitor, suggesting that observational fear altered GABAergic rather than glutamatergic transmission. Consistently, IPSCs recorded in PFC layer V pyramidal cells exhibited more depression during 5 Hz train of electrical stimulation in observational fear group. Surprisingly, dendritic IPSCs, isolated by puffing picrotoxin on the soma of the recorded cell, showed less depression during 5 Hz train of electrical stimulation. Moreover, the differences between observational fear and control groups were eliminated with bath application of CGP 52432, a GABAb receptor inhibitor. To further test the effect on somatic and dendritic IPSCs, we used optogentics to selectively stimulate either somatically projecting parvalbumin (PV) interneurons or distally projecting somatostatin (SOM) interneurons in PFC. For observational fear group, IPSCs evoked by 5 Hz optical stimulation of PV interneurons showed more depression, while the ones from SOM interneurons showed less depression. These findings suggest that in mice after emotional trauma the balance of inhibition shifted from soma to distal dendrites in PFC layer V pyramidal cells. This may allow inputs to PFC deep layer to have stronger impact on PFC layer V pyramidal cells than inputs to superficial layer.

Title: Regulation of synaptic plasticity by the dark/light cycle

Authors: *K. HE[1], S. HATTAR[2], A. KIRKWOOD[3];
[1]Mind/Brain Inst., The Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurosci. (JHMI),Department of Biol., [3]The Zanvyl Krieger Mind/Brain Institute,The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Normal sleep is crucial for learning and memory formation. Moreover, a wealth of evidence indicates that the learning-related changes in synaptic connectivity initiated during the waking states are further consolidated and enhanced during the sleep stages. Most likely these synaptic changes require activity-dependent forms of plasticity such as long-term potentiation (LTP) and depression (LTD). Indeed, manipulations that disrupt the induction of LTP and LTD also prevent the consolidation of learning during sleep. In this context, it is well established that sleep-deprivation severely impairs the induction and expression of LTP. However, whether LTP and LTD are regulated by the natural sleep/wake cycle is still unclear. As a step into that direction we compared LTP/LTD in acute hippocampal slices harvested from mice that were sacrificed at the end of either the 12 h DARK cycle (mostly awake) or the 12 h LIGHT cycle (mostly sleep).We found that the magnitude of LTP and LTD is greatly reduced at the end of the light cycle, consistent with the idea that LTP/LTD-like activity is recruited to consolidate learning and memory during sleep.

Title: Hippocampal theta rhythm provides different modulation of long-term potentiation and spike excitability at the basal and apical dendrites of hippocampal CA1 pyramidal cells

Authors: C. S. H. LAW[1], *L. LEUNG[2];
[1]Physiol. and Pharmacol., [2]Univ. Western Ontario, London, ON, Canada

Abstract: The hippocampal theta rhythm facilitates memory formation. This study investigated the temporal relation of long-term potentiation (LTP) with the hippocampal theta rhythm. Theta rhythm consists of a wave of somatodendritic depolarization, but the depolarization of apical and basal dendrites of hippocampal CA1 pyramidal cells peak at a similar theta phase (Leung, J Neurophysiol 52: 1051). Thus, we hypothesize that the population spike excitability evoked by excitation of the apical and basal dendrites peak at a similar phase of the theta rhythm. We also expect that LTP at the basal and apical dendritic synapses to be maximal at a similar theta phase. Previous studies reported apical dendritic LTP at the peak of the apical dendritic theta, but did not quantify the relation between LTP and theta phase. Rats (~300 g) were anesthetized by urethane. Stimulating electrodes were placed in stratum radiatum and stratum oriens, to excite apical and basal dendrites of CA1 pyramidal cells, respectively. A 16-channel electrode array (50 μm between electrodes) recorded field potentials in CA1. Burst stimulation (5 pulses at 200 Hz, 3 x response threshold) was used to induce LTP, and a single pulse (~1.5x population spike threshold) was used to evoke a population spike. Apical (or basal) LTP was measured by the rising slope of the excitatory current sink at the apical (or basal) dendritic layer. Theta phase was derived from the theta field potentials recorded at stratum lacunosum-moleculare (90° = positive peak). Maximal population spikes evoked by single-pulse stimulation of the apical and basal dendrites occurred at the falling phase of theta (120°-160°). LTP was maximal when the burst stimulation occurred during the rising phase of theta, which was 306°-30° (basal LTP) and 333°-24° (apical LTP). The magnitude of LTP decreased gradually when tetanized at a phase different from the optimal phase. For the LTP averaged 30-120 min, there was a significant linear correlation of the LTP with deviation from the optimal phase [basal: $R2=0.23$; $p<0.05$; $N=25$, and apical: $R2=0.31$; $p<0.01$]. We conclude that theta rhythm sets up a temporal (or phase) gradient of synaptic plasticity at the basal and apical dendrites of hippocampal pyramidal cells. Both basal and apical LTP were optimal during the rising phase of the distal apical dendritic theta rhythm, distinctly different from the phase of maximal spike excitability that occurs in the falling theta phase. Possible mechanisms will be discussed.

Title: The effect of tissue on current shunting during anodal tDCS

Authors: *M. P. JACKSON, W. TUCKER, R. JANKORD;
Wright Patterson AFB, Wright Patterson AFB, OH

Abstract: Jackson M, Tucker W, Jankord R Transcranial Direct Current Stimulation (tDCS) is a non-invasive, inexpensive method of treating various psychological diseases, as well as improving memory and cognition. The purpose of this study was to examine the impact of tissue on current shunting during anodal tDCS *in vivo.* This study compares *in vivo* brain changes from anodal tDCS when an electrode is placed on the skull versus on the skin. Anodal tDCS was applied to Sprague-Dawley rats for 60 minutes. The anodal electrode (25 mm^2, 0.00 mm to -5.00 mm Bregma) was applied to the skull utilizing the following current densities (A/m^2): Sham (n=4), 6 (n=4), 12 (n=4), 20 (n=3), 40 (n=4), and 100 (n=3). tDCS was applied to the scalp utilizing the following current densities: Sham (n=2), 20 (n=3), 40 (n=3), and 100 (n=3). Slide mounted 16 μm thick brain tissue was processed for histological examination using Hematoxylin and Eosin (H&E) staining. Histological effects were quantified using an Olympus BX-63 microscope with Q100 Blue Camera and CellSens software. Stimulation of the skull showed a reduction or absence of cortical tissue occurring at 20 A/m^2, having an affected volume of 0.17 mm^3. At 40 A/m^2 and 100 A/m^2, the average affected volume within groups was 6.76 mm^3 and 13.01 mm^3, respectively. When these same current densities (20, 40, and 100 A/m^2) were applied to the scalp, no evidence of cortical histological alteration was observed. This study showed that brain tissue alterations from anodal tDCS can occur at 20 A/m^2 when the electrode is placed on the skull, which is less than the tDCS safety threshold previously identified. Our *in vivo* model showed no histological differences between scalp tDCS groups, consistent with predictions of the tDCS computational models. These results show skin tissue significantly attenuates the effect of current density on the brain, and that skin tissue will shunt a portion of tDCS current when the electrode is placed on the scalp.

Title: Anodal transcranial direct current stimulation improves hippocampal-dependent learning and memory by boosting synaptic plasticity through epigenetic modulation of Bdnf gene

Authors: *M. V. PODDA[1], S. COCCO[1], A. MASTRODONATO[1], S. FUSCO[1], L. LEONE[1], S. A. BARBATI[1], C. COLUSSI[2], M. MAINARDI[1], C. RIPOLI[1], C. GRASSI[1];
[1]Inst. of Human Physiology, Univ. Cattolica, Rome, Italy; [2]Inst. of Cell Biol. and Neurobiol., Natl. Res. Council, Rome, Italy

Abstract: In recent years several clinical trials have suggested that transcranial direct current stimulation (tDCS) improves cognitive and motor functions in healthy subjects as well as in patients with neurological and neuropsychiatric diseases. However upon which neural substrates tDCS acts in the brain and how exactly this technique modulates brain activity is still poorly understood. We previously demonstrated that *in vitro* DCS of acute hippocampal slices induced polarity-dependent modulation of long-term potentiation (LTP) at Schaffer collateral (CA3)-CA1 synapses (Ranieri et al., 2012). The present study investigated the impact of anodal tDCS on hippocampal synaptic plasticity in mice at electrophysiological, molecular and behavioral levels. Results showed that LTP at CA3-CA1 synapses was increased in hippocampal slices from mice receiving anodal tDCS (350 μA for 20 min). Interestingly 24 h and 1 week after tDCS-mice showed enhanced hippocampal-dependent learning and memory assessed by Morris water maze and novel object recognition tests. Significant molecular changes were detected in the hippocampi of tDCS-mice compared to sham-stimulated controls. They included: i) enhanced phosphorylation of CAMKII and CREB (pCREB133); ii) pCREB binding to the Bdnf promoter I and recruitment of the HAT CBP to the same promoter; iii) S-nitrosylation of HDAC2. Activation of CBP and inhibition of HDCA2 could account for enhanced H3K9 acetylation on Bdnf promoter I and consequent increase of Bdnf expression that we detected 24 h and 1 week after tDCS at both mRNA and protein levels. Epigenetic regulation of Bdnf expression by tDCS was confirmed by results showing that the HAT inhibitor curcumin prevented tDCS-induced increase in Bdnf mRNA and protein expression as well as memory enhancement. Suppression of

Bdnf signaling with the TrkB receptor antagonist, ANA-12, similarly occluded tDCS-effects on memory, thus supporting the role of this neurotrophin in mediating tDCS effects on hippocampal plasticity. Data reported here advance our knowledge on the neural substrates responsible for tDCS-dependent enhancement of learning and memory that is of key importance for the implementation of non-invasive brain stimulation techniques in routine clinical practice. Furthermore, our results lend support to use tDCS to treat a wide range of brain diseases associated to impaired neuroplasticity.

Title: The effects of transcranial magnetic stimulation on single neurons: Evidence for induced changes in synaptic function and excitability

Authors: *N. MATHESON[1], J. B. H. SHEMMELL[2], P. W. BROWNJOHN[2], J. N. J. REYNOLDS[1];
[1]Dept. of Anat., [2]Sch. of Physical Educ. Sport and Exercise Sci., Univ. of Otago, Dunedin, New Zealand

Abstract: Transcranial magnetic stimulation (TMS) is applied to the human brain in order to non-invasively activate neural circuits. Under certain circumstances, repetitive TMS (rTMS) can alter the activity of these circuits for a time outlasting the stimulation period, as evidenced by changes in peripheral motor-evoked potentials (MEPs). In addition to gross changes in cellular excitability, these prolonged changes have been interpreted as due to the induction of synaptic plasticity. At a single neuron level however, the effects of rTMS are not well understood and the

induction of synaptic plasticity or prolonged changes in cellular excitability have not been demonstrated. We used a rat model to study the effects of TMS on membrane potentials of single pyramidal neurons and subthreshold monosynaptic responses. *In vivo* intracellular sharp-electrode electrophysiological recordings were made from single cortical neurons in urethane-anaesthetized Wistar rats, during the application of TMS. Spontaneous neuron activity was recorded in response to single pulse and rTMS. In addition, post-synaptic potentials (PSPs) elicited using electrical or magnetic stimulation of the ipsilateral hemisphere were investigated both pre and post rTMS. Single pulse TMS consistently elicited both PSPs and action potentials in spontaneously active cortical pyramidal neurons. These responses were reliably obtained following stimulation at rTMS intensities much lower than those used in many clinical settings. During rTMS trains, spontaneous rhythmical neuronal activity was disrupted and in many cases neuronal firing was induced. Following rTMS, neuronal excitability was altered as indicated by lasting changes in rheobase current. Furthermore, long term potentiation (LTP) was induced using intermittent theta burst stimulation. These results provide the first indication of the effects that both single pulse and repetitive TMS have on cortical neuron excitability and synaptic plasticity. With a better understanding of these effects it is hoped rTMS protocols may be more effectively targeted to specific neural circuits, in order to optimize clinical treatment of neurological disorders.

Title: Coordinated plasticity at inhibitory and excitatory synapses

Authors: T. RAVASENGA, *A. BARBERIS;
Istituto Italiano Di Tecnologia, Genoa, Italy

Abstract: Learning and memory are believed to depend on plastic changes of neuronal circuits due to activity-dependent potentiation or depression of specific synapses. Traditionally, inhibitory synapses were assumed to be relatively invariant to ensure reliable control of the

neuronal and network plasticity was hypothesized to mainly rely on the flexibility of glutamatergic excitatory synapses. Nevertheless, an increasing body of evidence has revealed that inhibitory synapses undergo several types of plasticity at both pre- and post- synaptic levels. Here, we characterized a form of postsynaptic potentiation (iLTP) induced by depolarizing protocols delivered to pyramidal cells in hippocampal cultures. We show that 40 sec depolarizing pulses (0 mV) applied to the postsynaptic neuron induced a stable IPSCs potentiation that persisted up to 45 minutes. We observed that similar potentiation of GABAergic current amplitude was induced by postsynaptic low frequency stimulation (2 Hz). We demonstrated that this form of iLTP was CaMKII dependent, in line with recent studies showing the involvement of CaMKII in a specific form of chemical GABAergic postsynaptic potentiation (chem-iLTP). Intriguingly, CaMKII is also crucial for LTP of glutamatergic synapses mediated by synaptic accumulation of AMPA receptors at postsynaptic site. This shared molecular determinant suggests a potential source of interplay between plasticity occurring at GABAergic and glutamatergic synapses. Such "plasticity coordination" is expected to be crucial for the balance of dendritic excitation vs. inhibition (E/I) during network activity. We observed here that the aforementioned depolarizing protocols induced depression at glutamatergic synapses (LTD), indicating a non-homeostatic relation between inhibitory and excitatory plasticity. In order to further explore this issue we investigated how plasticity induced at glutamatergic spines interferes with the strength of GABAergic synapses by using a glutamate UV-laser uncaging approach. We report here that glutamatergic LTP heterosynaptically affects the GABAergic synaptic strength at single synapse level. Our findings suggest that E/I balance can be selectively tuned in spatially restricted dendritic sub regions.

Abstract: Chronic exposure to morphine often leads to reductions in spine density culminating into functional impairment of learning and memory. Strategies aimed at reversing the synaptodendritic injury are thus warranted in the field. PDGF is a pleiotropic growth factor that is involved not only in embryonic development but also plays a vital role in neuronal proliferation/differentiation during adulthood. Previous studies have demonstrated that PDGF-BB exerts its neuroprotective effect via the induction of synaptic plasticity gene Arc. The goal of this study was to explore the role of morphine in mediating synaptodendritic injury and the neuroprotective role of PDGF-BB in restoring this defect. Our findings demonstrated that morphine via its binding to the mu opioid receptor mediated the reduction of spine density and the excitatory synaptic marker vGlut1 with a concomitant upregulation of inhibitory synaptic marker GAD65 in rat primary hippocampal neurons. Morphine also elicited oxidative stress via the NADPH oxidase-dependent generation of reactive oxygen species (ROS), which also was critical for morphine-mediated synaptic impairment. Neuronal endoplasmic reticulum (ER) stress induced by morphine was essential for synaptic injury, and this effect was abrogated in cells pretreated with ROS inhibitors. Using pharmacological approach we demonstrated that autophagy played a critical role in morphine-induced synaptic impairment and was downstream of both oxidative and ER stress. Intriguingly, exposure of morphine-treated neurons to PDGF-BB resulted in reversal of morphine-mediated loss of spine density. This effect was accompanied by rescue of morphine-mediated loss vGlut1 and a concomitant upregulation of GAD65. We thus conclude that morphine-mediated synaptic impairment involving oxidative stress via NADPH oxidase and the downstream ER stress-autophagy pathways could be restored by PDGF-BB. PDGF could thus be considered as a therapeutic strategy for ameliorating morphine-associated cognitive impairment.

Title: Anxiety elicits synaptic potentiation through activation of AMPA-receptor subunit GluA3

Authors: *M. RENNER, E. H. H. ALBERS, N. GUTIERREZ-CASTELLANOS, N. R. REINDERS, T. R. LODDER, C. I. DE ZEEUW, H. W. KESSELS;
Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: Emotions influence memory formation. Norepinephrine release during arousal creates vivid memories by facilitating the synaptic delivery of GluA1-containing AMPA-receptors. However, the synaptic mechanisms that explain why high norepinephrine levels fail to improve memory formation during severe anxiety have remained unclear. Here we show that intense fear induces a massive and transient synaptic potentiation in the hippocampus by activating AMPA-receptor subunit GluA3. Under basal conditions GluA3-containing AMPA-receptors are inactive and contribute little to synaptic currents. During anxiety a rise in intracellular cyclic AMP driven by norepinephrine restores GluA3 channel and receptor function, leading to an increase in synapse strength. When mice are in a state in which GluA3-containing AMPA-receptors are activated, the ability to encode contextual fear memories is attenuated. We propose that the activation of GluA3-plasticity during an anxious moment prevents memories from becoming too strong.

Title: Electrical theta-burst stimulation modulates interhemispheric inhibition after photothrombotic stroke

Authors: *L. J. BODDINGTON, J. P. GRAY, J. N. J. REYNOLDS;
Anat., Univ. of Otago, Dunedin, New Zealand

Abstract: Interhemispheric inhibition (IHI) is thought to be altered after stroke. In anaesthetized rats we found that application of low-intensity electrical stimulation in an intermittent theta-burst stimulation (iTBS) pattern to the motor cortex abolishes interhemispheric inhibition (IHI) onto the opposite motor cortex. In the rat photothrombotic model, we found a month after stroke that iTBS applied similarly to the contralesional motor cortex can improve functional recovery. We hypothesized that this functional recovery was related to the cellular effects of iTBS on IHI. In order to investigate the cellular mechanisms and to explore the potential for using electrical TBS as a stroke therapy, we made *in vivo* intracellular sharp electrode recordings in urethane-anaesthetized rats following stroke and measured IHI in the peri-lesional motor cortex. A photothrombotic stroke was induced in the rat motor cortex, followed by the implantation of a cortical electrode to the contralateral motor cortex one week or four weeks after stroke induction. Rats received either iTBS, continuous TBS (cTBS) or sham stimulation for three weeks after electrode implantation, and following this, measurements of IHI were made from the peri-lesional cortex. In all sham-stimulation treated rats, IHI from the contralesional hemisphere was no different from IHI measured in acute healthy rats. Interestingly, and contrary to our hypothesis, the chronic application of iTBS in either of the delay groups did not reduce IHI compared with sham-stimulated rats (13.0% inhibition iTBS vs 14.1% inhibition sham), however chronic application of cTBS did show a large increase in IHI (23.8% inhibition). Consistent with an enhanced IHI, contralateral cTBS also significantly lowered the excitability of the peri-infarct area as evidenced by the 70% maximal amplitude of the EPSP obtained using a standardized input-output paradigm (4.0 mV ± 2.9 for cTBS, $p<0.05$ compared to other groups, One-Way ANOVA, $F = 4.365$; 12.6 mV ± 6.7 for iTBS and 13.6 mV ± 6.6 for sham, no difference). Tonic alterations in IHI and peri-infarct excitability may explain why the chronic application of electrical cTBS after stroke tends to impair recovery in our rodent model. This however does not fully explain why functional recovery can improve after contralateral application of electrical iTBS. We propose that chronic iTBS may reduce IHI dynamically during motor initiation. Further investigations will determine whether increasing the dose of stimulation increases the effects on IHI and excitability and further modulates functional recovery.

Title: Functional characterization of SNPs in the CPG2 region of human SYNE1 with potential relevance to Bipolar Disorder

Authors: *M. A. RATHJE, S. LOEBRICH, E. NEDIVI;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Bipolar disorder (BD) is a debilitating neuropsychiatric disease. A large genome-wide association study (GWAS) investigating risk genes for BD identified a significant association in parts of the human SYNE1 gene homologous to the region of rat Syne1 encoding CPG2, a postsynaptic neuronal protein localized to excitatory synapses and an important regulator of glutamate receptor internalization. Deep sequencing of patient and control populations in the human CPG2 locus identified multiple single nucleotide polymorphisms (SNPs) within protein coding and regulatory regions. This suggests that variation in human CPG2 function may affect glutamate receptor cycling in a way that would influence susceptibility to BD. To investigate this, we mapped CPG2 transcripts in the SYNE1 gene and cloned a full-length human CPG2 cDNA. We show this transcript is expressed in human neocortex and hippocampus. Using a lenti-viral gene knock down/replacement strategy and surface receptor internalization assays, we found that human CPG2 localizes to dendritic spines in rat hippocampal neurons and is functionally equivalent to rat CPG2 in regulating glutamate receptor internalization. Using this molecular replacement strategy, we have identified SNPs in exonic regions of the SYNE1 gene that significantly decrease CPG2 function. Elucidating the role of CPG2 in synaptic function may provide important insight to the cellular mechanisms of glutamatergic neurotransmission and its implications for neuropsychiatric diseases such as BD.

Title: Subchronic vortioxetine increases levels of Arc protein and phosphorylation of S845-GluR1 in the mouse frontal cortex - a putative mechanism underlying its pro-cognitive properties

Authors: P. KUGATHASAN[1], M. GULINELLO[2], C. SÁNCHEZ[1], *Y. LI[1];
[1]Lundbeck Res. USA, Paramus, NJ; [2]Behavior Core Facility, Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Introduction: α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptors (AMPA-R) are critical for the regulation of synaptic plasticity (e.g. formation of long-term potentiation [LTP]), which is essential for learning and memory. Activity-regulated cytoskeletal protein (Arc) is an immediate early gene which regulates AMPA-R trafficking via endocytosis of its GluR1 subunit. Several studies indicate that phosphorylation of serine 831 (by protein kinase C and calcium/calmodulin-dependent protein kinase II) and serine 845 (by protein kinase A, PKA) on GluR1 are critical for surface expression of AMPA-R and formation of LTP. The antidepressant vortioxetine (VOR) shows beneficial effects on cognitive function in preclinical and clinical studies. Furthermore, VOR increased LTP in rat hippocampus slices and expression of Arc mRNA in the hippocampus and frontal cortex in mice. Aims: To examine effects of subchronic VOR on protein levels of Arc and GluR1, and phosphorylation of GluR1, at baseline (home cage) and after exposure to a novel environment (novelty, a condition may induce Arc expression). **Methods:** Female C57BL mice were treated for 1 month with VOR-infused or regular chow. The VOR dose targeted full occupancy of serotonin transporters. Brains from mice exposed to a novel environment (for 6 min) were collected after 1h (to allow for protein synthesis) and compared to mice kept in the home cages (n=6 per treatment condition). Arc, GluR1, p-S831-GluR1 and p-S845-GluR1 levels were measured in frontal cortex by western blotting. Results were normalized to glyceraldehyde-3-phosphate dehydrogenase (Arc, GluR1) or GluR1 (p-S845 and p-S831) levels, and expressed as fold changes compared to baseline controls. Novelty and VOR effects were analyzed by 2-way ANOVA followed by Tukey-Kramer t-tests. $p<0.05$ was considered significant. **Results:** VOR significantly increased Arc levels, especially in the group exposed to novelty. Novelty had no effect on Arc protein. Novelty, but not VOR, significantly increased total GluR1 levels. There were overall effects of novelty and VOR on p-S845-GluR1 levels, but post-hoc analysis showed that only VOR increased p-S845-GluR1 at both baseline and novelty conditions. Neither novelty nor VOR affected p-S831-GluR1 levels. **Conclusion:** VOR increased cortical Arc protein, particularly after exposure to novelty, and increased PKA-dependent p-S845-GluR1 levels. These mechanisms may be important for VOR's effects on synaptic plasticity, and possibly also for its beneficial effects on cognitive function.

Title: Functional cannabinoid-induced isolation of CA1 from CA3 in rodent hippocampus

Authors: ***R. SANDLER**[1], D. FETTERHOFF[2], T. BERGER[1], D. SONG[1], R. HAMPSON[2], V. MARMARELIS[1];

Abstract: Much of the research on cannabinoids (CBs) has focused on the effects they have at the molecular and synaptic level. However, the effects of CBs on the dynamics of entire circuits of neural populations' remains poorly understood, especially given that their effects at the cellular level are often opposing. For example, CBs have been shown to promote independent mechanisms which would both suppress and increase network excitation. Similarly, different studies have shown that CBs have both proconvulsant and anticonvulsant properties on seizures. This study aims to disentangle the effects of CBs on the functional dynamics of hippocampal networks by using data-driven nonparametric modeling. Six rodents were trained to criterion on the Delayed-NonMatch-to-Sample (DNMS) task. Each rodent was subjected to 10 control sessions and 10 sessions exposed to Tetrahydro-cannabinol (THC), the primary cannabinoid found in marijuana. During each session, a multi-electrode array was used to record activity from the CA3 and CA1 regions of the rodent hippocampus. Multivariate autoregressive (MVAR) models describing the dynamical transformation from CA3 to CA1 were estimated from the data Traditional modes of analysis showed THC had no effect on rate coding (MFR) and only a slight effect on temporal coding (theta power). Systems analysis however, showed that THC strongly reduced theta information flow from CA3 to CA1. Furthermore, on a network level, by reducing feedforward excitation and increasing CA1 feedback excitation THC led to a functional isolation of CA1 from CA3. Both of these effects were shown to be correlated with behavioral

impairments in rodents during the DNMS task. This work is to our knowledge the first attempt to use data-driven nonparametric modeling techniques to understand the effects of cannabinoids on neural circuits. Clarifying the effects of THC on the network level may provide insight in how to optimize the use of THC as an anticonvulsant drug.

Title: Online modulation of hippocampal oscillatory activity *in vivo*

Authors: ***D. A. KUZMIN**, E. C. NICHOLSON, M. WESTON, D. M. KULLMANN; Univ. Col. London, London, United Kingdom

Abstract: Network oscillations in the brain are a strong candidate mechanism to modulate the flow of information among anatomically connected regions. Available evidence for this hypothesis is however largely correlational. A direct test would require a tool to manipulate the frequency, amplitude and/or phase of population oscillations without preventing neurons from encoding information in a population rate code. Optogenetics enables temporally precise manipulation of populations of neurons. In order to test its potential use to manipulate on-going oscillations we expressed the red-shifted excitatory opsin C1V1 in hippocampal pyramidal neurons and recorded the local field potential with an optrode positioned in the pyramidal cell layer in CA3 or CA1 in either anaesthetized or awake mice. Feedback control of laser illumination achieved bidirectional modulation of the amplitude of a gamma oscillation elicited by a slowly evolving ramp laser command. Oscillation gamma amplitude could also be modulated when the oscillation arose spontaneously. This ‘oscillation clamp’ may prove versatile in probing the behavioral role of population oscillations, especially in relation to their proposed roles in mediating flexible functional connectivity in the brain.

Title: GABAergic interneuron subtypes differentially regulate beta and gamma band oscillatory activity of primary visual cortex in awake mice

Authors: ***G. CHEN**[1], M. J. RASCH[2], Q. YE[2], X. H. ZHANG[2];
[1]Inst. of Neuroscience,Chinese Acad. Of Scien, Shanghai, China; [2]State Key Lab. of Cognitive Neuroscience&Learning, Beijing, China

Abstract: Neuronal population activity in the intact brain often exhibits different rhythmic patterns of distinct frequency ranges (0.01-120 Hz). The neuronal oscillations reflect different brain states and participate in specific sensory functions or behavioral tasks. In the awaking states, the most ubiquitous oscillations are rhythms in the beta (12-35 Hz) and gamma frequency (35-90 Hz) bands. Inhibitory GABAergic interneurons, though constituting 15-20% of the population in the cortex, possess diverse subtypes and play important roles in modulating cortical oscillations. However, how different interneuron subtypes gate the generation of distinct band of oscillations remains elusive. We combined extracellular electrophysiological recording and optogenetic methods to examine the contribution of distinct GABAergic interneuron subtypes, somatostatin (SOM)- and parvalbumin (PV)- expressing interneurons, to rhythmic activities in primary visual cortex of head-fixed awake mice. We found that drifting grating visual stimulus can significantly induce slower beta (15-35Hz) and modulate faster gamma band (50-80Hz) oscillations simultaneously. With the optogenetic tagging, the identified SOM+ interneuron shows an involvement to induced beta but not gamma band oscillatory activity, however, PV+ interneuron possesses two subtypes: one preferentially involves into beta oscillation, and the other involves into both beta and gamma oscillations. Optogenetic silencing or activating one type of interneuron uncovered that SOM+ and PV+ interneuron paces lower (<20Hz) and higher (20-80Hz) frequency band activity respectively. Inactivation of SOM+ interneuron abolished only the visual induced beta oscillation, however, inactivating PV+ interneuron abolished both the visual induced beta and gamma oscillations. Computational modeling results quantitatively

show that beta oscillation is preserved only under balanced activity between SOM+ and PV+ interneurons, meanwhile, visual modulated gamma oscillation can be simulated by the firing change of PV+ interneuron. These results provide evidence that SOM+ and PV+ interneuron subtypes distinctively and synergistically contribute to beta and gamma band activities in primary visual cortex of behaving mice.

Title: Membrane potential dynamics of spontaneous and visually evoked gamma rhythmicity in V1 of awake mice

Authors: *Q. PERRENOUD[1,2], C. M. A. PENNARTZ[2], L. J. GENTET[3];
[1]Dept. of Neurobio., Yale Univ. Sch. of Medecine, New Haven, CT; [2]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Univ. Lyon 1, Lyon, France

Abstract: Cortical gamma rhythmicity (30-80 Hz) is believed to play important functions in neural communication and arises from the activity of parvalbumin-expressing interneurons (PV). However, the mechanisms underlying its emergence and temporal patterning in awake animals are unclear. Here, we characterized the intracellular activity of PVs and pyramidal cells (PYRs) during spontaneous and visually evoked gamma rhythmicity in layers 2/3 of V1 of awake mice using targeted patch-clamp recordings and synchronous local field potentials (LFPs). Strong gamma bouts (1-3 cycles) occurred when PVs and PYRs were depolarizing, entrained their membrane potential rhythmically and emerged from the activity of PVs with characteristics of an Interneuron-Network Gamma model (ING). PV firing phase-locked unconditionally to gamma rhythmicity. However, PYRs only phase-locked to visually evoked gamma oscillations. Taken together our results indicate that gamma rhythmicity is driven by correlated background synaptic activity and synchronizes the output of cortical neurons depending on external sensory drive.

Title: Phase-locked inhibition, but not excitation, underlies hippocampal ripple oscillations in awake mice *in vivo*

Authors: **J. GAN**, S.-M. WENG, A. J. PERNÍA-ANDRADE, J. CSICSVARI, *P. JONAS; IST Austria, Klosterneuburg, Austria

Abstract: Sharp wave-ripple (SWR) events, which occur during awake immobility and non-rapid eye movement sleep, are thought to play a key role in memory consolidation. However, the underlying synaptic mechanisms *in vivo* remain controversial (English et al. 2014, J Neurosci 34:16509; Maier et al. 2011, Neuron 72:137). We performed simultaneous whole-cell patch-clamp recordings from CA1 pyramidal neurons and extracellular local field potential (LFP) measurements in awake mice *in vivo*. Recordings were obtained after full recovery from initial anesthesia and habituation to the head-restraint configuration. During resting wakefulness, SWRs occurred with a mean frequency of 0.22±0.02 Hz (153 events in 6 mice). On average, SWR events had a duration of 55.2±1.8 ms, and contained 8.6±0.3 ripple cycles, generated at a frequency of 153.2±2.0 Hz. To examine the synaptic mechanisms of SWRs, we measured excitatory and inhibitory synaptic currents (EPSCs and IPSCs) in CA1 pyramidal neurons during SWRs *in vivo* under voltage-clamp conditions at -70 mV and +10 mV, respectively (series resistance 16±2 MΩ). SWR-associated peak conductance was 1.6±0.3 nS for excitation and 3.5±0.7 nS for inhibition, corresponding to an inhibition-to-excitation conductance ratio of 3.7±1.0. Thus, synaptic inhibition dominated over excitation. Furthermore, plotting EPSC and IPSC peak amplitude against SWR amplitude revealed a significant correlation for IPSCs, but not for EPSCs. Thus, the magnitude of inhibition, but not that of excitation, predicted the amplitude of SWRs. To evaluate the phase relation between synaptic currents and ripple oscillations *in vivo*, we performed slope analysis of synaptic currents (Maier et al. 2011, Neuron 72:137). Onsets of EPSCs and IPSCs were detected as the 1-25% steepest downward and upward slopes, respectively, in the synaptic current traces (1517 and 1305 events). The Hilbert transform of filtered LFP traces (100-250 Hz band pass) was computed, and onsets of EPSCs and IPSCs

were individually assigned to phase values. Whereas EPSCs were uniformly distributed (P=0.79), IPSCs were significantly clustered in the ascending phase of ripple cycles (P=0.02; phase angle: -26.2±39.4º). Thus, phasic inhibition, but not excitation, was phase-locked to individual ripple cycles. Consistent with these results, slope-triggered averages of the LFP were rhythmically modulated for upward slopes (i.e. IPSC onsets), but not for downward slopes (i.e. EPSC onsets). In conclusion, our results indicate that inhibition dominates over excitation during SWRs, and phasic inhibition, but not excitation, shapes ripple oscillations in the hippocampal CA1 region *in vivo*.

Title: Martinotti cells defined by Chrna2 coordinate layer V pyramidal cell activity

Authors: *M. M. HILSCHER[1,2], R. N. LEÃO[1,2], K. E. LEÃO[2], K. KULLANDER[1]; [1]Dept. of Neurosci., Uppsala Univ., Uppsala, Sweden; [2]Brain Inst., Federal Univ. of Rio Grande do Norte, Natal, Brazil

Abstract: GABAergic interneurons in the mammalian cortex possess a broad variety of morphological, neurochemical and electrophysiological properties. The somatostatin+ Martinotti cells (MCs), are the most prominent slow-inhibitory interneurons targeting distal dendrites of pyramidal cells (PCs). We identified the cholinergic nicotinic receptor alpha2 (Chrna2) as a marker to label layer V/VI MCs ($MCs^{\alpha2}$). We used a Chrna2-cre mouse line crossed with a fluorescent reporter (tdTomato) confirming that the layer V/VI $MCs^{\alpha2}$ exhibit the defining characteristic of a long axonal projection to layer I and extensive ramifications in layer IV. Immunohistochemistry showed that the vast majority of Tomato+ cells comprised a subpopulation of somatostatin+ interneurons. Whole-cell current- and voltage-clamp recordings were performed in the auditory cortex and confirmed that passive and active electrophysiological

properties of $MC^{\alpha 2}$ resemble the classical low-threshold spiking patterns of MCs. Recorded $MC^{\alpha 2}$ usually exhibited spike frequency adaptation and burst discharge when depolarized from hyperpolarized potentials. In paired recordings, layer V PCs showed long inhibitory postsynaptic potential rise times and synaptic depression upon electrical stimulation of the presynaptic $MC^{\alpha 2}$. Moreover, optogenetic manipulation of channelrhodopsin-activated $MCs^{\alpha 2}$ demonstrated that layer V PC spiking can be controlled by MCs^{α} via oscillatory inhibition of PC distal dendrites suggesting that MCs^{α} may play a key role for PC network coordination.

Title: Criticality is non-stationary in cortical neuronal networks

Authors: ***G. HAHN**[1], A. PONCE-ALVAREZ[1], C. MONIER[2], G. BENVENUTI[3], A. KUMAR[4], F. CHAVANE[3], G. DECO[1], Y. FRÉGNAC[2];
[1]Univ. Pompeu Fabra, Barcelona, Spain; [2]UNIC/CNRS, Gif-sur-Yvette, France; [3]INT, Marseille, France; [4]KTH, Stockholm, Sweden

Abstract: The brain is able to generate complex spatiotemporal activity patterns which endow cortical networks with the ability to process and store information about the environment. Recent theoretical and experimental studies proposed the theory of criticality as a potential mechanism for complex dynamics in neuronal networks. Signatures of critical systems such as power laws and long-range spatio-temporal correlations were found both in local field potentials (LFP) and spiking activity of *in vitro* and *in vivo* preparations and interpreted as the presence of critical neural dynamics. Here, we recorded spontaneous activity in the primary visual cortex of anesthetized cats and awake monkeys using different types of multi-electrode arrays, and studied critical features of spiking activity as a function of cortical state. We separated up to five different states with different levels of population synchronization in spiking activity which in the case of the monkey were correlated with the level of arousal. Assessment of criticality based on neuronal avalanche analysis revealed a strong dependence of avalanche distributions on cortical state with power laws only to be found in highly synchronized states. In contrast, markedly curved distributions were observed during desynchronized states. Moreover, we investigated the presence of criticality by using maximum entropy models to study the joint

spiking activity patterns during the different cortical states. This allowed us to extract relevant "thermodynamic" features of the ensemble activity, such as the heat capacity that characterizes the dispersion of energies attributed to the activity patterns. The analysis of heat capacity also shows significant state-dependence and confirms that synchronized states are closer to criticality than desynchronized states. Overall, our results indicate that critical features of spiking activity strongly depend on the cortical state and are non-stationary.

Title: Dissecting parvalbumin-cell receptor mechanisms underlying ketamine action

Authors: N. PICARD[1], *H. H. LEE[2], A. E. TAKESIAN[3], M. FAGIOLINI[3], T. K. HENSCH[3]; [2]Neurol., [1]Boston Children's Hosp., Boston, MA; [3]Boston Children's Hosp., boston, MA

Abstract: Ketamine is known to decrease cortical inhibition in humans and behaving animals, leading to cognitive deficits such as psychosis. The mechanisms underlying this ketamine action are far from understood but evidence points toward an effect mediated through fast spiking Parvalbumin (PV)-positive inhibitory interneurons. Here, we used genetic manipulations to selectively remove receptors from PV cells, to further understand the effect of a low dose of ketamine (8mg/kg) on cortical activity in mice. In anesthetized wild-type (WT) animals, single-unit recordings in visual cortex showed that a single ketamine injection rapidly increased both spontaneous activity and visually-evoked responses of pyramidal cells. As ketamine is a NMDA receptor antagonist, we first deleted the NMDA receptor 2A subunit specifically from PV cells by crossing PV-Cre mice with Floxed GluN2A mice. In these animals, the ketamine-induced

increase in pyramidal cell activity was delayed, but eventually reached control levels 60 minutes after the injection. This result fully explained a similar loss of the initial ketamine response in global NMDA-2A receptor knockout mice. Strikingly, whole-cell recordings *in vitro* revealed a broadening of PV-to-PV inhibitory postsynaptic currents (IPSC) in the presence of ketamine (McNally et al, 2011). To investigate the involvement of GABAergic inhibition in the ketamine response, we also recorded mice in which the GABAAR-alpha1 subunit was selectively removed from PV cells to mimic this IPSC broadening. In these mutants, ketamine now produced an opposite effect to that seen in WT, rapidly decreasing the firing rate of pyramidal cells. Importantly, NMDA receptor subunits were unaltered in PV-cells from these mice. At a system level, the electroencephalogram of awake WT mice exhibited an increase in frontal cortex gamma oscillations in response to low-dose ketamine. This effect was smaller in the PV-Cre:GABAAR-alpha1 knockout mice and enhanced in the PVCre:NMDA-2A mutants. Taken together, our results demonstrate that the excitatory/inhibitory balance within PV cells is essential for determining the response to low-dose ketamine

Title: Cell-type specific microcircuitry in the CA3 region of the hippocampus

Authors: *D. L. HUNT, N. SPRUSTON;
Howard Hughes Med. Inst., Ashburn, VA

Abstract: Cell-types and microcircuits have been canonically defined based on cellular morphology, physiology, and afferent/efferent projection patterns. While these criteria remain indispensible, the classical techniques used to establish these standards often lack the specificity necessary to dissect the complexity of intermixed but distinct pathways. Modern techniques utilizing transgenic mice and optogenetics have the ability to interrogate microcircuits with cell-type specificity, redefining our understanding of circuit architecture and function. Here we have identified at least two types of principal cells within the CA3 region of the murine hippocampus.

These two pyramidal cell-types have distinct morphological attributes, physiological properties, and connection specificity. By combining optogenetics and electrophysiology with high-resolution semi-automated neuronal reconstruction, we demonstrate distinct signatures of cell-type specific microcircuits in the CA3 region. One sub-population of CA3 principal neurons lack the characteristic thorny excrescences typically associated with canonical CA3 pyramids. These athorny pyramidal cells also have other distinct morphological features such as fewer dendritic branches, lower branch order, and decreased dendritic diameter compared to their thorny counterparts. Athorny neurons also exhibited bursting intrinsic firing patterns, higher input resistance and a more prominent post-spike afterdepolarization. Most strikingly, we utilized channelrhodopsin assisted circuit mapping and were unable to find any evidence that athorny cells receive direct mossy fiber input; however they do receive di-synaptic recurrent input from other CA3 cells. Together, these data suggest that this subpopulation of athorny bursting cells constitute a previously unrecognized feed-forward sub-layer embedded within the CA3 recurrent network.

Title: Electrical connectivity overrides individual neuron dynamics dictating homogenous network behavior

Authors: *A. S. STAGKOURAKIS, C. THÖRN PEREZ, A. HELLYSAZ, R. AMMARI, C. BROBERGER;
Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Rat tuberoinfundibular dopamine (TIDA) neurons exhibit robust synchronized low-frequency oscillations *in vitro*, providing a tractable mammalian system for the study of spontaneous network rhythms. While the TIDA oscillation appears to depend on intact gap junction coupling between neurons, the nature of electrical coupling and its contribution to network behaviour remains to be addressed. Here, we exploited an unexpected species difference to explore this issue. Whole-cell recordings were performed in male rat and mouse (P21-30) hypothalamic slices maintained in oxygenated artificial cerebrospinal fluid at near physiological temperature (ca. 34oC) under differential interference contrast visualization. While rat TIDA cells oscillated in robust synchrony and phase alignment, mouse TIDA neurons were found to exhibit rhythmic but uncoordinated oscillatory discharge. Mouse TIDA oscillations were of higher frequency (mouse: 0.4±0.05Hz, n=78; rat: 0.15±0.01Hz, n=85) and less regular and mouse TIDA neurons were more depolarized (oscillation nadir mouse: -51.1±0.9mV; rat: -66±1.1mV). Notably, whereas rhythmicity persists at constant frequency in rat TIDA cells upon progressive hyperpolarization via negative current injection, this manipulation causes the oscillation to collapse in the mouse (ca. -80mV, n=34). We next addressed if differences in electrical characteristics or connectivity might explain the discrepant network behaviour. Baseline membrane properties - as assessed by square pulse commands in current and voltage clamp - were not obviously different between the two species, and in both cases phasic discharge endures when fast synaptic transmission is blocked. However, substantial electrical connectivity was found in rat (n=32/64 pairs; 0.18±0.02 coupling coefficient), but was absent in mouse (n=0/40 pairs) TIDA neurons. These findings suggest that the presence of gap junctions not only synchronizes neurons but also determines network frequency. Investigation of the preferred frequency of individual TIDA neurons provided further support to this conclusion: while the cells in both species exhibit maximum impedance at the same frequency, this frequency in the mouse (n=18, 0.35±0.03Hz) is the same as oscillation frequency, whereas the rat oscillation frequency is significantly lower than the average preferred frequency of individual cells (n=31, 0.30±0.02Hz).

Title: Dynamical constraints on improving coding fidelity through the `sign rule'

Authors: *B. KRIENER, I. FIETE;
Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: It has been suggested that noise correlations, appropriately tuned, can substantially increase coding fidelity in neural representations compared to if noise is independent across neurons. For stimulus discrimination, correlations that decrease noise fluctuations along the stimulus-response direction improve information transfer compared to the uncorrelated case [1-3]. This observation is called the `sign ruleâ€™ in two dimensions, because noise correlations are of opposite sign from the stimulus-evoked (signal) correlations. Finally, large gains in coding capacity can result from realistically small microscopic correlations, if of the right variety [3]. We ask whether it is plausible to independently tune signal and noise correlations according to the sign rule, considering that in reality both are shaped by the recurrent network dynamics. We investigate simple models of neural networks in quasi-2D configurations, in which we derive the signal and noise correlations as a function of network parameters, including weights, for both stationary and time-dependent stimuli. In linear networks, optimizing weights to flatten noise along the stimulus direction results in vanishing signal-to-noise ratio (SNR), while maximizing the time-varying stimulus-content in the response yields finite fluctuation size along the stimulus direction that is independent of network parameters and can thus not be further minimized. We extend our analysis to balanced random networks of binary and leaky integrate-and-fire neurons. These networks can assume asynchronous-irregular activity states akin to what is observed in cortex, and pairwise correlations are inherently decreased by the ongoing recurrent inhibitory feedback [4]. Though this helps to reduce noise correlations, it also limits the achievable amount of stimulus content in the network response. We conclude that the form of correlation shaping required for the sign rule also modifies the stimulus response to the detriment of the SNR, at least in our network architectures. Title: NMDA receptor and protein kinase A signaling modulates firing properties of cerebellar stellate cells

Authors: *R. ALEXANDER[1,2], D. BOWIE[3];
[2]Integrated Program in Neurosci., [3]Pharmacol. and Therapeut., [1]McGill Univ., Montreal, QC, Canada

Abstract: In the mammalian brain, the action potential (AP) underlies the complex, oscillatory behavior of neuronal circuits orchestrated by a network of fast-spiking inhibitory interneurons and slower-spiking excitatory principal neurons. In the cerebellum, a region classically associated with motor coordination and learning, the stellate cell is one of several subtypes of GABAergic inhibitory interneurons found in the cerebellar cortex. We have observed a novel form of NMDA receptor-dependent firing rate modulation that increases the degree of inhibition on the cerebellar micro-circuit. Acute slices of cerebellar vermis were obtained from both male and female wild-type C57BL/6 mice by vibrating-blade microtome sectioning. Slices were continually perfused with saline solution and visually identified using an upright microscope. After establishing whole-cell configuration during patch-clamp recording, these cells exhibit a passive increase in AP frequency evoked by current steps over the course of recording (3.46 fold after 25 minutes), curiously also observed in excitatory granule cells but not Purkinje neurons. This increase in firing rate was found to be related to a hyperpolarization of AP activation threshold (-8.2 mV change, n=6 stellate cells), which allowed cells to spike earlier and more often. Performing cell-attached electrophysiological recordings with Na+-based pipette solution yielded no increase in spontaneous action current frequency, but after local application of NMDA agonist (1 mM) there was a chronic increase in number of spikes (56%, n=5 stellate cells) that closely mirrored the time course observed in whole-cell experiments. Repeating cell-attached recordings with high K+ internal pipette solution induced a similar chronic increase in spontaneous action currents but could be blocked by bath application of NMDA receptor antagonist D-APV (10 μM), suggesting this firing rate plasticity mechanism is effected by NMDA receptor signaling. Furthermore, inhibiting the activity of protein kinase A (5 μM PKI-(6-22)-amide), but not protein kinase C (1 μM Gö 6983), significantly attenuated the hyperpolarization of AP activation threshold over the whole-cell recording duration. Further investigation into the signaling cascade responsible for this firing rate increase has physiological relevance as a novel regulatory mechanism of inhibitory circuits. Our work will provide new insight into the role of NMDA receptor-dependent excitability modulation in the cerebellar circuit.

Title: Excitatory and inhibitory innervation of *in vivo* recorded and labeled individual dopaminergic neurons of the ventral tegmental area

Authors: *T. MONTERO, C. GONZALEZ-CABRERA, P. HENNY;
Lab. de Neuroanatomia, Dept. de Anatomia Normal, Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: Dopaminergic neurons of the ventral tegmental area (VTA) are involved in several functions such as behavioural reinforcement and motivation. The activity of VTA dopaminergic neurons is controlled by intrinsic membrane properties, which underlie tonic firing, and the activity of glutamatergic, cholinergic and GABAergic afferents, which mostly underlie phasic discharge and/or inhibition. While it is recognised that the distribution of synaptic afferents onto the somatodendritic domain affect the discharge patterns and responses of central neurons, it is yet unknown how the localisation of inputs can affect activity in VTA dopaminergic neurons. In fact, in rat SNc dopaminergic neurons it has been shown that the distribution of GABAergic inputs onto distal dendrites relates to the strength by which neurons respond to noxious stimulation (Henny et al., Nat. Neurosci., 2012). In order to understand the mechanisms that underlie driven activity in VTA dopaminergic neurons, we set up a project to study the somatodendritic distribution of glutamatergic and GABAergic synapses onto individual. In urethane anaesthetised adult mice, we recorded and labeled VTA single neurons using the juxtacellular technique, followed by brain fixation and histological processing. Dopaminergic phenotype of individual neurobiotin-labeled neurons was established by their immuno-positivity to tyrosine hydroxylase (TH). The presence of glutamatergic and GABAergic synaptic inputs onto neurobiotin labeled soma or dendrites, was determined using double labelling for the scaffolding protein homer1 (HOM) or gephyrin (GEPH), as markers of excitatory or inhibitory postsynaptic densities, respectively. The entire somatodendritic domain of neurons was observed and acquired using confocal microscopy, after which we used stereological tools to count and examine the distribution of synaptic inputs.

Title: Physiology and ion channel expression of axons of amygdala projection neurons

Authors: *J. GRUNDEMANN[1], S. KRABBE[1], E. VOGEL[1], K. BYLUND[1], C. MÜLLER[1], V. SENN[2], A. LUTHI[1];

Abstract: Axons are the principal elements of neuronal signal generation and propagation in the brain. Despite this central function, our knowledge of axonal physiology originates mainly from classical studies of peripheral and cranial nerves, which is typically generalized to the CNS. However, there is a growing body of evidence demonstrating that CNS axons are highly diverse between various brain areas with remarkable functional properties that influence neuronal output and signal transmission (Debanne et al., 2011). Most of these studies were performed in the cortex, hippocampus, cerebellum or auditory brain stem, whereas little is known about the physiological function of axons of amygdala projection neurons - pyramidal-like neurons which are critically involved in emotional learning and processing. Here we use a combination of direct axonal electrophysiological recordings and two-photon Ca2+ imaging to characterize the features of axonal action potential initiation, transmission and activity-dependent Ca2+ signaling in basolateral amygdala projection neurons. In addition, we investigated their axonal ion channel distribution and myelination pattern using immunohistochemistry and confocal imaging. These data will not only increase the knowledge of the physiological variety of CNS axon function, but also provide further insight into the functional properties of amygdala projection neurons, which are potential drug targets for the treatment of anxiety disorders. Abstract: In mammalian central neurons, action potentials are initiated in the axon initial segment (AIS) by Nav1.2 and Nav1.6 channels, and shaped and terminated by other voltage-gated ion channels. From the AIS, the AP travels down the axon towards the presynaptic site, but also back-propagates towards the soma. The role of axonal sodium channels in AP initiation and propagation is still incompletely understood, mostly because it is difficult to record from these channels at the AIS. Instead, most experimental evidence of axonal activity is obtained indirectly, from electrical recordings at the soma. We have previously developed a real-time computational procedure where a compartmental model of the axon is coupled to a live neuron using dynamic clamp. Here, we are investigating how the observed neuronal behavior, particularly the shape of the AP recorded at the soma, depends on the parameters of the axonal model, such as density and distribution of Nav channels.

Title: Neurons in rat retrosplenial cortex display heterogeneity of firing type

Authors: *A. N. NYE[1], C. SONG[1], J. R. MOYER, Jr.[1,2];
[1]Psychology, [2]Biol. Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The retrosplenial cortex is a structure that is connected with many different regions of the brain (hippocampus, parahippocampal regions, visual cortex, thalamic nuclei and rhinal cortices) in both primates and rodents. Furthermore, previous human and animal research suggests that the retrosplenial cortex plays a vital role in the learning and memory of spatial and contextual information. Recent data suggests that retrosplenial cortex is also involved in extinction of trace fear conditioning. Unfortunately, few studies have investigated the electrophysiological properties of retrosplenial cortical neurons. In the current study, coronal brain slices were prepared from experimentally naïve adult F344, and Sprague Dawley rats. An upright microscope equipped with infrared DIC optics was used for visualizing the neuron and patch electrode, and whole-cell recordings were made from neurons located throughout different layers of granular retrosplenial cortex. Electrodes included biocytin in order to confirm laminar location of neurons, and obtain detailed morphological analyses. Preliminary analyses of data from 28 neurons revealed several distinct firing patterns, which included regular spiking, late spiking, burst spiking, and double spiking neurons. Regular spiking neurons fired single action potentials at threshold. In contrast burst spiking neurons fired a burst of 3 or more action potentials, and double spiking neurons fired a doublet at threshold. Furthermore, a subset of neurons also displayed a pronounced afterdepolarization, but with higher current injections these neurons also fired a doublet. In response to a just-suprathreshold current injection, late spiking neurons delayed their firing until near the end of the .5-sec current injection (mean spike latency ~629 ms), as compared to neurons from all other firing types (mean spike latency 336 ms). These late spiking neurons also had a more hyperpolarized resting membrane potential (-70 mV versus -64 mV for other cell types) and a higher input resistance (355 MΩ vs. 150 MΩ for other firing types). Ongoing analyses are investigating the relationship between neuronal firing properties and morphological characteristics. These studies will contribute important physiological and morphological data and lay the foundation for understanding how retrosplenial cortex contributes to learning and memory as well as aging-related learning deficits.

Title: Reconciling neuromodulation and homeostasis

Authors: *T. O'LEARY[1], G. DRION[1], A. FRANCI[2], E. MARDER[1];
[1]Volen Ctr. For Complex Systems, Brandeis Univ., Waltham, MA; [2]Mathematics Dept., Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Neuromodulators can alter the activity state of neurons and circuits for prolonged periods. For example, during locomotion, motor circuits switch from one rhythmic state to another, or from quiescence to sustained pacemaking activity [1]. This continual switching poses a potential problem for so-called homeostatic mechanisms, which are traditionally believed to push activity levels toward a 'set point'. Here we show, using a very simple theoretical model of activity-dependent ion channel regulation [2], how pronounced and long-lived changes in activity can be induced by the action of neuromodulators without interfering with ongoing homeostatic regulation. We use physiologically relevant conductance -based models of central pattern generating neurons to illustrate the general theoretical principles. Furthermore, our results reconcile reliable modulation with underlying variability in the ion channels and receptors that are targeted by modulatory substances [3], and offer a clue as to why single modulator receptors sometimes target multiple currents in a neuron. Title: Dopamine modulation of motor cortical microcircuit

Authors: ***M. LE BON-JEGO**, A. MOHANRAJ, A. TAUPIGNON, J. BAUFRETON;
Inst. des Maladies Neurodégénératives CNRS UMR 5293, Univ. De Bordeaux, Bordeaux Cedex, France

Abstract: Voluntary movement is mainly a cortical activity and sub-cortical loops including the basal ganglia network are involved in the control of this voluntary movement. Parkinson's disease (PD) is characterized by a progressive degeneration of dopaminergic neurons in the substantia nigra, one of the structures of the basal ganglia. The resulting lack of dopamine is the cause of the typical symptoms observed in this disease characterized by rigidity, resting tremor and akynesia. To better understand what are the cellular and subcellular mechanisms of Parkinson’s disease, most people are focusing on the basal ganglia. However, it has already been shown that 1) the deep layers of the primary motor cortex (M1) received dopaminergic innervation and 2) *in vivo* the activity of neurons in M1 is altered in monkeys rendered parkinsonian. Indeed, neurons exhibiting tonic activity in normal condition switch to bursts of discharge which are synchronized among neurons. Thus, it possible that the dopaminergic innervation of the cortex can be crucial for the operation of this motor cortical microcircuit and consequently the lack of dopamine in PD may impact directly the activity of the cortical microcircuit. The aim of this work is to decipher the role of dopamine on the function of these motor cortical microcircuits in physiological and physiopathological conditions in mice. We use an experimental approach that combines *in vitro* conventional electrophysiology techniques (patch clamp in current or voltage clamp configuration), optogenetic and functional calcium imaging on acute brain slices of PVCreAi9T mice which have all Parvalbumin (PV) inhibitory interneuron fluorescent that allow to discriminate easily between PV IN and pyramidal neuron. We are currently testing the effect of dopamine 1) on the intrinsic properties of the different types of neurons, and 2) on the synaptic transmission between the different elements of the cortical microcircuit. Our results show that in normal condition, dopamine increases the excitability of most type of neurons through a D2 receptor-mediated effect.

Title: Linking the electrophysiological diversity of mammalian neurons to gene expression

Authors: ***S. TRIPATHY**, L. TOKER, D. TEBAYKIN, O. MARCARCI, P. PAVLIDIS; Ctr. for High-throughput Biol., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Brains achieve efficient function through implementing a division of labor, in which different neurons serve distinct computational roles. Neuronal computations are established through the expression of combinations of ion channels and associated proteins which define neuronal electrophysiological properties. Despite numerous studies characterizing neuronal physiological properties and gene expression patterns, linking neuron genomics to neuron function has been challenging due to the complexity of these heterogeneous data. Here, employing data integration and machine-learning approaches, we combine published reports of neuronal physiological properties with corresponding gene expression measurements. Specifically, we integrate NeuroElectro (www.neuroelectro.org), our database of literature-mined neuron-type physiological diversity, with public genome-wide microarray datasets from purified neuron types (e.g., Dougherty et al. 2008). Thus for 25-30 neuron types, like neocortical basket cells or striatum medium spiny neurons, we can correlate biophysical differences among these neurons with differential expression of specific genes or sets of genes. We demonstrate that relative differences among the genes that neurons express are significantly predictive of neuronal biophysical parameters (such as resting potential and input resistance; R2 = .65, .41). Our approach allows us to ask which genes, of the 20,000 in the genome, are most predictive of electrophysiological diversity. In addition to ion channel genes (such as BK channels, e.g. Kcnma and Kcnmb4), genes related to synaptic plasticity and neuronal differentiation (e.g.

Homer1 and Slit3) were also surprisingly correlated with neuronal physiology. Moreover, cross-referencing these gene lists with those implicated in mental disorders, we find that these genes are also disrupted in epilepsy, schizophrenia, and autism.

Title: Paradoxical effects of A-type potassium currents on neuron FI curves

Authors: ***G. DRION**, T. O'LEARY, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: Neural circuit function can be understood by viewing neurons as input-output devices, each with a characteristic curve describing how synaptic input is transformed into firing frequency. The shape of such a frequency-input (FI) curve is readily measured experimentally and is often characterized into two types of excitable behavior: Type I neurons, which smoothly transition from quiescence to firing at arbitrarily low frequencies as input increases, and Type II neurons, which exhibit a sharp jump to a non-zero frequency at threshold (Hodgkin, 1948; Rinzel and Ermentrout, 1989). Here we revisit the classic result that A-type potassium current (IA) 'linearizes' FI curves, transforming them from Type II to Type I (Connor and Stevens, 1971; Connor et al., 1977; Rush and Rinzel, 1995). Using recently developed analytical tools, we show that the classical account is incomplete: IA causes a second transition from Type I back to a Type II-like FI curve as its density increases. Furthermore, we show that completely unrelated currents, such as calcium currents, can cause the same transitions and that some IA currents

described in the literature cause paradoxical effects. These findings generalize across many neuron models that are found in the literature, regardless of the variety of voltage-gated conductances. Title: The depolarized after-potential following the spike in unmyelinated axons in the CNS reduces conduction failures occurring at fever-like temperatures

Authors: D. PEKALA[1], H. SZKUDLAREK[2], *M. RAASTAD[1];
[1]Dept Physiol, Emory Univ. Sch. of Med., Atlanta, GA; [2]Jagiellonian Univ., Krakow, Poland

Abstract: Most axons propagate action potentials (APs) with great fidelity at normal body temperature. However, conduction failures have been detected e.g. in demyelinated axons at fever-like temperatures. Whether such temperatures give failures in the very thin unmyelinated axons typical for cortex is not known. Therefore, we have investigated the influence of temperatures in the upper physiological range on AP propagation in cerebellar parallel fibers (PFs). We used cerebellar slices from 10 - 25 days old rats. Fast synaptic transmission was blocked by adding APV, DNQX and picrotoxin to standard bath solution. First, we recorded electrically elicited compound action potentials (CAPs), at two sites along the PF path, to distinguish between activation and propagation failures. Increasing the bath temperature from 30

to 37 oC reduced the amplitude of the CAPs proportionally at the two recording electrodes. Further increase to 39 - 43 oC decreased the amplitudes of the CAPs at the distal electrode more than at the proximal one. This suggests that some APs failed to propagate between the two recording sites, due to the high temperature. Interestingly, when we used 4 stimuli with 10 or 20 ms intervals, the amplitude of the 4th CAP at the distal electrode was reduced less than the amplitude of the 1st CAP at 39 - 43 oC. We hypothesized that the depolarizing after-potential (DAP) following individual APs in PFs could facilitate the propagation of the APs that followed the first AP in the train. A 13-17% reduction of latency of 2nd, 3rd and 4th CAP, compared to the 1st one, supported our hypothesis. Furthermore, the similar drop in latency of CAPs 2-4 suggested that the level of depolarization provided by the DAPs were similar for all APs in the train. To support that suggestion we studied the shape of the DAP at temperatures between 30 and 41 oC using a grease-gap technique. We confirmed that the DAP was present in PFs in that temperature range. and the shape of the DAP was relatively similar after each CAP in 4-stimuli trains. As we have shown earlier, the DAP can also be recorded from the granule cell soma when antidromically travelling APs invade the soma. This somatic invasion can be prevented by hyperpolarizing the soma. We utilized a level of hyperpolarization that made approximately half of the APs fail to invade the soma. When the 1st AP propagated all the way to the soma, the following APs never failed. Our results suggest that the DAP can reduce conduction failures, in an activity dependent manner, in situations with reduced safety factor, e.g. during fever.

Title: Size and dendritic localization of the axon initial segment correlates with *in vivo* spontaneous firing of individual substantia nigra dopaminergic neurons

Authors: *P. HENNY, R. C. MEZA;
Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: In substantia nigra compacta (SNc) dopaminergic neurons the axon usually emerges from a primary or higher order dendrite. Actions potentials are generated at the most proximal region of the axon, the axon initial segment (AIS). This unmyelinated region is enriched in sodium and other ionic channels, as well as scaffolding proteins such as Ankyrin-G (Ank-G). As shown in other central neurons, the molecular composition, size and location of the AIS is known to influence the neuron's activity. In order to describe the mechanisms that influence firing in SNc dopaminergic neurons, we carried out a project to examine whether the structural characteristics of the AIS relate to the spontaneous tonic firing pattern showed by these neurons *in vivo*. Adult male mice SNc neurons were recorded under urethane anaesthesia. Neurons were recorded during spontaneous activity at least 15 minutes before neurobiotin labelling using the juxtacellular method, after which animals were perfused and their brains removed and serially sectioned. Neurons were revealed using streptavidin-Cy3 and identified as dopaminergic using immunofluorescence for tyrosine hydroxylase. To determine the shape and localisation of the AIS, entire individual neurons were traced and 3D reconstructed from labeled fragments acquired with a confocal microscope. The localisation of the AIS was confirmed using further immunofluorescence staining for Ank-G. Structural analysis show variable dendritic origin and size of the AIS in SNc dopaminergic neurons. The two variables nonetheless relate in that length of AIS diminishes with distance from the soma. Notably, electrophysiological analyses show that AIS length/localisation predicts spontaneous basal firing rate, in that neurons with large/proximal AIS fire faster than neurons with small/distal AIS.

Title: Metabolic constraints on neuronal signaling

Authors: *M. L. GERTZ, Z. GREGURIC FERENCEK, Z. OBAIDA, J. R. CRESSMAN, Jr.;
George Mason Univ., Fairfax, VA

Abstract: Neuronal systems process information through action potential generation and transmission, synaptic transduction, and dendritic summation. These processes are driven by the dissipation of energy stored in the cells electrochemical gradients. Reduced gradients can significantly alter cellular function and ultimately lead to the failure of neuronal signaling. In order to maintain normal signaling, these gradients are reestablished through the conversion of ATP to ADP by the Sodium/Potassium pump. The concentration of ATP is primarily maintained through glucose metabolism. In order to elucidate the constraints on neuronal activity we use a conductance based model incorporating ionic dynamics and a simplified model of glucose metabolism. Ionic dynamics are modeled in thirteen compartments: three neuronal compartments, three glial compartments, six extracellular compartments and a vascular compartment. We utilize extracellular measurements of the potassium and oxygen responses from stimulation experiments performed in CA1 region of rat hippocampus to find the best fit values for parameters in our model. Here we utilize our calibrated model to investigate the limits of sustained and transient neuronal computation.

Title: The roles of Kv2 channels in regular and burst firing of action potentials in layer 5a and 5b neocortical pyramidal neurons

Authors: *G. S. NEWKIRK[1], D. PATHAK[2], N. C. DEMBROW[1,3], R. C. FOEHRING[2], W. J. SPAIN[1,3];
[1]Physiol. & Biophysics, Univ. of Washington, Seattle, WA; [2]Dept. of Anat. & Neurobio., Univ. of Tennessee, Memphis, TN; [3]VA Epilepsy Ctr. of Excellence, Seattle, WA

Abstract: We used somatic current injection in layer 5 Pyramidal neurons in brain slices from 3-8 week old mice expressing either Etv1-EGFP, Glt25d2-EGFP or Thy1-h-YFP to study the role

of Kv2 type potassium channels on repetitive firing. Recordings were from somatosensory (layer 5a Etv neurons or layer 5b Glt neurons) or motor cortex (layer 5b Thy1 neurons) perfused with bicarbonate buffered Ringers, ACSF, at 33-35oC. Under control conditions, Etv1 neurons showed spike frequency adaptation whereas Glt neurons showed little change in firing rate following an initial doublet during constant depolarizing current injection via the whole-cell patch-pipette. In most Thy1 neurons, the onset of repetitive firing in response to the depolarizing current step was delayed. Firing then gradually increased in rate (warm-up firing) for the duration of the step. Burst firing was rare for any layer 5a or 5b neurons in ACSF. In order to block Kv2 containing channels, we added 100 nM Guangxitoxin (GxTX) to the ACSF. Changes in evoked firing to current steps in Etv1 neurons were similar to what was previously reported in rat pyramidal neurons: inter-spike trajectories became depolarized and the firing rate decreased for large stimuli but increased to small stimuli (i.e. the firing rate to current relation, F-I, became shallower). In most Glt neurons regular firing was converted to an initial burst and inter-spike trajectories were depolarized for the duration of the current step with an increase in firing rate (steeper F-I relation without a change in rheobase). In response to GxTX, most of the Thy1 cells displayed a repetitive bursting pattern; spikes were followed by an enhanced fast ADP and the bursts rode on a summated ADP envelope. In some neurons repetitive bursting persisted for the duration of the current step. Thy1 neurons that showed a repetitive bursting pattern to current steps also showed enhanced gain to the theta frequency components of a noisy current step (exponential filtered noise, tau = 5 ms with SD adjusted to cause a 2 mV SD of membrane voltage at rest was combined with DC current adjusted to give 5 or 20 Hz mean firing rate). Multiple lines of evidence implicate bursting emanating from layer 5b pyramidal neurons as an initiator of epileptic seizures. Recently, a human epilepsy was found to result from a mutation of the Kv8.2 subunit (Kv8 channelepsy). The seizure activity is thought to arise from altered activity of heteromeric Kv2.1/ mutant Kv8.2 channels. We hypothesize that Kv8 channelepsy is due to the conversion of layer 5b pyramidal neurons to a burst mode of firing by decreased Kv2 channel activity.

Title: Genetic deletion of the sodium channel beta four subunit attenuates the Purkinje neuron resurgent sodium current and evoked firing frequency

Authors: *J. L. RANSDELL, P. M. ALLEN, J. M. NERBONNE;
Washington Univ., Saint Louis, MO

Abstract: The Sodium channel beta four subunit (Navβ4) is thought to play a pivotal role in the generation of the "resurgent" sodium current (I_{NaR}) and the ability of neurons to fire action potentials at high frequencies. Here, we generated a Navβ4 "knockout" mouse model (*Scn4b*$^{-/-}$) to investigate (1) the physiological role of Navβ4 in the regulation of sodium currents in Purkinje neurons (PNs) and (2) how these effects impact spontaneous and evoked PN firing. Previous studies have identified I_{NaR} in PNs and shown that this current generates an interspike depolarization and provides a mechanism for high frequency firing. I_{NaR} is thought to result from open-channel block of voltage-gated sodium channels by Navβ4 in competition with traditional sodium channel inactivation. This blocking Navβ4 particle is removed on repolarization, allowing resurgent sodium influx. Previous work has demonstrated that small interfering RNAs targeting Navβ4 diminishes I_{NaR} in cultured granule neurons and, although CA1 hippocampal neurons do not typically express I_{NaR}, intracellular addition of β4-like peptides produces I_{NaR}. These studies, while important in linking Navβ4 to the generation of I_{NaR}, do not directly demonstrate a physiological role for I_{NaR} in the generation of high frequency action potential firing. Here, we investigate the effects of *Scn4b* deletion on PN sodium currents and spontaneous and evoked firing in mature PNs. Current clamp recordings revealed no change in the spontaneous firing properties or in the waveforms of action potentials in *Scn4b*$^{-/-}$, compared with wild type (WT), PNs. However, the instantaneous firing frequency in response to depolarizing current injections is significantly ($p < .05$) attenuated in *Scn4b*$^{-/-}$ PNs. While we were unable to successfully clamp I_{NaR} in mature PNs, we find that the resurgent current in dissociated *Scn4b*$^{-/-}$ PNs is significantly attenuated (at -45mV *Scn4b*$^{-/-}$ = -306 ± 33pA, WT = -661 ± 43 pA, $p < .05$). These results indicate that loss of Navβ4 results in reduction of the I_{NaR} in PNs and impacts the ability of mature PNs to fire at high frequencies. Ongoing experiments are determining the effects of the loss of Navβ4 on the properties of the transient and persistent components of PN sodium currents. Further, to eliminate confounding influences of developmental and/or compensatory effects, we will determine the physiological effects of the acute knockdown of Navβ4 in adult PNs.

Title: Chronic intermittent hypoxic preconditioning in juvenile rats increases the intrinsic excitability of RVLM presympathetic neurons in response to acute hypoxia

Authors: M. KARLEN-AMARANTE[1], *D. ACCORSI-MENDONCA[2], C. E. L. ALMADO[1], D. J. A. MORAES[1], B. H. MACHADO[1];

Abstract: The effects of acute hypoxia (AH) on the intrinsic electrophysiological properties of RVLM presympathetic neurons from rats exposed to chronic intermittent hypoxia (CIH) or normoxic condition were evaluated. Bilateral microinjections of a fluorescent retrograde tracer (rodamine retrobeads) into the intermediolateral column of spinal cord (T3-T5) were performed in anesthetized male *Wistar* rats (P 21) to label the bulbospinal RVLM presympathetic neurons. Two days later, rats entered the protocol of CIH or normoxic condition for 10 days. On the 11th day, rats were deeply anesthetized to obtain brainstem slices and only the labeled RVLM presympathetic neurons were recorded using *whole-cell patch-clamp*. The intrinsic electrophysiological properties were analyzed before and after AH, which was produced by slice superfusion with hypoxic solution (95% N_2 and 5% CO_2) during 2 min in the presence of fast synaptic blockers. Under this condition, all recorded RVLM presympathetic neurons presented intrinsic pacemaker activity. The baseline intrinsic firing frequency of recorded neurons from normoxic and CIH group were similar (normoxic = 5.77 ± 0.79 vs CIH = 6.27 ± 0.86). In the normoxic group, AH produced a significant decrease in the RVLM presympathetic neurons firing frequency (basal = 5.77 ± 0.79 vs AH = 4.94 ± 0.44; $p< 0.05$, n=32), but in CIH group AH produced a significant increase in relation to the baseline condition (basal = 6.27 ± 0.86 vs AH = 8.56 ± 1.12; $p< 0.05$, n=20). These data show that the AH decreased the firing frequency of RVLM presympathetic neurons in normoxic group, while CIH preconditioning induced an increase in their firing frequency in response to AH. ***Financial support:*** *FAPESP, CNPQ and CAPES.*

Title: Adaptation of the excitability of CA1 neurons to chronic inactivity

Authors: *D. KARMELIC, V. PALMA, M. SANHUEZA;
Univ. De Chile, Santiago, Chile

Abstract: Correlation-based synaptic plasticity processes, such as long-term potentiation, generate positive feedback loops which by themselves result destabilizing for neuronal networks. This is prevented by a set of slower plasticity phenomena, termed 'homeostatic plasticity', acting in opposition to the changes in neural activity. These mechanisms include global scaling of the synaptic inputs to the neuron and changes in its intrinsic excitability through modification of different membrane conductances. Synaptic homeostatic plasticity of CA1 pyramidal neurons from organotypic hipocampal has been described in response to chronic inactivity, but it may not account for the robustness in the long-term firing rate observed *in vivo*. We therefore decided to study the homeostatic adaptation of the intrinsic excitability of CA1 principal cells in cultured slices. Using whole-cell recording we assessed, as a first step to describe such plasticity, the spiking frequency in response to depolarizing current injection in CA1 neurons from slices incubated in 1 μM TTX for 3 days compared to neurons from control slices. Neurons from TTX-treated slices show significantly more excitability, with higher firing frequencies at lower stimulation levels. We then measured the firing threshold using a current ramp and found no significant differences in this parameter, suggesting that changes in voltage-gated sodium channels do not explain the observed excitability increase. Resting membrane potential was also unchanged by the TTX treatment. Membrane resistance, on the other hand, increased considerably with chronic inactivity, from 105 ± 14 MΩ in control slices to 170 ± 31 MΩ in TTX-treated ones. Interestingly, blocking AMPA and $GABA_A$ receptors during the recording using CNQX and PTX, respectively, abolished almost completely the excitability differences, suggesting that the excitability increase in TTX-treated neurons is mainly the result of a decrease in the weight of synaptic conductances spontaneously open in CA1 neurons.

Title: Postnatal role of sox6 on maturation and function of cortical parvalbumin-expressing interneurons

Authors: *H. MUNGUBA[1], J. N. CARRIÇO[2], S. NILSSON[1], P. OBERST[1], A. B. MUNOZ-MANCHADO[1], R. BATISTA-BRITO[3], G. J. FISHELL[4], G. DI CRISTO[2], J. HJERLING-LEFFLER[1];

Abstract: Cortical interneurons undergo extensive synaptogenesis and maturation of intrinsic properties during the first weeks after birth. In particular, parvalbumin (PV)-expressing basket cell interneurons go through a transcriptional profile shift during the second postnatal week, believed to be indispensable for their maturation. We have previously shown that basket cells lacking early expression of transcription factor Sox6 fail to properly migrate and mature electrophysiologically. Because Sox6 is still expressed in these cells throughout adolescent maturation, we are interested in investigating its role on late maturation and synaptic function and maintenance. We utilized a conditional knockout strategy to specifically remove Sox6 in interneurons at different postnatal stages. Our preliminary results suggest that Sox6 is important for basket cell interneuron maturation but not maintenance. To investigate synaptic maturation and function, we are exploiting a gene gun transfection approach allowing a detailed characterization of PV interneurons' axonal branching and bouton density onto excitatory neurons. Moreover, we are performing pair recordings of PV interneurons and pyramidal neurons in order to characterize the synaptic phenotype.

Title: Alteration to cerebral hemodynamics modifies astrocytes Ca^{2+} activity in awake, behaving mice

Authors: *C.-H. T. TRAN, G. GORDON;
Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: The brain posses control mechanisms to regulate blood flow in order to meet metabolic demands. Functional hyperemia is an essential process in which increases in neural activity enhances cerebral blood flow. Astrocytes, which form an associated network with both neurons and blood vessels, have been shown to play a significant role in controlling blood flow accompanying changes in neural activity. Recent *in vivo* evidence conducted in anesthetized or slightly sedated animals questions the direct role of astrocyte intracellular Ca2+ in mediating functional hyperemia as spatial and temporal profile of astrocyte Ca^{2+} transients are poorly associated with the onset of vascular responses. Because anesthetics have dramatic effects on neural activity, astrocyte Ca2+ and hemodynamics, our objective was to uncover the spatiotemporal basis of the communication between astrocytes and the vasculature in fully awake, behaving mice. A craniotomy over the barrel cortex with the dura removed was performed. A custom build two-photon microscopy was used to image the vasculature and astrocytes Ca2+ from either C57Bl/6 mice or GLAST-cre-LSL-GCaMP3 mice or TEK-cre-LSL-ArchT3 mice. We found that 5-second whiskers' stimulation induced fast vasodilatory responses in penetrating arterioles but with endfoot and cell-wide Ca2+ transients that occurred with a delayed onset. Interestingly, the timing of these Ca2+ transients was typically observed at the peak of the sensory induced vasodilation. Thus, we tested the hypothesis that the vasculature communicates back to the astrocytes to modulate astrocytes Ca2+. We show that intraluminal perfusion of acetylcholine or phenylephrine alters cerebral hemodynamic responses that were followed by an alteration in astrocytes Ca2+ activity. To further test our hypothesis, we used a vascular endothelial specific promoter (TEK) to express archaerhodopsins (light-gated proton pumps that extrude protons from the cytoplasm to elicit hyperpolarization) to elicit vasodilation directly without neural or luminal manipulations. Activation of endothelial archaerhodopsins with brief application of yellow laser light induced fast vasodilation followed by an initiation of

endfoot Ca2+ transient. Our data redefine the uni-directional communication between astrocytes and the vasculature. We introduce a potential role of the vasculature as the modulator of astrocytes Ca2+ transients and propose that astrocytes may act as responders to changes in blood flow rather than rapid initiators of blood flow control.

Title: Glial involvement in transcranial direct current stimulation (tDCS)-induced plasticity

Authors: *H. MONAI[1], M. OHKURA[2], M. TANAKA[1], K. MIKOSHIBA[1], S. ITOHARA[1], J. NAKAI[2], Y. IWAI[1], H. HIRASE[1,2];
[1]RIKEN BSI, Wako, Japan; [2]Saitama Univ., Saitama, Japan

Abstract: Transcranical direct current stimulation (tDCS) is a treatment known to ameliorate various neurological conditions and enhance memory and cognition in humans. tDCS has gained traction for its potential therapeutic value, however, little is known about its mechanism of action. Using a transgenic mouse expressing G-CaMP7 in astrocytes and a subpopulation of excitatory neurons, we find that tDCS induces large-amplitude astrocytic Ca2+ surges across the entire cortex with no obvious change in the local field potential. Moreover, visual evoked potential (VEP) in the visual cortex was enhanced after tDCS. The enhancement of VEP was

dependent on alpha-1 adrenergic receptor and was not observed in IP3R2 knockout mice in which astrocytic Ca2+ surges are absent. Notably, microglial ramification was visibly reduced by tDCS. Together, we propose that astrocytic Ca2+/IP3 signaling plays a significant role in tDCS-evoked neural changes with the electrical field as an adjuvant of neuron-glia interactions and plasticity.

Title: The influence of astrocytic vesicular release on cognitive function

Authors: *J. F. OLIVEIRA[1], V. M. SARDINHA[2], S. GUERRA-GOMES[2], G. TAVARES[2], J. CORREIA[2], M. MARTINS[2], N. SOUSA[2];

Abstract: Astrocytes are emerging as important actors in the regulation of synaptic transmission and plasticity. They possess unique morphologic and phenotypic features that allow them to monitor their neighbourhood and dynamically respond to changes. Since impairments of astrocytic function seem to have implications in neurotransmission, metabolism and brain homeostasis, we hypothesized that they will influence neural networks, ultimately underlying behaviour alterations. Astrocytes were described to release gliotransmitters (such as glutamate, GABA, ATP or D-Serine) by several mechanisms, namely through SNARE complex-dependent

vesicular release. This process, named gliotransmission, allows them to communicate with, and modulate vicinal cells, namely at the level of synapses. Yet, the consequences of gliotransmitter release to the network function remain to be elucidated. We used the dnSNARE model of gliotransmission impairment to assess behaviour alterations, namely on the cognitive domain. These results were paired with electrophysiological characterization of the neuro-glial networks in cortico-limbic regions intimately related with cognitive processing: prefrontal cortex and hippocampus. The combination of these techniques will surely provide us with crucial information on the role of astrocytes in the modulation of neural activity, impacting ultimately in cognitive processes.

Title: Role of P2X7 receptor/HIF-1α signal pathway in astrocyte-mediated ischemic tolerance

Authors: *Y. HIRAYAMA[1,2], Y. IKEDA-MATSUO[3], S. KOIZUMI[2];
[1]Dept. Liaison Academy, Sch. Med., Univ. Yamanashi, Yamanashi, Japan; [2]Dept. Neuropharmacol., Interdisciplinary Grad. Sch. Med., Univ. Yamanashi, Yamanashi, Japan; [3]Dept. Pharmacol., Sch. Pharm. Sci., Univ. Kitasato, Tokyo, Japan

Abstract: In clinical settings, it is commonly observed that a mild ischemic episode protects neurons against a subsequent severe ischemic injury. This event is known as “ischemic tolerance”. Such short and mild ischemia, known as preconditioning (PC), itself does not cause brain damages, but instead, induces ischemic tolerance providing for future stronger injuries. We previously showed that PC-induced activation of astrocytes and subsequent upregulation of P2X7 receptor in these cells are essential for ischemic tolerance. However, a downstream signal(s) after activation of P2X7 receptor in astrocytes remains unknown. Here, we show that hypoxia inducible factor-1α (HIF-1α), a master molecule that induces various neuroprotective factors in neurons after ischemia, is responsible for the P2X7 receptor-dependent astrocyte-mediated ischemic tolerance in middle cerebral artery occlusion (MCAO) model *in vivo*. We investigated (1) spatiotemporal pattern of HIF-1α, (2) mechanisms underlying its upregulation, and (3) its pathophysiological consequence, showing difference in its roles between neurons and

astrocytes. (1) Using *in vivo* MCAO model in mice, we found that HIF-1α was expressed in both neurons and astrocytes after PC, but its spatiotemporal expression pattern in neurons was completely different from that in astrocytes. The upregulation of HIF-1α in neurons was early-onset and transient, whereas that in astrocytes was slow-onset and long-lasting (from 3 days ~). (2) Mechanisms underlying its upregulation were also different between neurons and astrocytes. The neuronal HIF-1α upregulation was dependent on oxygen (decrease), but astrocytic one was independent of oxygen but rather dependent on P2X7 receptor. We also confirmed these mechanisms using primary cultures of neurons or astrocytes. (3) Finally, we found that PC-induced upregulation in HIF-1α was essential for induction of ischemic tolerance. In P2X7 receptor-deficient mice, neither PC-induced ischemic tolerance nor HIF-1α upregulation in astrocytes was observed. On the contrary, PC could cause a transient HIF-1α increase in neurons but could not induce ischemic tolerance in these mice. Taken together, unlike a well-known oxygen-dependent pathway in neurons, astrocytes use a P2X7 receptor-mediated pathway to upregulate HIF-1α, thereby leading to induction of very strong ischemic tolerance.

Title: 7.0 Tesla MRI reveals electrostatic environment of the glia limitans

Authors: K. SUZUKI[1], K. YAMADA[1], Y. SUZUKI[1], I. L. KWEE[1,2], *T. NAKADA[1,2];
[1]Brain Res. Inst, Univ. of Niigata, Niigata, Japan; [2]Univ. of California, Davis, Davis, CA

Abstract: Recently, fluid-attenuated inversion recovery (FLAIR) MRI on a 7.0T system revealed a high intensity “rim” at the cortical surface corresponding to the glia rich surface layer, often referred to as the glia limitans (TGL). TGL is identified by electron microscopy (EM) as an electron rich layer just beneath the pia matter that is primarily made of astrocyte end feet. In this study, we examined the intrinsic MRI parameters of TGL in normal human adults to determine its specific structural characteristics. The results revealed a rather unique combination of MRI parameters. Spin density was found to be ca. 50% of that of cerebrospinal fluid (CSF). T1 was ca. 20% shorter than that of CSF, whereas T2 was virtually identical to that of CSF. The

observed spin density and T2 characteristics indicated that GL contains free water molecules similar to CSF but at almost half in density. The significantly shorter T1 of long T2 free water molecules implies that there is a nearby structure which facilitates T1 relaxation similar to ionic contrast agents. TGL is rich in the water channel aquaporin-4 (AQP-4), and as demonstrated by EM, TGL comprises a structure which can accumulate electrons under appropriate conditions. Given these anatomical characteristics, the unique MRI properties of TGL can only be explained as follows. TGL has a relatively low density of free water due to the functionality of AQP-4. This relatively "dry" condition establishes an electrostatic environment. Brain activities continuously provide electrons to flow through the cortex which can be trapped in TGL due to its electrostatic environment. The low free water density accounts for the low spin density with long T2. Facilitated energy exchange between spin and electrons results in a paradoxically short T1 for these free water molecules. The study represents the first direct support of the vortex theory of the brain (Nakada T, Cytotechnol 2009;59:145) which predicts that human association cortex is a biological realization of Kohonen's self-organizing map (Kohonen T, Proceeding of the IEEE 1990;78:1464).

Title: Increased expression of astrocytic connexins in AQP4 knockout mice

Authors: *S. KATOOZI, L. M. A. CAMASSA, S. RAHMANI, H. B. BOLDT, O. P. OTTERSEN, M. AMIRY-MOGHADDAM;
Univ. of Oslo/ Inst. of Basic Med. Sci., Oslo, Norway

Abstract: Aquaporin-4 (AQP4) is the predominant water channel in the brain. It is expressed in high density at the astrocyte endfeet membrane domains surrounding brain microvessels. AQP4 is colocalized with the inwardly rectifying potassium channel Kir4.1, leading to the suggestion that AQP4 is involved in K^+ homeostasis. However, AQP4-knockout (AQP4-KO) mice show a rather mild phenotype without any impairment of K^+ clearance. A recent study has shown facilitated K^+ redistribution and enhanced tracer coupling among astrocytes in the hippocampus of AQP4-KO mice (Strohschein et al. 2011). Based on this, we hypothesized that a compensatory increase in the expression levels of astrocytic connexins could explain the mild phenotype of AQP4-KO mice in regard to K^+ homeostasis. We investigated the expression and distribution of the two astrocytic connexins Cx43 and Cx30 in the brains of wild type (WT) and AQP4-KO mice. Using Western blotting we show that the expression levels of both Cx43 and Cx 30 are increased in AQP4-KO brains compared with WT. Moreover, immunogold analysis of parietal cortex and hippocampus show that the number of gap junctions per capillary profile and the number of connexins per gap junction are increased in the AQP4-KO mice. The most pronounced changes were observed in hippocampus where the number of connexin labelled gap junctions per capillary profile increased by 100% following AQP4 knockout. Our results provide a mechanistic basis for the facilitated K^+ redistribution, enhanced tracer coupling, and mild phenotype characteristic of AQP4-KO mice. *The first two authors contributed equally to this work.

Title: 3D modeling, tissue reconstruction, and quantification of astrocyte distribution in the adult mouse CNS at molecular resolution with intact thick tissue matter

Authors: *R. G. SATTLER, S. J. MILLER, J. D. ROTHSTEIN;
Brain Sci. Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Astrocytes are the most abundant cell type in the central nervous system (CNS). To date, astrocyte studies have focused on isolated anatomical locations of interest but fail to appreciate distribution across the whole CNS. Large regional quantification of astrocyte distribution and molecular subtypes of astrocytes may enable a better understanding of glial contributions to CNS disease. Furthermore, these imaging and molecular labeling tools may provide insight into affected areas previously undetected. In order to evaluate astrocyte distribution across the entire CNS, we performed the recently established method, CLARITY. Using a double transgenic mouse line that has unique, astroglial specific genetically encoded fluorescence reporters to visualize all protoplasmic astrocytes and an astrocyte subpopulation, we quantified the overall distribution throughout the CNS. This method also allows one to stain and re-stain tissue without destroying cellular structures or biological targets of interest. In addition, for the first time, we present a further optimized system that includes sequential sectioning of fixed tissue, 3D remodeling of cell structures, tissue reconstruction, and *in vivo* astrocyte specific quantification. Taken together, we believe this optimized method should be utilized to study astrocytes and other glia at molecular resolution across thick tissue matter in normal as well as diseased CNS.

Title: Establishing a novel two-photon imaging approach to access spinal motoneurons *in vivo*

Authors: *L. P. CARTAROZZI[1], A. SCHELLER[3], F. KIRCHHOFF[3], A. L. R. OLIVEIRA[2];
[1]Anat., [2]UNICAMP, Campinas, Brazil; [3]Universitätsklinikum des Saarlandes, Homburg, Germany

Abstract: Following axotomy, spinal motoneurons undergo chromatolysis, which is a retrograde reaction that takes place in the cell body. Such process leads to retraction of dendrites, synaptic stripping and a shift from transmitting phenotype to regenerative state. Several molecules related to the regenerative response are upregulated, allowing regrowth of the axon. A hallmark of the response to lesion is the rapid activation of astrocytes and microglia nearby affected motoneuron cell bodies, disturbing the pre-synaptic inputs. With the advent of *in vivo* imaging, new studies regarding fine changes related to neuronal/glial reaction following acute lesion can potentially be carried out. Recent reports have used advanced light microscopy approaches, such as two-photon laser scanning microscopy (2P-LSM), in combination with fluorophores/fluorescent proteins to image the CNS aiming to access cellular responses of glial cells after peripheral nerve injury. Of particular interest, temporal activation and role of different glial cells that become activated after lesion needs further investigation. So far, imaging of the spinal cord has been largely restricted to the superficial white matter of the dorsal horn, mostly due to the easier surgical approach. In turn, evaluation of deeper regions of the spinal cord, especially the ventral horn is challenging. However, it may provide a better understanding of the early motoneuron response to injury, allowing direct visualization of fast Ca2+ neuronal changes or structural alterations related to neuron/glia interactions. The present work aimed at establishing a new methodology to image spinal motoneurons *in vivo*, employing two-photon microscopy. For that purpose, we used the following transgenic mice: TgN(GFAP-eCFP) and TgH(CX3CR1-EGFP). The retrograde tracer Fluororuby was unilaterally injected in the gastrocnemius muscle from double transgenic mice in order to label motoneurons from the sciatic nerve pool. Six days after tracer injection, lumbar vertebrae laminectomy allowed exposure of the lateral aspect of the spinal cord at the lumbar intumescence for *in vivo* imaging. The results demonstrate that using a combination of transgenic animal models, retrograde tracer injection, 2P-LSM and appropriate surgical techniques makes possible *in vivo* imaging of deep spinal cord laminae, allowing motoneuron and circumjacent glial cells to be localized and evaluated in a real time fashion.

Title: Vessel-associated glioma cells co-opt vascular regulation

Authors: ***I. KIMBROUGH**, A. HONASOGE, L. CHAUNSALI, H. SONTHEIMER; Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Functional hyperemia is important to normal brain functioning. Glioma cells on the vasculature interfere with normal physiology by breaking the astrocytic endfoot attachment to the basement membrane (BM) of blood vessels, leaving them unresponsive to astrocyte-released vasoactive signals. Glioma co-option of vascular regulation can occur directly, through release of vasoactive molecules onto smooth muscle cells, or indirectly, through activation of astrocytic receptors, and subsequent release of vasoactive molecules. Chronic vasodilatory regulation through release of prostaglandins or K+, may lead to a persistent shunting of blood flow to a growing tumor. Alternatively, acute regulation of vasoconstriction by invading glioma cells, through release of arachidonic acid or high K+, could cause a transient decrease in vessel tone, enlarging the perivascular space for invasion. Therefore, co-option of vascular regulation is important to glioma cell survival, as vessel dilation may assure improved nutrient delivery, and constriction may facilitate invasion along the vasculature. In this study, we investigate how invading glioma cells regulate vascular coupling. We generated D54GCaMP3/Mrga1 glioma cells (MrgA1) expressing both GCaMP3 and RASSL (receptor activated solely by synthetic ligand). GCaMP3 is a GFP-bound Ca2+ sensor, while the RASSL (Mrga1) is tied to the TdTomato red fluorescence protein. The RASSL receptor is an artificial g-protein coupled receptor (GPCR) not expressed in mammalian cells. It is activated by FMRF, an exogenous and specific ligand, and induces an increase in intracellular Ca2+. Using time-lapse volumetric confocal microscopy and 3D reconstructions we show that bath application of FMRF on cultured Mrga1 cells leads to transient Ca2+ rises followed by changes in cell morphology and increased invasion. In acute slice experiments we show Mrga1 activation leads to transient Ca2+ rises in arteriole associated glioma cells followed by changes in vessel diameter. This effect was diminished in the presence of the K+ channel inhibitors Tram-34 and Paxilline suggesting that K+ release contributes to glioma-mediated vascular regulation. Using *in vivo* video time-lapse multi-photon microscopy, we show that activation of arteriole associated Mrga1 cells also leads to transient Ca2+ rises followed by vessel diameter changes. These diameter changes also diminished with K+ channel inhibitors. Taken together, our data suggest that gliomas are capable of assuming control of the vasculature along which they are invading, through a process that is Ca2+ dependent, likely involving Ca2+ activated K+ channels.

Title: The time course of the glial reactivity to deep brain stimulation. A longitudinal study of DBS in the Goettingen Minipig brain

Authors: *D. ORLOWSKI[1], A. MICHALIS[2], A. N. GLUD[1], A. R. KORSHØJ[1], L. M. FITTING[1], T. W. MIKKELSEN[1], A. MERCANZINI[2], A. JORDAN[2], A. DRANSARD[2], J. C. H. SØRENSEN[1];
[1]The Dept. of Neurosurg., Dept. of Clin. Medicine, Aarhus Univ., Aarhus C, Denmark; [2]Aleva Neurotherapeutics SA,, Lausanne, Switzerland

Abstract: The use of Deep Brain Stimulation (DBS) is constantly growing, and its indications include not only treatment of movement disorders, but also therapy of chronic pain, obesity, drug resistant psychiatric disorders and even Alzheimer disease. Despite broader use of DBS, the number of studies on analyzing the reaction of the brain tissue to the implanted electrode, especially in large animal models, is still very limited. In our experiment we tested DBS electrodes in a large animal model - the Goettingen minipigs. Twelve animals (females) were used in this study, one control and eleven with bilaterally implanted DBS electrodes into anterior striatum. 3, 6 and 12 months after implantation animals were sacrificed, perfused with 10% formalin and the brains were removed. Following 5 days of immersion in 30% sucrose the brains were divided into two hemispheres and tissue blocks containing electrode track were dissected free, embedded in OCT and frozen in isopentane cooled by dry ice. The brain tissue was sectioned into transversal 40µm sections containing electrode track using cryomicrotome and stained using Nissle and Eosine, anti-GFAPab or isolectin. The tissue reaction was analyzed on five levels following from the tip of the electrodes, in order to compare tissue response to the stimulation with non-stimulated tissue: four along the active part of the electrode (contacts areas), and the fifth lying approx. 5 mm above contacts (control areas). The sections were described both qualitatively and quantitatively. Quantitative assessment of the reaction to the implanted electrode was based on the semi-automatic measurement of the area covered by the staining. The areas of the tissue reaction and thickness of the glial scar were measured using the Fiji (ImageJ) program on microphotographs of the tissue areas of the sections containing

electrode track. Moreover, two independent blinded observers tried to differentiate histological response induced by stimulated versus non-stimulated electrodes on the basis of qualitative observations. Results and conclusions: Tissue reaction was limited to the relatively small area around the electrode and should be considered as a minor to mild reaction. The temporal pattern of the reaction indicates that tissue response stabilized over the time (reaction after 12 months were lower than after 6 months). We found no histological evidence that stimulated part of the electrode can trigger different tissue response than its non-stimulated part.

Title: Subcellular organization of the orientation map in visual cortical astrocytes

Authors: M. LÓPEZ-HIDALGO, *J. SCHUMMERS;
Max Planck Florida Inst., Jupiter, FL

Abstract: The analysis of calcium responses in astrocytes started a new era of understanding how these cells interact with neuronal circuits. Astrocytes respond with calcium elevations to sensory stimulation including visual stimulation. Previous work done in ferrets showed that astrocytes somas in visual cortex are tuned to visual stimuli with a similar spatial arrangement to neurons but with sharper orientation tuning curves. Advances in calcium imaging techniques as well as the use of genetically encoded calcium indicators now permit the analysis of visual-

evoked responses in the entire territory of astrocytes. Here, we studied the spatial and temporal dynamics of calcium responses in ferret visual cortex astrocytes expressing GCaMP6s (under control of the GFAP promoter) using two-photon laser scanning microscopy. We find robust visually-evoked calcium responses in processes throughout the entire territory of individual astrocytes. Our results show that the orientation tuning of these responses in astrocyte processes match the orientation map. In agreement with this, astrocytes located near pinwheel center have a gradual change in the tuning curve across their territory, representing a subcellular organization of the orientation map. More generally, this result suggests that astrocytes respond with extraordinary spatial specificity to local synaptic activity *in vivo*.

Title: Behavioral characterization of astrocyte Gs conditional knockout mice

Authors: *A. MADAYAG, K. M. BOYT, K. D. MCCARTHY;
Pharmacol., UNC Chapel Hill, Chapel Hill, NC

Abstract: Astrocytes are the most abundant cell type in the mammalian brain and exist in close proximity to other cells of the central nervous system, including neurons. Interestingly, astrocytes express many of the same receptors and signaling pathways as neurons. This lends the difficult task of dissecting the role of astrocyte signaling in brain function. Unfortunately, standard pharmacological methods lack cell specificity. Our laboratory utilizes astrocyte targeted transgenic and conditional knockout (cKO) models to investigate the role of astrocyte signaling in physiology, behavior, and pathology. Gs G-Protein Coupled Receptors (GsGPCR) are among the many signaling pathways expressed by both astrocytes and neurons and have been implicated in numerous neuro-pathological disorders. We generated a mouse line that affords us the ability to genetically recombine the Gs gene, and thus silence ligand-induced activation of GsGPCR signaling pathways in astrocytes. To inactivate GsGPCR signaling in astrocytes, adult GFAP:CreER^{T2}::Gs$^{flox/flox}$ (cKO) and Gs$^{flox/flox}$ (littermate control) mice were given 5 consecutive daily doses of tamoxifen (200mg/Kg, gavage) to activate inducible Cre-recombinase. We

previously reported that mice lacking astrocytic GsGPCR signaling (cKO) exhibited intact contextual memory in the Morris Water Maze and locomotion in an open field, and deficits in sensorimotor gating as measured by prepulse inhibition. Consistent with our previous findings, here we report that cKO mice exhibit intact contextual and cue memory as measured in a fear conditioning paradigm. We also measured normal social interaction as measured in a social preference paradigm. Conversely, we observed decreased open arm time by cKO mice in an elevated plus maze paradigm, suggesting an anxiogenic phenotype. Male, but not female cKO mice show hyperactivity to an amphetamine challenge, suggesting altered reward or corticostriatal neurocircuitry. Our findings suggest that Gs and thus GsGPCR signaling in astrocytes is important in certain animal behavior, however the lack of phenotypic differences in the majority of behavioral paradigms is surprising. It is important to verify the selectivity of the inducible Cre model. To do this, we have chosen to cross the GFAP:CreER^{T2} to multiple reporter lines of mice as this is more sensitive than measuring Cre expression with immunohistochemical staining. To further the field, we are interested in continuing our characterization of this genetic model in more complex behavioral tasks as well as isolate mechanisms that may contribute to observed phenotypes.

Title: Longitudinal *in vivo* imaging of tau pathology, microglial activation and neuronal loss in a mouse model of tauopathy

Authors: *N. SAHARA, A. ISHIKAWA, M. TOKUNAGA, T. MINAMIHISAMATSU, J. MAEDA, M. SHIMOJO, M. ONO, S. UCHIDA, I. MATSUMOTO, H. TAKUWA, M.-R. ZHANG, T. SUHARA, M. HIGUCHI;
Natl. Inst. of Radiological Sci., Chiba, Japan

Abstract: Accumulation of intracellular neurofibrillary tangles consisting of microtubule-associated protein tau is a major hallmark of tauopathy. Recent advances in positron emission tomography (PET) imaging research have led to significant breakthroughs with newly developed probes for tau depositions. This technology allows us to noninvasively examine the tau pathogenesis in living brains of humans and animal models. Our previous study has demonstrated that PET imaging with a tau radioligand, [^{11}C]PBB3, clearly visualizes tau deposits, which is closely aligned with disease symptoms. Here, we conducted a longitudinal PET and magnetic resonance imaging (MRI) of transgenic mice modeling tauopathy (rTg4510) and non-transgenic controls from 2 to 13 months of age, in order to examine the utility of small-animal *in vivo* imaging for pursuing links between tau deposition and neurodegeneration. Along with [^{11}C]PBB3, microglial activation was also visualized using a radioligand for the 18-kDa translocator protein (TSPO), [^{11}C]Ac-5216. In the rTg4510 mice, tau accumulation, neuroinflammation and forebrain atrophy became noticeable at 6 months of age, and retentions of tau and TSPO radioligands were inversely correlated to neocortical volumes. Postmortem immunohictochemical assays revealed that elevated TSPO signals in putative microglia were associated with accumulation of tau inclusions in the neocortex and hippocampus of rTg4510 mice. Our results indicate that temporospatial relationship among tau deposition, neuroinflammation and neuronal loss can be pursued by *in vivo* imaging of animal models. Non-invasive PET imaging combined with transgenic mouse models can be a powerful experimental tool to investigate mechanisms of neurodegenerative disease and evaluation of therapeutic interventions.

Title: A cellular model of tau-mediated NMDA receptor dysfunction

Authors: *E. E. PEREZ SOLIS, J. SEGOVIA-VILA, U. GARCÍA;
CINVESTAV, Gustavo A. Madero, Mexico

Abstract: Alzheimer's disease is characterized by the presence of two insoluble aggregates: amyloid plaques and neurofibrillary tangles. These aggregates participate in the neurodegenerative process underlying the cognitive deficits associated with this type of dementia. However, the main components of the aggregates, the amyloid peptide and tau protein, have neurotoxic effects prior to the formation of insoluble aggregates. It is considered that neuronal dysfunction begins at least 20 years before the appearance of clinical symptoms, when a synaptic deficit is already modifying the single and network properties of neurons, setting the stage for further deterioration of brain activity. Tau protein has come to be considered the effector of amyloid beta toxicity, because its multiple post-translational modifications change neuronal structure and signalling pathways. We are interested in the role that tau protein has in regulating the activity of receptors associated with learning, memory and toxicity, such as the NMDA-type glutamate receptor, a target of amyloid beta. Using the HEK293 and SH-SY5Y cell lines as models, we expressed both the eYFPNR-1A and eGFP-NR2B subunits, as well as the full sequence of tau protein, allowing us to have a functional receptor which activity is recorded through whole-cell patch clamp technique. In this condition we found that when tau protein is overexpressed the total evoked current of the NMDA receptor increases, suggesting this might be related to neurotoxicity. Tau protein undergoes a series of post-translational modifications such as phosphorylation and proteolysis that endow it with pathological characteristics. It has been previously reported that among these modifications proteolysis is a key one. A fragment of tau that comprises from amino acid 297 to 391 (three and half microtubule binding domain) has a greater capacity to form insoluble aggregates, it is present since the early stages of neurofibrillary tangle formation and increases in severe cases of Alzheimer's disease, however, it is not yet known whether it may affect synaptic function. We are currently testing if this fragment modifies the activity of the NMDA receptor in both cell lines, and the effect that tau aggregation has in the sensitivity to amyloid beta toxicity. This will give us a better understanding of how post-translational modifications and aggregation of tau affect the activity of the NMDA receptor and the role they play in Alzheimer's disease.

Title: Numb regulates Tau levels and axonal homeostasis in mouse retinal ganglion cells

Authors: *M. LACOMME, ESQ[1], J. CAI[1], M. CAYOUETTE[1,2,3];
[1]Inst. De Recherche Clinique De Montréal, Montreal, QC, Canada; [2]Dept. of Medicine, Univ. de Montréal, Montreal, QC, Canada; [3]Anat. and Cell Biol. department, McGill Univ., Montreal, QC, Canada

Abstract: Disruption of axonal structure or function can have devastating consequences for neuronal survival, as observed in various neurodegenerative diseases, but the mechanisms involved in the maintenance of axonal homeostasis remain poorly understood. Various studies have shown that endocytosis and vesicular trafficking is critical for neurite growth and survival. One particularly interesting endocytic player is the adaptor protein Numb, but its function in postmitotic neurons remains unclear. We therefore hypothesized that Numb might regulate vesicular trafficking of proteins involved in the maintenance of axonal structural integrity and neuronal survival. To address this question, we generated a conditional knockout (cKO) mouse of Numb (and its homolog Numblike) in retinal ganglion cells (RGCs) using the Cre/lox system. Although total RGC number was not altered in cKO at 6 months, we observed axonal swelling in cKO RGCs both *in vitro* and *in vivo*, suggesting altered axonal integrity that might increase susceptibility to cellular stress. To test this idea, we injected NMDA in the eyes of cKO and control mice and studied RGC survival 3 days later. Interestingly, while about 50% of RGCs were lost in control retinas, we found that more than 80% of RGCs degenerated in cKO, indicating that Numb is required to prevent RGC degeneration, at least under these conditions. Molecularly, we found that the levels of the microtubule-associated protein Tau were sharply increased in Numb cKO optic nerves, likely explaining the axonal swelling observed in cKO and the increased neuronal susceptibility to injury. Consistent with this idea, we found that Tau overexpression in RGC phenocopies Numb inactivation and causes axonal swelling, whereas siRNA-mediated knock-down of Tau rescues RGC death observed in Numb cKO after NMDA injury. Finally, co-immunoprecipitation experiments indicate that Numb interacts with Tau, suggesting a model in which Numb might function as an adaptor protein to control the endocytic trafficking of Tau in RGC axons. Together, these results identify Numb as an essential player in the maintenance of axonal homeostasis, possibly by regulating the trafficking of Tau proteins. Interestingly, anatomical changes have been detected in eyes of Alzheimer's disease patients before signs of cognitive impairment and because alteration in Numb isoform levels were observed in Alzheimer's patients and transgenic mutant mice, our findings point to a possible molecular mechanism underlying increased neuronal susceptibility in neurodegenerative diseases involving accumulation of Tau proteins.

Title: Brain aggregates; an effective *in vitro* cell culture system for drug screening targeting neurodegenerative diseases

Authors: *M. AHN[1], F. KALUME[2], A. OEHLER[1], R. PITSTICK[3], G. CARLSON[3], S. DEARMOND[1];
[1]Dept. of Pathology, UCSF, San Francisco, CA; [2]Dept. of Neurolog. Surgery and Pharmacol., Universtiy of Washington, Seattle, WA; [3]McLaughlin Res. Inst., Great Falls, MT

Abstract: Drug discovery for neurodegenerative diseases is very challenging because we often find discrepancies in drug efficacy from *in vitro* and *in vivo* studies. Current cell-culture systems used for *in vitro* drug screening assays suffer from many limitations. First, few cell-culture systems accurately model aging or neuropathological progression of neurodegenerative diseases in the brain. Second, drug efficacy can vary in different cell types such as dividing vs. stationary cells; the latter resembles non-dividing neurons in the brain. Drug screening for neurodegenerative diseases should be performed in non-proliferating neural cells. Brain aggregate culture (BrnAggs) derived from mouse brains at embryonic day 15 is a 3 dimensional sphere-shaped cell culture consisting of neurons, astrocytes, oligodendrocytes and microglia. We previously showed that they accurately represent neuropathogenic characteristics of prion disease (progressive accumulation of PrPSc and dendritic degeneration) and reflect *in vivo* efficacy of anti-prion compound effectively. Here, we optimized the BrnAgg preparation method suitable for a 96-well plate format drug screening assay and found that BrnAggs form functional networks by measuring field potential activities. Lastly, we examined whether BrnAggs can model tauopathies. We found similar neuropathological characteristics of tauopathies (increased phopshoprylated tau, ThioS-positive amyloids and dendritic degeneration) in aged BrnAggs

prepared from Tg 4510 mice expressing human tau with a P301L mutation. Infection with Tg 4510 mice brain homogenates exaggerates tau pathology in these BrnAggs. BrnAggs are 3D cell culture resembling neural components of the brain and can be prepared from many varieties of transgenic mouse models of neurological diseases such as epilepsy and tauopathies. We believe BrnAggs will serve as an effective *in vitro* cell culture system for drug discovery of many neurological diseases.

Title: Extracellular tau oligomers induce mislocalization of endogenous neuronal tau and axonal transport deficits

Authors: ***E. M. SWANSON**, L. MCMAHON, L. BRECKENRIDGE, S. SOM, G. S. BLOOM; Univ. of Virginia, Charlottesville, VA

Abstract: Tau is a neuron-specific, microtubule-associated protein enriched in axons, where its functions include direct binding and stabilization of microtubules, and regulation of axonal transport. CNS tau comprises six isoforms produced by the alternative splicing of a single tau gene, MAPT, with these isoforms characterized by the presence of zero, one or two N-terminal inserts, and three or four C-terminal microtubule binding repeats. Neuronal inclusions composed of hyperphosphorylated tau are a major histopathological feature of a series of neurodegenerative disorders known collectively as tauopathies, of which Alzheimer’s disease (AD) is the most

prominent. While the clinical and histological presentation of these disorders is heterogeneous, the majority share the following hallmarks: loss of the normal axonal distribution of tau; accumulation of insoluble, fibrillar tau aggregates in neurites and perikarya; synaptic dysfunction; and eventual neuron death. Familial mutations identified in the MAPT gene point to a causative role for tau in these disorders, with changes in the isoform ratio or aggregation propensity of tau causing fully penetrant neurodegenerative diseases. In this study, we demonstrate that externally applied oligomeric tau cause a loss of normal tau distribution within primary cortical neurons. Utilizing a quantitative assay to measure the extent of tau aggregation in cultured neurons, we demonstrate that tau oligomers are much more effective than tau monomers or fibrils at inducing tau redistribution within axons, that the extent of this disruption varies according to tau isoform, and that oligomers made from mixtures of all six CNS tau isoforms are much more potent than oligomers made from individual isoforms. Tau is known to play an integral role in the regulation of cargo transport along axonal microtubules, and we also show that this tau aggregation causes alterations in the normal, microtubule based trafficking of various classes of axonal membrane-bounded organelles. Cells treated with oligomeric tau showed significant increases in the anterograde velocity and run lengths of dense-core vesicle transport marked by neuropeptide-Y or BDNF, and lysosome trafficking was similarly affected. These results raise the possibility that soluble, pre-fibrillar oligomers of varying tau isoforms account for the prion-like spread of tau pathology *in vivo* in AD and non-Alzheimer's tauopathies, and point to mechanisms by which loss of physiological tau distribution lead to neuronal dysfunction.

Abstract: Background: Cholinergic cell loss in the basal forebrain, the major source of hippocampal cholinergic projections, has been implicated in Alzheimer's disease. The underlying mechanism associated with tau still remains unknown. Methods: Adult (6 to 8 months old) and Old (16 to 18 months old) mice overexpressing wild type human tau (Tg601 mice) were used. [18F]fluoro2deoxyDglucose ([18F]FDG) PET was taken without anesthesia. Voxel based SPM analysis was conducted to compare the images between age matched nonTg and Tg601 mice (N = 5) using SPM8 software. *Ex vivo* diffusion tenor (DT) MRI were performed using a 7 Tesla Biospec 70/16 MRI scanner . DT tractography was computed using the Diffusion Tooklkit and TrackVis software. Region of interest (ROI) analysis evaluated fractional anisotropy (FA), radial diffusibvity (RD), and axial diffusivity (AD) in the basal forebrain (vertical diagonal band of Broca [VDB], medial septum [MS] and horizontal diagonal band of Broca [HDB]). Acetylcholinesterase (AchE) activity and the amount of T, H and R transcripts of AchE mRNA were measured in 5 brain regions including the MS. The number of cholineacetyltransferase (ChAT) positive neurons in the basal forebrain will be quantified using the optical dissector method. Results: A SPM analysis of [18F]FDG PET revealed that hypometabolic areas appeared, involving the medial septum in adults and spread over the regions including hippocampal dentate gyrus. *Ex vivo* DT MRI tractography showed that the number of FA streamlines in the septohippocampal tract was lower in 3 old Tg601 mice than in 4 adult Tg601 mice (Figure). ROI analysis revealed that the FA value in the basal forebrain was significantly lower in old than in adult Tg601 mice while no significant difference in RD and AD values was detected. In old Tg601 mice, AchE activity and the amount of AchE mRNA T transcripts was higher exclusively in the septum. Conclusions: AchE upregulation in the septum may cause the selective degeneration of the septohippocampal cholinergic pathway in tauopathy model mice.

Title: Tauopathy: Discovery of small molecule modulators of tau phenotypes in human iPSC-derived neuronal models of Frontotemporal Degeneration

Authors: *M. SILVA[1], C. CHENG[1], S. REIS[1], C. TAU[3], D. LUCENTE[2], B. DICKERSON[2], S. J. HAGGARTY[1];

Abstract: Frontotemporal degeneration (FTD) disorders are characterized by progressive neuronal loss leading to dementia at a relatively young age and lack effective treatments to prevent its progression. Autosomal dominant forms of FTD are commonly associated with mutations in the MAPT gene encoding the Tau protein and characteristically exhibit potentially deleterious Tau protein aggregates in the frontal and temporal regions of the brain. With the goal of understanding the underlying pathology of FTD, identifying early disease markers, and identifying potential therapeutic targets, we have developed patient-derived, induced pluripotent stem cells (iPSCs) and differentiated neuronal cell models expressing a Tau variant associated with FTD (Tau-A152T). In this human neuronal cell model, independent clonal cell lines show, upon differentiation, rapid accumulation of Tau relative to control lines, both in hyperphosphorylated soluble, insoluble and high-molecular-weight protein forms, without differences in MAPT mRNA levels across lines. These data suggest that the accumulation of one or more particular Tau species is an early event in pathology preceding cellular toxicity and degeneration. Consequently, accumulation of Tau leads to reduced cellular resistance to specific stressors relevant to late onset neurodegeneration, including proteo-toxicity, excito-toxicity and mitochondrial function. To identify modifiers of Tau-associated phenotypes, we are pursuing the development of high-content, image-based assays that can support high-throughput screening of chemical libraries. A pilot screen in FTD patient iPSC-derived neuronal cells with known bioactive compounds, including FDA-approved or under clinical investigation, has revealed compounds targeting three main functional classes: autophagy protein clearance, neuronal signaling and the chaperone-protein folding pathways. Our lead compounds robustly downregulate steady-state levels of total and phosphorylated Tau, as well as insoluble Tau in neuronal cells, with less than a 24hr treatment. On-going studies are to further dissect modulation

of the folding and clearance pathways as a mechanism to alleviate Tau phenotypes associated with FTD and maintain protein homeostasis, including testing in iPSC-derived neurons from multiple families with Tau-P301L mutations. Collectively, we anticipate that this work will enable the discovery and validation of effective disease-modifying, targeted therapeutics, with relevance for a larger group of degenerative tauopathies and other dementias, such as Alzheimer's disease.

Abstract: Accumulation of insoluble Tau protein aggregates and stereotypical propagation of Tau pathology through the brain are common hallmarks of Tauopathies, including Alzheimer's disease (AD). Propagation of Tau pathology appears to occur along connected neurons, but whether synaptic contacts between neurons are facilitating propagation has not been demonstrated. Using quantitative *in vitro* models, we demonstrate that in parallel to non-synaptic mechanisms, synapses, but not merely the close distance between the cells, enhance the propagation of Tau pathology between acceptor hippocampal neurons and Tau donor cells. Similarly, in an artificial neuronal network using microfluidic devices, synapses and synaptic activity are promoting neuronal Tau pathology propagation in parallel to the non-synaptic mechanisms. Our work indicates that the physical presence of synaptic contacts between neurons facilitate Tau pathology propagation. These findings can have implications for "synaptic repair" therapies which may turn out to have adverse effects by promoting propagation of Tau pathology.

Title: Tau45-230 forms neurotoxic aggregates in Alzheimer's disease and related disorders

Authors: *A. B. FERREIRA, A. E. LANG;
Cell & Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: We have previously shown that beta-amyloid-induced calpain activation leads to tau cleavage and the generation of the tau45-230 fragment in Alzheimer's disease (AD) and related disorders. In addition, the expression of this fragment in otherwise healthy hippocampal neurons induces neurodegeneration followed by cell death. More recently, we generated and characterized transgenic mice that express tau45-230 in pyramidal hippocampal neurons. The analysis of their phenotype showed enhanced neuronal death, synapse loss, and behavioral defects when compared to wild type controls. To get insights into the mechanisms underlying the neurotoxic effects of tau45-230, we have assessed its ability to aggregate in the context of these diseases. For these studies, brain samples obtained from AD and other tauopathy subjects were homogenized and Western blot analyses were performed under non-denaturing conditions. Homogenates of brain samples obtained from age-matched subjects were used as controls. Our results showed the presence of tau45-230 aggregates of ~68 and 168 kDa molecular weight, respectively, in all AD and other tauopathy brain samples analyzed. These aggregates differ in their susceptibility to sarkosyl. Thus, while most of the 168 kDa aggregates were sarkosyl-insoluble, only half of the 68 kDa ones remained after incubation with this detergent. We determined next to what extent tau45-230 aggregates are neurotoxic. For these experiments, recombinant tau45-230 was aggregated in the presence of arachidonic acid. Oligomeric tau45-230 was purified and added directly to the culture medium of hippocampal neurons. Seven days in culture hippocampal neurons were incubated in the presence or absence of these aggregates for 24 hrs and their morphology and viability were assessed. Our results showed that tau45-230 aggregates were incorporated into neurons and induced degeneration and cell death. Together,

these studies suggest that tau45-230 oligomers may play an important role in the mechanisms underlying neurodegeneration in AD and other tauopathies.

Title: Modifiers of tau oligomer internalization in human neurons derived from iPSCs

Authors: ***M. USENOVIC**, S. NIROOMAND, J. J. RENGER, S. PARMENTIER-BATTEUR; Neurosci., Merck & Co., West Point, PA

Abstract: Neuronal inclusions of hyperphosphorylated and aggregated tau protein are a pathological hallmark of several neurodegenerative tauopathies, including Alzheimer's disease (AD). Increasing evidence suggest that tau pathology spreads throughout the brain via interconnected neurons, and that tau oligomers might be the transmitted pathogenic species. However, the molecular and cellular mechanisms of pathogenic tau transmission are not well established. We focused our research on defining the mediators of tau cellular internalization. Recently, it was suggested that cell-surface heparan sulfate proteoglycans (HSPGs) might play a role in tau cellular internalization. Our goal was to identify the specific molecular target within HSPGs that modifies tau uptake. We developed a model of tau oligomer internalization in human neurons derived from iPSCs, and performed a screen using lentiviral shRNAs to silence HSPGs. Internalized tau oligomers were detected based on fluorescent dye conjugated to tau protein. Here we present identified modifiers that clarify the involvement of HSPGs in tau internalization in a translatable model of human iPSC neurons. A better understanding of molecular mechanisms of tau internalization could lead to the discovery of novel therapeutic strategies that would inhibit tau pathology-spread and its consequences on neurodegeneration and cognitive dysfunction.

Title: Exploring the molecular overlap in the brain and plasma of repetitive mTBI and AD mouse models using proteomic technology

Authors: *J. O. OJO;
The Roskamp Inst., Sarasota, FL

Abstract: Traumatic brain injury (TBI) is a major cause of disability in the military and civilian population, and for many years has been known to be a major risk factor for Alzheimer's disease (AD). Although the existence of this relationship is well recognized, and the overlap and distinction between pathological features of AD and repetitive mTBI, have long been the subject of reporting and discussion, the precise nature of how TBI leads to or precipitates AD pathogenesis is currently not understood. To address this problem we are generating time-dependent molecular profiles of response to repetitive mTBI and AD pathogenesis in mouse models, using proteomic analyses. We are using the well-validated hTau mouse models that develops age-related tau pathological features, and our well-established model of mTBI in C57BL/6 mice. Brain and plasma from these animals have been collected at different ages (for hTau mice), or at different timepoints after repetitive mTBI (C57BL/6). Liquid chromatography/mass spectrometry (LC-MS), in source collision induced dissociation (SCID) approaches and Tandem Mass Tag labeling technology are being applied to develop molecular profiles of proteins species that are significantly differentially expressed as a consequence of AD or mTBI. Generation of proteomic analyses are ongoing for comparisons of TBI profiles at 24hrs, 3, 6, 9 and 12 months post-injury with profiles at 3, 9 and 15 months of age in the hTau models. We anticipate that the exploration of molecular profiles from these animal models will enable us to identify cellular pathways that have pathogenic significance in human conditions. Moreover, we further aim to explore these identified pathways as potential targets for therapeutic intervention. **Key words:** mild traumatic brain injury, Alzheimer's disease, animal models, transgenic mice, proteomics. This study is funded by a CDMRP award to FC (DoD/W81XWH-13-1-0253), and by the Roskamp Foundation.

Title: Overexpression of Tau protein induces a dispersion of the Golgi apparatus in neuroblastoma cells

Authors: *F. GARCIA-SIERRA[1], F. RODRÍGUEZ-CRUZ[2], F. M. TORRES-CRUZ[2], J. ESCOBAR-HERRERA[2], G. BASURTO-ISLAS[3];
[1]Dept. of Cell Biology, CINVESTAV- IPN, Mexico city, Mexico; [2]Cell Biol., CINVESTAV-IPN, Mexico city, Mexico; [3]Hlth. Sci. Department, Unidad Lerma, Univ. Autonoma Metropolitana, Estado de Mexico, Mexico

Abstract: Abnormal aggregation of Tau protein in the form of Paired Helical Filaments (PHF) is a pathological condition observed in hippocampal and cortical neurons of Alzheimer´s disease (AD) patients. Non-fibrillar aggregates of Tau are also observed in this pathology, however their pathological significance in the disease is still a debatable issue. Previously, we have probed that non-aggregated Tau causes morphological alterations in the nuclear architecture and plasma membrane blebbing when expressed in cultured neuronal and glial cells. In this study we further investigated whether Tau protein and several truncated Tau variants produce alterations in another membranous compartment, such as the Golgi apparatus. Cultured SH-SY5Y cells were transiently transfected with plasmids (pcDNA3.1Zeo(-)) containing the sequence for either full-length tau protein (Tau441) or several N- and C- termini truncated Tau variants. Cell morphology and protein expression were analyzed by immunofluorescence and confocal microscopy, and western-blotting analysis. After 48 hours of transfection, in 60% of the cells, Tau441 produced significant disruption of the Golgi ribbon structure into smaller elements dispersed from the narrow perinuclear area over the entire central part of the cell. Both Asp421 (Tau421) and Glu391 (Tau391) C-terminus truncated Tau variants produced similar results with no significant differences in the rate of Golgi dispersion. To evaluate the contribution of the N-terminus of Tau in the architecture and proper positioning of the Golgi apparatus in the cell, N-terminus truncated Tau constructs (Tau150-441; Tau123-391) were also expressed in SH-SY5Y cells. In accordance with other Tau variants, Tau150-441 and Tau123-391 also produced dispersion of this structure with no evidence of toxicity, as it was previously proposed. We also noticed that in the majority of the cells showing Golgi dispersion, a bundling effect of

microtubules was generated under the expression of either Tau441 or any truncated variant. These results may indicate that a mechanical force generated by Tau-induced microtubule bundling may be responsible for Golgi dispersion and that the repeated domain region of Tau is the main promoter of this effect

Title: Tau antibody-mediated prevention of seeding of tau pathology and associated toxicity

Authors: *E. E. CONGDON[1], D. SHAMIR[2], H. R. B. SAIT[2], S. RASOOL[2], E. M. SIGURDSSON[3];
[1]Dept. of Physiol. and Neurosci., [2]Neurosci. and Physiol., [3]Neurosci. and Physiology, Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Tau pathology spreads between neurons in culture and *in vivo* and can be targeted with antibodies both intra- and extracellularly. We have developed 4E6G7, a monoclonal antibody recognizing pSer404 tau, and used it successfully in multiple models. Here we assessed its efficacy in preventing toxicity and spread of tau pathology mediated by paired helical filament (PHF) preparation from an Alzheimer's subject. Primary JNPL3 (P301L) neurons were incubated for seven days with PHF alone (1 or 10 μg/ml), PHF and 4E6G7 (10 μg/ml) added together (P + A), 4E6G7 added 24 h after PHF (P > A), or PHF added 24 h after 4E6G7 (A > P). PHF induced toxicity as measured by LDH (57% and 85% increase at 1 and 10 μg/ml, $p \leq 0.05$) and NeuN (31% and 94% decrease, $p \leq 0.004$). In P + A and P > A samples, this toxicity was prevented with readouts at control values, except for NeuN in the 10 μg/ml P > A group, which was significantly higher (116% control, $p = 0.02$), suggesting some neurotropic effect of the antibody. PHF exposure also increased neuronal tau levels in the remaining neurons at both

doses when normalized for NeuN (2.1- and 5 fold at 1 and 10 μg/ml, $p \leq 0.01$), which were significantly reduced in both the P + A, and P > A groups ($p \leq 0.006$ - 0.0006), to (1 μg/ml) or somewhat higher (10 μg/ml, 1.5- and 1.2 fold, $p \leq 0.01$) than control values. PHF also increased the ratio of pSer199/NeuN (1.1- and 5 fold, $p \leq 0.02$) which was reduced to control values at both doses in both P + A and P > A groups. To ascertain whether antibody efficacy required internalization, we tested the P + A and P > A paradigms using microscopy and inhibitors of antibody uptake. In the P + A group, PHF and 4E6G7 formed extracellular complexes. In P > A cells, PHF was taken up by neurons, and 4E6G7 colocalized with it. Using an endocytosis inhibitor, we found that blocking 4E6G7 uptake had no effect on efficacy in the P + A group. In contrast, in P > A cells, blocking 4E6G7 uptake significantly reduced its protective effects (68% NeuN loss, $p = 0.00005$). Additional neurons were grown in microfluidic chambers (JNPL3 on one side, WT on the other) to assess the effect of 4E6G7 on PHF spread. PHF was added to the JNPL3 side, and 72 h later 24% of the WT cells contained labeled PHF material. The P + A group had significantly fewer positive cells (14%, $p = 0.01$), and the P > A group showed a strong trend towards reduced transmission (18% positive, $p = 0.06$). These data suggest that multiple mechanisms are occurring, and that both extracellular blockage and promotion of intracellular clearance are valid methods for preventing seeding of tau pathology and associated toxicity. Antibodies that can affect both pathways are likely to be more efficacious than those acting only within one compartment.

Title: Antibodies targeting truncated tau protein reduce tau pathology in primary neuronal and mixed cortical cultures

Authors: S. R. MODAK[1], M. SOLESIO[1], S. KRISHNASWAMY[1], E. E. CONGDON[1], *E. M. SIGURDSSON[2];
[1]Neurosci. and Physiol., [2]Neurosci. and Physiology, and Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Truncation of the tau protein at aspartate in position 421 (Asp421) is a characteristic feature of tauopathies such as Alzheimer's disease, and may have a role in their pathogenesis. Tau immunotherapy targeting various epitopes is a promising approach to treat these diseases. In this study, we investigated, in primary neuronal and mixed cortical cultures, the therapeutic potential of two monoclonal antibodies with high (5G2A3, 10^{-9} M) and low (1G11A10, 10^{-6} M) affinity for the free Asp421 epitope. The cultures derived from day 0 JNPL3 (P301L) mice were pretreated with paired helical filament (PHF) enriched preparation (1 μg/ml) from an Alzheimer's brain for 24 h, then washed and incubated with antibody (10 μg/ml) for further 24, 48, 72 and 96 h. Subsequently, western blots were conducted for phospho- and total tau protein to determine if the antibodies could clear PHF derived/induced tau proteins from the cultures. The higher affinity Asp421 antibody led to significant and sustained reduction in both phospho- (up to 87% at 96 h, $p<0.001$) and total tau (up to 54% at 96 h, $p<0.0001$) in the mixed culture, compared to control IgG which had no effect. This tau antibody had as pronounced effect in the primary neurons at 24 and 48 h (phospho-tau: 89% reduction at both time points, $p<0.001$; total tau: 58% at 24 h, $p=0.001$ and 45% at 48 h, $p=0.005$) that subsided a bit at the later time points (phospho-tau: 75% reduction, $p=0.003$ at 72 h and 68% reduction at 96 h, $p=0.008$; total tau: 6% reduction, $p>0.05$ at 72 h and 43% reduction, $p=0.006$ at 96 h). The lower affinity Asp421 antibody was less efficacious in reducing phospho- and total tau (up to 49% reduction at 96 h, $p<0.0001$ and 36% reduction at 96 h, respectively, $p<0.0001$) in the mixed cortical culture, and was ineffective in the primary neuronal culture to reduce either phospho- or total tau. In conclusion, this study clearly shows: 1) the therapeutic potential of targeting tau protein truncated at Asp421; 2) that higher affinity antibody against this particular epitope is more efficacious, and; 3) that greater efficacy is observed in mixed cortical cultures than in primary neurons, presumably because of contribution from phagocytic microglia that promote degradation of tau-antibody complexes. Neurons in mixed cultures are also healthier and, therefore, likely to be better suited to clear/degrade such complexes.

Title: Tau antibodies reduce tau levels in differentiated but not in non-differentiated human SH-SY5Y cells

Authors: *D. B. SHAMIR[1], E. M. SIGURDSSON[2];
[1]Neurosci. and Physiol., [2]Neurosci. and Physiology, and Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Our laboratory has pioneered targeting pathological tau proteins for clearance with immunotherapies. To further clarify the mechanism of action of tau antibodies, we have been using SH-SY5Y human neuroblastoma cells among other models. These cells take up tau antibodies, which co-localize within the endosomal-lysosomal system. To create a more physiological system we have differentiated our naïve SH-SY5Y cells using retinoic acid and brain derived neurotropic factor (BDNF), and characterized them using western blot analysis. As expected, the differentiated cells have greater total tau protein compared to non-differentiated cells (172%, p=0.025, n=7-8). Incubation for 24 hours with different tau antibodies to the S396/404 tau region led to reduction in total tau levels in differentiated (19-25%; p=0.004, n=15-16) but not in non-differentiated cells, compared to controls. Interestingly, during this 24 hour period, the differentiated cells took up less tau antibodies than their non-differentiated counterparts (45% vs. 83%; p<0.0001, n=8-12). Clathrin-mediated endocytosis inhibitor (Dynasore, 5 ug/ml), reduced antibody uptake by 39% in the differentiated cells (p=0.03, n=7) but had no effect in non-differentiated neurons (n=4). Measurement of tau levels are in progress. However, with our flow cytometry protocol we demonstrated that antibody uptake can blocked in non-differentiated cells with a bulk-mediated endocytosis inhibitor (Cytochalasin D, 1-10

ug/ml, 31-55% reduction, $p<0.0001$, $n=2$). In prior publications we have shown that antibody uptake in primary mouse neuronal cultures is mainly through clathrin-mediated endocytosis (~80%), and to a lesser extent (~20%) via bulk-mediated endocytosis (Congdon EE et al, JBC, 288, 2013). Our current findings indicate that differentiated culture models may be needed to determine the therapeutic efficacy of tau antibodies, but non-differentiated culture models may be useful to focus exclusively on the bulk-mediated pathway. However, the physiological relevance of such non-differentiated models is more limited as higher antibody uptake did not translate to greater efficacy compared to differentiated cells. Future studies will seek to clarify how antibody-mediated tau clearance pathways may differ in these two models.

Title: Alzheimer’s disease cellular model: 2,2’-dithiodipyridine-induced Tau oligomerization in primary rat cortical neurons

Authors: C. QIAN[1], K. L. KRAUS[1], *R. A. COLVIN[2];
[2]Dept Biol. Sci., [1]Ohio Univ., Athens, OH

Abstract: The self-assembly of microtubule-associated protein Tau is recognized as one of the primary hallmarks of Alzheimer’s disease (AD), which destabilizes micro-tubule (MT) assembly and facilitates formation of “prion-like” Tau oligomers. So far, the cellular models mimicking Tau aggregation are either based on genetic manipulations of several domains of Tau protein, or by application of high concentrations of chemicals that oxidize cysteines on Tau, forming an intermolecular disulfide bridge. However, a cellular model is lacking that shows controllable,

visible and quantifiable oligomerization of endogenous Tau in primary neurons. Tau self-assembly in rat primary cortical neurons was induced by applying the thiol oxidant 2,2'-dithiodipyridine (DTDP). Both immunofluorescent microscopy (IF) and immunoblotting (WB) using an antibody to total Tau were utilized to observe and quantify DTDP-induced Tau oligomerization. Immunofluorescent results showed that DTDP-induced Tau aggregation was both dose- and time-dependent. Treating cells with 10, 30, 60, or 100μM DTDP caused increased Tau IF of 114±10%, 195±24%, 178±28% and 275±29% in cell bodies; 110±5%, 139±3%, 123±2% and 166±17% in neurites, and 83±19%, 205±36%, 269±41% and 529±12% increase in Tau aggregates, respectively (mean ± SE, n=3). Treating cells with 30μM DTDP for 5, 15, 30, or 60min caused increased Tau IF of 124±13%, 166±19%, 200±40% and 222±12% in cell bodies; 104±11%, 127±7%, 115±8% and 152±22% in neurites, and 104±11%, 127±7%, 115±8% and 152±22% increase in Tau aggregates, respectively (mean ± SE, n=3). WB showed that incubating culture extracts with DTT reduced the detectable levels of high MW oligomers and dimers and DTT increased the levels of Tau monomers. This suggests that the self-assembly of Tau protein induced by DTDP was most likely attributable to intermolecular disulfide bond formation between cysteine residues on repeat domains of Tau. DTDP is well known to release zinc from zinc binding proteins, therefore, zinc chelator TPEN was tested on the DTDP-induced model. 100μM TPEN partially but significantly reduced the number of Tau aggregates induced by either 60μM or 100μM DTDP. These data show the pivotal role of intermolecular disulfide bond formation in shifting the balance toward assembly-prone conformations, increasing substantially the rate of formation of intracellular Tau aggregates. This research reveals an effect of increased intracellular free zinc in the process of Tau aggregation.

Title: The role of selective autophagy in neurofibrillary tangle pathology

Authors: *Y. XU, H. ZHENG;
Baylor Col. of Med., Houston, TX

Abstract: Tauopathies consist of a group of diseases, including frontotemporal dementias and the most common form Alzheimer's disease, and are characterized by the accumulation of intracellular neurofibrillary tangles (NFTs) composed of aggregates of hyperphosphorylated Tau protein and extensive neurodegeneration. Tau is normally localized to the neuronal axons where it binds and stabilizes the microtubules. Aberrant Tau phosphorylation leads to its dissociation from the microtubules followed by aggregation and redistribution to cell bodies and dendrites. Accumulating evidence has implicated impaired autophagy-lysosome pathway in neurodegenerative diseases including diseases of tauopathies. In this study, we examined the role of the autophagy receptor protein p62/SQSTM1 in tauopathy. We found that p62 is significantly increased in neurons of tau transgenic mouse models. Using a seeding based cell model in which tau aggregates can be induced by seeding with tau transgenic brain lysates, we found that overexpression of p62 specifically decreased insoluble tau while knockdown of p62 increased insoluble tau, suggesting that selective p62-dependent autophagy counteracts tangle pathology.

Title: Pathological forms of tau affects mitochondrial dynamics in Alzheimer´s disease

Authors: *R. A. QUINTANILLA, K. VERGARA, F. A. CABEZAS-OPAZO;
Inst. de Ciencias Biomédicas, Univ. Autónoma de Chile, Lab. of Neurodegenerative Dis., Santiago, Chile

Abstract: Accumulative evidence suggests that tau pathology and Aβ aggregates affects the neuronal function compromising energy supply and antioxidant response in Alzheimer´s disease (AD). Several reports have suggested that in AD, the mitochondria could be affected in terms of bioenergetics, transport, and dynamics. Defects in mitochondrial dynamics are related to changes in mitochondrial fission/fusion proteins, and previous evidence suggests that tau pathology could

affect this process. In this context, we analyzed the effects of pathological forms of tau on mitochondrial dynamics in neuronal cells and primary cortical neurons. In these studies, we expressed tau in the pseudo-phosphorylated form at S396/404 (T42EC) and caspase-cleaved tau (T4C3), and we evaluated changes in mitochondrial morphology using Mito-mCherry. Expression of T42EC did not induce significant changes in mitochondrial morphology compared to GFP and full-length tau. However, T4C3 and both pseudo-phosphorylated and caspase-cleaved tau (T42EC-C3) expression induced significant mitochondrial fragmentation, compared to cells that expressed full-length tau. Interestingly, concomitant with the mitochondrial fragmentation the neuronal cells that expressed T4C3 and T42EC-C3 presented an enhanced mitochondrial depolarization and superoxide production after treatment with Aβ fibrils. In addition, complementary studies were made in immortalized cortical neurons that expressed same constructs of tau to evaluate the expression of mitochondrial fission (Drp-1/Fis1) and fusion (Mitofusins 1, 2 (Mfn1, 2)/Opa1) proteins. Expression of T4C3 and T42EC-C3 significantly decreased total Drp-1 levels with no apparent effects in Opa1, Mfn1, and Mfn2. In contrast, full-length (T4) and pseudo-phosphorylated tau (T42EC) expression did not affect mitochondrial fission/fusion proteins expression in immortalized cortical cells. These observations are consistent with the mitochondrial morphology studies that showed an evident mitochondrial fragmentation in neuronal cells that expressed truncated and pseudo-phosphorylated tau. Altogether these findings indicate that the presence of pathological forms of tau affects mitochondrial dynamics and that this alteration could contribute to Aβ toxicity in neurons.

Title: Regulating proteostasis to control both normal and pathological tau biology

Authors: ***S. N. FONTAINE**, M. D. MARTIN, C. A. DICKEY;
Univ. of South Florida, Tampa, FL

Abstract: Chaperone proteins play an important role in identifying and correcting the proper conformation of proteins. Thus, the relationship between the microtubule associated protein tau and chaperones is unusual simply because tau is a disease-associated intrinsically disordered protein (IDP) that lacks a defined structure. Of particular interest is the interaction between tau and the constitutively expressed Hsp70 (Hsc70), as Hsc70 plays a number of important roles in the cell and also stabilizes tau levels. We have evidence that this stabilization of tau by Hsc70 can facilitate its pathogenesis in various ways. However, isoform selective Hsc70 inhibitors have not yet been developed. As proof-of-concept, we determined that a functionally inactive variant of Hsc70 facilitated tau clearance via the proteasome in brain, exactly mimicking what we predict selective inhibition of this Hsp70 isoform would cause. We determined that an altered interactome was responsible for tau clearance caused by this Hsc70 variant. Of note, this inactive Hsc70 variant recruited tubulin proteins compared to wildtype Hsc70, suggesting a role for Hsc70 activity in microtubule regulation. Indeed, using live cell imaging, Hsc70 facilitated microtubule assembly but only when it was active and surprisingly only when tau was present. In particular if Hsc70 activity was disrupted, microtubules were disrupted. In this way, active Hsc70 uses tau as a co-chaperone to regulate microtubule dynamics. Thus chronic treatment with an Hsc70 inhibitor would facilitate microtubule injury and cytotoxicity, but we found that taking a chemotherapeutic approach using intermittent dosing still promoted tau clearance without damaging microtubules. This suggests that strategies to restore the proteostasis network can be effectively used to treat disease when used in a regimen similar to that used for some chemotherapies and contraceptives.

Title: Pentobarbital-induced hypothermia modulates total and phosphorylated tau: implication of alpha7 nicotinic receptors

Authors: ***A. GOBERT**, F. IOP, V. PASTEAU, K. ALBINET, L. DANOBER, C. LOUIS, P. LESTAGE;
Inst. De Recherches Servier, Croissy-sur-Seine, France

Abstract: Background In Alzheimer's Disease (AD) and other tauopathies, paired helical filaments are described to be enriched in hyperphoshorylated tau proteins. Previous studies have shown that anaesthesia-induced hypothermia promotes extensive tau hyperphophorylation at various epitopes (Planel et al., 2007). The present study aimed at deciphering the role of α_7 nicotinic acetylcholine receptors (α_7nAChR) and the efficacy of central acting α_7 nicotinic ligands in inhibiting tau phosphorylation. **Method** Hypothermia was induced in wild-type (WT) male C57Bl/6J and α_7nAChR knock-out (KO) mice using pentobarbital injections. After ninety minutes, animals were sacrificed and whole brain extracts prepared. Total tau and phospho (pSer202, pThr181, pSer262, pSer396 and $pThr^{231}$) tau, as well as $GSK_{3\beta}$ and phospho $GSK_{3\beta}$ were quantified using an ELISA technique (MesoScale Discovery's electrochemiluminescence detection). In parallel, Western blot analyses were performed using different total and phospho tau antibodies. **Results** After anaesthesia-induced hypothermia total tau levels and its phosphorylation at Ser396 were decreased, while an increase in phosphorylation at Ser202 and Thr181 was detected using the ELISA technique. No significant changes were observed at the levels of Thr231 and Ser262 phosphorylation of tau and neither on $GSK_{3\beta}$ nor phospho GSK_3. In contrast, Western blot analyses, did not detect any changes in total tau levels, independent of the antibody used. Ser396 levels did not change neither. In accordance with the observation using ELISA detection, Western blot analyses revealed an increase of phosphorylation at the Ser202-Thr205 and the Thr181 epitopes, while at Thr231 no change could be detected. Hypothermia-induced changes in total or phosphorylated tau were not attenuated in α_7nAChR KO mice as compared to WT mice. Likewise, acute administration of α_7nAChR agonists, S24795 (3 mg/kg, ip) and ABT107 (0.3 mg/kg, ip), 30 min before pentobarbital did not influence hypothermia-induced alteration of total and phosphorylated tau levels. **Conclusions** Anaesthesia-induced hypothermia in wild-type mice results in changes at different phosphorylation sites of tau. Similar observations were made in α_7nAChR KO mice and after administration of two α_7nAChR agonists, suggesting that α_7nAChR do not play a critical role in hypothermia-mediated tau phosphorylation. All procedures using the animals conformed to the European Directive 2010/63/EU, and its adaptation to French law (décret 2013/118), on the protection of animals used for scientific purpose. Title: The effects of manipulating the de-ubiquitinating enzymes USP14 and UCH-L1 on the levels of TAU and polyubiquitinated proteins: relevance to Alzheimer's disease

Authors: *M. J. KIPROWSKA[1,2], A. STEPANOVA[3,4], A. GALKIN[3], M. FIGUEIREDO-PEREIRA[1];
[1]Biol. Sci., Hunter College, CUNY, New York, NY; [2]The Grad. Center, CUNY, New York, NY; [3]Sch. of Biol. Sci., Queen's Univ. Belfast, Belfast, United Kingdom; [4]Koltzov Inst. of Developmental Biol., Russian Acad. of Sci., Moscow, Russian Federation

Abstract: Impairment of the ubiquitin/proteasome pathway (UPP) plays an important role in Alzheimer Disease (AD) as indicated by the accumulation of ubiquinated and oxidized proteins detected in the AD brains. The accumulation of toxic aggregates in AD brains is attributed, in part, to UPP dysfunction, which occurs very early in the neurodegenerative cascade. Thus to enhance protein degradation by the UPP prior to aggregate formation could be a highly effective therapeutic approach to prevent/delay neurodegeneration in AD. A proposed strategy for promoting protein degradation by the UPP is inhibiting USP14. This deubiquitinase disassembles polyubiquitin chains potentially delaying degradation of proteasomal substrates. We assessed the protective efficacy of inhibiting USP14 pharmacologically with IU1 and genetically with siRNA, in rat cortical neurons treated with prostaglandin J2 (PGJ2). PGJ2 is an endogenous mediator of inflammation that induces the accumulation of ubiquitinated (Ub)-proteins. Firstly, we observed that high IU1 concentrations (HIU1, >25μM) blocked Ub-protein accumulation induced by PGJ2, while low IU1 concentrations (LIU1, ≤25μM) had no impact. In addition, HIU1 by itself or in combination with PGJ2 induced (a) neurotoxicity and (b) calpain-dependent cleavage of Tau, caspase and spectrin. Secondly, we established that HIU1 decreased ATP levels and inhibited mitochondrial complex I. Consequently, HIU1 blocked E1-mediated ubiquitin-activation and 26S proteasome assembly, which are energy-dependent processes. These data support that HIU1 prevents Ub-protein accumulation, in part, by blocking E1-dependent

ubiquitin-activation thus halting ubiquitination. Thirdly, we showed that USP14 knockdown by siRNA failed to promote Ub-protein degradation in neurons treated with PGJ2. Finally, we demonstrated that PGJ2 inhibits E1-activity, but still induces accumulation of Ub-proteins. These Ub-proteins are likely to be formed prior to and stabilized by the PGJ2-treatment. Accordingly, PGJ2 inhibits deubiquitinases like UCH-L1, thus potentially stabilizing polyUb-chains. In conclusion, both IU1 and PGJ2 diminish E1 activity. However, IU1 blocks Ub-protein accumulation, while PGJ2 promotes it. The contrast between the IU1- and PGJ2-impact on Ub-protein accumulation, could be related to the mechanism by which the targeted deubiquitinases destabilize polyUb-chains. In conclusion, a better understanding of the mechanisms by which distinct deubiquinases regulate the levels of polyUb-chains is critical for drug development to reduce the accumulation of aberrant proteins in neurodegenerative diseases such as AD.

Title: Tau phosphorylation plays a role in mRNA 3' end processing

Authors: F. E. KLEIMAN[1], J. E. BAQUERO[1], M. ORDONEZ[1], *A. ALONSO[2,1];
[1]Hunter Col., City University of New York, NY; [2]Deaprtment of Biol., Col. of Staten Island, CUNY, Staten Island, NY

Abstract: Tau is a microtubule-associated protein involved in a number of neurodegenerative disorders, including Alzheimer's disease (AD). In normal individuals, Tau is a highly soluble, non-phosphorylated protein that stabilizes microtubules in the cytoplasm of neurons. However, neurons in AD's contain insoluble hyperphosphorylated-tau aggregates known as paired helical filaments. Previous studies have shown that Pin1, a prolyl-isomerase initially identified as a mitotic regulator overexpressed in most human cancers, is involved in the regulation of Tau phosphorylation under different conditions. Furthermore, Tau has been functionally linked to another Pin1 substrate, the tumor suppressor p53 and some of its isomers. Interestingly, Dr. Kleiman's lab identified p53 as an activator of PARN-dependent mRNA deadenylation in the

nucleus as part of the DNA damage response. As Pin1, p53 and PARN are localized in the nucleus and are involved in the regulation of mRNA 3' end processing under different cellular conditions, we hypothesize that Tau might also localize in the nucleus of non-neuronal cells and functionally overlap with these factors. Our cellular fractionation assays with samples of HCT116 human colon carcinoma cell line indicated that tau isoforms are present in the cell nucleus. Interestingly, nuclear isoform patterns of Tau changed upon Pin1 inactivation, UV irradiation, p53 expression and/or phosphatase treatment. Using co-immunoprecipitation assays, we showed that some Tau isoforms can form (a) complex(es) with p53, Pin1 and PARN, and these interactions change under different cellular conditions. Strikingly, overexpression of Tau, but not of its phosphomimic mutants, induces nuclear deadenylase activity in CHO cells. Finally, siRNA-mediated knockdown of Tau decreases nuclear deadenylation in samples from HCT116 cells under non damaging conditions. Moreover, Tau knockdown further increases the previously described UV-induced deadenylation. Although more research is necessary, these preliminary results reveal a new potential role for Tau in the regulation of mRNA 3' processing. These findings also support the idea that factors involved in cancer and Alzheimer's disease might play a role in regulating gene expression by a functional interaction with the mRNA 3' processing machinery in different conditions, resulting in specific gene expression patterns.

Title: Phosphorylated tau has increased binding affinity to dynactin

Authors: *S. D. CRISH[1], W. J. GELDENHUYS[1], C. M. DENGLER-CRISH[1], G. N. WILSON[2];
[1]Pharmaceut. Sci., NEOMED, Rootstown, OH; [2]Biomed. Sci., Kent State Univ., Kent, OH

Abstract: Hyperphosphorylation of the microtubule-associated protein tau plays a major role in driving pathology in neurodegenerative conditions such as Alzheimer's disease (AD). In its normal phosphorylation state, tau acts to organize and stabilize the cytoskeleton in axons

whereas hyperphosphorylation reduces tau's affinity for microtubules. After tau disassociates from microtubules, it then "falls back" to the somatodendritic compartment where it forms neurofibrillary tangles that characterize AD. Both the loss of tau-mediated microtubule organization as well as abnormal translocation and aggregation of tau in non-axonal compartments negatively impact neuronal structure and function, leading to neurodegeneration. While much is known about tau's phosphorylation state influencing microtubule binding, little is known about the mechanism of tau translocation to the soma. Using co-immunoprecipitation techniques, we report here that phosphorylation of recombinant tau isoforms by glycogen synthase kinase 3-beta (GSK-3β) increases tau's affinity for dynactin - a major component of the retrograde axon transport machinery. Our data suggest that phosphorylation of tau causes it to bind to the retrograde molecular motors which transport it to the soma.

Title: Tau phosphorylation correlates with cellular tau uptake

Authors: *S. TAKEDA[1], S. L. DEVOS[1], S. WEGMANN[1], C. COMMINS[1], C. K. NOBUHARA[1], A. D. ROE[1], I. COSTANTINO[1], R. PITSTICK[2], G. A. CARLSON[2], M. P. FROSCH[1], B. T. HYMAN[1];
[1]Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [2]McLaughlin Res. Inst., Great Falls, MT

Abstract: Background Cognitive deficits in Alzheimer's disease (AD) are most closely linked with the progression of neurofibrillary tangles (NFTs) in a hierarchical pattern. Although the precise mechanisms for this characteristic tau pathology spread remain unknown, accumulating evidence suggests a transsynaptic transfer of the pathological form of tau between neurons. We previously found that high-molecular-weight (HMW) tau can be the endogenous form of tau involved in tau uptake and propagation. Here, we examined the role of phosphorylation in

cellular tau uptake. Methods Cellular tau uptake was assessed using FRET-based HEK-tau-biosensor cells (Holmes BB et al. PNAS 2014) or mouse primary neurons treated with brain-derived tau. Brain extracts (PBS soluble fraction) from a tau-transgenic mouse model (rTg4510, 12 months old) or human AD postmortem tissue (frontal cortices from five cases with Braak stage VI) were used to treat cells. Results First, we examined the effect of tau dephosphorylation on cellular uptake. Lambda phosphatase treatment dephosphorylated tau in rTg4510 brain extract without changing HMW tau levels; this resulted in a reduction of tau uptake in HEK-tau-biosensor cells. We then assessed tau uptake from phospho-tau-immunodepleted rTg4510 brain extract in primary neurons. Eight different phospho tau epitope specific antibodies (pS199, pT205, pS262, pS369, pS400, pS404, pS409, and pS422) were used for the immunodepletion. Phospho-tau-specific antibodies were less efficient at immunodepletion than the total tau antibody (HT7); however, some phospho-tau antibodies (pS199, pT205, and pS396) more efficiently reduced the neuronal tau uptake than did the total tau antibody. This suggests that they specifically interacted with a species of tau important for uptake. We then examined uptake efficiency of brain-derived tau from five different AD cases in HEK-tau-biosensor cells and found a positive correlation between uptake efficiencies and phospho-tau levels. Conclusions Three lines of data support the idea that phosphorylation is important for neuronal tau uptake: (i) enzymatically dephosphorylating the HMW tau blocks uptake; (ii) some phospho-tau-specific antibodies are able to block uptake; and (iii) uptake efficiency correlates with the extent of phosphorylation in biological samples. These observations indicate that phosphorylation may enhance cellular tau uptake.

Abstract: Objectives: Although several studies demonstrate that Tau aggregates can be transmitted from neuron to neuron, little information is available on the mechanism of spreading and on the molecular properties of the Tau seed. The aim of this study is to identify and characterize pathological species of Tau capable of transmitting pathology. **Methods:** Aggregates were isolated from *post mortem* AD and transgenic mice (male PS19 and female P301S) brain tissue. Biochemical characterization was done by Western blotting (reducing and non-reducing), SEC, ELISA and AlphaLisa. Aggregates were then evaluated in both cellular and *C. elegans* aggregation models and *in vivo* Tau injection models. **Results:** Biochemical analysis revealed that total and sarcosyl insoluble fractions from both AD derived material and transgenic animals contain Tau aggregates capable of triggering aggregation in a cellular model. When PHFs are injected in the cortex of P301L mice (mixed gender), Tau pathology (confirmed by native PAGE, Western Blot and IHC) is observed from one to three months after injection in injected and non-injected hemispheres. **Conclusions:** This study further characterized the molecular properties of PHFs and demonstrated that *in vitro* seeding capacity correlated with aggregate load. Injection experiments in Tau transgenic mice show that purified PHFs can trigger Tau aggregation *in vivo*. Confirmation of this seeding effect in a *C elegans* model is currently ongoing. Further injection studies with fractionated AD brain samples are needed to get more insight in the molecular properties of this type of seed.

Abstract: The majority of neurodegenerative tauopathies are associated with the pathological accumulation of additional amyloid proteins, notably amyloid-β in Alzheimer's disease (AD). Studies have shown that intermediate aggregates known as oligomers are the most toxic species in disease. The common toxic factor in these diseases, the tau oligomer, is a promising therapeutic target in mixed pathology diseases. We have recently shown that passive immunotherapy with a novel tau oligomer-specific antibody is effective in two different pure tauopathy models, P301L and Htau mice. Here we directly test the interaction between tau and amyloid oligomers and the efficacy of anti-tau oligomer immunotherapy in a model of AD. We have evaluated brain tissue and oligomers derived from AD patients for the interaction between amyloid proteins and tau using biochemical and immunohistochemical analysis with our novel oligomer-specific antibodies. To investigate the efficacy of immunotherapy with anti-tau oligomer monoclonal antibody (TOMA) in an AD model, we examined the behavior and pathology of treated Tg2576 mice. We found that Aβ oligomers can seed the aggregation of tau *in vitro* and are colocalized in disease, forming hybrid oligomers. Treatment with TOMA reverses cognitive detriment and decreases tau oligomer levels in Tg2576 mice, while increasing stable Aβ plaque levels. Our results suggest that oligomeric Aβ has a synergistic relationship with tau oligomers. This combined with passive immunotherapy results suggest that tau oligomers are a good therapeutic target in AD and potentially in other mixed pathology tauopathies. **Supported by:** The Alzheimer's Drug Discovery Foundation, The Cullen Trust and the Mitchell Center for Neurodegenerative Diseases.

Title: Fluorescent assays for the detection of beta-Amyloid and Tau modification enzymes: Pin1 and Glutaminyl cyclase

Authors: O. GURINOVICH, *C.-Y. KO, X. WANG, R. ZHANG, V. RAKHMANOVA; AnaSpec, Inc. EGT Group, Fremont, CA

Abstract: Alzheimer’s disease (AD) is one of the most common neurodegenerative diseases that lead to dementia. Hallmark of AD is the presence of senile plaques and neurofibrillary tangles in the affected brain. It is believed that senile plaques originate due to the aggregation of beta-Amyloid (Aβ) peptides while neurofibrillary tangles are caused by the accumulation of hyperphosphorylated Tau proteins. Both, Aβ and Tau, can undergo different modifications during cellular trafficking that may affect their aggregation properties. Thus, it is important to identify what enzymes can modify these two AD biomarkers and study modifying agents in more details. Glutaminyl cyclase, also known as Glutaminyl-peptide cyclotransferase (QPCT), and Peptidyl-prolyl *cis-trans* isomerase NIMA-interacting 1 (Pin1) are such enzymes which modify Aβ and Tau respectively. Pin1 catalyzes *cis/trans* isomerization of the phosphor-Serine/Threonine-Proline peptide bond of Tau protein. This leads to the Tau dephosphorylation and prevents it from forming neurophibrilary tangles. On the contrary, QPCT can catalyze production of pyroglutamic beta-amyloid peptides that aggregate much faster compared to the unmodified ones and may produce senile plaques at higher rate. In order to investigate properties of these two protein modifying enzymes, reliable assays for Pin1 and Glutaminyl cyclase activities have to be developed. We have designed two assays to detect activity of Pin1 and QPCT enzymes using fluorescent based peptide substrates. Both assays use long-wavelength green fluorophore that is released after enzyme and developer action and can be monitored at Ex/Em=490/520nm. Pin1 catalyzes change of fluorescent substrate into *trans* form that is

cleaved by the substrate developer and releases fluorophore much faster compared to the unmodified *cis* substrate. Thus, intensity of the fluorescent signal can be correlated with Pin1 activity in a sample. For the Glutaminyl cyclase assay, substrate is converted into the pyroglutamate form that is readily cleaved by the assay developer and generates green fluorescence. Both assays have sensitivity in nanogram range. QPCT assay was validated with human saliva and cerebrospinal fluid. Inhibitors for both assays were selected to ensure that they act on enzymes only and do not affect developer. Homogeneous format of both assays is ideal for inhibitors screening during drug discovery.

Title: Differential recognition of pathological forms of tau protein with N-terminal antibodies in tauopathies and *in vitro* assays

Authors: *B. COMBS, K. K. COX, C. HAMEL, N. M. KANAAN;
Col. of Human Medicine, Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI

Abstract: Tauopathies are characterized by the aggregation of tau protein and extensive neurodegeneration. Traditionally, several phosphoepitope-specific antibodies were used to observe tau neuropathology, but these markers do not indicate whether tau is in potentially toxic conformations. Recent work has shown that during the early development of tau pathology the protein undergoes conformational changes leading to aberrant exposure of the N-terminus. This region contains a phosphatase-activating domain that initiates a PP1-GSK3 signaling cascade resulting in disruption of anterograde fast axonal transport. Impaired axonal transport can facilitate synapse loss, axonal degeneration and ultimately neurodegeneration. Thus, antibodies that recognize the N-terminus of tau are uniquely positioned to detect early tau pathology and identify forms of the protein that may exert toxic effects on the cell. We have characterized several N-terminal antibodies to determine their specific epitopes and relative abilities to bind pathological tau in numerous tauopathies and *in vitro* assays. We found that small changes in the epitope can greatly affect antibody reactivity with recombinant tau monomers or aggregates, tau pathology in various human tauopathies, and rodent tau. Three of the antibodies displayed significantly greater affinity for aggregated tau than for monomeric tau while others had similar affinities for both forms of the protein in sandwich ELISAs. The differences in reactivity for monomeric and aggregated tau samples were absent in denaturing assays (e.g. Western blotting), indicating that some of these N-terminal antibodies identify pathological conformational states of the protein. The antibodies displayed differential abilities to detect canonical pathology in Alzheimer's disease, progressive supranuclear palsy, Pick's disease, corticobasal degeneration, and chronic traumatic encephalopathy. The antibodies that recognize conformational exposure of the N-terminus labeled early pre-tangle inclusions in neurons. These results indicate that some N-terminal antibodies are useful in identifying pathological species of tau in human disease as well as in *in vitro* assays. Moreover, conformational changes leading to exposure of the N-terminus occur early in disease progression and the differences observed from minor variations in epitopes suggest subtle differences in the conformation of the N-terminus exist in disease-related forms of tau.

Title: Regulation of RNA protein granule formation and tau mRNA expression by G3BP1

Authors: *R. BRANDT, F. SÜNDERMANN, M. IGAEV, B. NIEWIDOK, A. PEREIRA DA GRACA, L. BAKOTA;
Univ. of Osnabrueck, Osnabrueck, Germany

Abstract: RNA protein (RNP) granules play an important role in translational regulation and mediating mRNA stability. This may be also important for regulating the expression of the microtubule-associated protein tau, which is translated from different mRNA variants and is causally involved in tauopathies. We have previously reported that RNP granules modulate tau isoform expression and induce neuronal sprouting suggesting a morphoregulatory function of RNP granule formation during neuronal development and disease (Moschner et al. (2014) J. Biol. Chem. 289:16814-25). Ras-GAP Src homology 3 domain-binding protein 1 (G3BP1) is highly expressed in neurons, is present in stress granules, and may play an important role in granule formation and organization. G3BP1 is a multivalent phosphoprotein that contains four low complexity (LC) regions, which may play a role in nucleating RNP granules and mediating interactions with other cellular components. Here we addressed the question, whether LC regions and phosphorylation of specific residues in G3BP1 are involved in RNP granule formation and function. We prepared a panel of G3BP1 deletion constructs with different numbers of LC regions and phosphomimicking and phosphoblocking mutants. We developed a quantitative live cell imaging assay to analyze the dynamics of the interaction of photoactivatable GFP (PAGFP)-tagged G3BP1 constructs with RNP granules by fluorescence decay after photoactivation (FDAP) measurements. We report that G3BP1 interacts with RNP granules in a highly dynamic fashion. We show that the activities of G3BP1 to nucleate RNP granules and to interact with granules are mechanistically distinct, require different numbers of LC regions, and are modulated by phosphorylation and stress conditions. We demonstrate that regulation of tau expression requires the activity of G3BP1 to induce the formation of RNP granules. The data indicate that regulation of tau mRNA expression by G3BP1 requires the formation of RNP granules, that RNP granule formation is driven by the presence of multiple LC regions, and modulated by phosphorylation of G3BP1. Modulation of G3BP1 activity and dynamics may provide a new approach to influence tau expression in tauopathies such as Alzheimer's disease.

Title: Investigating the role of copper deficiency and zinc in a mouse model of late onset Alzheimer's disease

Authors: *S. N. HOWELL, K. N. BOGGS, J. M. FLINN;
Psychology, George Mason Univ., Fairfax, VA

Abstract: This study examines the roles of zinc (Zn) and copper (Cu), in a mouse model of late onset Alzheimer's disease (AD). Previous research has shown that excess Zn causes behavioral impairments in rats and mice; these impairments were remediated by the addition of copper to the Zn-enhanced water.This information suggests that excess Zn may be causing impairments through an induced Cu deficiency. To test this theory directly, we initially raised mice modeling early onset AD (hAPP; Swedish and Indiana mutations) on specialized Cu control and Cu deficient diets that differed only in levels of Cu (created with Harlan laboratory nutritionists). The results of that study implied that 1.) the effects of Cu and Zn may differ in the brain regions controlling different behaviors, and that 2.) the effect of enhanced Zn may not be entirely due to an induced Cu deficiency. Currently, we aim to explore this unexpected interaction further in a late-onset AD model. Specifically, we are interested in mice carrying the E4 allele of the APOE gene, which constitutes a high risk factor for development of AD, with some evidence showing that it may be protective early on. Male hAPP transgenic (Tg) mice were crossed with homozygous ApoE4 females to obtain a cross that models late onset AD. There are six groups (wildtype (Wt) and late-onset mice on (a.) lab water + Cu control diet, (b.) lab water + Cu deficient diet, or (c.) Zn-enhanced water + Cu control diet). Open field and odor habituation/dishabituation, Morris water maze (MWM) (spatial learning/memory) and sociability tasks are being assessed at 6 and 12 months of age allowing for examination of the potential early protective effects of the ApoE4 gene and identification of dietary interactions in early and late stages of the disease. Six month pilot open field data shows a significant interaction between genotype and diet (ApoE4, Cu deficient mice show the greatest distance traveled and the greatest velocity). All animals show normal odor habituation/dishabituation. Preliminary MWM pilot data indicates that, at 6 months, Wt and ApoE4 mice do not differ in latency across days. However, there is a trend towards a day X diet interaction, with Cu control mice showing faster latencies across days, as compared to the Cu deficient group. This study extends the examination of dietary effects to multiple types and stages of AD. This may identify specific dietary interactions that may be playing a role, since results in our early onset AD model differed from those in other studies that used diets with differing metal levels or metal ratios, such as the Cu/Zn ratio, and in non-nutritive substances, such as soy and phytates.

Title: APP/APOE4 mice show impaired nest building and circadian rhythm activity at 6 months

Authors: *J. M. FLINN, K. N. BOGGS, J. L. MINGOS, P. KAKALEC, S. N. HOWELL; Psychology, George Mason Univ., Fairfax, VA

Abstract: Mutations in certain genes are known to increase the likelihood of developing Alzheimer's disease (AD). While there are genetic risk factors associated with late onset AD, because of it's sporadic nature, it appears as though a combination of genetics and environmental factors likely play a role in development of AD after age 65. One known genetic risk factor for developing late onset AD is the presence of the ε4 allele of the ApoE gene, which is present in 40% of late-onset cases (National Institutes on Aging, 2015). Circadian rhythms (CR) and activities of daily living (ADL) become disrupted in Alzheimer's disease. Sundown syndrome or "sundowning" is a common circadian rhythm disturbance observed in patients with AD, which causes increased confusion and agitation in the evening, trouble sleeping, and altered levels of activity throughout the day (Cipriani, et al., 2015). Circadian rhythm activity can be measured in Alzheimer's mouse models by assessing their wheel running behavior. Activities of daily living in humans include behaviors such as bathing, dressing, and feeding. ADL behaviors can be observed in mice by using a simple nest construction assay*, which capitalizes on the natural tendency of mice to construct nests. The present study utilizes a mouse model of AD possessing both the APP mutation and the E4 allele to assess CR and ADL at 6 months. Preliminary data looking at nest construction in 6 month wildtype C57/6J mice (n=14) and APP/E4 mice (n=7) using shredded paper revealed significant impairment in nest building behavior in APP/E4 mice ($p<.01$); no significant difference was observed between males (n=6) and females (n=15). Preliminary data also suggests circadian rhythm irregularities in APP/E4 mice on a variety of CR measures such as bouts per day, which were higher in APP/E4 animals compared to wildtypes ($p<.01$). A difference in onset of activity between APP/E4 and WT animals was trending, and began earlier in the evening for WT animals ($p= .058$). Offset of activity was significantly different between APP/E4 and WT animals with a later offset for WT animals ($p < 0.01$). Specifically, wildtype animals begin their wheel running activity about an hour before E4 animals, and ended their activity an hour later than E4 animals. A sex difference was observed in these animals, with females having a longer average bout length compared to males ($p < 0.01$),

more counts per bout than males ($p < 0.01$), and a higher average peak rate than males ($p < 0.01$). In general, this suggests that females have increased overall activity compared to males. Future analyses will include additional data for 6 month animals, in addition to 9 and 12 month data.

Title: Impact of human APP overexpression on cerebral cholesterol metabolism in ApoBxAPP and APPSL mice

Authors: *C. SCHWEINZER[1], T. LOEFFLER[1], E. STEYRER[2], B. HUTTER-PAIER[1], M. WINDISCH[3];
[1]QPS Austria Gmbh, Grambach, Austria; [2]Inst. of Mol. Biol. and Biochemistry, Med. Univ. Graz, Graz, Austria; [3]NeuroScios GmbH, Graz, Austria

Abstract: Besides the focus on Aβ and Tau in Alzheimer's disease (AD), it is increasingly evident that other pathologic incidents, such as vascular pathologies, are associated with AD. Also lipids, especially cholesterol, are discussed to contribute to AD pathogenesis. Several studies showed that cholesterol impacts on APP metabolism and vice versa. Additionally, elevated plasma cholesterol in midlife is associated with an increased risk for AD. Interestingly, in mice overexpressing human apolipoprotein B-100 (ApoB-100) it was shown, that changes in the plasma lipid composition alone lead to cognitive decline at higher ages. To see whether this phenotype could be induced earlier by additional cholesterol uptake, a high-fat feeding study was conducted with animals overexpressing human ApoB-100 and/or human APPSL. ApoBxAPP, ApoB-100, APPSL and wild type (WT) mice, received either a standard chow or high-fat-diet (HFD) for 3 months. At an age of 6 months, all animals underwent several behavioral tests, including the Morris water maze task (MWM). Changes in cholesterol content and mRNA levels of cholesterol metabolism-associated genes were measured in cortices of all mice. While behavioral performance was not influenced by HFD, reduction of cortical free cholesterol levels and mRNA expression patterns under normal diet and HFD conditions in human APP overexpressing mice argue for an important role of APP in cerebral lipid metabolism From our

results we conclude that increased APP metabolism in ApoBxAPP and APPSL mice induces mechanisms to reduce free cholesterol levels.

Title: "Fatty Brain" resulting from altered ApoE expression following pubertal binge ethanol consumption in rats

Authors: *A. ASIMES[1], M. M. PRZYBYCIEN-SZYMANSKA[2], T. R. PAK[2];
[1]Cell and Mol. Physiol., [2]Loyola Univ. Chicago, Maywood, IL

Abstract: Apolipoprotein E (ApoE) is a carrier protein necessary for the delivery of cholesterol from astrocytes to neurons. ApoE mRNA expression and activity can be altered with alcohol exposure. Alcohol consumption among adolescents often occurs in a binge-like pattern, where the blood alcohol concentration (BAC) is raised above 0.08% in 2 hours, and can lead to various neurological and cognitive health risks in adulthood. These long-term consequences may be mediated by stable epigenetic modifications to the genome, also making them transferable to offspring. We tested the hypothesis that adolescent binge alcohol exposure decreases ApoE expression and function in the brain, leading to a "fatty brain" phenotype. Wistar rats were administered a repeated binge-EtOH exposure paradigm at early and late puberty (PND37, 67). They received 3g/kg of 20% (v/v) EtOH via oral gavage daily for 3 days, then 2 days vehicle and another 3 days EtOH. Animals were paired for mating 24h after the last EtOH dose, with pairs consisting of all combinations of EtOH- and vehicle-treated males and females. Litters were culled to 10 pups per dam and were left until PND7 when all animals were euthanized. The hypothalamus was extracted and both DNA and RNA were isolated. Primary astrocyte cultures were prepared from cortical tissue of both pups and parents (PND103). We found a decrease in ApoE mRNA expression in the hypothalamus of adult males exposed to EtOH, but no difference was measured in females. Correspondingly, there was an increase in cholesterol accumulation in cortical astrocytes of binge-EtOH exposed males compared to vehicle treated counterparts, but

there was no change in females. In the EtOH-naïve offspring of EtOH-exposed parents, we also found downregulation of ApoE in the hypothalamus. These results suggest that EtOH-induced downregulation of ApoE results in a decrease in astrocytic secretion of lipids, leading to “fatty astrocytes” and cholesterol-starved neurons.

Title: ApoE4 impairs brain insulin signaling and glucose metabolism

Authors: *N. ZHAO;
Mayo Clin. Jacksonville, Jacksonville, FL

Abstract: Diabetes and impaired insulin signaling in the brain have been linked to the pathogenesis of Alzheimer’s disease (AD). Epidemiological studies show that diabetic patients are at higher risk for AD. Levels of insulin, insulin receptor, and insulin signaling are lower in AD brains than normal individuals. The ε4 allele of the apolipoprotein E (*APOE*) gene is the strongest genetic risk factor for late-onset AD, whereas the ε2 allele is protective. Interestingly, the association between diabetes and amyloid pathology is particularly strong among *APOE4* carriers. In addition, recent clinical trials revealed that intranasal insulin administration significantly improves the cognitive function of AD patients in a manner that depends on *APOE* genotype. *APOE4* carriers, either as healthy adults or with dementia, have lower cerebral glucose metabolism in FDG-PET studies. Despite these observations in humans, the mechanism by which apoE isoforms differentially regulates brain insulin signaling and glucose metabolism remain unclear. Here we report apoE isoform-dependent glucose metabolism and insulin signaling pathways in mouse models. Specifically, we found that cerebral blood flow is reduced in apoE4-targeted replacement (TR) mice starting at a young age compared with apoE3-TR mice. Furthermore, aged apoE4-TR mice have reduced capacity to metabolize cerebral glucose compared to apoE3-TR mice upon glucose challenge when examined by *in vivo* microdialysis. The levels of glucose transporters, insulin receptor and signaling were significantly decreased in aged apoE4-TR mice. Finally, overexpression of apoE4 in astrocytes in a novel mouse model further suppressed insulin signaling. Our study provides novel insights into the pathogenic mechanisms of apoE4 and insulin resistance in AD, and suggests therapeutic strategies to

ameliorate abnormal insulin signaling and glucose metabolism in an apoE isoform dependent manner.

Title: Age effects on apoE lipidation in EFAD mice and human brain samples

Authors: *R. M. SALZMAN, S. GHURA, K. P. KOSTER, N. C. COLLINS, C. SMITH, L. M. TAI, M. LADU;
Dept. of Anat. & Cell Biol., Univ. of Illinois At Chicago, Chicago, IL

Abstract: The ε4 allele of the apolipoprotein (APOE) gene is the greatest genetic risk factor for Alzheimer's Disease (AD), while increased amyloid-β (Aβ42) causes familial AD. The soluble oligomeric aggregates of Aβ (oAβ) are recognized as a likely proximal neurotoxin. ApoE functions in the transport of lipid within the central nervous system (CNS). Lipid and cholesterol are added to apoE-containing lipoprotein particles by ATP-binding cassette transporters A1 and G1 (ABCA1/G1). Studies comparing brains of EFAD mice (5XFAD mice expressing human APOE) demonstrate that apoE in E4FAD mice is less lipoprotein associated/lipidated compared to E2FAD and E3FAD mice at 2-, 4- and 6 months. However, apoE lipoprotein-association/lipidation levels have not been measured in EFAD mice over 6 months of age. Thus, we hypothesize that with age, Aβ pathology increases anf apoE lipidation decreases. The goal of the current study is to determine apoE levels and apoE lipidation in 10-, 14-, and 18 month E2FAD, E3FAD and E4FAD mice. To confirm results from the transgenic EFAD mice, we measured apoE lipidation in AD versus control human subjects with APOE3/3, APOE3/4 and APOE4/4. A 3-step sequential protein extraction protocol, which facilitates the release of apoE from lipoproteins in the detergent fraction (TBS + 1% Triton X-100), was utilized to quantify lipoprotein-associated apoE (TBSX-apoE). ApoE levels in each fraction were measured by ELISA to produce an apoE extraction profile. In addition, TBS and TBSX fractions were analyzed by native gels. As well, levels of ABCA1 and ABCG1 were measured by Western blots. Results demonstrate that with age in the EFAD mice and AD status in human subjects,

apoE lipidation levels decreased (APOE4 > APOE3). In parallel, the levels of ABCA1/G1 protein were also decreased. Thus, data from both the EFAD mice and human brain samples provide evidence that apoE-lipidation state is one mechanism by which APOE4 may contribute to AD risk. Further, our data suggests that ABCA1/G1 may be important therapeutic targets to increase the lipidation of particulalry apoE4.

Title: Female and male sex hormones differentially regulate apolipoprotein J (ApoJ) in primary neurons

Authors: *S. K. WOODY, A. CHHIBBER, L. ZHAO;
Univ. of Kansas Sch. of Pharm., Lawrence, KS

Abstract: Alzheimer's disease (AD) is currently one of the most feared neurodegenerative diseases affecting over 5.4 million Americans. Though extensively studied, the molecular mechanisms that trigger the onset of AD are not completely understood nor has an effective treatment been developed. Therefore, before a treatment strategy is established, it is imperative that the field focuses on the identification of risk mechanisms that would allow for targeted prevention, risk reduction, or early intervention in the preclinical phase of AD. Apolipoprotein J (ApoJ), also known as clusterin, is a multi-functional chaperone protein shown to reduce Aβ42 aggregation and increase Aβ42 clearance. Recently, ApoJ has been highlighted by two independent genome-wide association studies that demonstrated a significant association between ApoJ variants and the development of late-onset AD (LOAD). Additionally, several studies have shown increased ApoJ expression in AD brain; however reduced ApoJ expression has been associated with aging and ApoJ polymorphisms. ApoJ is currently the third most

significant genetic risk factor for the development of LOAD, however the neurophysiological roles of ApoJ are largely unknown. Our recent analyses have demonstrated that ApoJ expression is significantly reduced in female brain with early aging; a time period that corresponds with a significant and irreversible decline in ovarian hormone levels. Additionally, our data indicate that the interaction between ApoJ and insulin-like growth factor 1 (IGF1) serves as a central contributor to the overall decline in energy metabolism in the early aging female brain. Led by these findings, we hypothesize that sex and sex hormones differentially regulate ApoJ expression in the brain and a deficiency in ApoJ expression negatively impacts brain metabolism in a sex dependent manner. In these studies we have conducted a set of experiments to determine the modulation of ApoJ by sex hormones in primary hippocampal and cortical neurons. These data present a possible mechanism by which sex and sex hormones differentially impact the etiology of AD; specifically, these data provide an essential foundation for understanding how the triad of sex and sex hormones, ApoJ, and brain metabolism regulate each other to modulate the risk for LOAD.

Title: Effects of ApoE isoforms on learning and memory in knock-in mice expressing the Danish dementia BRI2 mutant

Authors: *K. ISHIWARI, F. BIUNDO;
Microbiology & Immunol., Albert Einstein Col. of Med., Bronx, NY

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disorder among the elderly and characterized by progressive neuronal loss and dementia. Familial AD is caused by mutations that alter the proteolytic processing of amyloid β precursor protein (APP). Three major isoforms of apolipoprotein E (ApoE) exist in humans, ApoE2, ApoE3, and ApoE4, of which ApoE4 is the major genetic risk factor for late-onset familial and sporadic AD, although the

mechanism by which ApoE4 affects the pathogenesis of the disease is unclear. Familial Danish Dementia (FDD) is a neurodegenerative disorder caused by a mutation in the BRI2/ITM2b gene, whose protein product BRI2 inhibits APP processing. The FDD mutation results in loss of BRI2, leading to enhanced APP processing and the consequent release of potentially toxic APP metabolites. FDD and AD share clinical and neuropathological features. Moreover, BRI2/ITM2b has been identified as one of the candidate regulatory node genes predicted to mediate the common patterns of gene expression shared by healthy ApoE4 carriers and late-onset AD patients not carrying the ApoE4 allele (Rhinn et al., 2013), suggesting that FDD and AD have common pathogenic mechanisms. We generated a knock-in mouse model of FDD (FDDKI). FDDKI mice carry one mutant and one wild-type BRI2 allele, which is genetically congruous with the human pathology. FDDKI mice exhibit reduced long-term potentiation in the hippocampus and age-dependent memory deficits. The present study was conducted to examine how the FDD mutation might interact with ApoE isoforms in the regulation of cognitive functions and behavior. To that end, FDDKI mice were crossed with human ApoE targeted replacement mice, in which the mouse ApoE gene was replaced with either the human ApoE3 or ApoE4, and the resultant male mice of the F2 generation of four genotypes (ApoE3+/+, FDDKI/ApoE3+/+, ApoE4+/+, FDDKI/ApoE4+/+; n=16-25 per genotype) were assessed longitudinally for learning and memory at 4, 6, 12, and 16-17 months of age using a battery of tests including the Morris water maze and the Y-maze. The results showed that mice carrying the ApoE4 allele displayed working/short-term spatial memory deficits relative to mice carrying the ApoE3 allele starting in early middle age, while long-term spatial memory of ApoE4+/+ mice was not adversely affected even at 16-17 months, and that the FDD mutation impaired working/short-term spatial memory in mice carrying the ApoE3 allele and produced impaired long-term spatial memory in mice carrying the ApoE4 allele in middle age. The present results suggest that the FDD mutation may differentially affect learning and memory in ApoE4 carriers and non-carriers.

Title: ApoE dependent interactions of the α-secretase ADAM10 in Alzheimer's disease

Authors: *B. SHACKLETON[1,2], C. BACHMEIER[1,2], F. CRAWFORD[1,2];
[1]Roskamp Inst., Sarasota, FL; [2]The Open Univ., Milton Keynes, United Kingdom

Abstract: The ApolipoproteinE4 (apoE4) isoform is the strongest genetic risk factor for developing Alzheimer's disease (AD). While the exact mechanism in which apoE influences AD pathology is unknown, it has been associated with excessive Amyloid β (Aβ) deposition in the AD brain. Aβ is produced from the Amyloid Precursor Protein (APP) following sequential cleavage by the β- and γ-secretase enzymes. Alternatively, APP can be processed by the α-secretase, A Disintegrin And Metallo proteinase domain containing protein 10 (ADAM10). This protein exists as both a membrane bound and soluble protein (sADAM10) and results in the formation of the neurotropic soluble APPα from APP. Much of the focus in the field has been directed at potential therapeutics targeting the β-and γ-secretases. However, these approaches have yet to yield significant clinical improvements with several disappointing phase 3 trials. Here, we investigate the influence of apoE on the α-secretase pathway as a potential modulatory mechanism of AD pathology. In a cell free assay we observed apoE isoform and dose dependent effects on ADAM10 activity. This was supported by *in vitro* experiments showing apoE isoform dependent production of sAPPα in whole cells. To evaluate the impact of apoE on ADAM10 in the human population, we examined cortical brain tissue from control and AD subjects stratified by APOE genotype. No significant differences in ADAM10 expression or activity were detected in whole brain homogenate. However, significant apoE isoform and disease state differences in sADAM10 were detected in the soluble brain fraction. More specifically, sADAM10 levels are highest in apoE4/4 control samples compared to the other apoE genotypes. This interaction is not evident in the AD samples where the levels of sADAM10 remain low and static. The apoE isoform also effects the ability of sADAM10 to cleave substrate independent of the disease state (apoE2>apoE3>apoE4). This results in an interaction where the lower the activity of sADAM10, the higher the levels. However, this interaction appears to be lost in the AD samples. We hypothesise that this inverse correlation functions as a protective feedback mechanism to compensate for the reduced sADAM10 activity due to the apoE isoform present. In conclusion, this study demonstrates an isoform-specific influence of apoE on APP processing, which may provide a novel strategy for reducing ab burden in the AD brain.

Title: Unraveling the role of apolipoprotein E in age- and Abeta-related neuronal dysfunction

Authors: *J. A. KLICKSTEIN[1], K. KUCHIBHOTLA[2], L. WROBLESKI[1], S. WEGGMAN[1], M. ARBEL-ORNATH[1], E. HUDRY[1], B. T. HYMAN[1];
[1]Massgeneral Inst. For Neurodegenerative Diseas, Charlestown, MA; [2]Skirball Inst. of Biomolecular Med., New York Univ. Sch. of Med., New York City, NY

Abstract: Background: Impairment in synaptic plasticity and neuronal integrity are observed both in "normal" aging and Alzheimer's disease (AD), albeit to different magnitudes. Previous studies suggest that apolipoprotein E (apoE), the main lipoprotein carrier in the central nervous system, may be an important molecular modulator of both processes. Interestingly, the absence of apoE in mice has been shown to cause cognitive deficits, while the same genetic alteration alleviates amyloid pathology in AD transgenic models, thus eventually conferring a beneficial outcome in the disease. Using novel *in vivo* methodological approaches, this study aims to further our understanding of how apoE modulates resilience and susceptibility of the neural system in both physiological and pathological contexts. Results: Using *in vivo* calcium imaging in the visual cortex of awake animals, our preliminary results suggest that apoE disruption impairs neuronal tuning for the direction of visual stimuli in adult wild-type (Wt) mice (8-10 months), resulting in an increased proportion of broadly tuned cells and a decreased number of highly tuned responders. This functional impairment is further amplified in APPPS1 AD transgenic mice when compared with Wt; however, the absence of apoE in those mice tends to improve this particular phenotype (the percentage of highly tuned cells in APPPS1/APOEKO animals reaches similar levels as APOEKO). The orientation selectivity index, however, remains unchanged between all the experimental groups. Interestingly, the global amount of Aβ and the density of diffuse amyloid aggregates were not significantly different in APPPS1 and APPPS1/APOEKO mice (even though a lower amount of dense-core fibrillar deposits was observed), therefore emphasizing the role of apoE in modulating Aβ-related neuronal dysfunction rather than an effect on amyloid deposition. In aged mice (18 month old), the presence of a higher percentage of "off-responders" was observed in APPPS1 compared with Wt, APOEKO and APPPS/APOEKO animals, demonstrating that impairment of neuronal function may be specifically associated with the overexpression of AD-related genes and can be compensated by the absence of apoE. Conclusion: These results argue in favor of a complex role of apoE in maintaining neuronal function in a normal brain while alleviating amyloid-associated impairment of neuronal activity in aged transgenic mice. Further investigation of the synaptic profile of these different mouse lines will allow us to precisely associate our *in vivo* observations

in awake animals with changes in the distribution of pre- and post-synaptic elements, as well as changes in apoE-Aβ interactions.

Title: APOE2 protects against age-related memory decline: a clinical and pre-clinical evaluation

Authors: *M. SHINOHARA, T. KANEKIYO, J. FRYER, G. BU;
Dept. of Neurosci., Mayo Clin. Florida, Jacksonville, FL

Abstract: Objective: Apolipoprotein E (apoE), a major cholesterol carrier in the brain, is associated with a strong risk for Alzheimer’s disease. Compared to the risky APOE4 gene allele, the effects of the protective APOE2 gene allele are vastly understudied, and thus, need to be further clarified. Methods: We reviewed National Alzheimer’s Coordinating Center (NACC) clinical records and performed preclinical experiments using human apoE-targeted replacement (apoE-TR) mice, which do not show amyloid pathology. Results: Clinically, APOE2 allele protects against age-related cognitive decline. This effect is more prominent in homozygous carriers of APOE2, and is also seen in subjects without amyloid pathology. APOE2 especially protects against memory function decline. In animal studies, aged apoE2-TR mice also exhibited

preserved memory function in the water maze tests. Regardless, apoE2-TR mice showed similar or greater age-related changes in synaptic loss, neuroinflammation and oxidative stress compared to apoE3- or apoE4-TR mice. However, apoE concentrations in the cortex, hippocampus, plasma and cerebrospinal fluid (CSF) were positively correlated with memory performance across apoE isoforms, where apoE2-TR mice had higher apoE levels. More interestingly, apoE2-TR mice exhibited the lowest levels of cholesterol in the cortex, irrespective of higher levels in CSF and plasma. The cholesterol levels in the brain and CSF were oppositely associated with apoE levels and memory performance across apoE isforms. Interpretation: APOE2 protects against age-related memory decline independently of age-related synaptic/neuroinflammatory changes and amyloid accumulation, while apoE and its-associated cholesterol metabolism might contribute to this protective effect.

Title: Impaired interaction between apolipoprotein E and Alzheimer’s disease-associated mutation in TREM2

Authors: *Y. ATAGI[1], X. CHEN[2], C.-C. LIU[1], H. ZHENG[2], X. LI[1], C. VERBEECK[1], N. SAKAE[1], P. DAS[1], S. YOUNKIN[1], J. FRYER[1], G. BU[1];
[1]Neurosci., Mayo Clin. Florida, Jacksonville, FL; [2]Xiamen Univ., Xiamen, China

Abstract: Rare heterozygous mutations in the triggering receptor expressed on myeloid cells 2 (TREM2) have been identified as risk factors for number of neurodegenerative diseases such as late-onset Alzheimer’s disease (LOAD), Parkinson’s disease (PD), and frontotemporal dementia (FTD). TREM2 is a type I transmembrane receptor that is expressed in the cells of myeloid origin such as macrophage and osteoclast. In the central nervous system (CNS), it is expressed in the microglia, the resident immune cells of the CNS. TREM2 signals through its adaptor protein DAP12 to promote phagocytosis of apoptotic cells and to suppress the secretion of pro-inflammatory cytokines. Homozygous mutations in TREM2 or DAP12 result in Nasu-Hakola disease which is characterized by frontal dementia with multifocal bone cysts. It is believed that disease-linked mutations in TREM2 are loss-of-function mutations as many of them are clustered around putative ligand binding domain. The fact that some of the mutations also result in non-

functional truncated proteins or disrupt TREM2-DAP12 association further supports the loss-of-function pathway. Although phospholipids, HSP60, LPS, and other polyanionic molecules have been suggested to bind TREM2, the physiological ligand of TREM2 in the CNS has not yet been identified. Here, we show that apolipoproteins bind to TREM2 in biochemical assays. Apolipoproteins are a class of proteins that bind to lipids and form lipoproteins. Among different apolipoproteins, apoA1, apoE, and clusterin (apoJ) are found in the CNS, and apoE and clusterin are secreted by astrocytes. Of note, the ε4 allele of the APOE gene which encodes apoE4 is the strongest genetic risk factor for LOAD, and a SNP in clusterin has also been associated with risk of LOAD. In addition, all three apolipoproteins found in the CNS have been shown to play roles in inflammatory response. In this study, we show that apoA1, apoE, and clusterin bind specifically to extracellular domain of TREM2. ApoE preferentially binds to the surface of apoptotic neurons and promotes phagocytic uptake by microglia in a TREM2-mediated manner. More interesting, LOAD-linked TREM2 variant R47H shows significantly reduced binding to apoE. Our data suggest that loss-of-function in ligand binding might be a contributing mechanism underlying the association between TREM2 mutations and impaired microglial function in removing apoptotic cells or abnormal protein aggregates in neurodegenerative diseases. This study shed a light in the role of TREM2 in the CNS and suggests strategies to target TREM2-related neuroinflammatory pathways to treat neurodegenerative diseases.

Title: Effects of cholesterol and GM1 on the membrane actions of Amyloid beta in hippocampal neurons

Authors: ***E. FERNANDEZ**[1], F. J. SEPULVEDA[1], C. OPAZO[2], L. G. AGUAYO[1];
[1]Univ. De Concepcion, Concepcion, Chile; [2]Oxidation Biol. Laboratory, The Florey Inst. of Neurosci. and Mental Hlth., The Univ. of Melbourne, Melbourne, Australia

Abstract: Introduction The ability of beta-amyloid peptide Aβ to disrupt the plasma membrane through formation of pores and membrane breakage has been previously described, but the mechanism and molecular determinants for these effects are largely unknown. Therefore, we examined if the association and subsequent membrane perforation induced by Aβ was dependent on GM1 and cholesterol levels. **Results** The results showed that either decreasing cholesterol or increasing GM1 facilitated membrane perforation. For example, pretreatment of hippocampal neurons with MβCD significantly decreased the membrane levels of cholesterol (fluorescent-punctas/20μm: control=18±2 vs. MβCD=10±1, $p<0.05$). This was accompanied by a decrease in Aβ clustering at the membrane (Aβ fluorescent-punctas/20μm, control=37±3 vs. MβCD=23±3, $p<0.01$). Interestingly, membrane perforation with Aβ occurred much faster when the cholesterol content was diminished (time to establish perforated configuration (TEPC): control=8±2 vs. MβCD=2.3±0.5 min, $p<0.01$), suggesting that the presence of cholesterol in the membrane can modulate the distribution and the membrane perforation by Aβ. On the other hand, increasing GM1 by liposome facilitated the membrane perforation (TEPC: control=15±1 vs. GM1=6±1 min, $p<0.05$). Additionally, using Cholera Toxin Subunit-B (CTB) to block the interaction of Aβ with GM1, we found that membrane perforation was significantly attenuated. Furthermore, pretreatment with CTB decreased the membrane association of Aβ (fluorescent-punctas/20μm, Aβ: control=14±2 vs. CTB=8±2, $p<0.05$), suggesting that GM1 also plays a role in both association of Aβ with the membrane and in perforation. **Conclusion** Taken together, our results strongly suggest that membrane lipid composition can affect the ability of Aβ to associate and subsequently perforate the plasma membrane, thereby modulating its toxicity in hippocampal neurons.

Ctr., Jackson, MS; [4]Univ. of California and VA Med. Ctr., San Francisco, CA; [5]Gladstone Inst. of Neurolog. Disease, Univ. of California, San Francisco, CA

Abstract: We previously reported cognitive impairment in young and old mice expressing mouse apoE with domain interaction (Arg-61 mice). Considering the correlation between hippocampal volume and cognitive functions, and apolipoprotein E (apoE) isoform-dependent differences in hippocampal volume in humans, we hypothesized that impaired cognitive function of young Arg-61 mice results from lower hippocampal volume. We measured hippocampal volume and its sub-regions in Nissl stained sections of 5-month old female Arg-61 and C57BL/6J mice and quantified calretinin-positive neurons in the hippocampus by unbiased stereology. We also measured Amyloid beta (Aβ) levels in hippocampal homogenates by dot-blot analysis. Whole hippocampal volume was not different between Arg-61 and C57BL/6J mice; however, the granular cell layer (GCL) volume and the percentage it occupies in the hippocampus were larger in Arg-61 than in C57BL/6J mice. Subgranular zone (SGZ) calretinin (CR)-positive neuron number and density were higher in Arg-61 mice, suggesting that the larger GCL volume may result from more neurons being added to the GCL. Lastly, Aβ -which stimulates ectopic adult neurogenesis in mouse models of Alzheimer disease, was significantly higher in Arg-61 than in C57BL/6J mice. In conclusion, impaired cognitive functions in Arg-61 mice do not result from lower hippocampal volume. In contrast, the larger GCL volume and higher calretinin cell number and density suggest a compensatory attempt which may be due to amyloid beta perturbations, at least in part. Alternatively, these parameters may result from defective neural pruning in Arg-61 mice. Targeting apoEε4 domain interaction may thus be a viable prophylactic/therapeutic approach for apoEε4-dependent pathologies and increased susceptibility of apoEε4 subjects to AD.

Abstract: Alzheimer's disease (AD) is a highly prevalent disorder for which there are no effective therapies. Accumulation of amyloid beta (Aβ) peptides in the brain is associated with impaired cognition and memory, pronounced inflammatory dysregulation, and subsequent amyloid plaque deposition. Thus, drugs which promote the clearance of Aβ peptides and resolution of inflammation may represent viable therapeutic approaches. Agonists of nuclear receptors LXR:RXR and PPAR:RXR act to ameliorate AD-related cognitive impairment and amyloid accumulation in murine models of AD. The use of an agonist to the nuclear receptor RXR, bexarotene, as monotherapy against AD presents potential challenges due to the metabolic perturbations it induces in the periphery, most prominently hypertriglyceridemia. We report that the omega-3 fatty acid docosahexanoic acid (DHA), in combination with bexarotene, enhances LXR:RXR target gene expression of Abca1 and ApoE, reduces soluble forms of Aβ, and abrogates release of pro-inflammatory cytokines and mediators both *in vitro* and in a mouse model of AD. Moreover, DHA abrogates bexarotene-induced hypertriglyceridemia *in vivo*. Importantly, dual therapy promotes reductions in AD pathology and resultant amelioration of cognitive deficits *in vivo*. While monotherapy with either bexarotene or DHA resulted in modest effects *in vitro* and *in vivo*, combined treatment with both agents produced a significant additive benefit on associated AD-related phenotypes, suggesting that targeted combinatorial agents may be beneficial over single agents alone in treating AD.

Title: High fat diet aggravates memory deficits in APP mice and causes epigenetic changes

Authors: *A. Y. CARTER[1], V. L. REEVES[1], N. F. FITZ[1], J. SCHUG[2,3], I. LEFTEROV[1], R. KOLDAMOVA[1];
[1]Envrn. and Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA; [2]Functional Genomics Core, Dept. of Genet., Univ. of Pennsylvania, Philadelphia, PA; [3]Inst. for Diabetes, Obesity and Metabolism, University of Pennsylvania, PA

Abstract: Alzheimer’s disease (AD) is a multifactorial disease with various factors that influence risk. Environmental factors such as a diet high in fat and/or cholesterol can affect AD risk by acting on the epigenome. We have previously shown that high fat diet (HFD) exacerbates AD phenotype in APP23 mice and that an LXR agonist ameliorates this effect. 11-month-old APP23 mice were subjected to either control diet or HFD for three months. HFD aggravated spatial learning but not memory retention in a Morris Water Maze (MWM) behavioral paradigm. HFD significantly increased amyloid deposition in hippocampus and cortex as detected by X-34, and 6E10 anti-amyloid beta (Aβ) staining used to characterize compact and diffuse plaques in the brain respectively. To determine the effect of HFD on epigenome we utilized chromatin immunoprecipitation coupled with massive parallel sequencing (ChIP-seq) to map genome-wide changes in several chromatin marks: histone 3 Lys 4 tri-methylation (H3K4me3) and H3K9 acetylation (H4k9ac) associated primarily with active promoters, and H3K27me3 (part of Polycomb repression complex). Functional annotation clustering using DAVID and IPA web

tools revealed that epigenetic changes were mainly clustered in functional categories related to neuronal differentiation, neuron projections and synapses. Additional epigenetic changes were observed associated with mTOR and IGF-1 signaling pathways. These data were further validated in cell culture and *in vivo* using QPCR, Western blotting and IHC. We conclude that HFD causes epigenetic changes that potentially may affect transcriptional activity and expression level of genes important for developing AD, accelerating the course of the disease, or aggravating AD phenotypes.

Abstract: Retinoid X receptors (RXRs) are ligand-activated transcription factors that form permissive heterodimers with Liver X Receptors (LXR). We have previously shown that treatment of APP/PS1 mice with bexarotene, an RXR agonist, induced a significant improvement

of their cognitive performance. Although no effect of bexarotene treatment on plaques load or insoluble Aβ level in the brain was observed, biochemical analysis suggested improved clearance of soluble Aβ, including Aβ oligomers. To investigate the molecular mechanisms underlying this effect, we performed genome-wide differential gene expression analysis using high throughput massively parallel sequencing on libraries generated from cortices of Bexarotene or vehicle treated APP/PS1 mice. We further analyzed the differentially expressed genes using DAVID (Database for Annotation, Visualization and Integrated Discovery) web tool. We determined that the most significant Gene Ontology (GO) Biological Process categories are clustered in GO terms immune response, defense response and immunoglobulin mediated immune response. Chromatin immunoprecipitation (ChIP) with RXR antibody, followed by ChIP-QPCR and RT-QPCR expression assays were used to validate some genes of interest found differentially expressed in response to RXR activation, including the genes coding for the Triggering Receptor Expressed On Myeloid Cells 2 (Trem2), TYRO Protein Tyrosine Kinase Binding Protein (Tyrobp), Complement Component 1 Q Subcomponent (C1q) and Transthyretin (Ttr). Immunofluorescence assays showed significantly increased *in vitro* Aβ phagocytosis by Bexarotene treated BV2 microglial cells. The results of our study demonstrate that in AD model mice expressing human APP, gene networks up-regulated in response to RXR activation by the specific, small molecule, synthetic ligand Bexarotene may influence diverse regulatory pathways that are considered critical for cognitive performance, inflammatory response and Aβ clearance, and may provide an explanation of bexarotene therapeutic effect at the molecular level.

Title: Toll-like receptor 4 antagonism leads to protective effects in the E4FAD transgenic mouse model of Alzheimer's disease

Authors: *J. M. YORK[1], L. M. TAI[1], Y.-T. WANG[2], K. P. KOSTER[1], G. R. THATCHER[2], F. NEUMANN[3], M. LADU[1];

Abstract: Inheritance of the APOE4 gene for apolipoprotein E (apoE) is the primary genetic risk factor for Alzheimer's Disease (AD), yet a lack of understanding of the functional pathways involved in APOE4-associated risk impedes therapeutic design. Neuroinflammation is as an important early contributor to AD pathology and progression, and although the effects of apoE are multifactorial, increasing evidence supports a role for APOE genotype in amyloid-β (Aβ)-induced neuroinflammation in AD. Indeed, our published data in EFAD mice (which overexpress Aβ42 and express human APOE) demonstrate that microgliosis and astrogliosis are greater in E4FAD than E3FAD (expressing APOE4 and APOE3, respectively) mice. In addition, inflammatory mediators, as a result of toll-like receptor 4 (TLR4) activation, are increased in E4FAD mice relative to E3FAD mice. Complementing these *in vivo* findings, our *in vitro* data reveal that stimulation of TLR4 in mixed glial cultures with lipopolysaccharide (LPS; endotoxin) or oligomeric Aβ (oAβ) induces a similar neuroinflammatory response, as characterized by secretion of tumor necrosis factor (TNF)-α, an effect more pronounced with APOE4 than APOE3. Importantly, both LPS- and oAβ-induced responses are inhibited by Rhodobacter sphaeroides (LPS-RS), a biological TLR4 antagonist. In addition, our recent *in vitro* data demonstrate potent TLR4 antagonism of oAβ-induced responses using a novel synthetic glycolipid. Thus, our working hypothesis is that treatment of EFAD mice with small molecules will improve Aβ pathology and cognitive behavior in an isoform-specific manner. Pharmacokinetic (PK) analysis in wild type mice indicates that this novel synthetic compound is brain-penetrant, and approaches the *in vitro* EC50 concentration. Based on these PK and *in vitro* data, treatment of E4FAD mice demonstrate the anti-inflammatory effects of this compound. Together, these findings highlight the important role of APOE4-modulated TLR4 activation by endogenous ligands in AD, and the therapeutic potential of its antagonism.

Title: Astrocytic LRP1 mediates brain abeta clearance

Authors: *C.-C. LIU[1], J. HU[1], N. ZHAO[1], J. CIRRITO[2], D. M. HOLTZMAN[2], G. BU[1]; [1]Neurosci. Res. Dept., Mayo Clin., Jacksonville, FL; [2]Washington Univ., St. Louis, MO

Abstract: Alzheimer's disease (AD) has emerged as the most prevalent form of late-life dementia in humans. Accumulation of amyloid-β (Aβ) peptide in the brain is the first critical step in the pathogenesis of AD. While Aβ production is accelerated in familial AD, increasing evidence indicates that impaired clearance of Aβ is more evident in late-onset AD. Aβ accumulation leads to the formation of Aβ aggregates which disturb synaptic functions and may lead to eventual neurodegeneration. Astrocytes, the most abundant cell type in the brain, play an important role in maintaining neuronal homeostasis. The low-density lipoprotein receptor-related protein 1 (LRP1), which is abundantly expressed in neurons and glial cells, has been implicated in the pathogenesis of AD. Here we show that LRP1 plays a critical role in astrocyte-mediated Aβ clearance. Conditional knock-out of the *Lrp1* gene in astrocytes led to increased brain Aβ levels and exacerbated amyloid plaque deposition in amyloid model APP/PS1 mice without affecting Aβ production. Knockdown of LRP1 in primary astrocytes suppressed Aβ uptake and cellular degradation. In addition, silencing of LRP1 in astrocytes resulted in down-regulation of several major Aβ degrading enzymes including matrix metalloproteases MMP-9, neprilysin and insulin-degrading enzyme. Together, our results demonstrate that astrocytic LRP1 plays an important role in the clearance of Aβ. Our findings provide novel mechanistic insights into brain Aβ clearance pathways and have implications on designing new therapeutic strategies to treat AD.

Abstract: Recent publications from deCODE Genetics and others have identified variants in the lipid transporter, ABCA7 as risk factors for late-onset Alzheimer's Disease (LOAD). In addition, ABCA7 is thought to be involved in pathways increasingly linked to LOAD, including lipid homeostasis and phagocytic clearance of apoptotic cells. As human genetic data for ABCA7 continues to emerge, there is a need for greater understanding of its physiological function and involvement in the disease process. To that end, we describe here a series of biochemical, cell biological and histological studies to investigate the basic biology of ABCA7 and characterize a disease-linked variant. First, we have generated purified ABCA7 using scalable methods and established assays to measure its activity. Second, using ABCA7 reconstituted into proteoliposomes, we have confirmed its substrate-selectivity for phosphatidylserine. Third, we have compared ABCA7 and ABCA1 function in cholesterol efflux from cells and isolated membrane vesicles. Whether ABCA7 transports cholesterol has been controversial, and our data in heterologous cells suggest that ABCA7 does not significantly efflux cholesterol. Fourth, we have examined ABCA7 mRNA and protein localization in native cells and tissues under basal conditions and after various challenges. We have observed that ABCA7 protein clusters in putative phagosomes and endosomes during phagocytosis in rodent microglia, consistent with a role in debris clearance. As part of a comprehensive histological study in multiple tissues, we have also observed ABCA7 protein localization in multiple cell types in the CNS. Finally, we have verified that a recently identified high risk variant is a loss of function. These results contribute to a growing understanding of ABCA7 function in the CNS and potential links to AD.

Title: ABCA1 is necessary for bexarotene-mediated clearance of soluble amyloid beta from the hippocampus of APP/PS1 mice

Authors: *A. W. CORONA, N. KODOMA, B. CASALI, G. E. LANDRETH;
Case Western Reserve Univ., Cleveland, OH

Abstract: Alzheimer’s disease (AD) is characterized by impaired clearance of amyloid beta (Aβ) peptides leading to neurodegeneration and cognitive impairment. ApoE plays a critical role in the normal proteolytic degradation of soluble Aβ. This effect is dependent upon ABCA1-mediated transfer of phospholipids and cholesterol onto ApoE. To determine if the mechanism of action of the RXR agonist, bexarotene, is dependent on the induction of lipidated-ApoE, we crossed ABCA1-deficient (ABCA1 KO) mice with the APP/PS1 model of AD. Aged ABCA1 WT and ABCA1 KO APP/PS1 mice were treated for 7 days with vehicle or bexarotene (100mg/kg/day). As expected, bexarotene induced ABCA1 and ApoE expression and lipidation in the brain of ABCA1 WT APP/PS1 mice, but not in ABCA1 KO APP/PS1 mice. Bexarotene reduced levels of soluble Aβ 1-40 and 1-42 in the hippocampus of ABCA1 WT APP/PS1 mice, but this effect was absent in ABCA1 KO APP/PS1 mice. In contrast, insoluble levels of Aβ, and plaque loads were unaffected by bexarotene in this study, indicating that ABCA1-mediated ApoE lipidation is more important in clearance of soluble rather than insoluble Aβ. The effect of bexarotene on microglial inflammatory profiles, however, was independent of ABCA1 genotype. Importantly, bexarotene tended to reverse deficits in novel object recognition in ABCA1 WT APP/PS1 mice, but not in ABCA1 KO APP/PS1 mice. These data indicate that ABCA1-induced lipidation of ApoE is necessary for the ability of bexarotene to clear hippocampal soluble Aβ and ameliorate cognitive deficits.

Abstract: The pace of functional decline in Parkinson's disease (PD) is not entirely understood. Given that most longitudinal studies of disease progression have examined patients several years apart, there is an increased demand for tracking changes in brain function over a short period of time, within as well as outside the basal ganglia circuit. Here, we evaluated changes over one year in task-based functional magnetic resonance imaging (fMRI) in a large cohort of early stage PD (n = 40) and an age-matched group of healthy individuals (n = 25). A well-established precision grip paradigm was used, where patients were required to produce force with their more affected hand. PD patients were tested following a 14-hour withdrawal from antiparkinsonian medication. Gait, bimanual coordination, and cognitive status were also assessed, at recruitment (baseline) and 1 year later (follow-up). A region of interest (ROI) approach was employed to examine changes in blood-oxygen-level dependent (BOLD) signal in the following cortical and subcortical structures: putamen, hand area of the primary motor cortex (M1), supplementary motor area (SMA), and hand area of the cerebellum (lobules V-VI). Results show no functional change over the course of a year in any of these regions for controls. However, in PD the functional activity of the putamen, hand area in M1, and SMA declined significantly from baseline to follow-up. Other changes in PD included an increase in disease severity based on the

motor section of the Movement Disorder Society Unified Parkinson's Disease Rating Scale (MDS-UPDRS-III) and worsening of gait and bimanual coordination. No decline in cognition was detected in PD. In summary, early stages of PD are associated with decreases in the functional activity of key nodes within the basal ganglia and motor cortex but not the cerebellum. Importantly, the decline in cortical regions is steeper than in the basal ganglia, information which may prove crucial in the assessment of novel therapeutic agents in PD.

Title: Quantification of striatal dopaminergic uptake in Parkinson’s disease: A new multimodal method combining SPECT DaT and MPRAGE

Authors: *K. SMART, R. DURSO, E. MODESTINO;
Boston Univ. Sch. of Med., Jamaica Plain, MA

Abstract: Parkinson’s disease (PD) is a neurodegenerative disease caused by degeneration of nigral dopaminergic terminals in the caudate and putamen. Currently, when a clinical diagnosis of PD is equivocal, a single-photon emission computed tomography scan using the DaTscan radionuclide (SPECT DaT) is ordered. However, the clinical assessment of SPECT DaT scans depends on radiologists’ subjective judgment, which can pose problems for diagnostic accuracy. Furthermore, research studies generally do not quantify SPECT DaT scans when using them. The aim of this paper is to propose a method of quantification for SPECT DaT scans, to be employed in clinical and research environments. Each of the 4 subjects underwent a SPECT DaT scan and an MPRAGE scan (Magnetization Prepared Rapid Gradient Echo), an anatomical MRI (magnetic resonance image). The SPECT and MPRAGE scans were coregistered, and then a voxel-based quantification of the left and right hemispheric caudate and the putamen was performed in every subject. First, the percentages of voxels with intensities exceeding various pericalcarine baselines were calculated. This baseline was used because the pericalcarine gyrus in the occipital lobe has been shown to have little to no dopaminergic activity on SPECT DaT

scans. Next, asymmetry indices (AI) were calculated for two thresholds whereby the ratio of the voxel percentages in the right to the left hemispheric region was taken. Wilcoxon Signed-Rank tests and bootstrapping analyses were performed on both the caudate and the putamen in all four subjects to determine the significance of any detected asymmetry. The quantification data revealed asymmetries in the voxel intensities between the left and right putamen that were consistent with each subject's side of physical symptom onset: the right-onset PD subjects 1, 2, and 4 had putamen AI values of 11.08, 2.82, and 6.22, respectively, and the left-onset PD subject 3 had a putamen AI value of 0.61. Respectively, subjects 1-4 had caudate AI values of 3.22, 1.46, 1.64, and 2.24. The bootstrapping analyses found these asymmetries to be significant in five of the eight comparisons. In summary, this anatomically accurate, voxel-based quantification has potential to bring greater objectivity to the use of SPECT DaT scans in the diagnosis of PD. This methodology also allows for separately quantifying the caudate and putamen to analyze cognitive symptoms versus motor deficits. The accuracy of the data and the attributed conclusions could be enhanced by the inclusion of partial volume correction (PVC); therefore, future development of this method should involve PVC to account for the intrinsically poor resolution of SPECT scans.

Title: Functional neuroimaging of prefrontal cortex in Parkinson's disease using fNIRS: effects of cognitive task during seated and standing postures

Authors: ***G. KERR**, M. MUTHALIB, R. PEGORARO, L. ROEDER, I. STEWART, S. SMITH;
Queensland Univ. Technol., Brisbane Q4059, Australia

Abstract: AIM: Cognitive impairment is prevalent in Parkinson's disease (PD). Reduced cognitive function, particularly executive function, has been associated with poorer quality of life, decreased activities of daily living and increased balance and gait disturbance. The concurrent performance of cognitive tasks, while standing or walking also increases postural

instability. Neural circuits involving activation of prefrontal cortex and involved in executive function are thought to be critical for control of balance and gait. This study utilized functional near-infrared spectroscopy (fNIRS) imaging to determine how prefrontal cortex activation is affected during concurrent cognitive and balance tasks. METHODS: We utilized fNIRS to examine pre-frontal cortex alterations in concentration of oxy- (O2Hb) and deoxy-haemoglobin (HHb) in cerebral microcirculation blood vessels during performance of a cognitive task (verbal fluency) involving executive function. During this task participants were either seated or standing quietly on a force plate (Hur Labs, 100Hz). Groups of early stage Parkinson's disease and healthy control participants were assessed according to the following protocol repeated 5 times during sitting and standing: Baseline (30s), Verbal Fluency (30s), Recital of days of the week (30s). RESULTS: Both the control and the PD groups had similar performance in the verbal fluency and the week day recital tasks. In the control group, neuronal activation during the verbal fluency task (relative to baseline) caused an increase in regional blood flow (i.e., neurovascular coupling), which was characterised by an increase in O2Hb and a decrease in HHb in the right dorsolateral prefrontal cortical (DLPFC) region during the seated condition. These changes were observed in the DLPFC bilaterally during the standing condition. For the PD group during the verbal fluency task there was a bilateral increase in DLPFC O2Hb during the seated condition but this was greatly reduced in amplitude. During the standing condition there was negligible change in DLPFC O2Hb in both hemispheres for PD participants. There was negligible change in O2Hb during the week day recital task for both groups. CONCLUSIONS: These changes in O2Hb indicate that PD participants have reduced activation of the DLPFC during the performance of cognitive tasks involving executive function. Furthermore, during standing, activation of the DLPFC is further reduced, in contrast to control participants who have increased bilateral activation. This indicates that people with PD have either reduced activation of the same neural circuits or utilise different neural circuits to complete these tasks.

Title: Detecting an olfactory-based biomarker for early stage Parkinson's disease using diffusion tensor imaging

Authors: N. JOSHI[1], T. ROLHEISER[2], J. D. FISK[2], K. P. GOOD[2], N. KHAN[3], G. E. PHILLIPS[2], J. R. MCKELVEY[4], *H. A. ROBERTSON[1];
[1]Dalhousie Univ. Fac Med., Halifax, NS, Canada; [2]Psychiatry, [3]Diagnos. Radiology, [4]Med., Dalhousie Univ., Halifax, NS, Canada

Abstract: Diagnosis of Parkinson's disease (PD) requires the presence of motor symptoms although pre-motor changes such as olfactory loss and the deposition of α-synuclein aggregations in the olfactory bulb and tract precede the emergence of motor symptoms. Biomarkers based on such changes could help identify those at risk of PD. We sought to find biomarkers related to olfactory loss that might differentiate early-stage PD from healthy controls (HC) by using diffusion tensor magnetic resonance imaging (DTI). We used a Region of Interest approach to determine if anterior olfactory structures (AOS: olfactory bulb & tract) exhibit microstructural changes between PD and HC subjects. Ten early-stage (Hoehn and Yahr stage I or II) PD subjects and twenty-six matched HC subjects were compared. Olfaction was tested using the University of Pennsylvania Smell Identification Test (UPSIT). Magnetic resonance imaging employed a 1.5T GE scanner and sequences such as a coronal T2 FRFSE sequence as well as an axial DTI sequence (measuring water diffusion in 55 directions). The AOS on each side of the brain of every subject were traced manually using the coronal T2 images; the tracings were then registered to the DTI images. DTI measures generated included: Fractional Anisotropy (FA), Mean Diffusivity (MD), Axial Diffusivity (AD) and Radial Diffusivity (RD) which were compared between the two groups using a two-way ANOVA with side and disease state as independent variables. UPSIT scores revealed poorer olfaction in PD subjects. DTI-variables including MD, AD and RD were increased bilaterally in AOS of PD patients relative to HC. Additionally, the PD group demonstrated reduced FA in the right AOS relative to HC, and asymmetry of DTI measures of the AOS with reduced FA in right AOS compared to the left; this asymmetry was not seen among HC. Reduced FA in AOS for PD patients has been noted before although asymmetric FA reduction is a novel finding and may represent asymmetric atrophy of AOS white matter in early stage PD. These findings indicate that DTI measures of AOS aside from FA alone can differentiate early stage PD patients from HC and support the use of DTI of AOS in the development of multimodal biomarkers to identify premotor stages of PD.

Title: β-Amyloid PET predicts longitudinal cognitive performance in Parkinson's disease

Authors: *M. C. CAMPBELL[1], E. R. FOSTER[2], J. S. PERLMUTTER[2];
[1]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Introduction: Several lines of evidence suggest that abnormal β-amyloid (Aβ) deposition occurs in Parkinson disease (PD). Previous research on β-amyloid PET imaging with Pittsburgh compound B (PiB) in PD demonstrates that approximately 15-30% of non-demented PD already have elevated Aβ. However, little is known about the predictive ability of PiB binding for cognitive decline in PD. The purpose of this study was to examine the relationship between baseline PiB binding and longitudinal cognitive changes in PD. Methods: Baseline PiB binding in caudate, brainstem, and averaged across cortical regions (MCBP) and neuropsychological testing were obtained from 70 non-demented PD participants (31 with normal cognition, 39 with cognitive impairment). Follow-up neuropsychological testing was repeated two years after baseline assessment. For each of the primary cognitive domains (attention, memory, visuospatial, language, executive function), composite Z-scores were computed based on the average of the z-transformed individual tests; an overall cognitive composite Z-score was computed as the average of domain Z-scores. Hierarchical linear regressions, controlling for age, education, and baseline cognitive performance, were conducted to test the predictive ability of PiB binding for cognitive performance at the follow-up visit. Results: After controlling for age, education, and baseline cognitive performance, both brainstem and MCPB PiB binding significantly predicted attention performance at the follow-up visit for PD participants (full model, $p < .001$; brainstem R2 change = .03, $p = .03$; MCBP R2 change = .03, $p = .04$). Splitting PD participants by cognitive status revealed that for PD with normal cognition, brainstem PiB binding significantly predicted attention performance (full model, $p < .001$; brainstem R2 change = .14, $p = .009$). For PD with cognitive impairment, baseline brainstem PiB binding predicted memory (full model, $p < .001$; brainstem R2 change = .07, $p = .03$), and visual-spatial performance (full model, $p < .001$; brainstem R2 change = .09, $p = .03$) at follow-up. Conclusion: These data demonstrate that elevated brainstem PiB binding predicts cognitive decline in PD. Most notably, baseline brainstem PiB predicted follow-up cognitive

performance even after controlling for age, education and baseline cognitive performance. These findings suggest that brainstem PiB binding may be a useful prognostic marker of cognitive decline in PD.

Title: Parkinson’s disease targets intrinsic brain networks

Authors: *Y. ZEIGHAMI[1], M. ULLA[2], Y. ITURRIA-MEDINA[1], M. DADAR[1], K. LARCHER[1], V. FONOV[1], A. C. EVANS[1], D. L. COLLINS[1], A. DAGHER[1];

Abstract: Network propagation hypothesis of neurodegenerative diseases (e.g. Alzheimer's disease) proposes that degeneration spreads through brain via intrinsic brain networks. Here we test this hypothesis in Parkinson's disease (PD). We used the following data from the Parkinson's Progression Markers Initiative (PPMI), a multi-center study of de novo PD patients and healthy controls: T1 brain MRI at 3T, the Unified Parkinson’s Disease Rating Scale motor score (UPDRS III) and striatal binding ratio (SBR), a measure of dopamine innervation. Data from 232 PD patients and 117 HC were available. Regional atrophy was calculated using deformation based morphometry (DBM) and decomposed into spatially independent maps using independent

component analysis (ICA). The deformation values from each ICA component were compared between PD and HC. In order to compare PD atrophy to intrinsic brain networks, ICA maps were compared to seed based functional connectivity map with Substantia Nigra (SN) as seed. We also investigated the relation between regional functional connectivity and structural deformation. ICA estimated 30 independent components. PD patients had higher deformation values in only one of the networks (p=0.003 Bonferroni correction). This PD-ICA component includes the entire basal ganglia, amygdala, hippocampus, insula, anterior cingulate cortex, and premotor areas. There was a significant correlation between DBM values in the PD-ICA component and both SBR ($r=0.22$, $p<0.001$) and UPDRS III ($r=-0.26$, $p<0.0001$). The resting state network identified with the SN Seed was spatially correlated only to the PD-ICA network ($r=0.3$), out of the 30 ICA components. Regional functional connectivity was significantly correlated with regional structural deformation ($r = -.41$, $p<.0001$). The set of regions demonstrating disease-related atrophy in PD correspond to an intrinsic network in healthy brain. Moreover, the deformation in a given region was inversely proportional to functional distance from the presumed disease epicenter in the SN. This supports the network propagation hypothesis in PD.

Title: C-terminal-truncated alpha-synuclein smart molecule: a novel blood-brain barrier permeable diagnostic and therapeutic molecule for Parkinson's disease

Authors: *A. CARTIER, R. BHATT;
ICB International, Inc., La Jolla, CA

Abstract: Development of blood-brain barrier (BBB) permeable biologics that specifically target alpha-synuclein (α-syn) has great clinical potential for treatment, early diagnosis, monitoring of disease progression and therapeutic efficacy of drugs in patients at risk or afflicted with Parkinson's disease (PD). We have developed SMART Molecules (SMs) to deliver diagnostic and therapeutic agents across the BBB to specific targets within the Central Nervous System (CNS). Our SM approach utilizes the target specificity of conventional antibodies, and BBB permeability of small molecule drugs to create novel biologics ideal for *in vivo* imaging of pathological brain lesions and therapeutic purpose. We have generated SMART Molecules for full length (α-syn-SM) and C-terminal truncated alpha-synuclein (CT-α-syn-SM) since α-syn is a major pharmaceutical target for PD as its progressive accumulation, deposition and aggregation is a pathological hallmark of this disorder. Furthermore, CT-α-syn species have been shown to form toxic fragments enhancing α-syn oligomerization. In this study, the unique specificity and BBB permeability of α-syn-SM and CT-α-syn-SM was evaluated. We utilized brain tissues derived from human PD patients and α-syn transgenic (tg) to characterize the specificity of α-syn-SM and CT-α-syn-SM to detect α-syn species. We further assessed the binding specificity of these SMs using peptides corresponding to various regions of full length α-syn. We have also evaluated the BBB permeability of our SMs in α-syn transgenic mice that received a single low dose injection of each SM or a conventional mouse antibody against α-syn. Our data demonstrate that both SMs demonstrate superior blood-brain penetration compared to conventional antibodies, and exquisite specificity for α-syn species. Our long-term objective is to utilize α-syn-SM and CT-α-syn-SM to develop: 1) diagnostic imaging biomarkers in conjunction with an *in vivo* imaging modality, and 2) therapeutic molecules to target and remove toxic forms of α-syn. The clinical utility of these SMs is currently under investigation. This study is partly supported by the Michael J. Fox Foundation.

Abstract: Neuroimaging with PET biomarkers and resting-state functional connectivity with MRI (rs fcMRI) has provided new insights into the pathophysiology of cognitive dysfunction that occurs in most people with Parkinson disease (PD). We combined these imaging modalities with biochemical and pathologic protein measures from CSF and brain tissue in a large longitudinal cohort of more than 260 people with PD (with or without cognitive impairment) and controls. We have found that comparison of PET data using the Aβ amyloid biomarker [11C]Pittsburgh compound B (PiB) in PD participants with postmortem findings reveals the importance of such assessments for meaningful interpretation of the PET findings, and better understanding of the pathophysiology of dementia associated with PD. Aβ amyloid distribution in PD differs from that in Alzheimer disease, even when controlling for cognitive impairment. Aβ1-42 levels in CSF in those with PD positively correlate with α-synuclein levels suggesting that Aβ amyloid in brain may reflect severity of brain synucleinopathy. Furthermore, reduced coherence of the sensorimotor resting-state functional network correlates with reduced CSF levels of α-synuclein in PD. Functional connectivity within the dorsal attention network (DAN) and default mode network (DMN) decreased over time in non-demented PD participants and baseline resting-state network strength predicted cognitive performance. Together these findings help define the role of proteinopathy in cognitive dysfunction in PD and highlight the importance of multimodal studies to validate neuroimaging biomarkers. Title: Differences in brainstem volumes on MRI in Parkinson's disease patients vs. persons whose DAT scans did not show evidence of dopaminergic deficit (SWEDD)

Authors: *C. D. SCHROEDER, G. T. STEBBINS, J. G. GOLDMAN;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Objective: To compare regional brainstem atrophy patterns on magnetic resonance imaging (MRI) scans in Parkinson’s disease (PD) patients and persons whose DAT scans lack evidence of dopaminergic deficits (SWEDDs). **Background:** Braak’s pathological staging of PD hypothesizes that there are early changes in the brainstem, progressing from the medulla to the midbrain substantia nigra, and eventually the neocortex. Previous studies have shown differences in brainstem volumes between PD patients and healthy controls. SWEDDs have abnormal motor findings (e.g., tremor, dystonia) and thereby be “mistaken” clinically for PD; however, unlike PD patients, they do not exhibit dopaminergic deficits on dopamine transporter (DAT) scans. **Methods:** MRI brain scans (3T Siemens, T1-weighted MPRAGE sequence) and subject characteristics were obtained from the Parkinson's Progression Markers Initiative (PPMI) at 12 month follow-up. The sample included 148 PD patients (clinical symptoms, positive DAT scans) and 23 age-matched SWEDDs (clinical symptoms, negative DAT scans). Whole brain voxel-based morphometry analyses were conducted using SPM8. Images were smoothed with a 6mm kernel. Regions of interest for midbrain, pons, and medulla were identified using the Wake Forest University Pickatlas and extracted from modulated non-linear scans. Gray matter volume differences between PD and SWEDD groups were examined using t-tests. Predictive value of volume for group classification was assessed with a binary logistic regression. **Results:** PD and SWEDD subjects did not differ significantly in age or sex. Compared with the SWEDDs, the PD

group exhibited significant voxel-wise decreased gray matter volume in the midbrain (mean [SD] PD 0.15 [0.02] SWEDDs 0.16 [0.02], p=0.03) and the pons (mean [SD] PD 0.049 [0.007], SWEDDs 0.053 [0.012], p=0.04). In a logistic regression, midbrain volume successfully predicted diagnostic group (χ^2=4.48, p=0.03). **Conclusion:** PD and SWEDD groups could be differentiated by MRI-derived brainstem atrophy patterns, specifically in the midbrain and pons. This finding suggests that midbrain gray matter volume on MRI may be useful in differentiating parkinsonian/movement disorders that may overlap clinically but differ in DAT scan evidence of dopaminergic deficits. **Acknowledgments:** T32AG000269-15 (CDS), Data used in the preparation of this article were obtained from the Parkinson's Progression Markers Initiative (PPMI) database (www.ppmi-info.org/data). Title: Alterations in the default mode network in de novo, untreated Parkinson's disease patients with mild cognitive impairment

Authors: *S. L. KLETZEL[1], B. C. HARTON[1], A. KOPICKI[1,2], A. A. HERROLD[1,3], T. L.-B. PAPE[1,3,4];
[1]Res. & Develop., Edward Hines Jr. VA Hosp., Hines, IL; [2]Adler Univ., Chicago, IL; [3]Northwestern Univ., Chicago, IL; [4]Marionjoy Rehabil. Hosp., Wheaton, IL

Abstract: In Parkinson's disease (PD), mild cognitive impairment (PD-MCI) is a common non-motor symptom and a risk factor for developing dementia. Currently there are no effective treatment options for PD-MCI. Resting state functional connectivity (rsFC), as measured with Functional Magnetic Resonance Imaging (fMRI), is a method to investigate neurobiological mechanisms underlying cognitive impairment. The Default Mode Network (DMN) is believed to support cognition, and dysfunction of the DMN is associated with cognitive impairment in PD (Baggio, 2015). To date, all reported rsFC PD studies that have investigated cognition have included participants on dopaminergic medication. These medications can influence cortico-striatal network rsFC (Kwak 2010) and it is possible they may influence DMN rsFC. In this study we (i) describe DMN rsFC in newly diagnosed, never medicated PD-MCI patients compared to newly diagnosed, never medicated PD patients with normal cognitive function (PD-NC) and healthy controls (HC) and (ii) correlate cognitive test scores with DMN rsFC between groups. Imaging and neuropsychological data were obtained from the Parkinson's Progression Marker Initiative (PPMI; www.ppmi-info.org). Participants were evaluated for memory, visuospatial function, executive function, and attention. In our data analysis, participants were grouped based on Montreal Cognitive Assessment (MoCA) total scores: PD-NC (MoCA >25; n=25), PD-MCI (MoCA 21-25; n=7) and HC (MoCA >25; n=6). DMN rsFC was assessed using independent component analysis and region of interest analyses. Imaging data revealed that PD-MCI participants had mostly hypoconnectivity in parietal regions, the precuneus and anterior cingulate cortex compared to HC. Verbal fluency scores correlated negatively with connectivity in the right temporal parietal region. Compared to PD-NC, PD-MCI had hyperconnectivity in the ventral prefrontal cortex (PFC) and hypoconnectivity in parietal and frontal cortical regions and the posterior cingulate cortex (PCC). Visuospatial scores correlated negatively with medial PFC and precuneus connectivity. Memory scores correlated positively with left PCC connectivity. These data suggest that there are changes of DMN rsFC in PD-MCI and some of these changes may underlie cognitive impairment. Moreover, such changes cannot be attributed to PD medications. Future analyses will focus on rsFC of other cognitive networks and how these measures correlate with cognitive test performance. Collectively, these imaging and neuropsychological assessments may be useful in identifying PD-MCI biomarkers that can be targeted for cognitive rehabilitation therapies.

Abstract: Parkinson's disease (PD) is a progressive neurological motor disorder, characterized by difficulty initiating movement, resting tremors, slowness of movement, and muscular stiffness. Standard volumetric analysis of brain images can miss subtle disease related alterations in structures in patients with PD. Shape analysis of subcortical region boundaries reveals more subtle, localized effects. In the present study, we applied, medial demons surface registration, a surface-based parametric shape analysis to seven subcortical regions: left and right amygdala, nucleus accumbens, putamen, caudate, globus pallidus, hippocampus, and thalamus. After shape registration, two surface measures - radial thickness and dilation ratio (Jacobian determinant) - were used to quantify local shape differences. Structural T1-weighted whole-brain MRI scans were obtained from the Parkinson's Progressive Markers Initiative (PPMI; 116M:68F mean age = 61.5M:58.7F healthy controls and 264M:142F mean age = 61.9M:60.9F PD subjects). Subcortical parcellations were obtained using FreeSurfer 5.3. We performed mass-univariate tests for group differences between controls and PD subjects, controlling for age, sex, ICV and handedness. Shape signatures of the following regions were significantly different after False Discovery Rate (FDR) correction for multiple comparisons (critical q in parentheses, higher implies greater effect): right and left thalamus (q=0.0102, q=0.001), left pallidum (q=3.39e-04) for dilation ratio measures (TBM). For radial thickness measures (RAD), significant differences were found in the right and left thalamus (q=0.00144, q=1.69e-04), right pallidum (q=0.0012)

and right caudate (q=4.76e-04). P-maps localizing group differences are shown in Figure 1, and are consistent with previous findings in PPMI. This study suggests that subcortical shape differences can be used as biomarkers for mapping disease effects on the brain.

Title: Mild depressive symptoms are related to *in vivo* myelin load in Parkinson’s disease

Authors: ***J. SOJKOVA**[1], D. DEAN, III[1], S. HURLEY[2], S. JOHNSON[1], B. B. BENDLIN[1], A. L. ALEXANDER[1], C. GALLAGHER[1];

[1]Univ. of Wisconsin, Madison, WI; [2]Oxford Ctr. for Functional Magnetic Resonance Imaging of the Brain, Oxford, United Kingdom

Abstract: Title: Mild depressive symptoms are related to *in vivo* myelin load in Parkinson's disease Background: Depression, a common non-motor symptom in Parkinson's disease (PD) affecting approximately 60% of patients, may present as one of the early signs even 5-10 years prior to onset of motor symptoms. Evidence for the role of a myelin-centered model of human brain function in psychiatric conditions has been accumulating with several recent investigations directly focusing on the role of myelin in depression. A novel *in vivo* imaging method, multi-component Driven Equilibrium Single-Pulse Observation of T1 and T2 (mcDESPOT), allows estimation of voxel-wise myelin water fraction (MWF). We hypothesized that greater depressive symptom burden quantified by the Geriatric Dementia rating scale (GDS) will be associated with lower myelin content in PD patients. Methods: 26 nondemented PD patients (mean age: 66.4+/-9.6 years) and 33 controls (mean age: 65.8+/-7.7 years; $p>0.05$) from the Longitudinal MRI Biomarkers in Parkinson's disease study (LMPD) were imaged using mcDESPOT. Depression was assessed using the GDS (30-questions version) during the imaging visit. Given the skewed distribution of GDS scores, log GDS was used as a predictor. Voxel-wise linear regression analysis was used to determine the relationship between depression and myelin content, using Statistical Parametric Mapping software (SPM12). Analyses were adjusted for age, sex and education ($p<0.05$, uncorrected). Results: Patients with PD endorsed more depression compared to controls ($p<0.05$). GDS scores were in the subclinical range, and did not correlate with disease duration or levodopa equivalent dose. In the voxel-wise analysis, higher GDS scores in PD were associated with lower MWF across extensive bilateral subcortical regions, most prominently in posterior brain regions with distinct delineation of posterior forceps of the corpus callosum. Conclusion: To our knowledge, this represents the first investigation of the relationship between myelin load and subclinical depressive symptoms in PD. Using a novel *in vivo* imaging technique, we demonstrate that decrements in myelin load are associated with subclinical levels of depressive symptomatology detected by a psychometric measure. These findings add to a growing body of literature suggesting that depression is associated with myelin alterations. Further investigation is needed to determine the factors that underlie this association.

Title: Attention task-related changes to intrinsic functional connectivity in Parkinson's disease

Authors: *T. MADHYASTHA[1], A. LEE[2], M. K. ASKREN[2], J. B. LEVERENZ[3], T. MONTINE[2], T. GRABOWSKI[2];
[1]Dept. of Radiology, [2]Univ. of Washington, Seattle, WA; [3]Cleveland Lou Ruvo Ctr. for Brain Hlth. at Cleveland Clin., Cleveland, OH

Abstract: Correlations among low frequency spontaneous fluctuations in the blood oxygen level-dependent (BOLD) signal at rest reflect the connectivity of intrinsic large-scale networks in the brain. In Parkinson's disease (PD) these networks are disrupted, perhaps contributing to cognitive impairments that ultimately afflict the vast majority of PD patients. To examine the relationship between resting state network disruption and task-related performance, we use a novel technique called network kernel analysis to compare fine-grained network ensembles that include overlapping cortical elements obtained at rest and during the Attention Network Task (ANT) in 24 patients with PD (ages 45-86, 17 male) and 21 controls (ages 41-76, 9 male). PD participants were on average slower and less accurate than controls on the ANT. We confirm that the network kernels obtained during the ANT are the same as those obtained at rest. We compared a general linear model with task-related explanatory variables to one that also incorporated intrinisic network kernel activity to explain cue and target-related activity in regions of interest obtained from Fan et. al, 2005. A likelihood ratio test, Akaike and Bayesian information criteria all indicate that including network kernel activity in a mixed effects model better explains signal in all but two regions of interest. The differences in partial correlations between network kernels in PD and controls were largely the same same during task as at rest (although not necessarily significant after correcting for multiple comparisons), with the exception that at task the correlation between the default mode network and caudate/putamen was lower in PD, and the correlation between the intraparietal sulcus regions and the nucleus accumbens was higher in PD. Despite these group differences, within-subject intrinsic network activity changes in PD reflected task-related normalization (i.e, correlations that were higher in PD than controls at rest decreased during task, and vice versa). We hypothesize that these task-related changes may contribute to task performance. Examining only correlations that were significantly different between PD and controls, we found that greater decrease in correlation between hippocampal activity and the frontal control network during task was related to higher accuracy ($p_{cor} < .001$), and was lower in individual fast trials than slow trials for PD, but not controls. Therefore, intrinsic dynamics may help to understand cognitive impairments in

Parkinson disease by reflecting physiological alterations to networks, compensatory or pathological, that support task performance.

Title: Striatal - motor cortex functional connectivity in moderate pd and psp

Authors: ***A. S. KURANI**[1], R. G. BURCIU[2], R. SEIDLER[4], M. S. OKUN[3], N. R. MCFARLAND[3], D. E. VAILLANCOURT[2];
[1]Dept. of Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Dept. of Applied Physiol. and Kinesiology, [3]Dept. of Neurol., Univ. of Florida, Gainesville, FL; [4]Sch. of Kinesiology and Dept. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Resting state fMRI is used in the current study to measure low frequency fluctuations in the blood oxygen level dependent signal to identify differences in functional connectivity (FC). The study included 20 healthy controls, 20 moderate parkinson disease (PD) and 20 progressive supranuclear palsy (PSP) subjects. All subjects taking medication were tested after overnight withdrawal from medication. Voxel-wise analyses compared each group with controls as well as across patient groups to identify significant clusters ($P < .05$, corrected) of difference. Seed regions included the caudate, anterior/posterior putamen, Pre-SMA and SMA. When patient groups were compared directly, PSP subjects exhibited reduced posterior putamen - temporal lobe and occipital gyrus FC as compared with PD. Z scores in this region were significantly negatively correlated ($R = -0.703$; $p < 0.001$, corrected) with gait measurements and significantly correlated ($R = 0.358$; $p < 0.0491$, FDR corrected) with Purdue Pegboard Test Both task. Also, when comparing PD patients directly with PSP, the SMA seed region showed significantly greater differences in FC patterns across the patient groups compared with the other seed regions. PSP had decreased SMA - cortical motor areas, temporal lobe and posterior cingulate gyrus FC compared with PD. PSP exhibited increased SMA - basal ganglia, inferior parietal lobe and occipital lobe FC compared with PD. Gait severity, as measured by the gait

items of the MDS-UPDRS, was strongly correlated (R=.620; p<0.0002, corrected) with SMA - basal ganglia functional connectivity Z scores in PD and PSP groups. We provide evidence that PSP subjects exhibited greater changes in FC patterns for basal ganglia and cortical motor seed regions when compared with controls and PD subjects. Of the basal ganglia seed ROIs, the posterior putamen showed the largest degree of changes between the patient groups as well as with controls. These findings are supported by previous studies which have found that the posterior putamen is most affected in PD compared with controls, and extends this finding to PSP compared with controls and PD. Our findings suggest also that the posterior putamen is affected to a larger extent in PSP than in PD. Additionally, the SMA seed ROI showed the greatest change in FC across patient groups. The SMA - basal ganglia FC was positively correlated with clinical gait measurements and negatively correlated with manual dexterity measurements. Furthermore, the increased SMA - basal ganglia FC in PSP compared with controls and PD suggests that this pathway is enhanced in PSP and that there may be another pathway mediating the SMA changes observed in PSP.

Title: Neuroanatomical changes predictive of motor decline in mild Parkinson's disease

Authors: *L. BAEHR, M. GROSSMAN, D. WOLK, C. MCMILLAN;
Neurol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Parkinson disease (PD) is a progressive neurodegenerative disease that is characterized as a movement disorder. As clinical trials emerge for the treatment of PD it is important to identify early prognostic biomarkers of longitudinal decline. The Unified Parkinson's Disease Rating Scale Part III (UPDRS III) is the most commonly used motor evaluation in the clinical study of PD. In this study we evaluate whether neuroimaging can be used to identify early prognostic estimates of longitudinal UPDRS-III decline in early Parkinson's disease (ePD) patients who are drug naïve and within 2 years of initial diagnosis. We evaluated 83 ePD patients and 70 demographically comparable controls downloaded from the publically available Parkinson's Progression Markers Initiative (PPMI) dataset. All participants had a baseline T1-weighted MRI and UPDRS-III score at baseline and at 24 months. Grey matter density was calculated using Advanced Normalization Tools (ANTs) and we performed voxelwise regression analyses in SPM8 to relate baseline MRI to longitudinal UPDRS-III. The UPDRS-III score was calculated as a total of numeric ratings including measures of rigidity, tremor, gait, and stability for baseline visit and 24-month follow up. PD patients exhibited an average increase in UPDRS-III score of 6.7 points (+/-8.41) across a 24-month period as compared to controls that demonstrated no substantial change from baseline (0.17+/-2.26). A repeated measures ANOVA revealed that diagnosis had a statistically significant effect on UPDRS-III rate of change [$F(1,151)= 39.73$, $p = .001$]. MRI regression analyses related change in UPDRS-III score over a 24-month period to thalamus, putamen, and posterior cingulate ($p<0.05$). Specifically, regions known to support movement regulation, signaling, and intrinsic motor control networks appear to have predictive utility. Our findings are consistent with the hypothesis that neuroimaging may provide a prognostic biomarker of longitudinal motor decline and may be particularly useful in the context of clinical trials for ePD.

Title: Abnormal recruitment of left prefrontal cortex underlies impaired working memory in Parkinson's disease

Authors: ***T. HATTORI**[1,2,4], S. HOROVITZ[2], P. KUNDU[5], R. REYNOLDS[3], C. LUNGU[2], E. WASSERMANN[2], M. HALLETT[2];

Abstract: Objective: Parkinson's disease (PD) patients often develop cognitive impairment. To date, functional MRI (fMRI) using a cognitive task has been insufficiently investigated during disease evolution. We aimed to identify the neural underpinning of impaired working memory in PD patients. Method: 18 patients with cognitively normal PD (PD-CogNL), 16 with PD with mild cognitive impairment (PD-MCI), and 12 with PD with dementia (PDD) and 18 healthy subjects (controls) were enrolled. While multi-echo time fMRI images were taken in a 3 Tesla MRI scanner, subjects performed an n-back task, including n=0, 1, 2 and 3-back task conditions, and responded each time by pressing a button to indicate whether the current letter was the same as the previous n-back letter. Accuracy for the n-back task was evaluated with the d prime index. Brain activation patterns were compared between patient groups and the control group. The cortical areas where activation was correlated with the d prime index were explored in all PD patient groups. Results: The d prime index for 2- and 3-back tasks was significantly lower in the PD-MCI and PDD groups compared with the controls. In the 1-, 2-, or 3-back task versus 0-back task condition, PD patients and controls had robust activation in the bilateral insular, dorsal cingulate cortex; dorsolateral and ventrolateral prefrontal cortex; and medial and lateral posterior parietal cortex (Fig.1). In the 3-back task versus 0-back task condition, PDD patients had less activation in the frontoparietal network consisting of the prefrontal and parietal cortices, compared with controls (Fig.2). Furthermore, the d prime index for the 2- and 3-back tasks was correlated with activation of the left prefrontal cortex in the 2-back or 3-back versus 0-back task condition in all PD patient groups, respectively (Fig.3). Conclusion: Abnormal recruitment of the frontoparietal network, particularly the left prefrontal cortex, underlies the impaired working memory performance in PD patients.

Title: Micro-structural differences in white matter between Atypical Parkinsonism and Parkinson's disease

Authors: K. JUNG[1,3], Y. CHANG[3], *M. LEE[1,3], H. S. KIM[1], C. G. CHOI[1], S. C. JUNG[1], C. S. LEE[2], S. J. KIM[1], N. KIM[1,3];

Abstract: Diffusion tensor imaging (DTI) is a useful modality for evaluating micro-structure of white matter of brain. It is well-known for differentiating Parkinsonian syndromes such as multiple system atrophy (MSA) and progressive supra nuclear palsy (PSP). The present study examined differences between MSA, PSP, Parkinson's disease (PD) and normal subjects by using DTI. DTI were obtained from 21 patients with MSA, 24 patients with PSP, 21 patients with PD, and 18 healthy subjects. Fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD) were computed by using FMRIB's diffusion toolbox. To test differences among them, a tract-based spatial statistics was performed with 1 factor-4 level ANOVA design. The significant level was corrected by controlling the family-wise error rate (alpha value 0.05). All two-sample t-test were considered as two covariates including age and gender. Results of the FA and RD test were significant, but that of MD and AD were not significant. FA of MSA and PSP groups were lower than that of healthy control group and FA of PSP group was lower than that of PD group. RD of MSA and PSP groups were higher than that of PD and healthy control groups. In addition, MD of PSP group was higher than that of PD and healthy control groups. In summary, micro-structure of white matter of MSA and PSP may be different from PD and healthy control. Our results can support that there are different mechanisms among atypical Parkinsonism (MSA and PSP) and PD.

Title: MAPT gene polymorphism is associated with abnormal uncinate fasciculus integrity in normal population

Authors: *A. BAYANI ERSHADI[1,2], A. ABDOLALIZADEH[3], N. ABBASI[3], B. MOHAJER[3], M. AARABI[3];
[1]Tehran Univ. of Med. Sciences, Student's S, Tehran, Iran, Islamic Republic of; [2]Zanjan Univ. of Med. Sci., Zanjan, Iran, Islamic Republic of; [3]Student's Scientific Res. Ctr., Tehran Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: Objective: Parkinson’s disease (PD) is a neurodegenerative disorder resulting from the interplay of genetic and environmental factors. One of the disease associated single nucleotide polymorphisms (SNPs) is rs2942168 in the MAPT gene. MAPT polymorphisms are associated with uncinate fasciculus (UF) abnormalities using the Diffusion Tensor Imaging (DTI).

Recently, it has been shown that older adults with rs2942168 may develop mild parkinsonian signs, especially bradykinesia, which has been correlated with Fractional Anisotropy (FA) of UF in PD patients in another study. Thus, we used DTI to investigate white matter integrity of the UF in healthy carriers of this SNP. Methods: Subjects and Genetics: We used Parkinson's Progression Markers Initiative (PPMI; www.ppmi-info.org). Subject's IDs were obtained from the genetic data using PLINK (http://pngu.mgh.harvard.edu/~purcell/plink/) . 11 healthy carriers and 19 age and sex matched healthy controls were included. 3T MRI was used for the diffusion data (64 gradient directions with b-value of 1000 s/mm2). Image Analysis: The DWI data were reconstructed using ExploreDTI. In brief, the diffusion tensors were robustly estimated based on RESTORE algorithm, EPI distortion, head motion correction and the B-matrix reorientation was performed. Deterministic full brain tractography with stopping criteria of FA = 0.2 and 45° curvature threshold was done. Regions of interest (ROI) using "AND" Boolean operator were drawn on the temporal and the ipsilateral frontal in the connecting area of the two lobes. "NOT" was used to omit the anatomically unrelated fibers. Finally, mean FA and mean Apparent Diffusion Coefficient (ADC) of each tract were acquired. Statistics: Statistical Analyses were performed using IBM SPSS v22. Shapiro-Wilk test was used to test for normality. Multivariate analysis of Covariance between FA and ADC was done with age, sex, handedness and education as covariates. Significant results with p-value < 0.05 were reported. Results and Discussion: The normality test of FA and ADC indicated that our data is normally distributed. The results of MANCOVA showed significant differences between Right UF of the carriers and non-carriers ($p = 0.04$, mean estimated: Carriers = 0.435, non-carriers = 0.415). Other results were not significant. We showed that the integrity of right UF is decreased in the carriers of this SNP. Regarding the involvement of UF integrity in bradykinesia, we propose that genetic related impairment in this tract can explain some of the impairments observed in the carriers of the SNP. Further evaluations with clinical data in patients with Parkinson is suggested.

Title: Intraoperative fmri as a potential biomarker of dbs-evoked adverse effect

Authors: *W. GIBSON[1], P. TESTINI[2], C. EDWARDS[3], J. FELMLEE[4], K. GORNY[4], K. WELKER[4], B. KLASSEN[5], H.-K. MIN[3], K. LEE[2];
[1]Mayo Grad. Sch., Rochester, MN; [2]Neurosurg., [3]Physiol. and Biomed. Engin., [4]Radiology, [5]Neurol., Mayo Clin., Rochester, MN

Abstract: Introduction: Deep brain stimulation (DBS) of the Ventralis Intermedius thalamic nucleus (VIM) is a highly effective therapy for essential tremor (ET). Inappropriate stimulation of the adjacent Ventralis Caudalis nucleus due to targeting error can cause patients to experience unpleasant sensory side effects, which can limit the therapeutic effectiveness of a given DBS electrode. The advent of an intraoperative biomarker of DBS-evoked paresthesias could eliminate the need for patients to remain awake during surgery, which would greatly enhance patient comfort. We aimed to test the hypothesis that intraoperative fMRI in anesthetized patients could be used to detect differential blood oxygen level-dependent (BOLD) effects during DBS at paresthesia-evoking versus non-paresthesia evoking parameters. Methods: Patients with ET underwent bilateral VIM DBS. During battery implantation surgery, a unilateral DBS lead was externalized and connected to an external pulse generator. Stimulation was applied using a block paradigm during gradient echo echo-planar imaging acquisition. While under general anesthesia, patients underwent four fMRI scans, each using a different bipolar stimulation paradigm (0-1+, 1-2+, 2-1+, 3-2+; 3V 130Hz 90us). The presence or absense of stimulation-evoked paresthesia at each setting was evaluated during the first post-operative DBS programming visit. All pulse sequences were previously safety tested, and a strict specific absorption rate limit (< 0.1 W/kg) was observed. All patients provided informed consent and all protocols were approved by Mayo Clinic IRB. Results: Both paresthesia-inducing and non-paresthesia inducing VIM DBS resulted in robust BOLD response in ipsilateral sensorimotor cortex, thalamus, and contralateral cerebellum ($pFWE < 0.05$, one sample t test). Differential activation of these structures was observed due to paresthesia-evoking versus non-paresthesia-evoking parameters ($pFWE < 0.05$, paired t test). Conclusions: Our results suggest that VIM DBS for ET exerts distributed effects on the dentato-rubro-thalamo-cortical network. In addition, we conclude that intraoperative fMRI may hold potential as a biomarker for optimal electrode placement in VIM DBS.

Title: Diffusion MRI and connectivity of the STN in Parkinson's patients undergoing DBS treatment

Authors: *M. PETERSEN[1], T. E. LUND[4], D. G. ZEIDLER[4], R. SANGIL[4], J. FRANDSEN[4], N. SUNDE[2], F. ROSENDAL[2], K. ØSTERGAARD[3];
[1]CFIN - Ctr. of Functionally Integrative Neurosci., Aarhus Univ. Hosp., Aarhus C, Denmark; [2]Dept. of Neurosurg., [3]Dept. of Neurol., Aarhus Univ. Hosp., Aarhus, Denmark; [4]Ctr. of Functionally Integrative Neurosci., Aarhus Univ., Aarhus, Denmark

Abstract: High frequency deep brain stimulation (DBS) in the subthalamic nucleus (STN) is an effective treatment for Parkinsonian patients with motor fluctuations and dyskinesia. DBS treatment decreases the use of medication and increases quality of life. In recent years, there has been a tendency to operate on patients at an earlier stage of the disease than before. During DBS surgery, electrodes are positioned bilaterally in the STN and allow stimulation of this region and nearby tissue through electrical impulses. Intraoperative microelectrode recording and test stimulation are imperative in achieving optimal treatment effect and avoiding negative side effects. The surgical planning and target location is traditionally based on direct visual identification of the STN and reference anatomical landmarks on T2- and T1-weighted magnetic resonance imaging (MRI) scans. The STN is known to have three functionally distinct regions (sensorimotor, associative and limbic), as established from primate studies. However, these cannot be identified visually using conventional MRI and the exact DBS target within the STN is based on empirical evidence and surgical experience. The dorsolateral region of the STN receives projections directly from the motor cortex through the 'hyperdirect' cortico-subthalamic pathway. Recent research indicates that this pathway plays a central role in mediating the effects of DBS. Recent advances in diffusion MRI and tractography allow us to map and examine the fiber pathways of the brain non-invasively. By examining the structural connectivity of the STN and nearby regions, we aim to learn more about which pathways are impacted by DBS. Implementing a high-resolution, readout segmented EPI diffusion sequence (1h30min), with reacquisition of segments affected by (cardiac) motion, combined with an advanced probabilistic tractography method (based on constrained spherical deconvolution), we have demonstrated an STN connectivity pattern highly consistent with the known anatomy of the region. We have furthermore been able to delineate a structural pathway consistent with the hyperdirect pathway, projecting to a part of the dorsolateral STN. We are currently refining and evaluating this technique as part of the pre-surgical planning for DBS treatment. Identification of the hyperdirect pathway and sensorimotor region of the STN would be an important contribution to this planning

phase. Once established and standardized, this technique could prove invaluable for optimizing neurosurgical planning by allowing us to target specific fiber pathways.

Musashi Kosugi Hosp., Kanagawa, Japan

Abstract: Objective: Adenosine A_1 receptors (A_1Rs) interact negatively with dopamine D_1 receptors (D_1Rs) in direct pathway neurons of basal ganglia circuits, while adenosine A_{2A} receptors (A_{2A}Rs) negatively interact with dopamine D_2 receptors (D_2Rs) in indirect pathway neurons. We recently reported that A_{2A}Rs were asymmetrically down-regulated in de-novo patients with Parkinson's disease (PD), and were increased in the putamen of PD patients with dyskinesia (1). However, the roles of A_1Rs remain unclear in the PD patients unlike A_{2A}Rs. In this study, we investigated striatal density for A_1Rs in de-novo PD patients, measured with positron emission tomography (PET) and [7-methyl-^{11}C]-(*E*)-8-(3,4,5-trimethoxystyryl)-1,3,7-trimethylxanthine (^{11}C-MPDX). **Methods:** We studied 10 de-novo PD patients. To confirm early diagnosis of PD, they were also examined for dopamine transporters (DATs) and D_2Rs by PET using ^{11}C-2β-carbomethoxy-3β-(4-fluorophenyl) tropane (^{11}C-CFT) and ^{11}C-raclopride (^{11}C-RAC), respectively. We also recruited 10 elderly healthy volunteers for ^{11}C-MPDX PET and 8 volunteers for ^{11}C-CFT and ^{11}C-RAC PET. A dynamic series of decay-corrected PET scans was performed for 60 minutes starting at the time of the injection of 700 MBq of ^{11}C-MPDX. The values for binding potential (BP_{ND}) in the putamen and head of caudate nucleus were calculated using an averaged tissue time activity curve (tTAC) and the Logan graphical analysis assuming that the k_2 in the cerebellum as a reference region was 0.23 l/min (2). For DATs and D_2Rs, we also calculated the uptake ratio index (*URI* = {uptake in putamen - uptake in cerebellum}/{uptake in cerebellum}) of ^{11}C-CFT PET and ^{11}C-RAC PET. Unpaired *t*-test was used to compare the BP_{ND} of ^{11}C-MPDX and *URI* of ^{11}C-CFT and ^{11}C-RAC PET. The level of significance was set at $p<0.05$. **Results**: There was no significant difference with the BP_{ND} for ^{11}C-MPDX between the patients and the controls, although PET demonstrated decrease of the *URI* of ^{11}C-CFT and increase of the *URI* of ^{11}C-RAC in the patients. In the patient with PD, we observed putaminal asymmetry in the *URIs* of ^{11}C-CFT and ^{11}C-RAC but not the BP_{ND} for [^{11}C]MPDX. **Conclusion**: In the putamen of early PD, D_2Rs are asymmetrically up-regulated and A_{2A}Rs are asymmetrically down-regulated as compensation for the decrease of dopamine (1). However, past studies did not demonstrate such alteration in D_1Rs of PD measured with [^{11}C]SCH23390 PET. Our study also suggested that A_1Rs seemed to be monotonous as well as D_1Rs in the striatum, and that the direct pathway was not involved in early PD. **References**: 1. Title: Overlapping neural correlates of impulsivity and hypomania in Parkinson's disease

Authors: *F. SCHWARTZ[1], M. TAHMASIAN[1,2], K. WILLIAMSON[1], L. ROCHHAUSEN[1], F. MAIER[1], L. TIMMERMANN[1], A. DRZEZGA[2], T. VAN EIMEREN[2], C. EGGERS[1]; [1]Neurol., Univ. Hosp. of Cologne, Koeln, Germany; [2]Nuclear medicine, Univsersity Hosp. of Cologne, Koeln, Germany

Abstract: Impulsive behaviors and hypomania are common non-motor symptoms in Parkinson's disease (PD). Several neuroimaging studies demonstrated particular brain regions being involved in impulsive behavior including the orbitofrontal cortex, anterior cingulate cortex, medial prefrontal cortex and insula. Moreover, other studies revealed brain regions including the anterior cingulate and parahippocampal cortex, as well as inferior frontal gyrus being associated with hypomania. The aim of this study is to find out the regional similarities associated with impulsivity or hypomania in PD. We recruited 24 right-handed, non-demented, not-depressed PD patients and performed two separate multiple regression analyses between FDG-metabolism data and total Barratt Impulsiveness Scale (BIS 11) scores and between FDG-metabolism data and Mania Self-Rating Scale (MSS) scores in SPM8. Subsequently, we compared FDG-metabolism associated with impulsivity and hypomania. Data demonstrated overlapping regions in the middle frontal gyrus, superior frontal gyrus, and supplementary motor area. Our findings provide evidence that impulsivity and hypomania in PD have overlapping neural correlates, suggesting specific brain areas being linked with both of the symptoms.

Title: Impulsivity is associated with increased metabolism of the fronto-insular network in Parkinson's disease

Authors: ***M. TAHMASIAN**[1,2], L. ROCHHAUSEN[1], F. MAIER[1], K. L. WILLIAMSON[1], A. DRZEZGA[2], L. TIMMERMANN[1], T. VAN EIMEREN[2,1], C. EGGERS[1];
[1]Dept. of Neurol., [2]Dept. of Nuclear medicine, Univ. Hosp. of Cologne, Koeln, Germany

Abstract: Neuroimaging studies demonstrated that the fronto-insular network is involved in impulsive behaviors. We aimed to compare glucose metabolism (as proxy of neural activity) among patients with Parkinson's disease (PD), who presented different levels of impulsivity. Twenty-four PD patients were divided into two groups based on their Barratt Impulsiveness Scale 11 (BIS) scores. Subjects underwent 18-Fluorodeoxyglucose positron emission tomography (FDG-PET) and voxel-wise group difference of FDG-metabolism was analyzed in SPM8. Subsequently, we performed partial correlation analysis between the FDG-metabolism and BIS scores, controlling for covariates of no-interest (i.e. age, sex, severity of disease and levodopa equivalent daily doses). Voxel-wise group comparison revealed higher FDG-metabolism in the right orbitofrontal cortex, anterior cingulate cortex, medial prefrontal cortex, and insula in patients with higher impulsivity compared to patients with lower impulsivity. Moreover, patients showed a positive correlation between the FDG-metabolism and BIS scores. Our findings provide evidence that higher impulsivity is associated with increased FDG-metabolism within the fronto-insular network in PD.

Abstract: Accumulation of aggregated α-synuclein in Lewy bodies and Lewy neurites is the pathological hallmark of Parkinson's disease (PD). Accumulation of aggregated α-synuclein in dopaminergic neurons accompanies neuronal degeneration leading to motor symptoms associated with the disease. To date, there is no agent available to image aggregated α-synuclein *in vivo*, which would benefit disease diagnosis and monitoring, patient selection for clinical trial and monitoring efficacy of a potential therapeutic. In this poster, we will describe research funded by the Michael J Fox Foundation (MJFF) towards the development of an imaging agent capable of selectively detecting aggregated α-synuclein in human patients. The development of a radiolabelled screening ligand to enable screening of compounds in PD brain tissue will be presented along with the approach being used to optimise ligands. Compound properties have been optimised relative to successful clinical imaging agents and successful brain uptake will be presented for an example containing a positron emitting isotope. Data showing how radiolabelled compounds detect aggregated human α-synuclein in a transgenic mouse brain model (A30P) will be included.

Title: *In vitro* characterization of a C-11 or H-3 labeled PDE10A radioligand and its potential implementation for progression of Parkinson's disease

Authors: H. LIU, H. JIN, X. YUE, X. ZHANG, J. LI, H. FLORES, Y. SU, J. S. PERLMUTTER, *Z. TU;
Washington Univ., Saint Louis, MO

Abstract: PET imaging has provided a great tool for *in vivo* measurement of impaired striatal dopaminergic function in Parkinson disease (PD). However, the striatal uptake of current presynaptic dopaminergic ligands in the advanced stage of PD shows a flooring effect and is not correlated well with the full severity of motor parkinsonism. Phosphodiesterase 10A (PDE10A), a postsynaptic biomarker, plays a key role in the regulation of brain striatal signaling. PET imaging with a PDE10A radioligand may serve as an alternative measurement of striatal signaling dysfunction in PD. Here, we further characterized the *in vitro* binding properties of a C-11 or H-3 labeled PDE10A radioligand [^{11}C]**TZ1964B or** [^{3}H]**TZ1964B**, and evaluated its potential as a biomarker for PD progression using MPTP nonhuman primate (NHP) model of PD. *In vitro* binding assays in rat striatum homogenates and *in vitro* autoradiographic studies in rat brain slices revealed a nanomolar binding affinity of the tritiated analog [^{3}H]**TZ1964B** to rat striatum (K_d =1.25 ± 0.20 nM). The striatal binding of [^{3}H]**TZ1964B** was blocked by a PDE10A inhibitor MP-10. Both autoradiography and microPET imaging confirmed that the specific binding of the radioligand was found in the striatum (target region) but not in the cerebellum (reference region), with a target-to-reference ratio of 5.50-7.50. In the MPTP-treated NHP, the striatal binding potential (BP_{ND}) of [^{11}C]**TZ1964B** in the infused (right) side was 40-60% lower compared to the contralateral (left) side, while the tracer uptake of [^{11}C]**DTBZ**, a well-known vesicular monoamine transporter 2 radioligand, is invisible, only 5-10% remaining in the lesioned striatum. The data demonstrated [^{3}H]**TZ1964B** has a high binding affinity and good specificity for PDE10A. Moreover, [^{11}C]**TZ1964B** is able to assess the decline of the striatal

PDE10A expression in NHPs following MPTP treatment, suggesting PET measurement of the decrease of PDE10A in striatum may be a more accurate methodology for monitoring progression of PD, especially in the advanced stage.

Title: Early onset Parkinson's disease (EOPD) progression as monitored by hyperechogenicity of the substantia nigra (SN)

Authors: ***S. RAVI**[1], K. VENKITESWARAN[1], V. SHIVKUMAR[1], N. HARID[1], T. GILMOUR[1], C. LIEU[1], R. SAADI[1], D. DANG[1], J.-L. WANG[2], Q. YANG[2], T. SUBRAMANIAN[1];
[1]Neurol. and Neural and Behavioral Sci., [2]Radiology, Pennsylvania State Univ. Col. of Med., Hershey, PA

Abstract: Early Onset Parkinson’s Disease (EOPD) is characterized by disease onset between ages 41-60, have high risk for treatment related complications, and need close monitoring for disease progression. Substantia nigra (SN) hyperechogenicity measured by Transcranial Sonography (TCS) is an established biomarker to differentiate PD from other forms of parkinsonism. We tested the hypothesis that SN hyperechogenicity can be used as a biomarker for disease progression from stage I (unilateral parkinsonism) to stage II (bilateral parkinsonism)

in EOPD patients. A total of 27 EOPD patients who met UK Brain Bank criteria for PD, did not have genetic forms of PD, and were in Stage I disease as determined by the Unified Parkinson's Disease Rating Scale (UPDRS) in the "off" state were offered this prospective single blind study. TCS was performed and evaluated by a blinded rater using a Siemens Acuson Sequoia Ultrasound system (2.5 MHz transducer). Planimetric measurements of SN hyperechogenicity >0.2 cm^2 were classified as significant on each side. Three patients had poor acoustic window, 1 patient dropped out, and 23 patients completed the study. Patients were seen for baseline evaluations (V1), returned for visit 2 (V2) 1 year later and then for visit 3 (V3) 1.5 years post V1, and visit 4 (V4) 2 years post V1. At V1, hyperechogenicity that met >0.2cm^2 area by planimetry was only found on the contralateral SN (N=22) in all but one patient. Side specific UPDRS on the unaffected side was 0 in all enrolled subjects at V1, including the one patient with bilateral SN hyperechogenicity >0.2cm^2. At V1 mean contralateral and ipsilateral SN hyperechogenicity was 0.267 ± 0.046 cm^2 and 0.091 ± 0.079 cm^2 respectively. By V2, 48% of the patients displayed hyperechogenicity above the 0.2cm^2 threshold ipsilaterally. By V4, the mean ipsilateral SN hyperechogenicity was measured to be 0.294 ± 0.062 cm^2. Mean UPDRS score was 12.04 ± 1.022 at V1 and 17.92± 2.142 at V4. Twenty-two percent of the subjects showed an average SN hyperechogenicity progression time to reach threshold ipsilaterally of 603 ± 50 days. Forty-eight percent of the subjects showed an average progression time of 401 ± 100 days. Patients with right-side symptom onset showed an ipsilateral progression rate of 0.000225 ± 7.68E-05 cm^2/day. Patients with left-side symptom onset showed an ipsilateral progression rate of 0.000247 ± 6.04E-05 cm^2/day. In all 22 patients ipsilateral SN hyperechogenicity gradually increased in area to exceed the 0.2 cm^2 threshold prior to developing stage II disease as determined by the UPDRS part III testing, indicating its usefulness as a biomarker for EOPD progression from stage I to stage II.

Title: DNMT3B polymorphisms is associated with Parkinson's disease

Authors: *J. PEZZI[1], C. M. B. ENS[1], M. FIEGENBAUM[1], A. F. SCHUMACHER-SCHUH[2], M. L. F. CHAVES[2], A. L. CAMOZZATO[1];
[1]UFCSPA, Porto Alegre, Brazil; [2]UFRGS, Porto Alegre, Brazil

Abstract: Background: Parkinson's disease (PD) is a neurodegenerative disorder mainly characterized by motor symptoms, such as bradykinesia, rigidity and rest tremor. Epigenetic mechanisms have been implicated in syndromes associated with neurodegenerative disorder, but little is known about the role of epigenetics in PD. DNA methylation, one of the main epigenetic mechanisms, is a complex process carried out by specific enzymes, such as DNMT1 and DNMT3B. This study aimed to investigate the association between DNMT1 and DNMT3B polymorphisms and PD. Methods: Three hundred and twenty-eight subjects [108 healthy controls (HC) and 220 with PD] were assessed. DNA was obtained from whole blood, and genotypes were detected by an allelic discrimination assay using TaqMan® MGB probes on a real-time PCR system. The polymorphisms studied were rs2162560 and rs759920 (DNMT1) and rs998382, rs2424913 and rs2424932 (DNMT3B). Results: For both genes, the polymorphisms were in strong linkage disequilibrium. For two of the polymorphisms investigated, considering the DNMT3B enzyme, the minor allele was associated with Parkinson's disease (rs998382: 31.07% HC vs. 51% PD, OR 2.01, $p<0.001$; rs2424913: 35.04% vs. 50%, OR 1.96, $p<0.046$). No significant difference between PD and the control group were observed for DNMT1 polymorphisms. Conclusions: This study is one of the first describing a significant association between DNMT3B polymorphisms and PD. This enzyme, which is responsible for methylation in a general way, may be involved in PD.

Title: Cholinergic system and mobility: a TMS study to unveil the effect of motor-cognitive combined rehabilitation in Parkinson’s disease

Authors: *L. AVANZINO[1], E. PELOSIN[1], C. OGLIASTRO[1], G. LAGRAVINESE[1], A. RAVASCHIO[1], A. MIRELMAN[2], J. M. HAUSDORFF[2], G. ABBRUZZESE[1];
[1]Univ. of Genoa, Genoa, Italy; [2]Tel-Aviv Med. Ctr., Tel-Aviv, Israel

Abstract: Patients with Parkinson's disease (PD) have a heightened risk of falls and a reduced ability to allocate attention. Deficits in the cholinergic system may contribute to both of these problems. Based on the assumptions that brain plasticity requires both physical and behavioural interventions that are tailored to reorganize specific brain circuits, it has been shown that exercise could enhance neuroplasticity targeting motor and cognitive circuitry. The aim of the present study was to assess the effects of a motor-cognitive combined rehabilitative approach on cholinergic function in patients affected by PD. This study involved 11 PD patients (mean age: 74 ±6) with a history of 2 or more falls recruited for the V-TIME study[1]. Cholinergic activity in the brain was estimated with short latency afferent inhibition (SAI), a TMS technique that assesses an inhibitory circuit in the sensorimotor cortex. SAI was measured by conditioning motor evoked potentials, elicited by TMS of the motor cortex, with electrical stimuli delivered to the median nerve at different inter-stimulus intervals (ISI) ranging around 20 ms. Motor-cognitive combined rehabilitation consisted of a multi-modal treadmill-training program augmented by virtual reality[1]. Participants were trained for 12 weeks, 3 times a week. TMS evaluations were performed at baseline (V1), after 6 weeks of treatment (V2), at the end of the 12 weeks training program (V3) and 1 month after the end of the treatment (V4). At baseline, data collected from the PD population were compared to those collected in 15 age- matched healthy subjects by means of a RM-ANOVA with GROUP and ISI as main factors. The effect of training on SAI in PD was evaluated by means of a RM ANOVA with VISIT and ISI as main factors. Results showed that, at V1, SAI was decreased in PD with respect to healthy subjects ($p<0.05$). The comparison of different doses of training on cortical cholinergic activity showed a significant effect of VISIT ($p=0.042$). SAI was increased already after 6 weeks of treatment and remained increased after 12 weeks training and 1 month after the end of training, with respect to baseline ($p <0.05$). In conclusion, our data showed that PD patients had a weakened SAI, a neurophysiological measure of central cholinergic transmission. Further, a motor-cognitive combined rehabilitation induced measurable changes of short latency afferent inhibition, thus suggesting plastic modifications of cholinergic transmission. Title: Dexmedetoidine modulates neuronal activity in subthalamic nucleus during surgery for Parkinson's disease

Authors: A. RAZ[1], C. A. AMLONG[1], *M. I. BANKS[2], D. A. RUSY[1], K. A. SILLAY[1,3]; [1]Anesthesiol., [2]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI; [3]Semmes-Murphey Neurologic & Spine Inst., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Introduction: Implantation of chronic electrodes for deep brain stimulation (DBS) in the sub-thalamic nucleus (STN) is often performed using micro-electrode recordings (MER). When possible, this is performed purely under local anesthesia to avoid interference of the anesthetic drugs with the MER. However, the absence of sedation may lead to discomfort and anxiety for the patient, which can limit the procedure and occasionally even expose the patient to risk. Previous studies have demonstrated that dexmedetomidine is a useful sedative for these procedures. However, there is limited information regarding its effect on neural activity in the STN and hence its effect on MER quality. We recorded the activity of STN neurons in Parkinson's patients undergoing DBS electrode implantation with dexmedetomidine sedation to evaluate its effect. **Methods:** Following IRB approval, and patient consent, we recorded the activity of electrode trajectories in five patients undergoing bilateral DBS electrode implantation in the STN for the treatment of advanced Parkinson's disease. Following STN identification on the second side electrode advancement was paused. Neuronal activity was recorded at this point while patients were sedated with dexmedetomidine and then allowed to wake up. We compared the root mean square (RMS) and beta band (13-30Hz) oscillation power of the multi-unit electrical activity recorded by the microelectrode before, during and after recovery from sedation. RMS was normalized to values recorded in the white matter. **Results:** We were able to achieve a satisfactory level of sedation (observer's assessment of alertness/sedation of 1-3) with dexmedetomidine during the allocated time in 4/5 patients. MUA during dexmedetomidine sedation was decreased in all patients. Mean normalized RMS dropped from 2.8±1.5 to 1.6±1.1 during sedation (0=0.026 paired ttest). Total power in the beta band did not significantly change (p=0.34 paired ttest). Recovery from dexmedetomidine was slow, and in all patients the normalized RMS values did not reach baseline levels during the time allocated for the study (30 minutes). **Conclusions:** In this small sample, we demonstrated that dexmedetomidine decreased

average neuronal firing in the STN, as expressed in the RMS of the multi-unit activity. As multiunit activity is the major factor in determining the STN borders during MER, it would be prudent to avoid using this drug during this procedure. The slow recovery from this effect does not support the use of dexmedetomidine even during early phases of the procedure.

Title: Deep brain stimulation battery decay of Activa PC neurostimulators; initial clinical data

Authors: *R. P. PATEL[1], R. J. DIPAOLA[2], S. F. DANISH[1], S. WONG[2], E. L. HARGREAVES[1];
[1]Div. of Neurosurg., [2]Neurol., Robert Wood Johnson Med. School, Rutgers Univ., New Brunswick, NJ

Abstract: Deep Brain Stimulation (DBS) is an established adjunct neurosurgical treatment for movement disorders. At the heart of the DBS system is the neuromodulation device. Medtronic's most recent Activa (PC) neurostimulator is purported to have a 2-5 year battery life. We have followed 27 Parkinson's patients implanted from January 2010 to December 2011, targeting the STN and powered by Activa PCs. Presently, more than half (14/27) have had their neurostimulators exchanged, while another ten (10/27) still retain their initial neurostimulator. The remaining (3/27) were lost to follow up. Thus, we have continuously tracked data from (20/27) implanted individuals, and the start and end data from an additional (4/27). Battery start values ranged from 3.08V to 3.17V with a mean value of 3.14V (sem .0039). Battery end values ranged from 2.22 (EOS) to 2.60V with a single outlier at 2.69V (performed prematurely due to incarceration status) with a mean value of 2.55V (sem .03). Battery life durations of those that crossed the ERI 2.60V value ranged from 2.12 years to 4.47 years with a mean value of 3.58years (sem .17). Of the neurostimulators that continue to perform, the present durations range from 3.47years to 4.18years with a mean value of 3.73years (sem .10). Examination of the plotted battery charge decay curves suggests a cubic spline best fit with an initial concave up followed by a concave down. The first upward concavity is characterized by a rapid decline from the respective start values to a leveling off value ranging from 2.95V to 3.0V occurring by the

end of the initial six months. The level plane occurs between the battery charge values of 2.95V to 2.88V, lasting from 6 months to 3.5 years dependent upon programmed neurostimulator parameters. The second downward concavity declines more rapidly as the battery runs down with durations of approximately a year. The initial upward concavity was fairly homogenous across curves, while the downward concavity was fairly heterogeneous fanning out to cross the 2.60V ERI threshold at different durations, dependent upon programmed neurostimulator parameters.

Title: Effects of gm1 ganglioside administration on cognitive, motor, and sensorimotor functions in Parkinson's disease patients

Authors: *J. S. SCHNEIDER[1], C. YANG[2];
[1]Dept Pathol, Anat. & Cell Biol, Thomas Jefferson Univ., Philadelphia, PA; [2]Publ. Hlth. Sci., Pennsylvania State Univ., Hershey, PA

Abstract: A single center, double-blind, delayed start study was conducted to examine symptomatic and disease-modifying effects of GM1 ganglioside in Parkinson's disease (PD). Seventy-seven subjects with PD were randomly assigned to receive GM1 for 2.5 years (early-start) or placebo for 6 months followed by GM1 for 2 years (delayed-start). Seventeen matched PD subjects received only standard-of-care and were followed to obtain comparative information about disease progression. The primary outcome measure was change from baseline of the Unified Parkinson's Disease Rating Scale (UPDRS) motor scores. At 6 months, the early-start group had statistically significant improvement in UPDRS motor scores vs. a significant worsening of scores in the delayed-start group. The early-start group also showed a sustained benefit vs. the delayed-start group at the end of the study period. These results suggested that GM1 may have symptomatic and potentially disease modifying effects on PD. We now present secondary outcome data from this study that show additional effects of GM1 treatment on motor

and non-motor symptoms in PD patients. Subjects performed a number of cognitive tests (e.g., tests of auditory attention, verbal fluency, executive function, visuospatial learning and memory) and objective motor and sensorimotor integration tests (e.g. finger tapping, pronation/supination, sensorimotor tracking task) at baseline and at various time points during the course of the 2.5 year study. In support of data obtained with UPDRS ratings, early-start subjects showed significant early improvements in a number of motor function measures, compared to delayed-start and comparison subjects and maintained improvements throughout the study period. Delayed-start subjects improved after switching from placebo to GM1. Subjects receiving GM1 also showed improvements in some cognitive functions (e.g., visuospatial learning, verbal fluency) over time compared to the standard-of-care comparison subjects. These data provide further support for the use of GM1 ganglioside as a potential treatment for PD.

Title: Computational modeling of stimulation-evoked dopamine release recorded with fast scan cyclic voltammetry

Authors: *J. TREVATHAN[1], J. L. LUJAN[2], K. H. LEE[2];
[2]Neurologic Surgery, [1]Mayo Clin., Rochester, MN

Abstract: Background Maximizing long-term efficacy of deep brain stimulation (DBS), a surgical therapy for movement and psychiatric disorders, requires frequent adjustment of stimulation parameters to compensate for the dynamic and progressive nature of such disorders.

Recent animal studies suggest that therapeutic DBS is associated with specific changes in neurotransmitter concentration measurable by electrochemical techniques. Thus, neurochemical monitoring coupled with feedback control of stimulation is a promising mechanism for optimizing the balance between symptom reduction and stimulation-induced side effects during DBS. The objective of work was to characterize the non-linear and time-varying dynamics of electrical stimulation evoked neurotransmitter release across various animal models and thus provide an important step towards closed-loop control of DBS based on neurochemical feedback. **Methods** In a cohort of Sprague-Dawley rats the medial forebrain bundle was electrically stimulated while fast scan cyclic voltammetry was used to record evoked dopamine (DA) release in the caudate. In both a cohort of swine and a single non-human primate the substantia nigra pars compacta / ventrotegmental area was stimulated while DA release was recorded within the anterior caudate. The kinetics of single-pulse stimulation-evoked DA release was mathematically modeled and a least-squares fit used to extract unique features of release. These features were used to train artificial neural networks (ANN) to model the relationship between stimulation parameters and DA release. Model validation was performed by calculating the Pearson's correlation between predicted model responses and a set of stimulation-evoked responses not used for model training. **Results** The mathematical models of DA release kinetics were able to fit the stimulation-evoked releases recorded in rats, swine, and a non-human primate. The ANNs trained on features of the kinetic model were able to characterize the relationship between stimulation parameters and DA release. **Conclusions** In both small and large animal models the non-linear and time-varying dynamics of DA release can be mathematically described. Development of these models describing stimulation-evoked neurochemical release is an important step towards understanding neurotransmitter release in the context of DBS as well as developing novel stimulation paradigms and closed-loop DBS systems that improve therapeutic efficacy. **Funding** This work was supported by the National Institutes of Health NINDS (R01NS084975 award to JLL, and R01 NS 75013, R01 NS 70872, K08 NS 52232 awards to KHL), and The Grainger Foundation.

Title: Towards the implementation of a novel DBS electrode for targeted neural activation

Authors: *D. V. NESTEROVICH, A. WILLSIE, C. BUTSON, A. DORVAL;
Univ. of Utah, Salt Lake City, UT

Abstract: We have developed a novel electrode lead design for deep brain stimulation (DBS), a surgical intervention for several neurological disorders including Parkinson's Disease (PD). Our design, the micro DBS (μDBS), has 1760 electrode contacts, each with stimulation and recording capabilities. The organization of the contacts allows control over the size, shape, and direction of the induced electric field to fit the target area of stimulation without stimulating nearby tissue. The plus-shaped cross-section of the μDBS results in an 80% reduction in volume compared to existing clinical DBS electrodes, which decreases damage to the brain during lead placement. Despite these advantages, it is far easier to program manually the 4 contacts on conventional DBS leads than to determine optimal stimulation parameters for 1760 contacts. For the μDBS to gain acceptance, determination of parameter settings must be automated. Given an anatomical target area of stimulation, we seek an optimization method that will determine the most appropriate active contacts to generate neural activation within the target. To ensure the optimal treatment through the novel electrode in a patient-specific manner, the target area must be precisely defined within each patient. A 3D rendering of the subcortical target area will be derived from patient MRI data. Electric fields will be modeled through a finite element model of the μDBS with tissue conductivities derived from diffusion tensor imaging (DTI). The model will be created in SCIRun, a computational modeling package developed by the SCI Institute, and be used to calculate the volume of tissue activated for various contact configurations. We will use the Hessian matrix of second spatial partial derivatives, generated from an ideal scenario of target activation and manipulated through Newtonian optimization methods, to converge upon optimal contact configurations. This iterative algorithm will maximize percentage of target stimulated while minimizing stimulation outside the target. Combining this optimization process with the novel electrode may improve treatment for PD and enable symptom alleviation for a wide range of neurological conditions not presently treated with DBS.

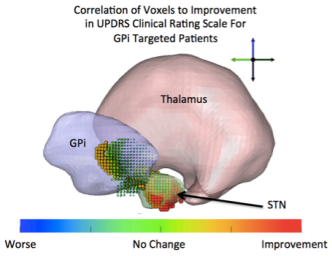
Title: Identification of Deep Brain Stimulation targets from a cohort of Parkinson's disease patients

Authors: *G. DUFFLEY[1,2], D. CHEN[3], K. FOOTE[4,6], M. OKUN[5,6], C. R. BUTSON[1,2]; [1]Bioengineering, Univ. of Utah, Salt Lake City, UT; [2]Scientific Computing and Imaging (SCI) Inst., Salt Lake City, UT; [4]Neurosurg., [5]Neurol., [3]Univ. of Florida, Gainesville, FL; [6]Ctr. for Movement Disorders and Neurorestoration, Gainesville, FL

Abstract: Introduction: Deep Brain Stimulation (DBS) is an established treatment for Parkinson's Disease (PD). Our goal in this study is to identify stimulation target(s) across a cohort of PD patients with DBS leads implanted in the subthalamic nucleus (STN) or internal segment of the globus pallidus (GPi). Materials and Methods: Our cohort consisted of 52 PD patients who received unilateral DBS, 23 in GPi and 29 in STN. Clinical improvement was measured as the difference in Unified Parkinson's Disease Rating Scale (UPDRS) scores from pre-surgical baseline to 4 months after surgery. We used a previously published computational approach to predict the effects of DBS in each patient and build a probabilistic atlas of regions associated with therapeutic effects. All voxels included in analysis were stimulated in at least three patients. Results and Discussion: We observed variability in lead location among subjects in this cohort. The standard deviation in lead locations for STN DBS were: 1.568 mm along the medial-lateral axis; 2.103 mm along the anterior posterior axis; 2.046 mm along the dorsal-ventral axis. In turn, this resulted in differential activation of subregions around the surgical targets (STN and GPi). Among STN patients we observed regions where stimulation was associated with a mean improvement of 7.67 points on total UPDRS (total range of scores ranged from -6.33 to 24.33). Interestingly, we observed that the GPi patients with the best outcomes were those who were also stimulated in the STN (Figure 1). Conclusions: Our results combine computational models and clinical outcomes across a cohort of PD patients to identify regions where stimulation is correlated with improvement or worsening as measured using UPDRS. These results provide predictions of outcomes that can be prospectively tested in future patients. References: Butson, C. R., Cooper, S. E., Henderson, J. M., Wolgamuth, B., & McIntyre, C. C. (2011). Probabilistic Analysis of Activation Volumes Generated During Deep Brain Stimulation. NeuroImage, 54, 2096-2104.



Correlation of Voxels stimulated with change in UPDRS rating score: The high end of the color bar indicates a change of +12 in the UPDRS score at 4 months over baseline. The low end of the color bar indicates a change of -12, which indicates the patient actually performed worse. On average, the GPi targeted patients had a mean in change in score of -.10, and a standard deviation of 5.80.

Title: Activity based interventions for individuals with Parkinson’s disease: An occupationally focused systematic review

Authors: *K. A. PICKETT, R. N. MASSART, K. J. LATHROP, A. MALSCH, S. E. GOLOFF;
Univ. of Wisconsin - Madison, Madison, WI

Abstract: Parkinson disease (PD) is a chronic neurodegenerative disease characterized by both motor and non-motor dysfunction. Along with the well known motor symptoms of tremor, bradykinesia, rigidity, and postural instability, depression, sleep disruption, cognitive changes, digestive system problems and falls are also prevalent. Exercise of both the group and individual types have been repeatedly shown to positively affect some of these symptoms; however, the exercise approaches, research designs and quality of results has varied greatly across studies. From the clinical perspective, discerning which avenues of intervention are best suited for this population is vitally important. To this end, four areas of interest were isolated from the PD exercise literature: falls, social engagement, depression, and activities of daily living. Methods. Using these topic areas, four systematic reviews were conducted using the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines to search peer-reviewed literature using key search terms relevant to each content area. All searches excluded case studies and single subject designs. Results. Papers that met the inclusion criteria were isolated for each topic area: falls (n = 10), social engagement (n = 9), depression (n = 10), and activities of daily living (n = 7). Multiple types of interventions were shown to positively affect patient well-being. Additionally, several pharmacological interventions reported side effects, which may have reduced the treatment effect. Discussion. Findings indicate that while there is a plethora of research in this general area, many of the studies have been under powered, did not properly match groups or failed to properly control for systematic biases. The current body of literature reveals several areas of need for research. Additionally, it is clear from the summed collection of studies that rehabilitation therapists (Occupational and Physical Therapists) have a broad set of methodologies to consider as possible avenues for intervention. Future clinical intervention designs should strive to create change for individuals with PD by implementing interventions which are meaningful and effective for the individual.

Disorders, Shizuoka, Japan; [7]Central Res. Lab., Hamamatsu Photonics K.K., Hamamatsu, Japan

Abstract: *Introduction:* Previous animal studies have indicated that a new anti-PD drug Zonisamide (ZNS) may have a neuroprotective effect on neuroinflammatory process occurring in Parkinson's disease (PD). To evaluate this ZNS neuroprotective effect in humans, we examined changes in microglial activation prior to and after ZNS treatment in early-stage PD patients using [^{11}C]-DPA713 PET. *Methods:* Eleven PD patients (mean age 68.1±7.1) at Hoehn and Yahr (HY) stage 1~2 without dementia (Mini-Mental State Examination>23) or depression (normal Self rating Depression Scale) and age-matched controls underwent [^{11}C]-DPA713-PET measurements. We divided PD patients into two groups: PD with ZNS and PD without ZNS. All patients were followed-up and the second PET scan was performed one year later. The binding potential (BP_{ND}) was estimated using simplified reference tissue model. Statistical Parametric Mapping was used to compare regional BP_{ND} levels between the PD and control groups. To examine the ZNS effect on BP_{ND}, we compared the BP_{ND} increase between PD with and without ZNS groups using regions of interest analysis. *Results:* Significant increases of [^{11}C]-DPA713 BP_{ND} were found at the somatosensory parietal cortex in the HY stage 1 PD group and over the extensive brain regions in the HY stage 2 PD group. [11C]-DPA713 BP_{ND} at the second PET scan in the PD without ZNS group was significantly increased in the amygdala, anterior cingulate cortex, caudate, putamen, thalamus, posterior cingulate cortex, superior and middle frontal cortex, and parietal cortex, although PD with ZNS group did not show significant differences. *Conclusion:* These results indicated that microglial activation proceeds unilaterally as parkinsonism worsens during the early stage (HY 1 to 2) in PD. During this stage, ZNS treatment might be effective in reducing the neuroinflammation in PD.

Title: Can individuals with Parkinson's disease perceive complex auditory cues to correct movement?

Authors: ***T. PINKHASOV**[1], E. VASUDEVAN[2], M. SCHEDEL[3], D. WEYMOUTH[3], J. LOOMIS[3], L. MURATORI[4];
[1]Stony Brook Univ., Albertson, NY; [2]Hlth. and Rehabil. Sci., [3]Consortium for Digital Arts Culture and Technol., [4]Physical Therapy, Stony Brook Univ., Stony Brook, NY

Abstract: Gait disturbances are a characteristic feature of Parkinson's disease (PD) and are some of the most debilitating aspects of the illness. Current pharmacological treatments are ineffective at improving gait, but therapies that utilize different modalities to provide external cues to initiate and maintain movement have shown promise. Auditory cues in particular have been successful at improving gait speed and step variables. Recently this work has extended into the use of music as a cue for the rhythmical components of gait. A recent area of investigation in our

lab is the creation of personalized prolonged musical cues to correct gait deviations and prevent freezing and falls in persons with PD. The goal of the present study is to investigate the ability of individuals with PD to perceive auditory distortions and correct those distortions imbedded in different musical pieces. Data collection includes data from twenty individuals with PD and twenty healthy, age-matched peers. Participants listen to three pieces of music from three different genres (classical, rock, jazz) until they feel they are familiar with the music. Using a specifically developed iPad application, three different distortions are separately superimposed on each song creating nine possible combinations of sounds (i.e., song 1-3 x distortion 1-3). Participants listen to each of these in a random order for three trials for a total of 27 experimental trials. Participants manipulate a slide bar, the range of which corresponds to a randomly generated distortion "curve" with varying amounts of distortion but only one point of zero distortion. Participants are told they can take as much time as necessary to find that point of no distortion on each trial. The error between the level of distortion recorded and true zero is recorded. Our results show that individuals with PD have greater error than healthy individuals when correcting sound distortions ($p<0.01$ collapsed across conditions) but all participants were able to calibrate the songs to a very low level of distortion. In addition, there was an effect of song and distortion such that error correction was differentially effected by type of song and/or distortion for both healthy and persons with PD. The results suggest that music distortion can be used as a means of providing information about movement errors to people with PD. However, the type of music and distortion will impact the ability to optimize performance.

Minneapolis, MN; [3]US Naval Hosp., Okinawa, Japan; [4]Neurol., [5]Univ. of Florida, Gainesville, FL

Abstract: The growing accessibility of deep brain stimulation (DBS) for movement disorders has made optimization of the technology a necessary next step. Traditional DBS pulses are rectangular-shaped with a passive recharge and the pulses can be delivered at a selected frequency, amplitude and duration (pulse width). We sought to assess the tolerability, effectiveness and efficiency of non-conventional DBS settings in Parkinson's disease (PD) and essential tremor (ET) patients. A randomized and blinded pilot study was performed using clinical rating assessments (Unified Parkinson's Disease Rating Scale, Tremor Rating Scale) and quantitative measures of motor function (accelerometer for tremor and bradykinesia, Peg board test, Timed Up-and-Go test, and GaitRite walking assessment). The study was a comparison of DBS subjects in the clinically optimized stimulation settings versus several non-conventional DBS settings, including: a biphasic pulse tested at and 30% below the clinical voltage; the traditional pulse at an irregular frequency with a coefficient of variance of 20%, tested at and 30% below the clinical voltage; 50% lower pulse width, tested at and 50% higher than the clinical voltage. Energy-consumption of all non-conventional settings was calculated and compared. Eleven subjects (8 PD and 3 ET) were tested and had a mean age of 62 years (range 47 to 75 years) and the mean disease duration for PD subjects was 11 years (range 8-18 years) and for ET subjects was 20 years (range 6-40 years). STN (n=7) was the most common target, followed by VIM (n=3), then GPi (n=1). Comparison with DBS-off and clinically optimized settings revealed that most non-conventional settings were effective, with one setting clearly eclipsing clinical settings over the optimized clinic setting (square biphasic pulse). The novel biphasic waveform setting captured tremor which had been under incomplete control in some subjects. Energy-consumption of the non-conventional settings was variable. This randomized, blinded pilot study investigated the effectiveness and efficiency of non-conventional settings utilizing clinical rating scales and quantitative measures in a clinic outpatient environment. Many of these settings were well-tolerated effective and efficient in PD and ET subjects. The biphasic waveform has potential clinical utility to provide symptom-specific relief in select patients who do not respond maximally to the commercially-available settings. The adoption of these non-conventional settings into clinical practice and the potential for updating the firmware on an already-implanted DBS device are appealing practice solutions and require further exploration.

Title: Serotonin 5HT2A receptors in patient with Parkinson's disease with visual hallucinations

Authors: *S. CHO[1,2], A. STRAFELLA[1,2], M. CRIAUD[1], C. LI[1], M. ZUROWSKI[3], S. DUFF-CANNING[2], A.-C. VIJVERMAN[2], V. BRUNO[2], C. AQUINO[2], P. RUSJAN[1], S. HOULE[1], S. FOX[2];
[1]Ctr. For Addiction and Mental Hlth., Toronto, ON, Canada; [2]Toronto Western Res. Inst. and Hosp., Toronto, ON, Canada; [3]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Visual hallucinations (VH) are common in Parkinson's patients (PD) and are one of the strongest predictors of cognitive decline in PD. Central 5-HT system may have significant implication for understanding VH and cognitive/behavioral changes in PD with VH. The aim of this study was to investigate the association of the cognitive/behavioral changes of those PD patients who developed VH with the serotonergic system using PET measurement of cortical bindings of [18F]setoperone, a high-affinity antagonist of the 5-HT2A receptors. In total, 19 PD patients (8 PD without VH and 11 PD with VH) underwent PET scan. Individual binding potential (BP) map was calculated using the simplified reference tissue model using the cerebellum as a reference after the frame-based motion correction in each participants. Image preprocessing and statistical analysis were conducted with SPM 8. No statistically significant differences were found for clinical features except hallucination-subscore ($F= 20.5$, $P < 0.001$). In patients with VH, there was significant negative correlation between hallucination subcore and total MoCA score ($r = -0.61$, $P < 0.05$), indicating that higher level of hallucinations is directly related with lowered level of overall cognitive function in this patients group. We did not find any significant correlation between level of hallucination and BDI ($r = -0.01$, $P = 0.97$). Comparison between PD with and without VH disclosed several brain regions with BP differences in [18F]setoperone. VH group appears to be reliant on decreased BP in the right insula, bilateral dorsolateral prefrontal cortex, right orbitofrontal cortex, right middle temporal gyrus and right fusiform gyrus, thus suggesting significant abnormalities in 5-HT2A receptor

binding in these patients. In summary, in PD patients with VH, 5-HT2A receptor availability seemed to be affected in associative regions in the prefrontal and temporal cortex, thus possibly suggesting an abnormal functioning of those regions associated with cognitive and visual processing.

Title: The use of WINCS and Diamond electrode to perform wireless neurotransmitter monitoring in a patient with Parkinson's disease

Authors: *M. A. BABU[1], S. PAEK[2], P. MIN[2], C. BLAHA[2], J. TOMSHINE[2], M. MARSH[2], D. JANG[3], S.-Y. CHANG[2], K. BENNET[2], K. LEE[2];

Abstract: Introduction: Prior work demonstrated that neurochemical monitoring can be performed during deep brain stimulation (DBS) using carbon fiber microelectrodes (CFM) and the Mayo-developed Wireless Instantaneous Neurotransmitter Concentration Sensing (WINCS) system. However, CFMs lack the durability to provide long-term neurochemical recording. Here, we demonstrate use of WINCS and diamond electrode-based electrochemical recording in Parkinson's disease patients. Methods: Mayo Clinic IRB approval was obtained for these studies.

Parkinson's disease patients were evaluated and approved for DBS neurosurgery by the Mayo Clinic DBS Committee. WINCS recordings were obtained during frame-based stereotactic DBS neurosurgery for Parkinson's disease. Diamond-coated microelectrodes were placed 2 mm anterior to the trajectory of the DBS electrode, which was placed in the subthalamic nucleus (STN). PPV was applied at 5 Hz (200 ms between two binary pulse sweeps), 400 V/s sweep rate, with respect to a reference electrode, from -0.4 V to 1.5 V back to -0.4 V. Results: Utilizing the novel diamond microelectrode, we were able to perform intra-operative neurochemical recordings. Oxidation peaks that were consistent with adenosine were observed when the electrode was implanted, advanced, removed, and when the DBS lead was advanced. Interestingly, tremor activity monitored by wireless accelerometer was abolished during lead insertion and was associated with putative adenosine release. No complications in the patient were observed intra-operatively or post-operatively. Conclusion: Diamond-coated microelectrodes in conjunction with WINCS can provide unique neurochemical information at the site of DBS lead placement. These novel technologies may facilitate our understanding of neurochemistry's role in brain function as well as help to elucidate the mechanism of DBS action. Acknowledgement: This work was supported by the National Institutes of Health NINDS (R01 NS 75013, R01 NS 70872, U), and The Grainger Foundation.

Abstract: Introduction: Parkinson´s disease (PD) is characterized by the impairment and death of dopaminergic neurons (DAn) in the Substantia Nigra pars compacta (SNpc), however there are symptoms of the disease other than those derived from events in the brain that do not receive as much attention. There is evidence that early signs of PD may occur in the gastrointestinal tract up to 20 years before motor symptoms become apparent.In this study, we sought to characterize the gastrointestinal symptoms in the colon and examine inflammation in the cervical lymph nodes in MPTP-lesioned mice, with and without human dopaminergic transplants. Methods: Adult C57BL/6 mice were injected i.p. with MPTP.One week later, they received a transplant of human ventral mesencephalic hVM1 clone 32 (human neural stem cells, hNSCs), or buffer, in the striatum and from this point on they were given immunosuppressant treatment. Four months post-transplantation, tissue samples were collected, and processed for immunohistochemical studies and/or used for protein extraction. Results: DAn degeneration was observed upon treatment with MPTP along with TH+ cell loss in the SNpc by immunohistochemistry, and behavioral anomalies; both of these factors were alleviated by hNSCs transplant. Non-CNS, cervical lymph nodes and colon, histological samples were studied.In the former, there was an increase in size in MPTP-treated mice as well as an augmentation in mast cell density compared to buffer-treated mice; these were potentiated in stem cell-treated mice.In colon protein studies, β-III-tubulin expression decreased in mice treated with MPTP and in hVM1 cell-transplanted mice, there was a prevention of further degeneration. COX-2 and NFkB expression increased in all stem cell-treated mice compared to naïve animals, demonstrating an activation of inflammatory pathways. Conclusions: Cell replacement therapy is focused on brain neurodegeneration and amelioration of central neurological symptoms while little focus is put on peripheral symptoms including those stemming from the enteric nervous system. Our study shows that the MPTP model leads to DAn degeneration accompanied by behavioral deficits and other alterations that occur outside of the CNS which could possibly be related to the prodromal symptoms of PD. Among these, an increase in lymph node area and mast cell density, and colonic inflammation. Stem cell transplants alleviated DAn loss, but possibly also contributed to a larger lymph node size and mast cell content,in addition to modulating colonic inflammation. For translational purposes and potential early diagnosis, events other than those of brain pathology need to be taken into account

Abstract: From previous functional magnetic resonance imaging (MRI) studies in Parkinson's disease (PD) we know that the motor-related activity of the posterior putamen (pPUT) is reduced compared to that of healthy controls. Recently, diffusion MRI studies of the posterior substantia nigra (pSN) revealed increased free water levels in PD. Moreover, we know that the selective monoamine oxidase type B (MAO-B) inhibitor rasagiline provides a good control of parkinsonian symptoms, and is considered a promising disease-modifying drug candidate for PD. Here, we sought to determine the extent to which functional and structural integrity of the nigrostriatal circuit differed between PD patients already receiving rasagiline as part of their treatment regimen (n = 16) and patients treated with other antiparkinsonian drugs (n = 18). We had PD patients and a group of age-matched controls (n = 18) perform a well-established precision grip task in the MRI scanner, and we collected additional clinical and diffusion MRI measures. Importantly, the two PD groups had similar disease duration and disease severity and all tests were performed after 14-hour withdrawal from medications. As rasagiline is known to act upon dopamine metabolism, our main hypothesis was that PD on rasagiline will have a higher blood-oxygen-level dependent (BOLD) fMRI signal in the pPUT and reduced levels of free water in the pSN as compared to PD on other drugs. Current results: 1) confirm previous studies, and show a reduction in putaminal activity and increase in nigral free water in both PD groups as compared to controls; 2) add to the existing literature by showing that nigral free water predicts putaminal activity in PD, and clinical measures such as bimanual coordination; 3) and show that the rasagiline group have significantly higher BOLD signal in the pPUT and lower free water levels in the pSN than PD on other drugs. Together, these preliminary findings provide the first neuroanatomical evidence to support the proposed disease-modifying effects of rasagiline in PD, and open new avenues for the inclusion of functional and diffusion MRI measures in prospective, placebo-controlled studies establishing its long-term neuroprotective properties.

Abstract: Myoclonus dystonia (MD, DYT11) is a severe, childhood-onset neurological disease characterized by myoclonic jerks and dystonia, often accompanied by comorbid psychological conditions or epilepsy. DYT11 is an autosomal dominant MD form, caused by paternally inherited loss-of-function mutations in the maternally imprinted *SGCE* gene, whose protein product (eScg) is widely expressed in cerebral cortex, basal ganglia and hippocampal neurons. No gross structural defects have been found in affected patients, and, indeed, the pathophysiology is still largely unknown. By using electrophysiological approaches, we investigated intrinsic synaptic properties of striatal neurons in a DYT11 dystonia mouse model. We found no significant changes in the intrinsic synaptic properties of either striatal medium spiny GABAergic neurons (MSNs) or cholinergic interneurons (ChIs) recorded from Sgce+/- mice, compared to control Sgce+/+ mice. Recent findings suggest a role of *SGCE* in the regulation of dopamine D2 receptor (D2R) expression. Therefore, we explored the responses to D2R activation in striatal cholinergic interneurons. D2R activation by quinpirole resulted in a physiological reduction of spontaneous tonic firing activity in both genotypes. Dopamine modulates striatal plasticity. Thus, we also investigated the expression of short and long-term synaptic plasticity in the striatum of both Sgce+/- and Sgce+/+ mice. While short-term synaptic

plasticity was unaffected, Sgce+/- mice exhibited a significant impairment of corticostriatal long-term depression (LTD), compared to wild-type littermates. These experimental data provide evidence in support of an impairment of dopamine transmission in Sgce+/- mice. Further investigation is required to clarify the synaptic mechanisms underlying such impairment.

Title: PRRT2 deficiency causes paroxysmal dystonia in mice

Authors: ***M. S. LEDOUX**, J. XIAO, Y. XUE, E. M. MARQUEZ-LONA, S. R. VEMULA; Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: *PRRT2* loss-of-function mutations have been associated with familial paroxysmal kinesigenic dyskinesia (PKD), infantile convulsions and choreoathetosis, benign familial infantile seizures, hemiplegic migraine, and episodic ataxia. Dystonia is the foremost involuntary movement manifest by patients with PKD. At present, there is no unanimity on the neuroanatomical substrates of dystonia and several other paroxysmal disorders of the CNS. *Prrt2*$^{fl/fl}$ mice were generated with KOMP-CSD knockout first, promoter driven, targeted ES cells which harbor a lacZ-loxP-neo cassette. X-Gal staining was used to define the temporal and spatial distribution of *Prrt2* expression. The lacZ-loxP-neo cassette was removed via crossing to Flp deleter mice and *Prrt2* simple KO mice were subsequently generated via crosses with Cre deleter mice. Mice were examined with blinded assessments of open-field behavior and a battery of sensorimotor tests. QRT-PCR showed that *Prrt2* is neuronally-restricted. In brain, the highest levels of *Prrt2* expression were noted in cerebellum, with significantly lower expression in cerebral cortex and striatum. Expression was reduced by 50% in *Prrt2*$^{+/-}$ mice and completely absent in *Prrt2*$^{-/-}$ mice. QRT-PCR was corroborated with Western blots using brain and liver tissue. Overall, X-Gal staining showed that *Prrt2* expression was minimal in cerebral cortex and

striatum at all developmental time points. The highest expression levels were seen in cerebellar cortex (granule cells), cerebellar nuclei, thalamus, and piriform cortex with moderate expression in hippocampus and brainstem. The majority of *Prrt2*$^{+/-}$ mice and all of the *Prrt2*$^{-/-}$ mice have exhibited behavioral arrests and semi-rhythmic seizure-like truncal movements by P7 that peaked at P11 to P13. By P10, *Prrt2*$^{-/-}$ and *Prrt2*$^{+/-}$ mice manifest overt PKD, mainly dystonic, with variable involvement of the trunk and limbs. All of the witnessed episodes have lasted less than 2 min and are quite similar to human PKD in terms of clinical features. The majority of paroxysmal events (seizures, dyskinesias, dystonia, and other) seen in *Prrt2*$^{-/-}$ and *Prrt2*$^{+/-}$ mice resolve by P20. In comparison to WT littermates, *Prrt2*$^{-/-}$ mice show reduced open-field activity prior to P14 and increased open-field activity after P16. The PKD model that we have generated has strong etiologic and face validity. The distinctive *Prrt2* expression patterns in mouse brain and our *Prrt2* mouse model with conditional potential provide a powerful platform for understanding the neuroanatomical framework of dystonia, paroxysmal dyskinesias, epilepsy and other paroxysmal disorders of the CNS.

Title: Cholinergic function in mouse models of DYT-TOR1A dystonia

Authors: *K. L. ESKOW JAUNARAJS, C. N. THOMPSON, D. G. STANDAERT;
Dept of Neurology, CNET, Univ. of Alabama-Birmingham, Birmingham, AL

Abstract: Cholinergic function in mouse models of DYT1 dystonia. Karen L Eskow Jaunarajs, Chelsea N Thompson, and David Standaert DYT1 dystonia is a hyperkinetic movement disorder that is due to a ΔGAG mutation in the gene *TOR1A*, encoding the protein torsinA. Several lines of evidence suggest that striatal cholinergic interneuron activity may be enhanced in DYT1

dystonia. Clinically, anticholinergic drugs are the most effective pharmacological treatments available for DYT1 and other types of dystonia. In animal models of DYT1 dystonia, electrophysiological recording of cholinergic interneurons indicates paradoxical excitation in the presence of D2 receptor agonists. To date, acetylcholine levels have not been measured *in vivo*. We used a DYT1 ΔGAG knock-in mouse model (DYT1 KI) to investigate whether a hypercholinergic striatal state exists using *in vivo* microdialysis. In a between-subjects design, male wild-type and DYT1 KI mice were implanted with striatal microdialysis probes and perfused with artificial cerebrospinal fluid containing 0, 10, 100 and 500 nM neostigmine in an escalating-dose paradigm. Samples were collected and analyzed for extracellular acetylcholine. Results showed that DYT1 KI mice had 10-fold higher baseline levels of striatal acetylcholine compared to littermate controls. Responses to neostigmine at each dose trended higher in DYT1 KI mice. Ongoing studies in mice with acetylcholine cell-specific knockout of the *dyt1* gene (Ch-DYT1-KO) will enable us to determine whether hypercholinergic activity is due to cell-autonomous torsinA dysfunction in cholinergic cells. Further investigation of cholinergic activity in these models is necessary in order to elucidate the precise mechanisms and consequences of elevated striatal acetylcholine activity in mice with mutations in the gene encoding for torsinA.

Title: Gene expression profiling in CIZ1-deficient mouse cerebellum

Authors: *S. R. VEMULA, J. XIAO, M. S. LEDOUX;
Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: A missense mutation in *CIZ1* (c.790A>G, p.S264G) was linked to autosomal dominant cervical dystonia in a large multiplex Caucasian pedigree (OMIM- 614860, DYT23).

CIZ1 is a p21 (Cip1/Waf1)-interacting zinc finger protein, robustly expressed in brain, and plays a role in DNA synthesis at the G1/S cell-cycle checkpoint. A *Ciz1* gene trap KO mouse model (intron 1) was generated to examine the functional role(s) of CIZ1 in terminally-differentiated neurons and contributions of CIZ1 to DNA repair in the mammalian brain. Total RNA from mouse cerebellum was harvested from 8 adult *Ciz1*$^{-/-}$ mice and 8 age- and gender- matched WT controls. *Ciz1* expression was virtually absent in KO mice. Whole-genome gene expression data derived from the MouseWG-6 v2.0 Expression BeadChip (Illumina) was analyzed with GeneSpring^{TM}. The *t*-test statistic was used to identify significantly dysregulated genes. Ingenuity Pathway Analysis (IPA) was used to model differentially regulated molecular/cellular networks. Genes involved in cell morphology, cellular function and maintenance, cell death and survival, cell signaling, and cell cycle were up-regulated (≥ 1.5X). *Erdr1*, erythroid differentiation factor 1, which plays a role as a pro-apoptotic factor and acts via the ERK pathway, showed the highest up-regulation (1.93X, p = 9.64E-04). The top up-regulated network is involved in the inflammatory response, cellular growth and proliferation, and cell-to-cell signaling and interaction. Down-regulated genes (≥ 1.0X) are involved in cellular development, cell cycle, cellular growth and proliferation, gene expression, and cellular movement. Similarly, down-regulated networks include those related to cell-to-cell signaling and interaction, inflammatory response, cell cycle and cell-mediated immune response. Enriched KEGG pathways for up-regulated genes include olfactory transduction, metabolic pathways, regulation of action cytoskeleton, and ECM-receptor interaction. Enriched KEGG pathways for down-regulated genes include metabolic pathways, Wnt signaling, and calcium signaling. In aggregate, these data are compatible with the following: (1) CIZ1 plays a role in CNS development and cell-cycle control, (2) up-regulation of cell cycle genes may compensate for CIZ1 deficiency in our KO mouse model, and (3) pathogenic dystonia-associated *CIZ1* mutations may operate via gain-of-function.

Title: Altered resting state functional connectivity MRI in adductor-type laryngeal dystonia

Authors: *S. A. NORRIS[1], M. C. CAMPBELL[2], J. M. KOLLER[2], A. Z. SNYDER[2], J. S. PERLMUTTER[2];
[1]Neurol., [2]Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Introduction: Adductor laryngeal dystonia (ADLD) is a task-specific dystonia that causes altered voice quality and projection. In genetic and non-genetic forms of isolated dystonia, functional imaging data suggest abnormalities in the basal ganglia, primary sensorimotor cortex, cerebellum, SMA, and thalamus. Tasks and ongoing movement during image acquisition confound interpretation in many of these studies. Based on functional and structural imaging data in isolated dystonia (including laryngeal dystonia) we hypothesize that functional connectivity will be disrupted in resting state networks including cerebello-thalamo-cortical and cortico-basal ganglia-thalamic networks in those with ADLD. Methods: Resting-state BOLD scans (Seimens 3T Trio) were obtained from ADLD participants (N = 23) -with (N = 13) or without (N = 10) botulinum toxin injections- and controls (CTL, N = 23) matched for gender, age, handedness, and head movement. Participants with excessive movement were excluded from all analyses (ADLD = 4; CTL = 3). Seed based functional connectivity analyses focused on sensorimotor cortical regions, basal ganglia, and cerebellar regions. Between-group analyses of resting-state functional connectivity compared all ADLD and CTL participants. Fisher z-transformed correlation coefficients were extracted for significant seed-clusters and confirmed with Monte-Carlo simulation. Results: ADLD participants demonstrated significantly altered functional connectivity compared to controls. A caudate seed demonstrated increased correlation with ipsilateral somatosensory cortex and decreased correlation with cerebellar cortex. A cerebellar seed demonstrated weaker correlations with inferior frontal gyrus, insular cortex, somatosensory cortex, and caudate. A somatosensory cortex seed demonstrated weaker correlations between cerebellum, thalamus and increased correlation with caudate and inferior frontal gyrus. Conclusion: Data demonstrate altered functional connectivity in a-priori regions of interest in the somatosensory cortex, basal ganglia and cerebellum using resting state MRI data in those with ADLD. Resting state functional connectivity analyses reveal functional brain network changes associated with this task-specific dystonia.

Title: Multi-sensor based biomechanical characterization of cervical dystonia determines optimal onabotulinumtoxinA treatment parameters

Authors: O. SAMOTUS, H. MORADI, F. RAHIMI, *M. S. JOG;
Dept Neurol, Univ. of Western Ontario, London, ON, Canada

Abstract: Background: Assessing cervical dystonia is challenging to accomplish visually as the complexity of CD involves variations in rhythm, velocity, amplitude, and direction. Individualizing focal therapy commonly results in a dosing regimen associated with mediocre relief of symptoms. Biomechanical sensors can be applied as an objective method to measure head and neck biomechanics and thus simplifies the ease of diagnosis and accurate selection of optimal onabotulinumtoxinA injection parameters. Objective: To simultaneously quantify torticollis and superimposed dynamic movements in multiple degrees of freedom in order to identify dystonic neck muscles for onabotulinumtoxinA focal therapy. Methods: 24 drug-naïve CD participants were injected with onabotulinumtoxinA at week 0, 16 and 32 and attended follow-up visits six weeks following a treatment. Clinical rating scales (TWSTRS and UDRS) and kinematic assessments were completed at all visits. Kinematic recordings involved an inclinometer positioned above the right ear and a goniometer at C2 and T2 spinal segments to capture severity of natural head and neck twisting in three degrees of freedom (DOF): rotational, lateral, and vertical tilts. Static posturing, measured as angular deviation from calibrated neutral head position, and dynamic movements measured by angular RMS amplitude were collected. Dosing and muscle selection were based on both kinematic data and clinician's experience. Results: Mean TWSTRS-total score significantly improved from study baseline to weeks 6 and 16 by 17.1% and 10.1%, respectively. Kinematics objectively isolated static head posturing (angular deviation > 5.5 degrees) from dystonic movements (angular RMS amplitude > 0.35 degrees). Participants who presented with static posturing at baseline displayed a reduction in severity by 42.0%, 12.3% and 18.4% in lateral, vertical, and rotational DOFs, respectively. Participants with dystonic movements showed a decrease in severity by 28.8%, 35.2%, and 23.1% in lateral, vertical, and rotational planes of motion. Conclusions: Kinematics provides an objective understanding of neck biomechanics and can easily identify hyperkinetic muscles for focal therapy.

Title: Analysis of TAF1 gene splice variants in fibroblasts and iPS cells-derived neural stem cells from patients with X-Linked Dystonia-Parkinsonism

Authors: J. DHAKAL, *N. ITO, W. T. HENDRIKS, N. WAKABAYASHI-ITO, C. A. VAINE, C. LIU, D. SHIN, K. SHIN, T. MULTHAUPT-BUELL, N. SHARMA, X. O. BREAKEFIELD, D. C. BRAGG;
Program in Neurosci., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Background X-linked Dystonia-Parkinsonism (XDP) is a neurodegenerative disease endemic to the Philippines. The pathogenic genetic lesion is unclear, but previous studies identified a disease haplotype consisting of (a) 5 single nucleotide changes, designated disease-specific sequence changes (DSC1,2,3,10,12) in a region containing the *TAF1* gene; and (b) an SVA-type retrotransposon insertion in intron 32 of *TAF1*. One study also identified a brain-enriched TAF1 variant, N-TAF1 that was decreased in XDP caudate relative to controls (Makino et al. 2007). However, it is not clear if this decrease in N-TAF1 expression occurred secondary to neurodegeneration, or if it may be a primary effect of genotype that could contribute to XDP pathogenesis. **Objective and Methods** The goal of this study was to compare expression of transcripts derived from exons 1-38 of *TAF1*, and of N-TAF1 in particular, in XDP vs. control cells. Fibroblasts were derived from 5 XDP patients and 5 unaffected family members as controls, reprogrammed to induced pluripotent stem cells (iPSCs), and re-differentiated into neural stem cells (NSCs). Genotyping was confirmed via PCR and Sanger sequencing. Neural

conversion was confirmed via immunostaining for nestin, Pax6, and Musashi. Relative expression of TAF1 transcripts was assessed by qRT-PCR using a panel of primers spanning the entire gene. **Results** All XDP cell lines were positive for all haplotype markers, including the SVA, whereas controls had wild-type sequences at all positions. Most TAF1 transcripts did not differ significantly in XDP vs. control cells. In fibroblasts, five TAF1 variants were significantly lower in patients vs. controls. The most significant changes involved transcripts incorporating exons around intron 32 bearing the SVA, as well as ones derived from exons 34-36. N-TAF1 is derived from an alternative exon, 34', in this same region, and it was not detectable in fibroblasts. As positive controls, N-TAF1 expression was confirmed at low levels in human neuroblastoma cells and at relatively high levels in RNA from multiple human brain regions. Transcripts differentially expressed in fibroblasts were also significantly different in NSCs, along with N-TAF1 and one additional transcript. Of all TAF1 variants, N-TAF1 showed the largest fold difference in expression between XDP and control NSCs. **Conclusions** XDP-related sequence variation in *TAF1* appears to affect expression of multiple transcripts. Neural-specific expression of N-TAF1 and decreased expression in XDP vs. control cells are consistent with previous reports and indicate that this cellular phenotype is not a secondary consequence of cell loss in the brain.

Title: Voice tremor in spasmodic dysphonia: a multi-modal neuroimaging study

Authors: D. KIRKE, G. BATTISTELLA, M. CHOY, V. KUMAR, E. RUBIEN-THOMAS, *K. SIMONYAN;
Neurol., Mount Sinai Sch. of Med., New York, NY

Abstract: Spasmodic dysphonia (SD) is a primary focal dystonia affecting the laryngeal muscles during speech production. In one-third of patients, SD co-exists with voice tremor (SD/VT). While there has been recent progress in understanding brain functional and structural alterations in SD, the pathophysiological basis of VT remain less clear. The aim of this study was to examine structural and functional brain abnormalities in 20 SD vs. 20 SD/VT vs. 20 healthy controls (HV) using functional MRI (fMRI) during symptomatic speech production, voxel based morphometry (VBM) and diffusion tensor imaging (DTI). We found that, while both SD and SD/VT groups showed widespread increases of activation in the sensorimotor cortical regions, basal ganglia, thalamus and cerebellum, the SD/VT patients had additionally increased activity in the right fronto-temporo-parietal cortex and bilateral cerebellum. The differences between the SD and SD/VT groups were also observed at the structural level. SD patients showed distinct white matter abnormalities in the right genu of the internal capsule, which was in line with previous findings in these patients, whereas SD/VT patients exhibited white matter changes in the right thalamus and gray matter alterations in the postcentral gyrus, cerebellum and brainstem. These findings indicate that, compared to healthy subjects, SD and SD/VT patients share the same abnormalities of brain function and structure, possibly attributed to SD symptoms. On the other hand, VT appears to contribute additional brain abnormalities along the cerebello-thalamo-cortical pathway, which are not present in patients with isolated SD. As the debate on whether VT is an integrated part of SD or a stand-alone disorder continues, our data provide brain organizational evidence that VT is likely a co-occurring disorder rather than a sub-symptom of SD. This knowledge may be important for designing new therapeutic options targeting disorder-specific abnormalities in SD and SD/VT.

Title: Vibratory feedback and visualizations increase muscle awareness and task performance in subjects with dystonia during a redundant, one-dimensional myocontrol task

Authors: *S. A. LIYANAGAMAGE[1], M. BERTUCCO[1], T. D. SANGER[1,2];
[1]Biomed. Engin., USC, Los Angeles, CA; [2]Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: We have previously used scaled vibratory feedback on children with secondary dystonia, and have seen improvement in their motor function after one month of practice. We have also seen that scaled forms of vibration cause significant increases in muscle use without a significant increase in overall performance. However, we still do understand why vibration behaves in this manner. We decided to approach the problem from a different angle by looking into the world of coaching to find concepts that could be used in motor skill training. Upon extensive literature review and an ongoing survey, we have decided visualizations play an important role in motor skill improvement. We hypothesize that scaled vibration is sport coaching-like i.e. it is able to manipulate a person's limb movements indirectly by bringing awareness to those areas of the body that need to be changed. In order to translate this concept to the field of motor control, we designed a 5-block, unilateral myocontrol Fitt's Law experiment in which subjects manipulated their arm to control a cursor on the computer. The brachioradialis and FDI muscles contributed to cursor movement, while the ADM did not (we didn't tell this to the subjects). Blocks 1 and 3 were baseline measurement blocks where we conducted 10 sets of trials, each presenting 5 target sizes. In block 2, we placed a vibratory feedback device on their brachioradialis while they performed the same task. In block 4, we showed subjects a fist clenching/unclenching movement, and asked them to continue the task using this movement, with the expectation that their performance and muscle use would change significantly with this visualization added. Then, in block 5, we asked them to complete the task using the best movement they saw fit in order to test how they adapt their movements after the two interventions. Preliminary results show that vibration of the brachioradialis muscle is able to reduce overall movement time, while visualization causes an increase. However, it was seen that subjects were able to reach a significantly reduced movement time in block 5 by using a hybrid of the movement they were using in block 1 and the one they were taught in block 4. These results show we are able to use vibration and visualization to manipulate subjects to increase efficiency of movement. The study is ongoing, and we believe there is much to be learned using such a paradigm with regards to changes in muscle use in children with dystonia since the ability to bring awareness within a noisy muscle environment will prove extremely useful to them. We believe that this paradigm can aid in improving specific motor skills and overall performance.

Title: Investigating premotor-parietal connectivity in writer's cramp patients

Authors: N. THIRUGNANASAMBANDAM, A. S. PILLAI, J. A. SHIELDS, *M. HALLETT; Human Motor Control Sec, NINDS/NIH, Bethesda, MD

Abstract: Patients with writer's cramp demonstrate task-specific dystonic symptoms of the hand during handwriting, while no symptoms are observed during other similar distal motor tasks. Recent studies postulate that impaired cortical connectivity could be partly responsible for the task specific symptoms. Functional MRI studies have shown that the left premotor and posterior parietal cortices are part of the task-specificity network. The resting state connectivity between these 2 regions and the connectivity during handwriting was decreased in WC patients on fMRI. The connectivity between premotor and parietal areas during handwriting has, however, not been explored with EEG. In the present study, we hypothesized that left premotor-parietal connectivity would be lower in writer's cramp patients than healthy controls during handwriting. We are currently recruiting writer's cramp patients and age- and sex-matched healthy controls for this study. We record 32-channel EEG while the participants performed one of the following tasks - handwriting or sharpening a pencil or imagining writing/sharpening. We calculate the task-related power (TR-Pow) and imaginary part of coherence (TR-ImCoh) between left premotor (FC5) and posterior parietal (P3) cortices. Our preliminary results show that alpha TR-Pow decreased for the actual motor tasks and increased for the imagination tasks in both subject groups. The alpha TR-ImCoh increased the most during writing in healthy controls, while it decreased in patients. This study confirms the fMRI results and can be further exploited to evaluate dynamic changes.

Title: Genetic inducible silencing of cerebellar synapses in mice

Authors: *J. WHITE, R. V. SILLITOE;
Baylor Col. of Med., Houston, TX

Abstract: The cerebellum is critical for several motor functions including coordination, learning, and balance. It is therefore not surprising that damaging the cerebellum impacts movement. However, while we are rapidly gaining a better appreciation for how the anatomical and molecular landscape is affected in cerebellar disorders, knowledge of how neuronal activity within the cerebellum is altered in motor disease is still poorly understood. To address this problem, we devised an approach to manipulate the different steps of signal processing in the cerebellum in order to determine how different synapses contribute to motor behavior. We have found that the silencing of Purkinje cell synapses, by removing vesicular GABA transporter from Purkinje cell axon terminals, disrupts the normal wiring and firing of the circuit, which ultimately leads to disequilibrium and ataxia. But, in order to disentangle the roles of the Purkinje cell from its surrounding microcircuit during motor processing, we stepped back a synapse to silence glutamatergic input into the cerebellar cortex. We accomplished this by removing vesicular glutamate transporter from presynaptic axon terminals in order to gain insight into the behavioral and pathophysiological role of afferents. We show using mouse behavior, high-resolution anatomy and *in vivo*, awake electrophysiology that constitutive loss of glutamatergic synaptic transmission leads to a very different behavioral phenotype compared to silencing the Purkinje cells themselves. Similar to our mice with silenced Purkinje cells, the mice with silenced afferent signaling show abnormal firing within the cerebellar circuit, but instead of disequilibrium and ataxia, these mice exhibit severe muscle co-contractions that impede normal movement. Our data suggest that loss of afferent neurotransmission leads to cortical processing errors that cause cerebellar nuclear neurons to fire with abnormal properties. We propose that multiple cerebellar cortical deficiencies might be corrected and motor function restored by therapeutically targeting the cerebellar nuclei.

Title: TorsinA regulates adaptation to chronic stress *in vivo*

Authors: *G. BEAUVAIS[1], N. BODE[2], J. L. WATSON[1], H. M. WEN[3], K. A. GLENN[3], P. GONZALEZ-ALEGRE[4,5];

Therapy, The Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: DYT1 dystonia is a disabling neurological that causes repetitive twisting involuntary movements. DYT1 is caused by a GAG deletion in the TOR1A gene encoding the endoplasmic reticulum (ER) resident AAA+ ATPase torsinA. The cellular function of torsinA remains unknown. Experimental evidence from several laboratories suggests that torsinA protects neurons under conditions of ER stress by assisting in the degradation of misfolded proteins via ERAD, and the ΔGAG mutation impairs this function. As a result, ER stress is a potential regulator of disease penetrance and severity. However, this hypothesis has never been tested in mammalian models *in vivo*. Here, we evaluated the behavioral, histological and biochemical consequences of chronic ER stress in DYT1 ΔGAG knock-in (KI) mouse model. P58IPK is an ER chaperone that binds to proteins being imported into the ER to promote proper folding. p58IPK-null mice are sensitive to ER stressors in different somatic tissues including pancreas and the gut, likely as a result of increased input of misfolded proteins. However, they do not exhibit brain abnormalities. Therefore, combining abnormal P58IPK and torsinA function might lead to increase input and reduced output of misfolded proteins from the ER, triggering a neurological phenotype. To test this hypothesis, we crossed DYT1 knock in (KI/+) with p58IPK (-/+) mice. We obtained the expected number of animals for all possible genotypes except for DYT1 (KI/+)/ p58IPK (-/-), suggesting a genetic interaction during development. However, behavioral evaluation of surviving animals did not show any abnormalities in behavior specific to that genotype. Protein analysis demonstrated activation of ER stress responses upon loss of p58IPK in cerebellum, striatum and cortex of 2-week and 9-month old mice. Interestingly, some changes were found to be age- and region-specific. Unbiased proteomic analysis through 2DIGE of brain lysates followed by MS/MS identification of dysregulated proteins indicated that combining torsinA and p58IPK dysfunction alters levels of proteins implicated in protein quality control pathways and calcium signaling. In sum, our findings suggest that torsinA might modify the neuronal response to chronic ER stress from embryonic development to adulthood.

Title: Enhanced glutamatergic synaptic transmission in a DYT1 dystonia mouse model, evaluated by membrane-potential imaging

Authors: *S. IWABUCHI, N. C. HARATA;
Dept. of Mol. Physiol. & Biophysics, Univ. of Iowa, Iowa City, IA

Abstract: Dystonia is a hyperkinetic movement disorder and is characterized by sustained or intermittent muscle contractions that cause abnormal repetitive movements and postures. Patients with dystonia are subject to increased brain excitability in the absence of apparent neurodegeneration. Thus, one of the main pathophysiological features of dystonia appears to be abnormal control of neuronal excitability, e.g. an imbalance in excitatory glutamatergic and inhibitory GABAergic synaptic transmission. However, to date we have only limited information about whether the excitability at the single-neuron level is affected in the absence of experimental manipulation of glutamatergic and GABAergic synaptic transmission. We have tested the net excitability of brain neurons of a dystonia model in the absence of antagonists of ionotropic glutamate and GABA receptors. Specifically, we prepared primary cultures of hippocampal neurons from a ΔE-torsinA knock-in mouse model of DYT1 dystonia, the most common form of inherited dystonia. We evaluated the excitability of these neurons following electric field stimulation, by imaging the membrane potential changes using a fluorescent indicator FluoVolt. In wild-type neurons, field stimulation led to an action potential, followed by 1) hyperpolarization lasting several 10's of ms, 2) no change in membrane potential, or 3) a small depolarization. All these responses were blocked by the Na^+-channel inhibitor tetrodotoxin,

suggesting that they were caused by action potentials. In some neurons, a stimulus-triggered action potential was followed by multiple action potentials, each preceded by slowly rising depolarization reminiscent of glutamate-mediated excitatory postsynaptic potentials (EPSPs). The latter responses were blocked by CNQX, an antagonist of AMPA-type ionotropic glutamate receptors. Thus we were able to identify the individual action potentials, depolarizing EPSPs and membrane hyperpolarization. Heterozygous mutant neurons more frequently exhibited depolarizing responses following stimulation than their wild-type counterparts, and these responses were blocked by CNQX. Our results demonstrate that glutamatergic synaptic transmission is enhanced in brain neurons of the DYT1 dystonia mouse model.

Title: Role of major and brain-specific Sgce isoforms in the pathogenesis of myoclonus-dystonia syndrome

Authors: *J. XIAO, Y. XUE, S. R. VEMULA, M. S. LEDOUX;
Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Loss-of-functions mutations in *SGCE* which encodes ε-sarcoglycan (ε-SG) cause myoclonus-dystonia syndrome (OMIM-159900, DYT11). The ubiquitous ε-SG protein (major isoform, 12 exons) and a brain-specific protein, derived from alternative exon 11b (13 exons), are reportedly localized in different synaptosomal membrane fractions: post- and pre-synaptic membrane, respectively. Moreover, deficiency of the brain-specific isoform may be central to the pathogenesis of DYT11. However, no animal model supports this hypothesis. Gene trapped ES cells (CMHD-GT_148G1-3, intron 10 -major isoform) were used to generate a novel *Sgce* mouse model with absent expression of both the ubiquitous and brain-specific isoforms of *Sgce* on the C57BL/6J background. In WT mouse brain, cerebellum showed significantly higher relative expression of the brain-specific isoform. Homozygotes ($Sgce^{-/-}$) and paternal heterozygotes

showed 60-70% reductions in expression of total *Sgce* (short isoforms preserved) although expression of the major and brain-specific isoforms was absent. Immunohistochemical assessments in WT mice using several ε-SG antibodies revealed punctate patterns of immunoreactivity of variable size, shape and density in motor regions of the CNS, with overall reductions in *Sgce*$^{-/-}$ mice. Genome-wide gene expression data using RNA derived from adult cerebellum showed moderate up-regulation of inflammatory response and moderate down-regulation of cell-to-cell signaling and interaction, cell death and survival, and cellular growth and proliferation genes in paternal heterozygotes. Over 50% of paternal heterozygote and *Sgce*$^{-/-}$ mice exhibited a variety of subtle motor abnormalities between P10 to P13. Abnormalities noted in older paternal heterozygote and *Sgce*$^{-/-}$ mice included reduced body weight, altered gait dynamics, and reduced open-field activity. Overt spontaneous or stimulus-sensitive myoclonus was not apparent on the C57BL/6J background. Our data suggests that short *Sgce* isoforms may compensate, in part, for deficiency of the major and brain-specific *Sgce* isoforms.

Title: The epidemiological and molecular analysis of Paroxysmal kinesigenic dyskinesia in Japan

Authors: H. TANGE[1], M. OHISHI[1], N. KUROTAKI[1], Y. MORIMOTO[1], S. ONO[1], Y. KUSUMOTO[1], S. YAMADA[1], K. SHIROTANI[3], N. IWATA[3], K. YOSHIURA[4], *N. MORI[2], H. OZAWA[1];
[1]Neuropsychiatry, [2]Nagasaki Univ. Sch. of Med., Nagasaki, Japan; [3]Genome-based Drug Discovery, Nagasaki Univ. Sch. of Pharmaceut. Sci., Nagasaki, Japan; [4]Human Genet., Nagasaki Univ. , Atomic Bomb Dis. Inst., Nagasaki, Japan

Abstract: Paroxysmal kinesigenic dyskinesia(PKD) is characterized by recurrent, brief attacks of involuntary movement triggered by sudden voluntary movement. For example, patients often show dystonic movements in standing up suddenly, breaking into a run, and etc. The attacks more than one hundred times a day cause difficulties in daily life. Some PKDs are thought be

familial and others are sporadic. In 2011, PRRT2 on chromosome 16 is responsible for PKD reported by the Chinese group. A year later, our group found that the mutation is almost concentrated into c.649dupC (p.Arg217Profs*8) and involved in benign infantile seizure. Additionally, several reports show that PRRT2 is related to not only infantile seizure, but also migraine, and other epileptic disorders. The papers of both Wood H. in the Nat Rev Neurology (2012) and one of Scheffer IE.'s in the Nat Rev Neurology (2013) emphasized the PRRT2 gene in clinical neurology. In this situation, we proposed epidemiological study of PKD in Japan and have performed the molecular analysis to estimate the relationship between PKD and its complications. First, we conducted the survey by using a questionnaire about the frequency and the complications of PKD, and the medical treatments of the members of both Japanese Society of Neurology and Japanese Society of Child Neurology. Japanese Society of Psychiatry and Neurology kindly recommended the study. A total of all members are 6000 and the response rate of a questionnaire was about 50%. In this survey, 426 cases of PKD have reported by members of these societies. Interestingly, 147 cases had various complications including epileptic seizure, autistic disorders, bipolar disorders and other neurological disorders. Until now, we analyzed PRRT2 mutations in 60 cases resulting c.649dupC of PRRT2 is main gene alterations as reported previously. However, some cases have no mutation of PRRT2. We will perform further investigation utilizing the next generation sequence technology in the cases without any PRRT2 mutation. Otherwise, we are estimating clinical features of pure PKD and PKD with other complications combined with genotype of each case. Our study will show the genotype – phenotype correlation of PKD. Also, we could shed light on the molecular genetic aspect of neuropsychiatric diseases including autistic disorders, mood disorders based on the results of molecular analysis of PKD. This study received the ethical approval from the Committee for Ethical Issues in Human Genome and Gene Analysis at Nagasaki University, Japan. Also, this study is supported by Health Labour Sciences Research Grant.

Title: ε-sarcoglycan interacts with components of the dystrophin-associated glycoprotein complex and other membrane proteins in the brain

Authors: F. A. CARLISLE[1], A. J. WAITE[1], Y. CHAN[3,4], *A. R. ISLES[2], D. J. BLAKE[1]; [1]MRC CNGG, [2]Cardiff Univ., Cardiff, United Kingdom; [3]Ultragenyx Pharmaceut. Inc., Novato, CA; [4]McColl-Lockwood Lab. for Muscular Dystrophy Res., Carolinas Med. Ctr., Charlotte, NC

Abstract: Mutations in SGCE, which encodes the membrane glycoprotein ε-sarcoglycan, cause a form of the neurogenic movement disorder myoclonus-dystonia syndrome (MDS). However, mutations in the genes encoding the related α-, β-, δ- and γ-sarcoglycans cause limb-girdle muscular dystrophy (LGMD). LGMD patients have no reported MDS-associated symptoms, while MDS patients have no muscle pathology. In muscle, the sarcoglycans form a sarcolemmal heterotetrameric complex that is a subcomplex of the dystrophin-associated glycoprotein complex (DGC) and is disrupted in LGMD. Differences in the composition of sarcoglycan complexes between brain and muscle could contribute to the lack of neurological symptoms in LGMD patients; therefore we carried out immunoaffinity purification of ε-sarcoglycan from rodent brain to identify components of ε-sarcoglycan-containing complexes. We found that brain ε-sarcoglycan isoforms co-purified with β-, δ- and ζ-sarcoglycan as well as other DGC components and further membrane proteins. In addition, a direct interaction between ε-sarcoglycan and ζ-sarcoglycan was detected *in vitro* and in the SGCD mutant BIO14.6 hamster. These results indicate that ε-sarcoglycan is part of a prototypical sarcoglycan complex in brain, but may also form non-canonical complexes with ζ-sarcoglycan and other proteins. This variation in the composition of brain ε-sarcoglycan-containing complexes may contribute to the distinct phenotypes of sarcoglycan-related LGMD and MDS.

Title: Abnormal twisting movements and selective loss of maturing striatal cholinergic interneurons in forebrain-conditional Tor1a knockout mice

Authors: *S. S. PAPPAS, W. T. DAUER;
Dept Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Dystonia is a movement disorder characterized by prolonged involuntary twisting movements. Abnormal basal ganglia function is implicated as a key cause of dystonic movements, but the cellular basis for striatal dysfunction remains undefined. DYT1 dystonia, the most common inherited form of primary dystonia, is caused by a dominantly inherited loss of function mutation in the TOR1A gene (encoding the protein torsinA). We modeled dystonia-related neuronal dysfunction in forebrain motor circuits by conditionally deleting torsinA from forebrain GABAergic and cholinergic neurons (Dlx5/6 - Tor1a conditional knockout mice - "Dlx-cKO"). Similar to DYT1 subjects, Dlx-cKO mice exhibit abnormal twisting movements that emerge during juvenile CNS maturation. These dystonic-like movements coincide with the exclusive degeneration of striatal cholinergic interneurons, predominantly in the dorsolateral motor region. Moreover, the abnormal movements are reduced by the same antimuscarinic treatment used clinically, highlighting the predictive validity of the model. We are examining cell and circuit level abnormalities in surviving cholinergic neurons to determine the mechanism whereby anticholinergic compounds rescue a phenotype characterized by loss of cholinergic neurons, and to understand the molecular basis for the selective loss of dorsolateral striatal interneurons during neurodevelopment. This behaviorally symptomatic mouse model of dystonia provides a powerful platform for identifying specific circuits and cell types that drive abnormal motor function in DYT1 dystonia.

Title: A *Drosophila* model of human DYT1 dystonia

Authors: *N. WAKABAYASHI-ITO[1], R. R. AJJURI[2], B. W. HENDERSON[2], O. M. DOHERTY[2], X. O. BREAKEFIELD[1], J. M. O'DONNELL[2], N. ITO[1];
[1]Neurol., Massachusetts Gen. Hosp., Boston, MA; [2]Biol. Sci., Univ. of Alabama, Tuscaloosa, AL

Abstract: Dystonia represents the third most common movement disorder in humans with over 20 genetic loci identified. *TOR1A (DYT1)*, the gene responsible for the most common primary hereditary dystonia, encodes torsinA, an AAA ATPase family protein. Most cases of DYT1 dystonia are caused by a 3 bp (GAG) deletion that results in the loss of a glutamic acid residue (ΔE302/303) in the carboxyl terminal region of torsinA. This torsinAΔE mutant protein has been speculated to act in a dominant-negative manner to decrease activity of wild type torsinA. *Drosophila melanogaster* has a single torsin-related gene, *dtorsin*. Null mutants of *dtorsin* exhibited locomotion defects in third instar larvae. Levels of dopamine and GTP cyclohydrolase (GTPCH) proteins, which is encoded by *Punch*, were severely reduced in *dtorsin*-null brains. Further, the locomotion defect was rescued by the expression of human torsinA or feeding with dopamine. Here, we demonstrate that human torsinAΔE dominantly inhibited locomotion in larvae and adults when expressed in neurons using a pan-neuronal promoter Elav. Dopamine and tetrahydrobiopterin (BH_4) levels were significantly reduced in larval brains and the expression level of GTPCH protein was severely impaired in adult and larval brains. When human torsinA and torsinAΔE were co-expressed in neurons in *dtorsin*-null larvae and adults, the locomotion rates and the expression levels of GTPCH protein were severely reduced. These results support the hypothesis that torsinAΔE inhibits wild type torsinA activity. Similarly, neuronal expression of a *Drosophila* DtorsinΔE equivalent mutation dominantly inhibited larval locomotion and GTPCH protein expression. These results indicate that both torsinAΔE and DtorsinΔE act in a dominant-negative manner. We also demonstrate that Dtorsin regulates GTPCH expression at the post-transcriptional level. This *Drosophila* model of DYT1 dystonia provides an important tool for studying the differences in the molecular function between the wild type and the mutant torsin proteins.

Title: Functional imaging of head movements in healthy volunteers and in cervical dystonia

Authors: *C. N. PRUDENTE[1,2], R. STILLA[3], C. BUETEFISCH[3], T. KIMBERLEY[2], X. HU[3], K. SATHIAN[3], E. HESS[3], H. JINNAH[3];
[1]Neurol., EMORY UNIVERSITY, Atlanta, GA; [2]Univ. of Minnesota, Minneapolis, MN; [3]Emory Univ., Atlanta, GA

Abstract: Background: The neuroanatomical substrates for head movements in humans are not well delineated. It is not clear whether neck muscles are controlled by the ipsilateral or contralateral hemisphere, and the location of the neck region in the motor homunculus is still debated. This lack of information about normal head movements is relevant to cervical dystonia (CD), a disorder characterized by involuntary contractions of neck muscles. Current understanding of the neuroanatomical basis of CD is limited. We addressed the neuroanatomical substrates of head movements in normal individuals and in CD using functional magnetic resonance imaging (fMRI) and an isometric head task. Purpose: The experiments had two main goals: to delineate the neural basis for normal head movements in normal people and to identify abnormalities associated with CD. Methods: Scanning was conducted during isometric head rotation to the right or left. Isometric wrist extension with either hand was examined as a positive control condition. Electromyography recordings during scanning ensured compliance with tasks. Results: Seventeen healthy volunteers and 16 individuals with CD participated in the study. Isometric head rotation in healthy volunteers induced significant activation in the bilateral precentral gyrus, both medial and lateral to the hand area, as well as in the bilateral supplementary motor area, insula, putamen, and ipsilateral cerebellum. CD subjects had an overall broader activation of cortical and subcortical areas, except in the medial precentral gyrus. However, statistical comparisons failed to reveal significant differences between groups. Analyses of CD data normalized to the side of torticollis indicated that head tasks in the direction of abnormal movements were associated with more activation in the ipsilateral anterior cerebellum, whereas moving the head in the opposite direction involved more activity in sensory and motor cortical areas. Conclusions: The findings in healthy humans suggest that head movements are controlled bilaterally in the precentral gyrus. Furthermore, the results in CD subjects imply significant asymmetries of brain activity associated with the torticollic and non-torticollic directions of head movements.

Title: Distinct and shared patterns of resting-state functional connectivity alterations in task-specific and non task-specific primary focal dystonia

Authors: *G. BATTISTELLA[1], P. TERMSARASAB[1], R. RAMDHANI[1], K. SIMONYAN[2]; [1]Dept. of Neurology, Icahn Sch. of Med., New York, NY; [2]Dept. of Neurol. and Otolaryngology, Icahn Sch. of Med., New York, NY

Abstract: Although the task specificity in dystonia is a clinically well-defined phenomenon, its pathophysiology is poorly understood. In this study, we examined large-scale neural networks underlying the task specificity in dystonia by utilizing a two-tiered network analysis of multivariate independent component analysis (ICA) and graph theoretical analysis in patients with task-specific dystonia (15 TSD: writer's cramp and laryngeal dystonia), non-task specific dystonia (18 NTSD: cervical dystonia and blepharospasm) and healthy controls (15 HV). ICA was performed using the MELODIC tool in the FSL software; between-group differences in functional connectivity among the spatial components were assessed using a dual regression analysis and one-way ANOVA at a corrected $p \leq 0.05$. Graph analysis was performed using the Brain Connectivity Toolbox; 212-region whole-brain parcellation was applied to extract individual time series and construct fully weighted undirected correlation matrices by calculating a zero-leg Pearson's correlation coefficients between each pair of regions, which was followed by the assessment of community-based network structure based on segregation and clustering of functional within-network communities. Compared to HV, all patients showed extensive bilateral decreases within the sensorimotor networks (SMN), including the primary sensorimotor, premotor, inferior parietal, superior/middle temporal cortices and supplementary motor area, and within the frontoparietal network (FPN), including the left prefrontal cortex and bilateral middle temporal gyrus. Direct comparisons between TSD and NTSD showed SMN differences in the bilateral primary somatosensory cortex in NTSD and the right sensorimotor cortex in TSD, while FPN differences were found in the inferior parietal cortex in TSD only. Graph analysis showed differences in nodal participation in five neural communities in patients vs. HV, which led to either expansion or reduction of these communities with subsequent reconfiguration of global network topology in TSD and NTSD. Compared to HV, NTSD had significantly increased nodal

degree and decreased nodal strength, whereas TSD had abnormal formation of hubs in the left insula and bilateral temporal cortex. Our results indicate that focal dystonias are network disorders, which are characterized by greater cortical involvement in TSD possibly attributed to a finer sensorimotor control of highly learned human behaviors, such as writing and speaking.

Title: Altered dopamine receptor 1-positive medium spiny neuron activity and impaired motor-skill transfer in Dyt1 ΔGAG heterozygous knock-in mice

Authors: *F. YOKOI[1], H. CHEN[1], M. T. DANG[3], J. LIU[4], J. R. GANDRE[1], K. KWON[1], R. YUEN[5], S. N. ROPER[2], Y. LI[1];
[1]Neurol., [2]Neurosurg., Univ. of Florida, Gainesville, FL; [3]Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Ctr. for Neurodegeneration and Exptl. Therapeutics, Neurol., Univ. of Alabama at Birmingham, Birmingham, AL; [5]Radiology, St. Louis Univ., Saint Louis, MO

Abstract: DYT1 dystonia is a movement disorder caused by a trinucleotide deletion (ΔGAG) in DYT1 (TOR1A), corresponding to a glutamic acid loss in the C-terminal region of torsinA. Functional alterations in the basal ganglia circuits have been reported in both DYT1 dystonia patients and rodent models. However, the role of the direct pathway in the pathogenesis is not yet clear. Here, the direct pathway was analyzed in Dyt1ΔGAG heterozygous knock-in (KI) mice. Since the contribution of the direct pathway to motor-skill learning has been suggested in another pharmacological rat model injected with a dopamine receptor 1 (D1R) antagonist, we developed

a novel motor-skill transfer test and analyzed the performance in Dyt1 KI mice. Methods; D1R binding assay: The striatal homogenates were incubated with [3H]SCH-23390, filtered through glass filters and measured by a liquid scintillation counter. D1R autoradiography: The coronal brain sections were incubated with [3H] SCH-23390 and exposed to an imaging plate. Western blot: The striatal D1R and other membrane protein levels were measured by either fluorescence or chemiluminescence systems. Quantitative real-time RT-PCR: The relative quantities of the striatal D1R mRNA were analyzed with SYBR. Immunohistochemistry: The striatal D1 neurons were stained in the coronal sections and counted. Electrophysiology: The miniature excitatory postsynaptic currents (mEPSCs) were recorded with TTX on direct pathway EGPF-labeled medium spiny neurons in the brain slices by a whole-cell voltage-clamp. Motor-skill transfer test: Mice in treated group were trained for two weeks on a treadmill for 5 minutes each day. Two days after the training, all mice were tested on a rotarod for three trials in one day. The control was untrained mice. Results and Conclusions; Dyt1 KI mice exhibit decreased striatal D1R binding activity and D1R protein levels, suggesting an alteration of the direct pathway. The decreased D1R may be caused by translational or post-translational processes since Dyt1 KI mice had normal levels of striatal D1R mRNA and a normal number of striatal D1 neurons. The levels of striatal ionotropic glutamate receptor subunits, dopamine transporter, acetylcholine muscarinic M4 receptor and adenosine A2A receptor were not altered suggesting a specificity of affected polytopic membrane-associated proteins. Dyt1 KI mice also exhibited altered mEPSCs, suggesting a functional alteration of the direct pathway. Consistent with the D1 antagonist model, Dyt1 KI mice showed motor skill transfer deficits. Further characterization of both the direct and the indirect pathways in Dyt1 KI mice will aid the development of novel therapeutic drugs.

Abstract: The human sodium leak current channel (NALCN) is implicated in many genetic forms of the movement disorders such as dystonia and dyskinesia. Mutations in NALCN cause similar abnormalities in mice, *Drosophila* and *C. elegans*. Reduced NALCN expression in *Drosophila* altered locomotive behavior and circadian rhythms although the flies were viable and fertile. Also, they displayed a narrow abdomen phenotype with 'hesitant walking' and had altered sensitivities to general anesthetics such as halothane. Loss-of-function mutation in *C. elegans* NALCN caused animals to move extremely slowly and when touched on the tail they showed a fainting or freezing response similar to frozen gait in Parkinson's disease patients. Gain-of-function mutation in NALCN caused an extremely active phenotype; worms showed excess coiling, turns and reversals similar to dystonia and dyskinesia. We think that mutations in NACLN disrupt the depolarization-repolarization balance by changing the relative concentrations of sodium, calcium and potassium inside the cell. Previously, we showed that it is possible to correct movement of NALCN loss-of-function animals with nicotine and K^+ channel blockers. Therefore, we hypothesized that we should be able to correct movement in gain-of-function (*gf*) mutant animals [*unc-77* (*e625*) allele] with a similar strategy. In order to evaluate the movements of the worms, we observed spontaneous movement, startle response and foraging (food seeking) behavior. Our studies with potassium channel activators on *gf* animals remain inconclusive except 2-aminoethoxydiphenyl borate (2-APB). 2-APB is a pharmacological agent with various actions such as such as inhibiting inositol trisphosphate receptors, transient receptor potential channels, and gap junctions; and modifying store-operated calcium channels function. Beside 2-APB, we discovered several pharmacological agents such as nimodipine, flunarizine and ethoxzolamide that improve or correct the movement of *gf* animals in the foraging assay. These drugs potentially share a common mechanism of action by regulating calcium flux. We hope to discover specific pharmacological agents that target the NALCN. Drugs that can correct behavioral deficits caused by NALCN mutations may be useful for the treatment of human movement disorders.

Title: BDNF and NMDA receptor expression in X-linked dystonia Parkinsonism neural stem cells

Authors: *L. ZHANG[1], D. M. MCCARTHY[2], T. J. MORGAN, Jr[2], K. SHIN[3], W. T. HENDRIKS[3], D. C. BRAGG[3], P. G. BHIDE[2];

Abstract: X-linked dystonia Parkinsonism (XDP) is characterized by progressive torsion dystonia accompanied with or followed by Parkinsonism. The mechanisms of XDP pathogenesis are poorly understood. However, selective loss of striatal patch neurons, likely due to excitotoxic injury, is believed to be a major contributor. We reprogrammed fibroblasts from XDP patients and neurologically normal (control) family members. Genotyping confirmed that the XDP patients contained all known XDP haplotype markers, whereas the controls did not. Pluripotent cells were converted to neural stem cells (NSCs), which exhibited characteristic NSC morphology and molecular markers. NSCs were examined for protein expression by western blot. Both XDP and control NSCs expressed the BDNF receptor TrkB. Control NSCs did not express either of the two NMDA receptor subunits examined, namely subunit 1 or 2B. However, the XDP NSCs expressed subunit 2B but not 1. Since NMDA receptors 1 and 2 mediate excitotoxicity, we exposed control NSCs to NMDA directly and assayed excitotoxicity by LDH release. NMDA (25, 50 or 250 μM) exposure even for 12 hr did not produce excitotoxicity confirming the absence of the NMDA receptors in control NSCs. The expression of NMDA receptors in the XDP patient derived NSCs suggests increased vulnerability of the cells to NMDA excitotoxicity supporting the notion that excitotoxic injury is associated with XDP neuropathology. Since the XDP patient derived NSCs also express TrkB receptors, and since BDNF is known to be protective against NMDA-induced neurotoxicity, we are examining whether exogenous BDNF can protect XDP patient derived NSCs from NMDA induced excitotoxicity. Collectively, our data promise novel insights into mechanisms of XDP neuropathology and a protective role for BDNF.

Title: Overriding upstream reading frames associated with L-dopa responsive dystonia and other human diseases

Authors: *L. JONES, E. DAVILA, L. K. GOODE, P. G. BHIDE, I. ARMATA;
Florida State Univ., Tallahassee, FL

Abstract: Within the human genome, approximately 28% of genes contain at least one functional upstream translation start codon (uATG). Translation initiation at a functional uATG can result in a uATG-initiated peptide and competitively prevent the initiation of translation at the canonical start codon (cATG) and production of the physiological cATG-protein. The competition between the uATG and cATG functions as a regulatory mechanism to control and maintain optimal levels of the cATG-protein. The remaining 72% of the human genes are devoid of uATGs and optimal translation levels are solely achieved by the presence of the cATG. A variety of human diseases are the result of single nucleotide polymorphisms (SNPs) that introduce one or more novel uATG in the upstream region of genes (72%). As a result, the competition arising from the uATG leads to downregulation or even abolishment of the cATG-translated protein. Such SNPs have been linked with manifestation of cancer, thrombotic predisposition, cleft lip syndrome, β-thalassemia and other serious human diseases. We have uncovered a -22C>T SNP within the upstream region of the GCH1 gene that introduces a functional uATG. The GCH1 gene normally lacks uATGs. Introduction of this -22C>T uATG leads to translation of a short, mutant peptide with a distinct amino-acid sequence and function compared to the physiological cATG-translated protein. The uATG competes with the cATG and nearly eliminates the GCH1 protein leading to manifestation of dopa-responsive dystonia. Presently, there is no treatment for diseases associated with uATGs. We used the GCH1-uATG/cATG as a model to develop sensitive high-throughput screening (HTS) to identify compounds that promote read-through of the uATG allowing initiation of translation on the normal cATG. Compounds that tilt the balance toward the cATG promoter will result in restoration of normal cATG-translation levels and thus, can serve as potential therapeutic agents for the whole group of uATG-related diseases.

Title: Cytoskeletal and mitochondrial-related protein changes within the DBA/2J visual projection

Authors: *G. N. WILSON[1,2], D. M. INMAN[2], S. D. CRISH[2];
[1]Kent State Univ., Kent, OH; [2]Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Cytoskeletal changes and deficits in axonal transport are among the earliest hallmarks of many neurodegenerative diseases, including glaucoma. Addressing these pre- and early degenerative changes in abnormal protein accumulation and cytoskeletal modifications may provide the best opportunity for treating these disorders prior to functional loss. Microtubules provide the substrate upon which molecular motors travel while transporting cargo along the axon. Organization of this microtubule matrix is mediated by the microtubule-associated protein tau. Site specific phosphorylation of tau has received special attention for its role in neurodegenerative disorders like Alzheimer's disease. Using magnetic bead multiplexing, enzyme-linked immunosorbent assays, and immunofluorescence we found early elevations in total tau and phospho-tau (ptau231) within the optic nerve of pre-glaucomatous DBA/2J mice followed by an age-dependent decrease. Interestingly, ptau231 and total tau were significantly elevated in retina of older DBA/2J mice, suggesting a translocation of phosphorylated tau from axons into somatodendritic compartments. Also using protein multiplex assays, we quantified levels of Park5 (Uchl1) and Park7 (DJ-1) in retina and optic nerve of pre-glaucomatous, early, and late glaucomatous DBA/2J mice and found pre-glaucomatous elevations in the optic nerve, while not observing elevations in the retina until animals reached late glaucomatous ages. Both of these proteins have been shown to play a role in neurodegeneration and to play a potential role in protein kinase regulation, involved in post-translational modification of cytoskeletal elements. Park 7 is involved in mitochondrial quality control and has been shown specifically to affect extracellular signal-regulated kinase (ERK). As predicted, activated ERK1/2 levels within the retina were elevated in the same DBA/2J age groups; we also observed that phosphorylation of ERK peaked at early glaucomatous ages (8-10 months) in both retina and optic nerve. Phosphorylated ERK levels remained significantly elevated in the retina even at ages representing late glaucomatous pathology (12-15 months). Understanding how these cytoskeletal

and mitochondrial-related protein changes impact the progression of glaucoma may present new therapeutic avenues for this debilitating disease.

Title: Alterations in complex ii of the electron transport chain are associated with elevated mitochondrial respiration in btbr mouse model of autism spectrum disorder

Authors: ***Y. AHN**, R. MYCHASIUK, N. CHENG, N. C. YEE, R. TOBIAS, J. M. RHO; Pediatrics, Alberta Children'S Hosp. Res. Inst., Calgary, AB, Canada

Abstract: Autism spectrum disorder (ASD) is a highly prevalent neurodevelopmental condition that is characterized by specific behavioral and cognitive impairments, and is believed to arise from heterogeneous causes. Although a single and unifying pathophysiological mechanism is unlikely, there is growing evidence that mitochondrial dysfunction may play a critical role in provoking behavioral symptoms. Here, we hypothesized that impaired mitochondrial bioenergetics may be a contributing factor in ASD pathogenesis. To demonstrate this, we examined mitochondrial functional parameters in acutely isolated mitochondria from the frontal and lateral temporal neocortices of BTBR mice which have been widely studied and validated as a clinically relevant murine model of ASD. Specifically, for each BTBR or control (C57) animal, we measured the mitochondrial oxygen consumption rate (OCR) using a Seahorse Bioscience XF24 analyzer, and also determined ATP levels and ROS production using standardized assay kits. We observed significantly higher OCR levels in BTBR mice ($p<0.001$, N=7/group). Further, compared to control animals, we found that ATP levels were increased in BTBR mice (1.10±0.13 vs. 1.90±0.18; $p<0.001$; N=12/group) and ROS production was decreased in BRBR mice (1700±130 vs. 1100±180; $p<0.05$; N=4/group). To determine an underlying mechanism for the observed higher mitochondrial respiration in BTBR mice, we measured mitochondrial oxidative phosphorylation (OXPHOS) protein levels using western blot assays. Among the 5

complexes in the electron transport chain (ETC), Complex II expression was significantly increased in BTBR mice (1.000±0.005 vs. 1.300±0.056; $p<0.001$, N=8/group). As complex II is composed of 4 subunits (SDHA, SDHB, SDHC, and SDHD), we quantified their relative gene expression in frontal and temporal cortices using RT-qPCR. Sdha was decreased in BTBR mice, but this was not significant. Expression levels of Sdhb, Sdhc, and Sdhd were also increased in BTBR mice ($p=0.15$ for Sdhb; $p=0.054$ for Sdhc; $p=0.029$ for Sdhd, N=6/group). Furthermore, the activity of the Complex II enzyme, succinate dehydrogenase (SDH), was significantly higher in autistic mice than C57 controls ($p<0.001$, N=6/group). Collectively, these observations suggest that the dysregulation of the mitochondrial respiratory function, especially abnormalities of Complex II in brain may be an important contributor to the autistic phenotype of BTBR mice, and provide further evidence that abnormalities in mitochondrial function may underlie in part the behavioral features of ASD.

Title: Modeling Shankopathies in genetically edited human induced neurons

Authors: *F. YI, T. DANKO, T. SUDHOF;
Mol. and Cell. Physiol., Stanford Univ., Stanford, CA

Abstract: The clinical and genetic landscapes of human neurological disorders are often highly heterogeneous thereby molecular mechanisms behind them remain largely elusive. As the most profound member of the Shank gene family, Shank3 is an important synaptic protein enriched in the postsynaptic density (PSD) of excitatory glutamatergic synapses where it scaffolds an extensively complex protein density. It is one of the most promising candidate genes for autism spectrum disorders (ASD) and intellectual disability (ID), as well as considered primarily responsible for clinical manifestations of the Phelan-McDermid syndrome (PMS; 22q13.3 deletion syndrome). Enormous previous efforts have been spent to study the Shank3 deficiency in neuronal diseases using mouse genetic models or human induced pluripotent stem cells

(iPSC). However, major neuronal or behavior manifestations observed from those models were incongruent, which further adds to the elusivity of the functional involvement of Shank3 in disease development. Besides, innate limitations of mouse models in studying human neurological disorders and the fact that a direct proof of functional role of Shank3 in human neurons was negligible due to the inaccessibility of human neurons harboring Shank3 mutation in a clean genetic background are major obstacles in studying Shank3 in human neurological diseases. In this regard, here we report the generation of conditional Shank3 knockout human neurons based on gene editing in human embryonic stem cells (ESC). Induced neurons (iN) differentiated from human ESC conditionally deficient in Shank3 revealed neuronal morphological and synaptic deficits when closely compared to their conditional control counterparts. Our model recapitulated major defects in neuronal morphology and synaptic transmission observed in previous Shank3 mouse or human PMS iPSC models; moreover, our model revealed an unappreciated role of Shank3 in affecting intrinsic neuronal properties. Indeed, our conditional gene knockout approach renders us significant advantages over previous models in investigating the authentic functional readouts of Shank3 deficiency in human neurons with clean genetic background. Novel discoveries of intrinsic electrophysiological property defects caused by Shank3 haploinsufficiency in human neurons will be presented.

Title: Characterization of ASD-associated Shank proteins in early development of rat hippocampal neurons

Authors: *S. C. HALBEDL, M. SCHOEN, T. BOECKERS, M. SCHMEISSER;
Inst. for Anat. and Cell Biol., Ulm Univ., Ulm, Germany

Abstract: Shank1, Shank2 and Shank3 are essential scaffold proteins of the postsynaptic density (PSD) of excitatory glutamatergic synapses. In the PSD, Shank proteins multimerize and build

large molecular platforms thus providing multiple protein-protein-interaction sites, thereby linking postsynaptic receptors with their downstream signaling proteins and the actin cytoskeleton of dendritic spines. Over the last decade, mutations in those genes were found to play a central role in the pathogenesis of neuropsychiatric disease, predominantly autism spectrum disorders (ASD). Interestingly, two studies have already implicated a role of Shanks in early development of primary hippocampal neurons by revealing Shank2 and Shank3 immunoreactivity in growth cones (Du et al., 1998; Durand et al., 2012). For a more detailed analysis of Shanks in early neuronal development, we started to examine rat hippocampal neurons at distinct early developmental stages (DIV1, DIV2, DIV3, DIV4 and DIV7) before synaptogenesis takes place. So far we could show that all Shanks are indeed found in early rat hippocampal neurons and that they exhibit interesting expression dynamics and subcellular localizations over time, strongly supporting a novel role in early neuronal development compared to their well-known function during the formation of postsynaptic specializations. We are now using different *in vitro* and *in vivo* model systems to elucidate the role of these proteins in early neuronal differentiation and will present interestingly new results on the poster.

Title: Novel signaling and neurodevelopmental mechanisms in a mouse model of psychiatric pathogenesis

Authors: *R. E. STANLEY, P. M. MARTIN, A. E. FREITAS, A. P. ROSS, B. N. R. CHEYETTE;
Psychiatry, UCSF, San Francisco, CA

Abstract: The Wnt/β-catenin signaling pathway is broadly involved in neural development and is considered a potential pathogenic neurodevelopmental pathway in psychiatric illness. DISC1,

mutations in which confer susceptibility to schizophrenia as well as to other major psychiatric disorders, regulates this pathway in developing neurons. GSK3, the central kinase in this pathway, is a pharmacological target of the mood-stabilizing agent lithium. Recent human genetic studies have increased interest in Wnt signaling by finding that mutations in several components of the pathway confer genetic susceptibility to autism spectrum disorders (ASD). We have been investigating neurodevelopmental and behavioral functions of DIXDC1, a DISC1-interacting protein that also regulates Wnt/β-catenin signaling during neural development. We have generated a Dixdc1 knock-out mouse and performed neurodevelopmental, behavioral, and pharmacological studies in these animals, combined with human genetic analyses focused on the DIXDC1 locus, and rescue and gain-of-function experiments involving human alleles of Dixdc1. Mice homozygous for loss-of-function of Dixdc1 are viable and appear normal. We have found that loss of Dixdc1 leads to dose-sensitive deficits in behavioral assays thought to model depression and social behavior. These deficits are responsive to correction by acute administration of lithium or a small-molecule GSK3-inhibitor. Forebrain pyramidal neurons from Dixdc1 knock-out animals have normal dendritic arborization but reduced dendritic spines and glutamatergic synapses. These phenotypes can be rescued by expression of a wild type human DIXDC1 cDNA, but not by some rare alleles found in ASD patients. Moreover, a subset of these rare alleles with aberrant Wnt/β-catenin signaling activity have dominant-negative effects in neurodevelopmental assays. Our data support a role for Dixdc1 in the generation of excitatory synapses in the forebrain and suggest that this occurs downstream of activity in the Wnt/β-catenin signaling pathway within differentiating pyramidal neurons. Moreover, our data suggest that this is highly sensitive to DIXDC1 allelic dosage and to rare missense alleles at this locus, with effects on complex behaviors in animal models relevant to psychiatric pathology.

Abstract: Both the medial prefrontal cortex (mPFC) and the amygdala have been repeatedly implicated in the etiology of autism-spectrum disorders (ASD). Presently, there is significant evidence that autism is the neural network phenomenon which may reflect dysregulation of functional interactions between certain regions of the brain, including the mPFC and the amygdala. The amygdala receives strong projections from the mPFC and contributes to regulation of social behaviors. As the deficit in social behaviors is one of the hallmarks of autism, it is possible that the functional connectivity between the mPFC and amygdala may be affected during the development of ASD. We explored this possibility by assaying the effects of Poly I:C-triggered maternal immunoactivation (MIA), an animal model of ASD, on neurotransmission in projections from the mPFC to the basolateral nucleus of the amygdala (BLA) in the offspring of immunoactivated female mice. The BLA was targeted in the course of these recordings because it is most densely innervated by prefrontal fibers. Using optogenetic techniques, we found that MIA was associated with increased synaptic strength in glutamatergic projections from the mPFC to neurons in the BLA without affecting functional expression of channelrhodopsin. Potentiation of synaptic responses was not accompanied by changes in the paired-pulse ratio, suggesting a postsynaptic expression mechanism. In contrast, the magnitude of GABAergic inhibitory postsynaptic responses resulting from activation of local circuit interneurons in the BLA by prefrontal fibers was diminished in the offspring of immunoactivated mice. Therefore, the balance between excitation and inhibition in mPFC-BLA projections was shifted toward a greater functional efficiency of excitation. The latter, resulting in the enhanced probability of neuronal firing in the BLA in response to incoming afferent signals arising from the mPFC, could potentially contribute to autistic-like behavioral modifications in the offspring of immunoactivated mice.

Abstract: Both genetic and environmental factors are thought to contribute to neurodevelopmental disorders with maternal immune activation (MIA) being a risk factor for both autism spectrum disorders and schizophrenia. Here, using different cellular and molecular approaches with electrophysiological and behavioral analysis, we have investigated synaptic structure in the somatosensory cortex of MIA mouse model. Using *in vivo* multiphoton imaging, we determined that there is reduction in number and turnover rates of dendritic spines, sites of excitatory synaptic contacts in the cortex of young MIA offspring. The spine impairments, confirmed by confocal analysis, persisted into adulthood and correlated with increased repetitive behavior, an ASD relevant behavioral phenotype. Analysis of synaptic inputs revealed an increase in proportion of dendritic spines that were contacted by both excitatory and inhibitory presynaptic terminals (VGluT1and GAD) and these structural impairments were accompanied by altered excitatory and inhibitory synaptic transmission. Furthermore, we have confirmed that MIA results in increase in the surface expression of the major histocompatibility complex I (sMHCI) proteins in brain slices. Finally, a postnatal treatment of MIA offspring with the anti-inflammatory drug, ibudilast, prevented both synaptic and behavioral impairments. Our results suggest that altered inflammatory state associated with maternal immune activation results in increased level of sMHCI and in impaired synaptic development persisting into adulthood but which can be prevented with early anti-inflammatory treatment.

Title: Dysfunction of microglia-mediated reorganization of dentate gyrus-CA3 circuits in a mouse autism model

Authors: *K. SHIBATA, R. KOYAMA, K. MORISHITA, Y. IKEGAYA;
Lab. Chem. Pharmacol., Grad. Sch. Pharmaceut. Sci., Univ. Tokyo, Tokyo, Japan

Abstract: Selective pruning of inappropriate synapses by microglia is fundamental to the development of functional neural circuits. Increasing evidence suggests that one of the earliest events in autism spectrum disorders (ASDs) is the deficits in a balance between excitatory and inhibitory synapses; however, whether and how microglia-mediated synapse elimination is involved in synaptic dysfunction in ASDs remains unknown. We report that microglia-mediated synapse elimination was attenuated in the hippocampus of mouse offspring from mothers that experienced maternal immune activation (MIA), which is known as a risk factor for ASDs in offspring. In control mice, the dentate gyrus-CA3 synaptic connections were refined through activity- and microglia-dependent elimination of the mossy fiber synapses through postnatal 2 to 4 weeks old. In contrast, the elimination of mossy fiber synapses by microglia was attenuated in mice whose mothers experienced MIA during pregnancy. Importantly, the excess synapses were detected as early as postnatal 4 weeks old and maintained throughout adulthood. Finally, voluntary wheel running from postnatal 4 to 8 weeks old enhanced microglia-mediated engulfment of the mossy fiber synapses in MIA groups and successfully decreased the synapse density to control levels. This process was also mediated by microglia. Thus, our finding suggests that the early-life deficits in microglia-mediated synapse elimination take place in ASD hippocampus and that exercise in adolescence may prevent MIA-dependent synaptic imbalance in ASDs.

Title: Identifying translating mRNAs involved in pathological synaptic plasticity

Authors: *S. R. THOMSON[1], M. F. BEAR[2], E. K. OSTERWEIL[1,2];
[1]Ctr. for Integrative Physiol., Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Fragile X syndrome (FXS) and Tuberous Sclerosis Complex (TSC) are single-gene syndromic disorders that share a high incidence of autism spectrum disorder and intellectual disability (ASD/ID). Because they are genetically defined and can be effectively modelled in animals, the study of these disorders has been valuable in understanding the molecular mechanisms of ASD/ID. Both FXS and TSC are caused by mutation of genes that function in mRNA translation. In the *Fmr1*$^{-/y}$ mouse model, basal protein synthesis is excessive and there is an exaggeration of long-term depression (LTD) induced by Gp1 metabotropic glutamate receptor (mGluR) activation in hippocampal CA1. In the *Tsc2*$^{+/-}$ mouse, hippocampal protein synthesis and mGluR-LTD are deficient. Mice bred to carry both *Fmr1*$^{-/y}$ and *Tsc2*$^{+/-}$ mutations display normal protein synthesis rates and mGluR-LTD. Thus, FXS and TSC mouse models exhibit mirror alterations in the same cellular process, synaptic protein synthesis, suggesting a point of convergence for multiple genetic causes of ASD/ID. The identity of the mRNAs translated to support mGluR-LTD, and mis-translated at *Fmr1*$^{-/y}$ and *Tsc2*$^{+/-}$ synapses, is not known. We are addressing this question using Translating Ribosome Affinity Purification (TRAP) to isolate mRNAs specifically translated in CA1 pyramidal neurons and dendrites of *Fmr1*$^{-/y}$, *Tsc2*$^{+/-}$, and *Fmr1*$^{-/y}$x*Tsc2*$^{+/-}$ mutant mice. Using this approach, we can compare the translatomes of WT versus mutant neurons, under both control and LTD conditions. Our preliminary experiments show a consistent isolation of CA1 pyramidal cell-specific translating mRNAs from whole hippocampus or from acute hippocampal slices. We are identifying these mRNAs in WT and mutant samples using next-generation RNA sequencing, and performing follow up studies to assess the role of identified targets in plasticity and the pathogenesis of ASD/ID. Unexpectedly, our preliminary results show that mRNA encoding the GluA2 subunit of the AMPA-type glutamate receptor (AMPAR) is overrepresented in *Fmr1*$^{-/y}$ ribosomes in CA1 pyramidal neurons. Metabolic labeling experiments confirm that GluA2 is over-translated in *Fmr1*$^{-/y}$ hippocampal slices. We are currently investigating the role of this change in the pathological phenotypes observed in the *Fmr1*$^{-/y}$ hippocampus.

Title: Tsc2-deficiency induced mTOR hyperactivity impairs spatiotemporal dynamics of mitophagy in neurons

Authors: *D. EBRAHIMI-FAKHARI[1,3], A. SAFFARI[3], L. WAHLSTER[2], A. DINARDO[1], M.-J. HAN[1], M. SAHIN[1];
[1]Neurol., [2]Stem Cell Program, Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [3]Pediatric Neurol., Heidelberg Univ. Hospital, Ruprecht-Karls Univ. Heidelberg, Heidelberg, Germany

Abstract: Objectives: Tuberous sclerosis complex (TSC) is a neurodevelopmental disorder caused by mutations in *TSC1* or *TSC2,* which encode critical regulators of mTORC1. Loss of *TSC1* or *TSC2* renders an mTOR hyperactive state resulting in abnormal neuronal metabolism and impaired autophagy. Whether this leads to deficits in mitochondrial trafficking or mitochondrial degradation by autophagy (mitophagy) is unknown. Using TSC as a genetically tractable model, the objective of this study is to determine whether mTOR hyperactivity alters the spatiotemporal dynamics of mitochondrial transport and mitophagy in neurons. **Methods:** To study mitochondrial turnover, we use a combination of gene knockdown, pharmacology, live imaging probes, time lapse confocal microscopy, immunocytochemistry and biochemical assays in cultured embryonic rat neurons and cortical neurons differentiated from induced pluripotent

stem cells (iPSC) of TSC patients and controls. **Results:** Knockdown of *Tsc2* in neurons leads to uncoordinated axonal transport of mitochondria, which is reversed by treatment with the mTORC1-inhibitor rapamycin. Following acute loss of mitochondrial membrane potential ($_m\Psi$), depolarized mitochondria are rendered stationary with a subset showing enhanced retrograde transport in control neurons. No such retrograde transport pattern is found in *Tsc2*-deficient neurons, pointing to impaired translocation and clearance of damaged mitochondria from axons. The presence of mitochondria with reduced $_m\Psi$ in neurites is confirmed in iPSC-derived cortical neurons from TSC patients. Examining the spatiotemporal dynamics of mitophagy, we find that *Tsc2*-deficient neurons show enhanced Parkin-translocation to mitochondria at baseline. Large p62-positive aggregates and enlarged LC3-positive autophagic vesicles accumulate, suggesting reduced turnover through autophagy. Probing the recruitment of the autophagy machinery following induction of mitophagy, we find impaired formation and turnover of autophagosomes in *Tsc2*-deficient neurons. Impaired autophagosome-lysosome fusion is quantified using a GFP-mCherry-LC3 tandem assay. Mitochondria-targeted mKeima is employed to quantify mitophagy. **Conclusions:** TSC provides a genetically tractable model to examine the impact of hyperactive mTOR signaling on mitochondrial transport and turnover. Specific deficits in axonal and global mitophagy are present in *Tsc2*-deficient neurons. Accumulation of damaged mitochondria in axons could lead to impaired synaptic signaling and thus may contribute to complex disease manifestations such as autism-spectrum disorder or intellectual disability.

Title: Examining the role of dixdc1 in neural connectivity and autism spectrum disorder

Authors: *V. KWAN[1], C. HUNG[1], N. HOLZAPFEL[1], K. HABING[1], N. MURTAZA[1], S. WALKER[2], S. SCHERER[2], K. HOPE[1], R. TRUANT[1], K. SINGH[1];

Abstract: Emerging studies suggest that molecules in the Wnt signalling pathway are important for the development of neural connectivity and are associated with autism spectrum disorders (ASDs). We are studying a Wnt signalling molecule named DIX domain containing-1 (DIXDC1), a homolog of Disheveled and Axin that has previously been linked to psychiatric disorders. Preliminary results, using mouse *in vitro* and *in vivo* models, show that decreasing the expression of DIXDC1 reduces dendrite outgrowth, and dendritic spine formation and maturation. Additionally, we found that DIXDC1 may function through an actin-dependent mechanism to regulate actin dynamics and polymerization. We also found that phosphorylation of DIXDC1 mediates dendritic spine formation through modulation of actin dynamics. Finally, using exome sequencing of families with ASDs, we discovered rare inherited genetic variants in DIXDC1. Expression of these variants in primary neurons causes impaired dendrite and dendritic spine development. Future work being conducted will reveal the role of DIXDC1 in neurodevelopment using electrophysiological approaches to determine its impact on neuronal function and ASDs. Together these data suggest a novel DIXDC1 pathway for synaptic development and its possible role in neural connectivity defects associated with ASDs.

Title: Synaptic alterations in the striatum and the cortex of a new mouse model of autism spectrum disorders: JAKMIP1 knock-out mouse

Authors: *L. GALVAN[1], J. BERG[2], J. Y. CHEN[1], C. CEPEDA[1], D. GESCHWIND[2], M. S. LEVINE[1];
[1]Semel Inst. For Neurosci. and Human Behavior, BRI, UCLA, Los Angeles, CA; [2]Neurogenetics Program, Dept. of Neurology, and Ctr. for Autism Res. and Treatment, Semel, UCLA, LOS ANGELES, CA

Abstract: Autism spectrum disorders (ASD) are developmental conditions characterized by alterations in social interaction, communication and behavior. Major effect mutations such as the inherited duplication of 15q11-q13 (dup(15q)) or FMR1 gene (Fragile X mental retardation), are associated with ASD. Mutations in the FMR1 gene lead to the loss of FMR protein, a translational repressor. Its absence disturbs synaptic plasticity and neuronal development. Animal models of Fragile X syndrome do not display a robust behavioral phenotype. Interestingly, previous studies analyzing the transcriptome of lymphoblastoid cells from autistic males diagnosed with ASD and Fragile X syndrome, ASD and dup(15q), and idiopathic ASD revealed that all patient groups had altered levels of janus kinase and microtubule-interacting protein 1 (JAKMIP1). The present study examined electrophysiological alterations in a recently generated JAKMIP1 knock-out (KO) mouse. These animals displayed a striking stereotypical behavioral phenotype consisting of "jumping." This motor stereotypy suggested a potential involvement of basal ganglia circuits. We investigated whether the striatum could contribute to the development of the phenotype in these animals. We recorded medium-sized spiny neurons (MSNs) in the dorsal striatum of male juvenile (P14) and male adult (2-3 months) JAKMIP1 KO and wildtype (WT) littermate mice using whole-cell patch clamp recordings in voltage clamp mode. Cortical pyramidal neurons (CPNs) in layer II/III also were recorded in adult KO and WT mice. In the striatum, adult JAKMIP1 KO mice displayed a significant increase in frequency of spontaneous inhibitory (IPSCs) and excitatory postsynaptic currents (EPSCs) suggesting up-regulation of GABA and glutamate neurotransmission in MSNs. In the cortex, adult JAKMIP1 KO mice also showed an increase in spontaneous EPSC frequency but did not display changes in IPSCs. To examine glutamate receptor-mediated responses in MSNs we used electrical stimulation to evoke AMPA receptor (AMPAR)- and NMDA receptor (NMDAR)-mediated currents. The amplitude of the AMPAR response was not altered at both ages. In contrast, the charge and the decay time of the NMDAR response were significantly increased in the P14 but not in the 2-3 month KO mice. Interestingly, a proportion of KO MSNs showing an AMPAR response failed to display a NMDAR response at both ages. These results demonstrate that there are significant alterations in synaptic activity in the cortex and striatum of JAKMIP1 KO mice. Future studies will be aimed an uncovering the cellular mechanisms for these changes in neuronal communication.

Title: Neuronal overexpression of AT-1 causes an autistic-like phenotype in the mouse

Authors: *R. HULLINGER[1], L. MI[2], J. WANG[2], E. BOMBA[2], J. DOWELL[2], C. BURGER[2], E. CHAPMAN[2], J. DENU[2], L. LI[2], L. PUGLIELLI[2];
[1]Univ. of Wisconsin- Madison, Madison, WI; [2]Univ. of Wisconsin, Madison, WI

Abstract: The import of acetyl-coA into the lumen of the ER by AT-1/SLC33A1 is an essential step in the secretory pathway that regulates the N(ε)-lysine acetylation status of ER resident and transiting proteins (J Cell Sci 2010;123:3378; J Biol Chem 2012; 287:22436). Our group has demonstrated that lysine acetylation within the ER is essential for ER mediated quality control. Specifically, properly folded proteins are acetylated and proceed through the secretory pathway, whereas unfolded/misfolded proteins are retained and subjected to ER associated degradation (J Biol Chem 2014;289:46). In addition, our group has shown that decreased activity of AT-1 leads to aberrant autophagy in cell lines (J Cell Sci 2010;123:3378; J Biol Chem 2012; 287:29921), and causes neurodegeneration, inflammation, and propensity to infections and cancer in a mouse model (J Neurosci 2014;20:6772). Heterozygous mutations in AT-1 have been identified in patients affected by autosomal dominant spastic paraplegia-42 (SPG42) while homozygous mutations have been identified in patients affected by severe neurodevelopmental delay and childhood death. Finally, a duplication of AT-1/SCL33A1 has been reported in patients with autism spectrum disorder and intellectual disability. In the present study, we sought to investigate the consequences of increased activity of AT-1. To investigate this, we generated the AT-Tg mouse model that selectively overexpresses AT-1 in neurons. These animals demonstrate cognitive deficits and autistic like social behaviors, aberrations in synaptic plasticity, dramatic enhancements in dendritic spines and branch formation, and widespread proteomic changes. In addition, we found that AT-Tg animals display widespread increases in the expression of mitochondrial enzymes related to acetyl-coA production, suggesting that increased movement of acetyl-coA into the ER causes downstream compensatory mechanisms in mitochondrial activity.

Furthermore, we discovered that AT-Tg animals display epigenetic changes marking global increases in transcription. In conclusion, our results indicate that increased expression of AT-1 can cause an autistic-like phenotype by affecting key neuronal pathways.

Title: Excessive Ras-MAPK-dependent synaptic clustering drives enhanced motor learning in the MECP2-duplication mouse model of syndromic autism

Authors: ***R. T. ASH**[1], S. A. BUFFINGTON[2], P. G. FAHEY[2], J. PARK[2], H. LU[2], M. COSTA-MATTIOLI[2], H. Y. ZOGHBI[3], S. M. SMIRNAKIS[1];

Abstract: We hypothesized that an imbalance between synaptic stability and plasticity could explain the rigid, restricted behaviors and at times savant-like behaviors seen in autism. The goal of our study was to test this hypothesis by linking changes in synaptic plasticity to a robust learning phenotype in an animal model of autism *in vivo*. We found an increase in the stabilization of dendritic spines formed during rotarod motor learning in the mouse model of MECP2 duplication syndrome, a high-penetrance form of syndromic autism. This increased stabilization is mediated entirely by spines that form cooperatively in clusters. The number of clusters formed and stabilized predicts the mutant's enhanced motor learning and memory phenotype. The Ras-MAPK signaling pathway was found to be hyperactive in MECP2-duplication motor cortex specifically after training. Inhibition of Ras-MAPK signaling normalizes clustered spine stabilization and rescues motor learning behavior in mutants. We propose that excessive cooperative stabilization of synaptic clusters driven by hyperactive Ras-MAPK signaling during learning leads to "overfitting" of movement representations that can

improve motor control but poorly generalize -- that is, a rigid and restricted behavioral repertoire -- in this form of syndromic autism.

Title: Physiological effects of an ASD-associated mutation in CaMKIIα

Authors: ***J. R. STEPHENSON**, X. WANG, B. C. SHONESY, J. S. SUTCLIFFE, R. J. COLBRAN;
Vanderbilt Univ., Nashville, TN

Abstract: Autism spectrum disorder (ASD) is a common neurodevelopmental disorder that affects 1-2% of the population and involves deficits in social interaction and communication, along with repetitive or stereotyped behaviors and resistance to change in routines. ASD is a predominantly genetic disorder, and roles exist for both common genetic variation and rare, more penetrant risk alleles in contributing to genetic liability. Numerous rare, ASD-associated genetic mutations impact synaptic proteins, indicating that disruptions in the protein networks involved in synaptic development, architecture and plasticity contribute to ASD etiology. Thus, a current major focus is to understand molecular mechanisms that link ASD-associated mutations to disruptions in neuronal signaling pathways that control synaptic transmission. One key regulator of synaptic function is calcium/calmodulin-dependent protein kinase II (CaMKII), which phosphorylates several synaptic substrates and serves a structural role through interaction with diverse CaMKII-associated proteins (CaMKAPs). Our recent proteomic analyses of synaptic CaMKII complexes found that several ASD-linked proteins are associated with CaMKII in the brain (Baucum et al., 2015. ACS Chem Neurosci **6**:615). Here, we confirm that CaMKIIα and Shank3 can be co-immunoprecipitated from co-transfected HEK293 cells. Moreover, a *de novo* mutation in *CAMK2A* –encoding CaMKIIα— was recently identified in an ASD proband in a

whole exome sequencing study (Iossifov et al., 2014. Nature **515**;216) . Our data indicate that this mutation dramatically decreases CaMKIIα substrate phosphorylation, autophosphorylation at key regulatory residues, and interaction with various CaMKAPs. Furthermore, we have found that over-expression of the mutated CaMKIIα in primary hippocampal neurons at different developmental stages causes multiple changes in dendritic morphology. These studies provide novel mechanistic insights into a potential role for CaMKIIα in ASD and will advance our understanding of the impact to synaptic development and function caused by ASD mutations.

Title: Neuregulin-1 promotes redox-dependent neuronal cobalamin metabolism by stimulating cysteine-dependent glutathione synthesis

Authors: *R. C. DETH[1], N. HODGSON[2], M. TRIVEDI[1], M. SCHRIER[1], Y. ZHANG[3]; [1]Pharmaceut. Sci., Nova Southeastern Univ., Davie, FL; [2]Neurol., Harvard Med. Sch., Boston, MA; [3]Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Neuregulin-1 (NRG-1) is a key neurotrophic factor involved in energy homeostasis and CNS development. Impaired NRG-1 signaling is associated with neurological disorders, especially schizophrenia. Cobalamin (Cbl), also known as vitamin B12, is an essential micronutrient which mammals must acquire through diet and neurologic dysfunction is a primary clinical manifestation of Cbl deficiency. Here we show that NRG-1 stimulates neuronal synthesis of bioactive Cbl species adenosylcobalamin (AdoCbl) and methylcobalamin (MeCbl) in SH-SY5Y neuronal cells by both promoting conversion of inactive to active Cbl species and increasing neuronal Cbl uptake. Formation of active Cbls is glutathione (GSH)-dependent and the NRG-1-initiated increase is dependent upon its stimulation of cysteine uptake by excitatory amino acid transporter-3 (EAAT3), leading to increased GSH. The stimulatory effect of NRG-1 on cellular Cbl uptake is associated with increased expression of megalin, which facilitates Cbl transport in ileum and kidney. MeCbl is a required cofactor for methionine synthase (MS) and we demonstrate the ability of NRG-1 to increase MS activity, as well as affecting levels of methionine methylation cycle metabolites. The ability of lithium to promote megalin-related

transport activity has been previously described. Lithium treatment caused a significant increase in cysteine and GSH levels along with an increase in methylation capacity but a decrease in Cbl content. Thus our results identify novel neuroprotective roles for NRG-1 in terms of stimulating antioxidant and Cbl synthesis, as well as novel actions of lithium on redox and methylation status. These findings provide a potential mechanistic link between impaired NRG-1 signaling and neurological disorders such as schizophrenia.

Title: Neuronal adaptor protein Mint2/APBA2 associated in the pathogenesis of Autism Spectrum Disorders (ASDs)

Authors: ***Y. LIN**[1,2], K. CONNOR[2], A. E. DUPRE[2], G. M. DILLON[2], U. BEFFERT[2], A. HO[2]; [1]Dept. of Pharmacol. and Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [2]Biol., Boston Univ., Boston, MA

Abstract: Autism Spectrum Disorders (ASDs) comprise a heterogeneous group of neurodevelopmental disorders characterized by a complex genetic etiology. Mutations in the human *MINT2* gene (official gene name, *APBA2*) that encodes for a neuronal adaptor protein have been genetically-linked to ASD patients. In addition, several studies have independently identified copy number variants in the *MINT2* gene associated with ASD. Also, the *MINT2* gene maps to the distal portion of chromosome 15q13.1, a region commonly deleted in Prader-Willi and Angelman syndromes and duplicated in cases of autism, making *MINT2* an attractive candidate gene associated with autism. To date, the functional consequences of these Mint2 variants in neuronal development and physiology have yet to be examined. We hypothesize that Mint2 plays an important role in neuronal development and function. Previous studies have identified seven novel nonsynonymous coding variants in Mint2 in ASD subjects. We found that these Mint2 ASD mutants did not disrupt Mint2 expression; however, three of the Mint2 mutants (R4Q, T660M, and N723S) alter the binding and localization of its interacting partners and affect

Mint2 function. Since ASDs are associated with structural and functional abnormalities in neurons, we examined whether Mint2 ASD mutants altered axon polarization and dendritic branching. We found that the N723S Mint2 ASD mutant decreased axon length and dendritic branching. In addition, we found that the N723S Mint2 ASD mutant decreased the frequency of spontaneous miniature currents of excitatory synapse suggesting that the N723S Mint2 ASD mutant altered neuronal development and synaptic function. In addition to sequence variants, copy number variants of Mint2 may be responsible for severe ASD phenotypes based on the chromosomal location of the *MINT2* gene. Therefore, we examined whether overexpression of Mint2 altered neuronal development. We found that overexpression of Mint2 increased axon length and synaptic density which correlated with the increase in miniature event frequency in excitatory synapses suggesting that Mint2 alters excitatory presynaptic neurotransmitter release machinery. Our results indicate that sequence and copy number variants in Mint2 lead to dysfunction in neuronal development and that altered synaptic function of Mint2 is a potential mechanism that contributes to ASD pathogenesis. A better understanding of the molecular mechanism of how genes affect neuronal physiology will eventually lead to advances in diagnosis and treatment in ASD.

Title: The ependymal protein alpha-T-catenin contributes to autism through its age-dependent effect on ventricle size and neurogenesis

Authors: *S. S. FOLMSBEE, D. R. WILCOX, C. J. GOTTARDI;
Northwestern Univ., Chicago, IL

Abstract: Autism is a complex disease, with a wide variety of clinical presentations and a vast spectrum of neurologic dysfunction. Recently, single nucleotide polymorphisms and copy number variants in the cell-cell adhesion protein alpha-T-catenin has been implicated in the

development of autism, as well as other neurologic disorders with autistic-like behaviors. Even more striking, a recent study found that compound heterozygote mutations in alpha-T-catenin were linked to the development of autism. However, the vast majority of research of alpha-T-catenin is limited to its function in the heart, which is where it is primarily expressed. Although alpha-T-catenin has been found in detectable levels in the brain, the primary cell type expressing it, as well as its potential impact on brain function is unknown. Using an alpha-T-catenin total knockout (KO) mouse, we have found that alpha-T-catenin is indeed present in the brain, localizing to the ependymal cells lining the ventricles, but is absent in the cells of the choroid plexus and neurons. It co-localizes with other cadherin complex members, including N-cadherin and alpha-E-catenin. From immunofluorescence imaging of alpha-T-catenin KO brains, we detect an increase in the expression of alpha-E-catenin in the cell-cell junctions of ependymal cells, as well as a less apical distribution when compared to wild-types (WT). This suggests that the loss of alpha-T-catenin may induce an ependymal cell junction dysfunction, with a compensatory response in other adhesion proteins. Additionally, in the KO mice, there may be changes to the structure and overall presence of motile cilia on ependymal cells, based on a preliminary histologic analysis. There also is increased proliferation in the subventricular zone due to loss of alpha-T-catenin, as well as an increase in ventricle size, both of which are more prominent in aged mice. Most importantly, we have found that alpha-T-catenin KO mice show behaviors consistent with an autism-like phenotype. In mice allowed to age for many months, alpha-T-catenin KO mice show increased self-grooming behaviors when compared to WT, which is an established measure of autism-like behavior in rodent models. Together, our data show that alpha-T-catenin is indeed present in the brain, specifically in the cells lining the ventricles. Furthermore, the loss of alpha-T-catenin in the brain may contribute to autistic phenotypes through dysfunction of ependymal cell-cell adhesion, increase in neurogenesis, and enlargement of the ventricles.

Miller Institute for Basic Research in Science

Title: Circuit-level E/I-ratio disruption in ASD mouse models: a common model of sensory hyperexcitability?

Authors: *M. W. ANTOINE[1], P. SCHNEPEL[2], D. E. FELDMAN[2];
[1]Miller Inst. for Basic Res. in Sci., Univ. Of California, Berkeley, Berkeley, CA; [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Given the genetic heterogeneity of autism spectrum disorder (ASD), is there a common pathology at the neural circuit level? A major hypothesis is that ASD involves increased excitation-inhibition (E-I) ratio and hyperexcitability in local neocortical circuits, which may underlie seizure proclivity and hypersensitivity to sensory stimuli. To test this model, we are comparing circuit physiology and sensory processing in primary somatosensory (S1) cortex across multiple ASD mouse strains. S1 is a reasonable site to investigate ASD circuit dysfunction since 80-90% of ASD patients have sensory abnormalities including tactile hypersensitivity. Here, we report initial results from two ASD strains: contactin associated protein-like 2 (Cntnap2) and fragile X mental retardation 1 (Fmr1) mice. Using whole-cell recordings in S1 slices, we measured layer (L) 4-evoked (feedforward) EPSCs and IPSCs converging in single L2/3 pyramidal cells. In Fmr1-/y mice, EPSCs showed a non-significant trend toward reduction by 43% but IPSCs were reduced by 64% relative to controls (n = 17, 17 cells). As a result, E-I ratio in individual neurons was increased by 32%. In CNTNAP2-/- mice, EPSCs were reduced by 62% and IPSCs were reduced by 82% relative to CNTNAP2+/+ littermates (n=12, 12 cells), causing E-I ratio to increase by 40%. Thus, both strains showed a pronounced decrease in inhibition and increased E-I ratio. Reduced inhibition likely reflects reduced function of parvalbumin (PV) interneuron circuits, which mediate L4-L2/3 feedforward inhibition. To test whether these circuit changes affect sensory processing, we recorded in anesthetized Fmr1-/y and FVB mice, but initial data showed no change in L2/3 single unit whisker receptive field width or magnitude of whisker-evoked spiking responses to weak whisker deflections (n = 44, 21 units). Thus, other mechanisms may preserve sensory representations despite altered feedforward excitation, inhibition, and E-I ratio in L2/3 of FmR1-/y mice. Future measurements will assay local circuit excitability, and test additional ASD mouse strains. The long-term goal is to test the E-I ratio hypothesis and reveal what form(s) of circuit dysfunction, if any, are common in sensory cortex across genetically distinct forms of ASD.

Title: Convergent excitability defects in the prefrontal corticothalamic circuit unite diverse mouse models of autism

Authors: *A. C. BRUMBACK[1], V. S. SOHAL[2];
[1]Pediatric Neurol., [2]Psychiatry, Univ. of California, San Francisco, San Francisco, CA

Abstract: OBJECTIVE: Autism is one of the most heritable neurodevelopmental disorders, and though many genes have been linked to the condition, how these genetic changes translate into deficits in social interactions is largely unknown. Recent work suggests that defects in diverse genes and signaling pathways associated with autism converge upon the deep layer (L5/6) projection neurons within the prefrontal cortex (PFC). L5/6 of the medial PFC (mPFC) is comprised of at least two distinct classes of pyramidal neurons that project either subcortically (corticothalamic - CT cells) or to the contralateral mPFC (corticocallosal - CC cells). METHODS: We studied the physiology of these two subpopulations of mPFC L5/6 pyramidal neurons in three distinct mouse models of autism: prenatal exposure to valproate (VPA, a commonly used anticonvulsant and histone deacetylase inhibitor), knockout of the Fragile X gene (FMR1, an mRNA binding protein), and knockout of the Contactin Associated Protein-Like 2 gene (CNTNAP2, a cell adhesion molecule). RESULTS: We found that these three diverse autism models exhibit a common circuit-level deficit in prefrontal CT cell excitability. In the autism models, mPFC L5/6 CT cells had depolarized resting membrane potentials, decreased input resistance, and fired fewer action potentials in response to depolarizing current steps. Comparable changes were not seen in CC neurons. Previous work in our laboratory has shown that within the mPFC, D2R expression occurs largely (though not exclusively) within deep layer CT neurons. Therefore, to explore possible behavioral consequences of reduced mPFC CT cell excitability, we optogenetically inhibited D2R-expressing neurons. Surprisingly, acute optogenetic inhibition of D2R-expressing neurons within the mPFC increased social exploration in the VPA-exposure model of autism. CONCLUSIONS: Together, these results demonstrate a specific circuit-level defect in the mPFC associated with multiple etiologically distinct forms of autism. Furthermore, ameliorating abnormal activity in D2R-expressing, thalamically-projecting deep layer prefrontal neurons may represent a novel therapeutic strategy for social defects in

autism spectrum disorders. Supported by NIH and the Simons Foundation Autism Research Initiative.

Abstract: Autism spectrum disorders (ASDs) are common developmental neurological disorders, characterized by impaired social interaction and communication. Despite significant heritability of ASDs, their extreme genetic heterogeneity has proven challenging for gene discovery. Recent studies have shown that massively parallel sequencing using a targeted gene panel is particularly suited for diagnostic testing for genetically heterogeneous conditions. Therefore, we re-sequenced all the exons of the 700 ASD candidate genes in 500 patients with ASD and 500 control subjects and identified 800 novel missense rare variants in 200 genes. Furthermore, we identified that CDH13 gene, which encodes T-cadherin, showed the highest number of missense/nonsense mutations out of the 700 ASD candidate genes. Intriguingly, gene knockdown of CDH13 using RNA interference (RNAi) in excitatory neurons impaired excitatory synaptic transmission. Expression of wild-type CDH13 could rescue this defective excitatory

synaptic transmission, however, some of the ASD variants could not. Mass spectrometry analyses revealed a novel neuronal binding partner and the potential mechanism that confers the defective synaptic phenotypes by CDH13 knockdown. Our combined approaches will provide additional support to the growing evidence linking the dysfunction of neural cell-adhesion molecules to ASDs.

Title: Developmental *in vivo* cellular localization of Shank1 and Shank2 scaffold proteins

Authors: *S. M. COLLINS, R. GALVEZ, S. REED;
Psychology, Univ. of Illinois, Urbana, IL

Abstract: It is well known that development is a critical period that is in part characterized by remarkable synaptic changes within the neocortex. Anatomical studies have shown that neocortical synapse density and dendritic spine morphology have very distinct developmental patterns. However, the mechanisms underlying these synaptic changes remain elusive. One family of proteins that have been shown to mediate synaptic changes and thus may contribute to these developmental neocortical changes are the Shank family of scaffold proteins. In the brain, these proteins have been shown to be exclusively localized to the post synaptic density (PSD) of excitatory neurons. Studies exploring the role of Shank1 and Shank2 in synaptic plasticity have further demonstrated that genetic modulation of either can change synapse size and density. Furthermore, Shank1 and Shank2 genetic knockouts have been shown to be dramatically impaired on several learning paradigms that have been shown to cause neocortical synaptic plasticity. Similarly, preliminary data from our laboratory has shown an increase in Shank expression in primary somatosensory cortex during acquisition for the associative learning paradigm, whisker trace eyeblink conditioning (WTEB). Our laboratory has previously demonstrated that WTEB transiently increases dendritic spine density in layer IV of primary somatosensory cortex during task acquisition. Collectively, these data suggest that Shank1 and Shank2 play a critical role in both learning-induced and developmental neocortical synaptic

plasticity. However, the developmental expression profile of these proteins are unknown. The present study used immunofluorescence to determine the cell type and localization of Shank1 and Shank2 expression during four developmental time points that cover synaptic development in primary somatosensory cortex. These analyses will provide a better understanding of the role of Shank1 and Shank2 during development of neocortical neuronal properties.

Title: Involvement of p53 in neurodevelopmental toxicity of mercury and ethanol

Authors: *E. M. SAJDEL-SULKOWSKA;
Psychiatry, Harvard Med. Sch/BWH, Boston, MA

Abstract: Background: Regulation of neuronal stem cells (NSC) proliferation and differentiation is critical for normal neurodevelopment and especially sensitive to the environmental perturbation. Perinatal exposure to environmental toxins, mercury and ethanol (ETOH), has been linked to neurodevelopmental pathologies such as autism spectrum disorders (ASD) and fetal alcohol syndrome (FAS), yet the underlying mechanism(s) are not clear. We have shown previously that exposure of NCS *in vitro* to thimerosal (TM; an ethyl mercury preservative in biological materials), resulted in decreased cell proliferation and changes in expression of genes linked to neuronal survival; exposure of NSC to ETOH *in vitro* has been shown to interfere with cell differentiation. Altered expression of p53, a protein involved in regulation of both cell proliferation and differentiation has been implicated in both mercury- and ETOH-associated cell damage. Aims: The aim of the present study was to probe p53 involvement in neurodevelopmental toxicity of TM and ETOH. Methods: Rat embryonic NSC, and mouse wild type and p53 knockout NCS were cultured in proliferation media (StemCell Technologies). On day 6 in culture, TM (17 nM) or ETOH (100μM) were added to the media and cells were harvested 24hrs later. Additionally, the effect of toxins was measured in rat-P1 cerebellar cultures. Cell proliferation was determined by a direct and nonradioactive proliferation assay (MTT); gene expression was determined by qRT-PCR. Results: We report that the addition of

TM resulted in growth inhibition in rat embryonic NCS (72.5%), mouse wild type NCS (57%) and p53 knockout mouse NCS (38%); addition of TM to primary cultures resulted in growth inhibition and altered expression of genes related to cell survival. The addition of ETOH resulted in no significant effect in rat embryonic NCS, growth inhibition in mouse wild type NCS (79.5%), and in rat primary cultures (59%), but growth stimulation in p53 knockout mice NCS (50.5%). Summary: The results of this study support p53 involvement in the neurotoxity of both TM and ETOH. The data further suggest that p53 signaling pathway may contribute to TM-associated increase in NSC apoptosis, but ETOH-associated decrease in cell proliferation. Indeed, it has been shown that exposure of NCS to ETOH results in decreased expression of mitosis-related genes in p53-signaling pathway. Toxin-associated changes in cell apoptosis and/or cell proliferation may in turn alter the developmental stage-specific progenitor cell number critical for normal development thus contributing to neurodevelopmental pathologies.

Title: Macroautophagy pathway analysis in autism spectrum disorders

Authors: *A. HAM[1], H. LI[1], S. KUO[1], D. SULZER[2], G. TANG[1];
[1]Dept. of Neurol., [2]Dept. of Neurology, Dept. of Psychiatry,Department of Pharmacol., Columbia Univ., New York, NY

Abstract: Autism spectrum disorders (ASDs) are genetically heterogeneous, but different ASD genes may cluster into a smaller number of pathways, including the protein kinase mammalian target of rapamycin (mTOR). mTOR is a key molecule that regulates protein homeostasis by promoting protein synthesis and inhibiting macroautophagy (autophagy thereafter), a homeostatic degradation process whereby cellular proteins and organelles are engulfed by autophagosomes, digested in lysosomes, and recycled to sustain cellular metabolism. We recently discovered that mTOR is overactive in excitatory neurons in brains of a subset of ASD patients [Tang et al., 2014]. Excessive mTOR activity in ASD is associated with a increase in the density of dendritic spine synapses as well as a blockade in dendritic spine pruning, a postnatal developmental process during which unnecessary excessive excitatory synapses are eliminated. Autophagy deficiency in response to the faulty mTOR activity contributes largely to the ASD

synapse pathology. This study aims to screen for autophagy activities in peripheral blood cells and to provide a means to identify a subset of autism for treatment targeting autophagy pathway. We found a significant decrease in autophagy marker LC3II and an increase in autophagy substrate p62 in ASD-derived lymphoblasts, both suggest a low level of basal autophagy. Hyperactivation of mTOR is not seen in all lymphoblasts taken from individuals with ASD (<10 yrs), indicating addition regulatory mechanisms in autophagy impairment in ASD. We thus used the human autophagy RT² Profiler™ PCR array to profile the expression of 84 genes involved in autophagy in both control and autism lymphoblasts. The array includes genes that encode components of the molecular machinery and key regulators modulating autophagy in response to both extracellular and intracellular signals. Among these genes, we found that AMBAR1, Atg9A, ULK1, three genes involved in the formation of autophagic vacuoles and the initiation of autophagy, are downregulated. These transcriptional changes were validated at protein levels by western blot analysis in both ASD lymphoblasts and postmortem human brain. Our data provide further evidence that autophagy is downregulated in ASD, and autophagy-based biomarkers in peripheral lymphoblasts may predict a subset of ASD patients for targeted interventions.

Title: Prenatal environmental factors alone can induce autism and epilepsy in a rat model

Authors: *F. M. BERCUM[1], K. M. RODGERS[2], A. M. BENISON[3], Z. Z. SMITH[4], J. TAYLOR[4], E. KORNREICH[4], D. BARTH[4];
[1]UNIVERSITY OF COLORADO, Boulder, CO; [2]Univ. of Colorado at Denver, Denver, CO; [3]St. Jude Med., Denver, CO; [4]Univ. of Colorado at Boulder, Boulder, CO

Abstract: It has long been known that autism spectrum disorder (ASD) is strikingly comorbid with epilepsy, with over 30% of ASD patients also experiencing chronic recurrent seizures and a similar fraction of epilepsy patients with behavioral symptoms of ASD. These numbers rise as high as 60% when sub-convulsive epileptiform spikes are included in assessment of epilepsy.

While the comorbidity of ASD and epilepsy could hold clues to possible common mechanisms for both of these disorders and point the way to intervention strategies, there is a need for animal models to facilitate this work. Here we examined the effects of combining maternal stress with a perinatal teratogen terbutaline (currently used to arrest pre-term labor), both recognized risk factors in humans for ASD in offspring, on both ASD-like behavior (deficits in social exploration and vocalization and enhanced repetitive behavior) and spontaneous recurrent seizures in rats. We found that either treatment alone resulted in a subset of ASD-like behavior (vocalization deficits) and no signs of epilepsy. The combination of maternal stress and terbutaline produced the full triad of ASD-like behaviors and 50% of the rats also developed recurrent convulsive temporal lobe seizures. Furthermore, the remaining half of these animals displayed sub-convulsive spikes in the absence of seizures. We conclude that: 1) Combinations of teratogens are far more powerful than single treatments, a conclusion that should be extended to human studies of risk factors, 2) Both convulsive seizures and non-convulsive epileptiform spikes are closely associated with severe behavioral disturbances associated with ASD, and finally, 3) The present results represent not only a new and highly realistic animal model of epilepsy and ASD, but provide a platform for exploring mechanisms and developing anti-epileptiform/anti-ASD compounds.

Abstract: Valproic acid (VPA) exposure during pregnancy has been linked with increased incidence of autism, and has been demonstrated as a useful model of autism in mice. We examined the early behavioral and anatomical changes as well as molecular changes in mice prenatally exposed to VPA (VPA mice). In this study, we first showed that VPA mice showed impaired social recognition, developmental delays as assessed with self righting, eye opening and social recognition tests. In addition, we provide the first evidence that primary cultured neurons from VPA-treated embryos present an increase in dendritic spines, compared with those from control mice. Mutations in phosphatase and tensin homolog (PTEN) gene is also known to be associated with autism, and mice with Pten knockout show characteristics of autism. The protein levels of Pten and p-Akt was found to be reduced in the cerebral cortex and the hippocampus, and a distinctive anatomical change in the CA1 region of the hippocampus which is a similar to the Pten knockout model was observed. Taken together, our study suggests that prenatal exposure to VPA induces autistic behavioral and neuroanatomical changes via the reduction of Pten level and these changes were detectable in the early days of life.

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and social interaction, and restricted, repetitive patterns of behavior, interests or activities that manifest in early childhood. Research findings have

identified widespread changes in the immune system of children with autism, at both systemic and cellular levels. In order to identify individuals with ASD and initiate interventions at the earliest possible age, biomarkers for the disorder are desirable. To identify blood biomarkers of ASD we have used an unbiased screening approach for IgG biomarkers. We have used on-bead displays of thousands of different peptoids (N-substituted oligoglycines) to screen for candidate IgG antibody biomarkers for ASD. We have identified several peptoids (ASD1, ASD19-22) that unexpectedly bind higher levels of IgG in serum from typically developing (TD) boys compared to boys with ASD (n=50/group). The ASD1 peptoid binds >2-fold higher levels of IgG1 in TD serum than in ASD serum. Also, the peptoid-binding levels of IgG1 in the ASD boys is similar to that in older normal men (mean age = 66 years; n=53). In this Training Set of samples, the ASD1 peptoid predicts ASD with an accuracy of 66%. When we combine measurements of thyroid stimulating hormone levels with the ASD1 peptoid values from the same children, the ASD predictive accuracy is increased to 73%. These data suggest that combining peptoid and protein measurements can provide a useful blood biomarker for ASD.

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and social interaction, and restricted, repetitive patterns of behavior, interests or activities that manifest in early childhood. Research findings have identified widespread changes in the immune system of children with autism, at both systemic and cellular levels. In order to identify individuals with ASD and initiate interventions at the

earliest possible age, biomarkers for the disorder are desirable. To identify blood biomarkers of ASD we have used the Myriad Rules Based Medicine Luminex platform to measure inflammatory proteins in the blood of children with ASD (DiscoveryMAP 175+) (n=30 ASD and n=30 typically develop [TD] boys). We found 11 proteins, 7 of which were significantly different between the two groups (<0.05), that collectively predicted ASD vs. TD. Two of the most important proteins in the panel are interleukin-8 (IL-8) and thyroid stimulating hormone (TSH). These two proteins were cross-validated using the Meso Scale Discovery platform with ASD and TD boys (n=34-51/group; mean age 5 years). TSH levels were 26% lower in the ASD boys, whereas IL-8 levels were significantly higher in the ASD boys. When we used the combined levels of TSH and IL-8 to predict ASD, the predictive accuracy was 82%. These data suggest that a panel of serum proteins can be useful as a biomarker for ASD in boys. Research was supported by the Johnson Center for Child Health and Development.

Title: Left lateralized sexual dimorphism in cortical thickness in autism

Authors: *A. BEDFORD[1], M. M. PARK[2,3], G. A. DEVENYI[2], R. PATEL[2], M. CHAKRAVARTY[2,4];
[2]Cerebral Imaging Ctr., [1]Douglas Mental Healthy Univ. Inst., Verdun, QC, Canada; [3]Schulich Sch. of Med. and Dentistry,, Western Univ., London, ON, Canada; [4]Departments of Psychiatry and Biomed. Engin., McGill Univ., Montreal, QC, Canada

Abstract: Individuals with autism spectrum disorder (ASD) have been shown to have abnormal developmental trajectories of the cerebral cortex. Studies have shown cortical thickness (CT) to be increased in individuals with ASD compared to typical controls, yet results have been inconsistent. These findings have largely been based on male-dominant samples, despite reported differences in behavioural profiles and symptom severity between sexes, and little research has examined sex differences in altered cortical development in ASD. This study aims to identify the differences in cortical thickness between males and females with ASD, relative to healthy controls. MRI scans of 316 subjects (25 females with ASD, 38 female controls, 129 males with

ASD and 124 male controls, ages 6-30) were analysed, using a subset of the Autism Brain Imaging Data Exchange. Due to the disproportionate number of males in the dataset, we included in our analysis only the 3 sites with the largest number of female subjects, and which also used a Siemens Magnetom scanner. CT was estimated using the CIVET pipeline, and multiple linear regression were conducted at 40,962 CT vertices per hemisphere, to model the diagnosis by sex interaction, accounting for the age as a covariate. Correction for multiple comparisons were done using FDR. A diagnosis by sex interaction for CT was observed in the left orbitofrontal cortex, left dorsolateral prefrontal cortex, and left temporal pole, and survived 10% FDR, with the left orbitofrontal cortex also surviving 5% FDR. Males with ASD showed increased CT compared to male controls whereas females with ASD showed a decrease relative to female controls, with the magnitude of the difference in mean CT between the female groups being stronger than in the males. This interaction was significant in the same areas in the right hemisphere only at 15% FDR, indicating a possible left lateralization of the sex differences. Our results suggest that autism manifests differently in males versus females, and indicate the importance of stratifying by sex when studying the neuroanatomy of autism.

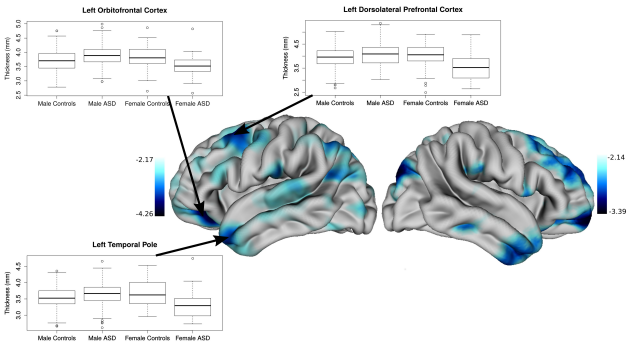

Figure. Diagnosis by sex interaction for cortical thickness in left hemisphere (at 10% FDR) and right hemisphere (at 15%FDR). Colour bars for the left and right hemispheres show the range of t-values displayed, from the FDR threshold to the minimum calculated t-value

Title: Dysregulation in metal homeostasis in autistic children compared to controls in jordan

Authors: *L. ALZGHOUL[1], N. ABU TARBOUSH[1], M. ELDAHABI[1], S. ALBDOUR[1], O. ABU HANTASH[2], B. ABU-IRMAILEH[3];
[1]Dept. of Physiol. and Biochem., [2]Fac. of Med., The Univ. of Jordan, Amman, Jordan; [3]Hamdi Mango Ctr. for Scientific Res., Amman, Jordan

Abstract: Metals ions play important roles in a variety of essential biological functions, and their homeostasis are generally firmly regulated via a system of metal transporters and binding proteins such as Metallothionein (MT). MT is cysteine rich metal binding protein that plays a role in metals homeostasis by regulating intestinal absorption of essential metals and detoxification of heavy metals. The lack or excess of essential minerals and trace elements are known to cause a variety of health problems, and could contribute to the etiology of Autism spectrum disorder (ASD). In addition, many studies suggest that children with ASD have decreased ability to excrete toxic metals which may play a role in the pathogenesis of ASDs. In human body, zinc (Zn) plays a critical role in cell proliferation, differentiation and signaling especially in the brain. And Zn deficiency has been frequently associated with symptoms that are core ASD. Hence, several studies have suggested the possible involvement of Zn deficiency in the pathophysiology of autism. On the other hand, Copper (Cu) is an essential trace element for living cells, and plays an important role in redox reactions. Although, both Zn and Cu bind to MT and can influences its synthesis by stimulating its gene transcription, nevertheless, Zn and Cu are considered as metabolic antagonists, where their concentrations tend to be inversely related. In the central nervous system, many studies highlighted the role of Zn and Cu in regulating glutamatergic synaptic function, and hence the proper development of the brain. Given the importance of zinc (Zn) and copper (Cu) metabolism for neurological functioning and detoxification of heavy metals, as well as regulating metallothionein levels, the aim of this study was to analyze the Zn, Cu and Cu/Zn ratio as well as MT levels in the blood samples of autistics compared to control kids in Jordan. Serum levels of Zn and Cu were measured using flamed - Atomic absorption and the Cu/Zn ratio was calculated. Furthermore, plasma MT levels were measured using Elisa kit. The Cu/Zn ratio and MT levels of children with ASD were compared with healthy age and sex matched subjects as controls. The preliminary findings of the present study were that: 1) increased Cu/Zn ratio in the serum of autistics compared to controls, and 2) a reduced metallothionein levels was also noted in autistics compared to control. Our present finding implicated the potential link between dysregulation in metal homeostasis as a possible environmental factor for the etiology of ASD. In addition, Cu/Zn ratio may be used as a dependent measure for the functional state of metal homeostasis, and serve as quick and early screening for ASD.

Title: Optimization of Golgi impregnation methods for analyses of dendritic complexity in human brain disorders

Authors: *R. K. WEIR[1], M. D. BAUMAN[2], C. M. SCHUMANN[2];
[1]Univ. of California, Davis, Sacramento, CA; [2]UC Davis MIND Inst., Sacramento, CA

Abstract: The amygdala, perhaps more than any other brain region, has been implicated in multiple neurodevelopmental and psychiatric disorders (Schumann et al., 2011). A widely held view is that the amygdala is essential for learning the emotional significance of a stimulus in the environment and coordinating an appropriate response. Aberrant structure and/or function of this system could have profound effects on human social and emotional behavior, which are common components of disorders such as autism and schizophrenia. Studies of amygdala size and volume highlight a difference in the growth trajectories of the amygdala through development from childhood to adulthood in these disorders (Schumann et al., 2004; Levitt et al., 2001). Although the underlying neurobiological mechanisms remain unknown, one hypothesis is that aberrant development of dendrites and synapses leads to improper neuronal connectivity of brain regions responsible for the emotional and social impairments at the core of these disorders. Therefore, our laboratory has focused on investigating neuronal morphology in the human brain of these disorders as well as in animal models. For example, we recently found aberrant dendritic morphology in a nonhuman primate model of brain development in offspring exposed to maternal immune activation (Weir et al., 2015). We have demonstrated successful staining specifically with the Golgi-cox method in our nonhuman primate studies of brains with short-term fixation. However, this method is less effective for staining human tissue that is typically in a fixative for months to several years (Rosoklija et al., 2003). In order to address this issue for our studies of neuron morphology in the human amygdala, we have developed an optimized protocol for staining human brain tissue using a modified version of the Golgi-kopsch technique. In brief, tissue blocks (1.5x1.5x0.8cm) are taken from the amygdala, immersed in solutions of 5% potassium dichromate with 30% formaldehyde (ratio 4:1 parts, 5 days), followed by 0.75% silver nitrate solution (3 days), this is then repeated (5% potassium dichromate (4 days) and 0.75% silver nitrate (2 days). Amygdala tissue blocks are then dehydrated, embedded in parlodion, and cut into 150μm sections. This protocol yields neurons that are well impregnated,

with clearly visible spines, and staining of glial cells is minimal, allowing for data collection on dendritic complexity and spine density. This method allows for the study of neuronal morphology in many neurodevelopmental and psychiatric disorders, including our study of amygdala dendritic arborization and spine density in autism brains compared to typically developing brains.

Title: Meta-analysis of region-specific transcriptome changes in the brain of autism patients

Authors: *D. VELMESHEV[1], M. MAGISTRI[2], N. KHOURY[1], M. FAGHIHI[2];
[2]Psychiatry, [1]Univ. of Miami, Miami, FL

Abstract: Autism is a neurodevelopmental disorder that affects 1 in every 68 children in the US. Symptomatically, autism is characterized by impaired social interactions, language deficits and repetitive behavior. Autism is a highly hereditary disease, and monozygotic twin studies revealed 90% concordance of autism in twin pairs. More than a hundred genetic loci have been associated with autism, most of them are rare de novo variants. These mutations have been shown to affect several core molecular pathways and cell types, including synaptogenesis and neural development pathways. However, in order to gain a better understand of autism pathogenesis and to develop treatment and prevention strategies, one needs to elucidate how multiple genetic variants converge of common molecular pathways and cause specific behavioral deficits. In order to approach this problem, we investigated whole-transcriptome gene expression changes in autism patients specifically in brain regions relevant to the disease pathology. In particular, we looked at changes that take place in the prefrontal cortex by performing RNA sequencing and bioinformatics analyses, and in the frontopolar prefrontal cortex, Broca's area, frontoinsular cortex, Brodmann area 19 and primary visual cortex using RNA-seq data deposited to National Database for Autism Research (NDAR). Meta-analysis of RNA-seq data revealed multiple genes and pathways dysregulated in the autism brain in a region-specific fashion, as well as common between regions that are involved in performing the same neural and behavioral tasks.

Interestingly, expression of these genes remained unchanged in the primary visual cortex, a region that has not been associated with the disorder. Thus, the candidate genes and pathways may represent true drivers of autism pathogenesis that by altering development, patterning and function of specific brain regions lead to characteristic behavioral abnormalities.

Abstract: The etiology of autism has yet to be determined. One of the important parts of the brain known to be involved in neuropathology of autism is prefrontal cortex (PFC). This region is critical for complex behaviors such as language, social behavior, memory, cognition and decision-making. People with autism display deficits in communication and social interactions that may be due to disruptions in neuronal communication and connectivity in PFC. Electroencephalography (EEG) recordings from the cerebral cortex of autistic patients exhibit an alteration of induced gamma activity patterns. The altered gamma activity pattern in autistic subjects indicates an imbalance in the ratio of excitation/inhibition in cerebral cortex. The cause of this imbalance is poorly understood. Many variants and mutations of different genes cause a disturbance of excitatory/inhibitory balance. Several studies point to alterations in molecular components of inhibitory synapse leading to autism. Postmortem brain tissue showed a reduction of GAD65 and GAD67 enzymes and a lower level of inhibitory GABA receptors in autistic individuals. Therefore, an alteration in the number of each subpopulation of interneurons might be a possible reason for imbalance of excitation/inhibition ratio. The majority of interneurons in the cerebral cortex can be classified in three major subtypes: parvalbumin+ (PV), calbindin+ (CB), or calretinin+ (CR) interneurons. These interneuronal subtypes have distinct morphologies, physiological properties, and connectivity patterns. We hypothesized that an alteration in number

of prefrontal cortical interneurons could explain, at least in part, the altered cognition phenotype present in autism. We quantified the number of interneurons in (Broadmann Area) BA9, A46 and BA47 of prefrontal cortex of autism and age-matched control subjects. Formalin-fixed human brain tissue from 10 individuals with autism and 10 age and sex-matched control subjects were obtained thought the Autism Tissue Program. We quantified the number of interneurons that express CB, CR, or PV, and calculated ratios for the number of interneurons expressing each marker. We found a decrease in PV+ interneurons in BA9, BA46 and BA47. Decreased PV+ interneurons can have an impact on the local and widespread circuit activity and neural communication in the cortex. Determining an alteration of specific subtype of interneurons in autism will address one of the mechanisms that could alter the excitation/inhibition balance in the cerebral cortex.

Title: Electron microscopic examination of axon density and myelin thickness in temporal lobe white matter in autism

Authors: *T. A. AVINO[1], X.-B. LIU[2], C. M. SCHUMANN[1];
[1]Psychiatry & Behavioral Sci., Univ. of California, Davis MIND Inst., Sacramento, CA; [2]Univ. of California, Davis, Davis, CA

Abstract: Background: Autism is often characterized as a disorder of aberrant cortical connectivity, which has been demonstrated through a number of functional and structural imaging methods. Functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) studies demonstrate desynchronized and disrupted cortical communication in autism. Additionally, diffusion tensor imaging (DTI) and structural MRI scans show abnormal growth trajectory and loss of white matter fiber integrity in autism particularly within the temporal lobes. However, the microanatomical mechanisms that underlie this large-scale deficit are relatively unknown and limited. **Objectives:** The goal of the present study was to assess the ultrastructural characteristics of axons within the temporal lobe white matter in individuals with autism relative

to their age-matched neurotypical counterparts. **Methods:** White matter from the superior temporal gyrus and fusiform gyrus was dissected from autistic and age-matched neurotypical subjects from 50µm frozen sections. The samples were prepared for ultrathin sectioning and electron microscopic analysis according to Schumann & Liu (2014). Myelinated axons were randomly selected for g-ratio analysis and imaged at high magnification (8,400x) whereby the myelin sheath thickness is calculated relative to the axon diameter. Data regarding the overall density and size distribution was acquired at medium magnification (4,800x) across 20 images (10µm x10µm each) per subject per region. **Results:** Consistent with previous reports, results from the g-ratio analysis indicate decreasing proportional myelin thickness with increasing axon diameter in both autistic and neurotypical subjects. However, these data show thinner myelination patterns across all axon sizes in the adult autistic subjects relative to their neurotypical counterparts. In addition, the individuals with autism show a lower density of axons across all axon sizes. These effects are present in both cortical regions but are more pronounced in the fusiform gyrus. **Conclusion:** The data are consistent with similar reports of alterations to reduced myelin thickness in areas of the frontal lobe in autism (Zikopolous & Barbas, 2010) and may contribute to increased diffusivity of the white matter. When taken together with the decrease in axon density across all axon sizes in the temporal lobe in autism, the results provide a basis for the observed neuronal communication deficit in the disorder at the ultrastructural level.

Title: Increased binding of MeCP2 and DNMT1 to RELN and GAD1 regulatory regions is associated with down-regulation of RELN and GAD1 mRNAs in postmortem prefrontal cortex of autism spectrum disorder (ASD) brain

Authors: ***A. ZHUBI**[1,2], Y. CHEN[3], E. DONG[3], E. H. COOK[3], A. GUIDOTTI[3], D. GRAYSON[3];

[1]Psychiatry, Univ. Ill at Chicago, Chicago, IL; [2]CHOICES Behavioral Hlth., OSF St. Elizabeth Med. Ctr., Ottawa, IL; [3]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Autism Spectrum Disorder (ASD) is neurodevelopmental condition characterized by symptoms related to social interactions/communication and restricted and repetitive behaviors. The ethiopathogenesis of ASD involves a dynamic interplay between environmentally-induced epigenetic mechanisms acting on numerous genes, including those identified in genome-wide association studies. We have focused our work on DNA writers (DNA methyltransferases and TET-cytosine dioxygenases) and readers (Methyl Binding Domain proteins) of these DNA marks. We are interested in the down-regulation of GAD1 and RELN and epigenetic modifications of the corresponding promoters of these genes. We used a small cohort of post-mortem human prefrontal cortex obtained from the Harvard Brain Tissue Resource with permission of the Autism Tissue Program. These include 11 control (CON) and 10 ASD subjects. We performed chromatin immunoprecipitation (ChIP) to measure the levels of binding of MeCP2 and DNMT1 to the GAD1, GAD2, and RELN promoters and gene bodies. We also performed methyl DNA- and hydroxymethyl-DNA immunoprecipitation to measure total 5-methylcytosine (5mC) and 5-hydroxymethylcytosine (5hmC) in the promoters of these genes. Real time qPCR was used for quantification and values were expressed as a percent of input DNA. We observed a significant (1.5-2 fold) decrease in the mRNAs corresponding to GAD 1 ($p=0.02$,t-test) and RELN ($p=0.03$,t-test) in ASD vs CON. In addition, MECP2 binds significantly more (>2 fold) to the promoters of GAD1 ($p=0.002$), GAD 2 ($p=0.006$) and RELN ($p=0.001$) in PFC of ASD. Similarly, DNMT1 binds significantly more (>2 fold) to the promoters of GAD1 ($p=0.006$), GAD 2 ($p=0.015$) and RELN ($p=0.028$) in FC of ASD. Interestingly, we observed a significant decrease in the GAD1 and RELN 5mC promoter levels and little change in the amounts of 5hmC in these genes in ASD. The increased binding of DNMT1 is likely the result of increased unmodified cytosines, which are recognized by the -CXXC- domain of DNMT1. The increased binding of MECP2 is not consistent with the altered levels of 5mC (or 5mC/5hmC ratio) at GAD1 and RELN and may be the consequence of either alternatively spliced variants or post-translational modifications of MECP2 that occur in ASD subjects.

Title: Examination of cell count and size within the superficial layers in autism

Authors: *A. T. KARST[1], J. J. HUTSLER[2];
[1]Univ. of Wisconsin, Oshkosh, Oshkosh, WI; [2]Psychology, Univ. of Nevada, Reno, Reno, NV

Abstract: Neurons in the superficial layers of the human cerebral cortex are involved in long-range cortico-cortical connections. These layers are of interest in studying the neuropathology of autism, as they could potentially play a role in altered connectivity between distal regions of cortex. Evidence for altered connectivity has been demonstrated with both functional as well as anatomical data (Just et al 2007, Hutsler & Zhang, 2010). Of particular interest to this study was whether differences in cell number and/or size were present in superficial layers II and III in individuals with autism in regions of cortex known to be implicated in terms of connectivity. Differences in cell size, specifically smaller cell size in individuals with autism, have been previously observed in particular layers of BA24b (Simms et al, 2009), BA44, and BA45 (Jacot-Descombes, 2012). Using an objective method to classify lamina transitions in Nissl stained tissue, regions of layers II and III for BA7, BA9, & BA21 were isolated and analyzed using a semi automated two-dimensional analysis for cell number and cell size. Analysis of cell number revealed differences for cortical layer and area, but no difference between individuals with autism as compared to control subjects was found. The analysis of cell size again revealed an effect of cortical layer and area, but this analysis additionally revealed a difference of diagnosis as well. The difference in diagnosis indicated that the cell size in individuals with autism were smaller than those of the controls.

Title: Neuronal streaming in the temporal cortex of control and autism children and adults

Authors: *E. C. AZMITIA[1], Z. T. SACCOMANO[2];
[1]Biol. 1009 Silver Bldg, NYU/ NYUMS, New York, NY; [2]Psychology, NYU, NY, NY

Abstract: Autism is a pervasive development disorder that is characterized by a wide spectrum of disorders and abnormalities in many brain structures. Evidence of disruption in neurogenesis, dysgenesis and migration are found in young autism brains (Courchesne, 1997; Wegiel et al, 2010). It is generally assumed that new neurons migrate from the ventricular zone into the cortical plate during early fetal development and then differentiate into the six layers of cortex before birth. However, up to the age of 18 months, corridors of migrating neurons extend from the ventricular zone through the white matter into the prefrontal cortex (Sanai et al, 2011). In our studies, cortical migratory streams were seen in adults as old 20 years of age. The postmortem brains were obtained from the Brain Bank for Disabilities and Aging in Staten Island, Harvard Brain Tissue Rep and the NICHD Brain and Tissue Bank for Developmental Disorders at University of Maryland, Baltimore. All autism patients were diagnosed using the Autism Diagnostic Interview-revised (ADIr) before death. The average age for the autism group (n =10; 14.5 yrs., range 2.8-28 yrs.) is similar to the control group (n = 10; 15.1 yrs., range 1.8-32 yrs.). Brain sections (50um) of the temporal lobe including the superior temporal gyrus were immunocytochemically stained with antibodies against vimentin, actin, GFAP and MAP-2 with DAB as substrate. GFAP-positive varicose fibers, a uniquely human trait, are seen extending down from the pia layer and up from the white matters at all ages. Vimentin-positive neurons are seen in layers II-VI at all ages in STG with more neurons in the deeper layers of autism brains. Actin positive neurons extend long dendrites from deep cortical layers towards layer I with more neurons in the upper layers in controls. Finally, MAP-2 positive neurons having a fusiform shape are seen streaming in the white matter and extending into the cortical layers at all ages. There are more MAP-2 positive neurons in the STG white matter at 20.8 yr in autism compared to 20.5 yr control. Quantitative comparisons between control and autism suggest an extended period of development in the autism brain. These results are consistent with the greater number of serotonin axons and angiogenic blood vessels previously seen in autism compared to control.

Title: The effect of bumetanide treatment in rodent models of autism

Authors: *D. C. FERRARI[1], R. NARDOU[1], M. CHIESA[1,2], N. LOZOVAYA[1], S. EFTEKHARI[2], R. TYZIO[2], M. BILLON-GRAND[1], N. BURNASHEV[2], Y. BEN-ARI[1,2]; [1]Neurochlore, Marseille, France; [2]INMED, INSERM U901, Aix-Marseille Univ., Marseille, France

Abstract: GABAergic signals are altered in autism and GABA-acting benzodiazepines exert paradoxical effects in patients with autism suggesting that, as in epilepsies, GABA excites neurons because of elevated intracellular concentrations of chloride. Indeed, we have recently shown that the oxytocin-mediated neuroprotective GABA excitatory-inhibitory shift during delivery is abolished in the valproate and fragile X rodent models of autism (Tyzio et al, 2014). During delivery and subsequently, hippocampal neurons in these models have elevated intracellular chloride levels, increased excitatory GABA, enhanced glutamatergic activity and elevated gamma oscillations. Maternal pretreatment with bumetanide restored in offspring control electrophysiological and behavioral phenotypes (Tyzio et al, 2014; Eftekhari et al, 2014). Our results suggest a chronic deficient chloride regulation in these rodent models of autism. We aim to elucidate if this deficient chloride regulation is a general feature of autism independently of the mutation, and if it can be restored by bumetanide treatment. Therefore we tested these alterations in the Shank3 KO mouse model of autism and the results will be presented.

Title: Human and Mouse Models of Rett Syndrome exhibit altered prenatal cortical development due to alterations in neurogenesis

Authors: *P. IP[1], N. MELLIOS[1], D. FELDMAN[1], S. D. SHERIDAN[2], S. KWOK[1], B. ROSEN[1], B. CRAWFORD[1], Y. LI[3], R. JAENISCH[3], S. J. HAGGARTY[2], M. SUR[1]; [1]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [2]Ctr. for Human Genet. Res., Cambridge, MA; [3]Whitehead Inst. for Biomed. Res., Cambridge, MA

Abstract: Rett Syndrome (RTT) is a neurodevelopmental disorder that, in the vast majority of cases, arises from mutations in the X-linked gene MECP2. MeCP2 is an epigenetic modulator of gene expression that has recently been shown to interact with miRNA machinery. In addition, MeCP2 itself has been implicated in several neurodevelopmental disorders. Multiple lines of evidence point to the importance of miRNA-mediated pathways downstream of MeCP2 in different stages of brain development and plasticity. We hypothesized that the pleiotropic effects of MeCP2 in prenatal development are mediated via a set of early regulated miRNAs. Towards that end, we used induced pluripotent stem cell (iPSC) RTT lines generated from patients, virally-mediated knockdown of MeCP2 in human embryonic stem cells (ESCs), TALEN-derived isogenic ESC RTT lines, and an Mecp2 mutant mouse model as complementary approaches to identify novel MeCP2-regulated miRNAs and examine their respective influence on neurogenesis and neuronal differentiation.. Via BrdU pulse labelling, we found that the proliferation rate of patient-derived and MeCP2-deficient neuronal progenitor cells was

significantly altered relative to control cells; this was accompanied by reductions in the expression of early neuronal markers and immature dendritic morphology. Our findings to date implicate aberrant regulation of prenatal neurogenesis as a result of MeCP2 deficiency. Taken together, our data support a novel miRNA-mediated pathway downstream of MeCP2 capable of influencing neurogenesis via interactions with central molecular hubs linked to autism spectrum disorders. Ongoing experiments are focused on elucidating the mechanisms of disease-related impairments in neurogenesis in both mouse and human organoid models of RTT, and translating these findings to scalable assays for novel therapeutic discovery

Title: Role of BDNF signaling in synapse formation and maintenance in MeCP2Null/y excitatory neurons

Authors: ***C. SAMPATHKUMAR**, Y.-J. WU, T. TRIMBUCH, C. ROSENMUND; Charité - Universitätsmedizin Berlin, Berlin, Germany

Abstract: Methyl CpG-binding protein 2 (MeCP2) is a transcriptional regulator whose loss-of-function mutations result in neurodevelopmental disorders such as Rett syndrome. Prior studies reported that either loss or doubling of MeCP2 results in reduced or increased synaptic output and glutamatergic synapse number, respectively. This study aims to understand the role of MeCP2 in regulating synapse formation in excitatory neurons and the significance of optimal brain-derived neurotrophic factor (BDNF) signaling in maintaining neuronal function in MeCP2 mutant neurons. We investigated morphology of hippocampal glutamatergic autapses derived from *Mecp2*$^{Null/y}$ and *Mecp2*^{Tg1} *mice and observed abnormal axonal and dendritic outgrowth, and reduced somata in Mecp2*$^{Null/y}$ *neurons. However, doubling of MeCP2 did not influence neurite outgrowth as evident from normal axon and dendrite development in Mecp2*^{Tg1} *neurons. To understand the role of BDNF signaling in this context, we overexpressed BDNF in Mecp2*$^{Null/y}$

autaptic neurons and found a significant rescue of synapse number and dendrite outgrowth as well as evoked excitatory postsynaptic currents (EPSCs) and readily releasable vesicle pool (RRP) without affecting release efficiency. This dramatic rescue was reverted back to Null/y levels upon either neutralizing BDNF function or application of Tropomyosin receptor kinase B (TrkB) antagonist, confirming that BDNF induced TrkB signaling is essential for normal neuronal function in Mecp2$^{Null/y}$ neurons. Taken all together, this study demonstrates the importance of BDNF signaling in maintenance of excitatory synapses in MeCP2 mutant neurons at single-cell level. Furthermore, this shows that regulation of BDNF could contribute in part to the pathophysiology of Rett syndrome.

Title: The TrkB ligand LM22A-4 rescues hippocampal LTP and Rett-like behavioral phenotypes in Mecp2 knockout mice

Authors: *W. LI[1], T. YANG[2], F. LONGO[2], L. POZZO-MILLER[1];
[1]Neurobio., The Univ. of Alabama At Birmingham, Birmingham, AL; [2]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Rett syndrome (RTT) is an autism-linked disorder caused by loss-of-function mutations in the gene encoding methyl-CpG-binding protein 2 (MeCP2), a transcriptional regulator that modulates expression of many genes, including the neurotrophin Bdnf. BDNF deregulation accounts for many sensory, motor, and cognitive deficits in RTT individuals, as well as in mouse models that recapitulate RTT phenotypic traits. We previously demonstrated that naïve hippocampal CA3->CA1 synapses are potentiated in slices from male Mecp2 KO mice, thus saturating long-term potentiation (LTP) (WL & LP-M, SfN 2014). Restoration of

BDNF function has a great potential to rescue these features, but BDNF's inability to across the blood-brain barrier has limited its pharmacotherapeutic use for systemic/peripheral treatment. Here, we used the small molecule LM22A-4, which has sufficient brain penetration and pharmacokinetics, and mimics BDNF signaling by occupying the binding pocket of the BDNF receptor TrkB (Massa et al. 2010). We treated female Mecp2 heterozygous (Het) mice at 4 months of age with LM22A-4 for 2 months (twice daily i.p. injections). Western immunoblots of hippocampal homogenates confirmed the activation of TrkB receptors and downstream signaling pathways in LM22A-4-treated Mecp2 Het mice. The general behavioral phenotype score, open field test, and dowel crossing test all showed significant improvements in locomotor activity and motor coordination in LM22A-4-treated Mecp2 Het mice. At the end of the 2-month treatment, acute slices were used for simultaneous electrophysiology and voltage-sensitive dye (VSD) imaging. Basal transmission at CA3->CA1 synapses and evoked spatio-temporal spread of VSD signals in area CA1 were enhanced in Mecp2 Het mice compared to age-matched female wildtype (WT) controls. In addition, LTP of fEPSPs and VSD signals were smaller in female Mecp2 slices than in WT slices. The 2-month LM22A-4 treatment reduced basal synaptic transmission and the spatio-temporal spread of VSD signals to WT levels, and restored LTP of fEPSPs and VSD signals to levels comparable to those observed in WT slices. Our findings provide preclinical evidence that the BDNF loop-domain mimetic LM22A-4 improves hippocampal function and RTT-related behavioral deficits, thus establishing the rationale for the treatment of RTT and other neurodevelopmental disorders with autistic features associated with MeCP2 dysfunction.

Title: Partial rescue of Rett syndrome phenotypes via modulation of NF-κB signaling and vitamin D supplementation in Mecp2-null mice

Authors: *J. L. MACDONALD[1,2], N. KISHI[1,3], J. D. MACKLIS[1];
[1]Stem Cell and Regenerative Biol., Harvard Univ., Cambridge, MA; [2]Dept. of Biol., Syracuse Univ., Syracuse, NY; [3]Lab. for Marmoset Neural Architecture, RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Mutations of the transcriptional regulator MeCP2 cause the X-linked autism spectrum disorder Rett syndrome (RTT), and MeCP2 has been implicated in several other neurodevelopmental disorders. Our previous results identified that cortical callosal projection neurons (CPN) increasingly express MeCP2 as they mature, and that loss of *Mecp2* function reduces their dendritic complexity in a largely cell autonomous manner. Focusing on CPN, we investigated genes and signaling pathways that function downstream of MeCP2 in cerebral cortex circuitry, and identified *Irak1*, a signaling kinase and scaffold protein within the NF-κB pathway. We confirmed that *Irak1* is up-regulated following *Mecp2* loss-of-function, and that over-expression of *Irak1* recapitulates the reduced dendritic complexity phenotype of *Mecp2*-null CPN, both *in vitro* and *in vivo*. We established that NF-κB pathway signaling is up-regulated with loss of *Mecp2* function or *Irak1* over-expression in cortical neurons. Importantly, we found that genetic attenuation of the aberrant NF-κB signaling in *Mecp2*-null mice not only ameliorates the CPN dendritic complexity phenotype, it significantly extends (~50%) the usually shortened lifespan of *Mecp2*-null mice. These results indicate that abnormal activation of NF-κB signaling is critically involved in RTT-like cortical dysgenesis, dendritic complexity, and reduced lifespan of *Mecp2*-null mice, and that NF-κB pathway modulation might offer a therapeutic target in RTT. There are many known inhibitors of NF-κB, including the hormone vitamin D. Interestingly, we identified that *Mecp2*-null mice, like many RTT patients, are vitamin D deficient. We investigated potential therapeutic treatment of *Mecp2*-null mice by dietary supplementation of vitamin D, and identified dose-dependent amelioration of CPN dendritic complexity and reduced soma size phenotypes, as well as a modest increase in lifespan. These results provide new insight into both the fundamental neurobiology of RTT, and potential therapeutic strategies via NF-κB pathway modulation.

Title: Chronic *in vivo* treatment of Rett mice with the free radical scavenger Trolox

Authors: O. A. JANC, M. A. HUESER, K. CAN, B. KEMPKES, *M. MUELLER;
Univ. Goettingen, Goettingen, Germany, Germany

Abstract: Rett syndrome (RTT) is a severe neurodevelopmental disorder affecting almost exclusively girls. After a normal development for the first year of life, complex and severe disease symptoms start to manifest. They include pronounced cognitive impairment, epilepsy, motor dysfunction, and potentially life-threatening breathing disturbances with intermittent systemic hypoxia. Mitochondria seem to be affected as well. Mouse models of Rett syndrome (MeCP2-deficient mice) replicate several of these symptoms. Rating mitochondrial function in male Rett mice (Mecp2-/y) revealed an intensified mitochondrial respiration, a less efficient cellular redox homeostasis, and an oxidative burden. Interestingly, these alterations become evident already at neonatal and presymptomatic stages. Therefore, they may critically contribute to the manifestation of typical RTT symptoms and/or facilitate disease progression. *In vitro*, we confirmed that the free radical scavenger Trolox, a vitamin E derivative, dampens neuronal hyperexcitability, reinstates synaptic plasticity, ameliorates cellular redox balance, and improves hypoxia tolerance in the isolated hippocampus of adult, symptomatic Mecp2- /y mice. Therefore, we now performed a placebo-controlled blinded systemic treatment of Mecp2- /y mice with Trolox, starting at very young, presymptomatic stages. To ensure most reliable compound dosing and administration, we performed intraperitoneal injections of either saline, 10 or 40 mg Trolox/kg body weight. Trolox-treated Mecp2- /y mice showed a normalization of blood glucose levels. Furthermore, low doses of Trolox improved the hypoxia-tolerance and synaptic short-term plasticity of Mecp2- /y hippocampus. Lipid peroxidation in cortical tissue samples was also less pronounced in Trolox treated mice. Systemic Trolox treatment did, however, not improve body weight or size, the regularity of breathing, motor function and learning, or exploratory behavior of Mecp2-/y mice. Rather, the frequent animal handling and intraperitoneal injections dampened some of the phenotypic differences among WT and Mecp2-/y mice, which may have masked potential merits of Trolox. In conclusion, our findings show that radical scavengers may be promising for the treatment of various aspects in RTT. However,

the very route of compound administration and the frequency of animal handling are critical parameters to be optimized in further trials.

Abstract: Mutations of the MECP2 gene cause Rett syndrome (RTT) and related autism spectrum disorders (Amir et al., 1999). MECP2 encodes a methyl-CpG-binding protein that has been proposed to function as a transcriptional repressor and activator. Despite numerous studies examining gene expression in murine models of RTT, it is still unknown which genes are first misregulated in the absence of Mecp2, leading to the onset of RTT phenotype. We recently discovered that Mecp2-null mice exhibit loss of visual function that correlates with onset of RTT phenotype (Durand et al., 2012). Here, we used Cap Analysis of Gene Expression (CAGE; Vitezic et al., 2014) to identify the changes in gene expression that underlie such regression. We analyzed the transcriptome of the visual cortex of Mecp2-null mice in comparison with wild-type

(WT) littermate controls at three developmental ages: eye opening (postnatal day 15; P15), peak of critical period plasticity (P30) and adulthood P60. Our data reveal no differentially expressed transcripts at the beginning of visual cortical development, P15, well before the onset of RTT phenotype. On the contrary, at the beginning of visual regression, P30, we identified 54 differentially regulated transcripts in the Mecp2-null mice. By P60, when Mecp2-null animals are severely visually impaired, we found 844 differentially regulated transcripts. Most of these genes were involved in neuronal connectivity and communication, metabolism and intracellular signaling. Our data identify the biological pathways perturbed in the visual cortex of Mecp2-null mice, before and after the onset of symptoms. Our study demonstrates the utility of CAGE in the investigation of genetic disorders. RIKEN Omics Science Center ceased to exist as of April 1st, 2013, due to RIKEN reorganization.

Title: Visual evoked potentials detect cortical processing deficits in Rett syndrome patients

Authors: J. J. LEBLANC[1,2], G. DEGREGORIO[1], V. K. VOGEL-FARLEY[1], K. BARNES[1], W. E. KAUFMANN[1,2], *M. FAGIOLINI[3,2], C. A. NELSON[1,2,4];

Abstract: Rett syndrome (RTT) is a neurodevelopmental disorder caused by mutation of the X-linked MECP2 gene and characterized by developmental regression during the first few years of life. Studies in the visual system of mouse models of RTT revealed impaired cortical processing with progression of the disorder using visual evoked potentials (VEP). The objective of this study was to investigate if the VEP can be used as an unbiased, quantitative biomarker to

monitor brain function in RTT patients. We recorded pattern-reversal VEPs in 34 girls with RTT and 20 typically developing controls (2-9 years old) using a low spatial frequency phase-reversing checkerboard stimulus. Girls with RTT exhibited a significant decrease in VEP amplitude that was most striking in the later stages of the disorder. RTT patients also displayed a slower recovery from the principal peak of the VEP response that was impacted by MECP2 mutation type. Visual acuity was also assessed in patients by modulating the spatial frequency of the stimulus. We found that patients displayed a deficit in discriminating smaller patterns, indicating lower visual spatial acuity in RTT, consistent with findings in Mecp2 knock-out mice. VEP is a method that can be used to assess brain function across species and in children with severe disabilities like RTT. Our findings support the introduction of standardized VEP analysis in clinical and research settings to probe the neurobiological mechanism underlying functional impairment and to longitudinally monitor progression of the disorder and response to treatment.

Title: Ketamine ameliorates visual evoked potential impairments in Mecp2 Heterozygous female mice

Authors: *E. CENTOFANTE, A. PATRIZI, N. PICARD, M. FAGIOLINI;
Neurol., Boston Children's Hosp., Boston, MA

Abstract: Rett Syndrome (RTT), a neurodevelopmental disorder, is caused by de novo mutation of MECP2 gene on X- chromosome and it is characterized by regression during the first few years of life. Recently, we have demonstrated that Mecp2-null mice exhibit impaired visual cortical processing that can be rescued by targeting NMDA receptor (NMDAR) expression and function. These results raise the questions whether 1) a similar defect is present in Mecp2 heterozygous (Het) female mice which are considered a closer model of the human condition;

and 2) administration of NMDAR antagonist ketamine can ameliorate cortical function in RTT. Here, we performed visual evoked potential (VEP) in adult Mecp2 Het that exhibited either mild or severe RTT-like symptoms, according to the 12-point RTT phenotypic score (Guy et al., 2001). Mecp2 Het mice displayed a significant decrease in the amplitude of VEP response in comparison with their wild-type (WT) littermates. Interestingly, such defect was already present in Mecp2 Het mice with mild symptomatology and worsened with the disorder progression. Moreover, VEP response to high spatial frequencies was lost, resulting in a shift down in the spatial frequency (SF) tuning curve and significantly lower spatial resolution. We then tested whether administration of low dosage of NMDAR antagonist, ketamine (8mg/kg, ip) for six weeks (two weeks on/two weeks off) was sufficient to ameliorate the visual function in Mecp2 Het mice. Interestingly, we found an increase in the VEP amplitude in comparison with the Het treated with vehicle. In addition, we observed this increase in the response to all stimuli resulting in an amelioration of the visual acuity. Together our results indicate that visual processing is impaired across Mecp2 mouse models and provide further evidence that targeting NMDAR function is a feasible and an effective therapeutic treatment for Rett Syndrome.

Title: Post-critical period Mecp2 de-silencing rescues aberrant visual circuits in a Rett syndrome mouse model

Authors: *A. J. SIMON[1,2], N. PICARD[2], M. TAYLOR[2], M. STANLEY[2], C. CHEN[2], M. FAGIOLINI[2];

Abstract: Rett syndrome (RTT), a neurodevelopmental disorder that results from *de novo* mutations in the MECP2 gene, is characterized by an initial apparently normal period of development followed by regression of motor, respiratory, and sensory functions. Growing evidence points to improper wiring of both excitatory and inhibitory synaptic circuits as the underlying cause. Remarkably, murine studies have demonstrated that motor and respiratory phenotypes can be reversed by late re-expression of *Mecp2*. However, it remains unclear whether sensory impairments can also be rescued. Uniquely, sensory circuits are only amenable to modification in response to external sensory experience during restricted critical periods in early postnatal life. Once windows of plasticity close, proper re-wiring is limited, if not impossible. Here we test 1) whether sensory system abnormalities in Mecp2 mouse models are reversible and 2) if the lateral geniculate nucleus (LGN) and the visual cortex (V1) are similarly sensitive to the loss and re-expression of *Mecp2* in $Mecp2^{loxstop/y}$ x Cre-ESR mice after tamoxifen administration. As in $Mecp2^{-/y}$ mice, we found that visual cortical circuits are indeed significantly impaired before the onset of the general RTT phenotype. Thalamic deficits such as eye specific segregation, conversely, appeared at a much later time point and well after those in primary visual cortex. Strikingly, de-silencing of *Mecp2* after the critical period for visual system plasticity was sufficient to allow recovery of key features of single-unit activity including spontaneous activity and maximal evoked activity at preferred orientations in visual cortical neurons. Furthermore, decreased response reliability of neurons in V1 can similarly be recovered by re-expressing *Mecp2* after this critical period. Our results indicate that cortical circuits are more sensitive to the absence of *Mecp2* than those in the LGN and that they can also be rescued in adulthood.

Title: Loss of MeCP2 causes urological dysfunction and contributes to death by kidney failure in mouse models of Rett Syndrome

Authors: *C. S. WARD[1], T.-W. HUANG[2], J. HERRERA[3], R. C. SAMACO[4], M. PITCHER[3], J. L. NEUL[1];

Abstract: Rett Syndrome (RTT) is a neurodevelopment disorder characterized by loss of acquired skills during development, autonomic dysfunction, and an increased risk for premature lethality. Clinical experience identified a subset of individuals with RTT that present with urological dysfunction including individuals with frequent urinary tract infections, kidney stones, and urine retention requiring frequent catheterization for bladder voiding. To determine if urological dysfunction is a feature of RTT, we queried the Rett Syndrome Natural History Study, a repository of clinical data from over 1000 individuals with RTT and found multiple instances of urological dysfunction. We then evaluated urological function in a mouse model of RTT and found an abnormal pattern of micturition. Both male and female mice possessing Mecp2 mutations show a decrease in urine output per micturition event. Furthermore, we identified signs of kidney failure secondary to urethral obstruction. Although genetic strain background significantly affects both survival and penetrance of the urethral obstruction phenotype, survival and penetrance of urethral obstruction do not directly correlate. We have identified an additional phenotype caused by loss of MeCP2, urological dysfunction. Furthermore, we urge caution in the interpretation of survival data as an endpoint in preclinical studies, especially where causes of mortality are poorly characterized.

Title: Neuronal hyperexcitability versus breathing abnormality in Mecp2-null mice

Authors: W. ZHONG, N. CUI, C. JOHNSON, M. F. OGINSKY, S. ZHANG, Y. WU, *C. JIANG;
Georgia State Univ., Atlanta, GA

Abstract: Neuronal hyperexcitability versus breathing abnormality in *Mecp2*-null mice Zhong W, Cui NR, Johnson MC, Oginsky FM, Zhang S, Wu Y, Jiang C. Department of Biology, Georgia State University, 100 Piedmont Avenue, Atlanta, GA 30303 Rett Syndrome (RTT) is a neurodevelopmental disorder caused mostly by disruptions in the *Mecp2* gene. Breathing abnormality is a characteristic of the disease, which contributes to the high rate of sudden death and brain development. The breathing abnormality is found in *Mecp2*-null mice, involving neurons in the locus coeruleus (LC). LC neurons in *Mecp2*-null mice show inadequate release of norepinephrine (NE), defects in CO2 chemosensitivity and hyperexcitability. The latter has been found in several other types of neurons in *Mecp2*-null mice as well. To understand the relationship of LC neuronal excitability with breathing, we perform studies in which LC neuronal excitability was quantitatively analyzed with breathing frequency (f) variation and apnea in wild-type and *Mecp2*-null mice at various ages. Our results showed that LC neuronal excitability increased with ages in *Mecp2*-null mice. So did the severity of breathing abnormality. Pearson analysis showed a strong correlation of LC excitability with age ($r = 0.70$, $P < 0.001$), apnea rate ($r = 0.84$, $P < 0.001$), and breathing frequency variation ($r = 0.58$, $P < 0.05$). Consistently, *Mecp2*-null LC neurons showed an age-dependent reduction in GABAergic synaptic inhibition as indicated by IPSC frequency and amplitude. The extrasynaptic $GABA_AR$ agonist THIP at a non-sedative dosage reduced LC neuronal hyperexcitability, alleviated breathing abnormalities, and expanded the lifespan of *Mecp2*-null mice. Therefore, these results strongly suggest that the Mecp2 disruption causes age-dependent deterioration in neuronal hyperexcitability together with breathing abnormalities, and stabilization of neuronal excitability benefits breathing and the lifespan of *Mecp2*-null mice.

Title: Alterations in MeCP2 dosage within dopaminergic neurons regulate startle and prepulse inhibition in mice

Authors: *S. SORIANO[1], D. R. CONNOLLY[2], C. S. WARD[3], C. M. MCGRAW[4], N. M. TRUONG[2], A. CHAHROUR[2], A. J. LIANG[2], H. Y. ZOGHBI[2], J. L. NEUL[3], R. C. SAMACO[2]; [1]Jan and Dan Duncan Neurolog. Res. Inst., Baylor Col. of Med., Houston, TX; [2]Mol. and Genet., Baylor Col. of Medicine/Jan and Dan Duncan Neurolog. Res. Abstract: Abnormalities in sensorimotor gating are prominent in neuropsychiatric disorders. For example, enhanced PPI has been reported in autism spectrum disorders (ASD) cases; in contrast, reduced PPI is a hallmark feature of schizophrenia (SCZ). Interestingly, basal acoustic startle response and prepulse inhibition (PPI) are oppositely affected in mouse models lacking or overexpressing the transcriptional modulator MeCP2, demonstrating a similar contrast to findings in ASD and SCZ. Given the role of the dopaminergic system in regulating aspects of motor function in *Mecp2* mouse models and its link to the modulation of sensorimotor gating, we set out to test the consequences of genetically manipulating MeCP2 expression within tyrosine hydroxylase (TH)-positive cells on acoustic startle and PPI. Using an allelic series of TH-positive conditional knock-out, conditional restoration, and conditional over-expression mice, we demonstrate that basal startle response is directly correlated with the level of MeCP2 dosage within this specific cellular population, and is dependent on the ongoing function of MeCP2 in adulthood. However, changes in PPI do not appear to directly correlate with MeCP2 dosage and is not affected by deleting MeCP2 in adult animals, suggesting that the neural circuits regulating startle and sensorimotor gating in MeCP2 mouse models may operate under separate cellular and developmental mechanisms. Ongoing studies aim to determine whether the expression of genes known to be implicated in startle and PPI are altered within TH-positive according to MeCP2 dosage. Taken together, these findings demonstrate the importance of cell specific MeCP2 dosage in sensorimotor gating and underscore the critical role of MeCP2 in modulating a specific phenotype commonly impaired in many neurological and neurodevelopmental disorders.

Title: Increased GFAP levels accompany neuronal loss in a mouse model of MeCP2 duplication syndrome

Authors: *J. M. FRANKLIN, L. WANG, S. R. D'MELLO;
Biol. Sci., Southern Methodist Univ., Dallas, TX

Abstract: Methyl-CpG-binding protein 2 (MeCP2), is a protein expressed from the X-chromosome that binds to methylated DNA, modifying chromatin structure to a transcriptional repressed state through the recruitment of co-repressors and histone deacetylases. More recently, it has been found to also activate gene expression by binding to promoters. Increased MeCP2 function resulting from gene duplication (or triplication) causes a distinct neurological disorder called MeCP2 duplication syndrome characterized by severe mental retardation, hypotonia, macrocephaly, epilepsy, progressive spasticity, and premature death. Little is known about molecular and cellular mechanisms underlying MeCP2 duplication syndrome. We are studying this disorder using a transgenic mouse model in which the locus containing the human MeCP2 gene is inserted on the X-chromosome. These mice (designated as MeCP2-Tg) recapitulate the neurological phenotype of patients with MeCP2 duplication syndrome and produce MeCP2 at about 3 times the normal amount. We have found that MeCP2-Tg mice display highly elevated GFAP expression within the hippocampus and cortex, but not in other brain parts starting at 12 weeks of age. Intriguingly, increased GFAP expression seems to be unconnected with neuroninflammation as we have found that the morphology of the astrocytes is similar to that of WT astrocytes and typical resting/non-reactive astroglia. Furthermore, we do not detect any changes in the number of microglia or the morphology of resting microglia. Moreover, we have also found that death of MeCP2 mice is preceded by neuronal loss in the hippocampus and cortex. We have found that the number of NeuN-positive neurons in the MeCP2-Tg mice are comparable to WT mice at 6 weeks of age; however, at 15 weeks of age there is a significant reduction in the NeuN-positive neurons in the cortex and hippocampus but not in the cerebellum. To confirm this, we used two other antibodies, CTIP2 and SATB2, which stain deep layer and superficial cortical neurons, respectively. Indeed, we have detected a reduction in SATB2 and CTIP2-positive neurons in the cortex. Based on our current evidence, we propose that MeCP2 duplication disorder is a neurodegenerative disorder.

Title: IGF1 treatment in RTT patients improve social and cognitive abilities in an open label study

Authors: ***D. TROPEA**[1,2], F. SCUSA[2], N. MORTIMER[1], A. BENINCASA[2], G. PINI[2]; [1]Trinity Col. Dublin, Dublin, Ireland; [2]Versilia Hosp., Tuscany Ctr. for Rett Syndrome, Lido di Camaiore (LU), Italy

Abstract: Rett syndrome (RTT) is a devastating neurodevelopmental disorder that has no cure. After 6-18 months patients show regression of acquired skills, motor and speech impairment, cardio-respiratory distress, microcephaly and stereotyped hand movements. The majority of RTT patients display mutations in the gene that codes for the Methyl-CpG binding protein 2 (MeCP2). Clinical observations and neurobiological analysis of mouse models suggest that defects in the expression of MeCP2 protein compromise the development of the central nervous system, especially synaptic and circuit maturation. Thus, agents that promote brain development and synaptic function are good candidates for ameliorating the symptoms of RTT. In particular, Insulin-like growth Factor 1 (IGF1) and its active peptide (1-3)IGF1 cross the Blood Brain Barrier, and therefore are ideal treatments for neurodevelopmental disorders, including RTT (Tropea et al., 2009). Indeed, both (1-3)IGF1 and IGF1 treatment significantly ameliorates RTT symptoms in a mouse model of the disease (Tropea et al., 2009; Castro et al., 2014). In a previous study we established that IGF1 is safe and well tolerated in Rett patients (Pini et al., 2012). In this study we assessed the social and cognitive abilities of 9 RTT patients treated with IGF1 and 10 untreated controls. Two independent observers blind to the identity of treated individuals observed footages of patients recorded in identical conditions at two different time points: T0 and T1-which corresponds to the pre-treatment and post-treatment phases for the treated patients-and comparable time for untreated controls. They evaluated the ability of the patients to interact with people and environment as well as the negative features of RTT and assigned a score from 1 to 5, where 1 represents heavy RTT and 5 absence of RTT. Even considering that this was an open labeled study, we find a significant improvement in the

cognitive and social abilities of the treated patients but not of the untreated controls. We find no differences in the performances of patients treated with antiepileptic medications. These results have applications to other pathologies considering that IGF1 has been shown to be effective in other disorders of the autism spectrum.

Title: Neuron-microglia interaction contributes to Rett syndrome pathology

Authors: ***M. HORIUCHI**, L. J. SMITH, I. MAEZAWA, L.-W. JIN;
Pathology and Lab. Med., Univ. of California, Davis, Sacramento, CA

Abstract: Rett syndrome (RTT) is an autism spectrum disorder primarily affecting girls. The patients develop normally until 6 to 18 months of age, when they start showing loss of neurodevelopmental milestones, motor and cognitive impairments, autistic features, seizures, and respiratory dysfunction. RTT is largely caused by loss-of –function mutations in the X-linked gene encoding methyl-CpG-binding protein 2 (MeCP2), an epigenetic regulator. Mecp2 knockout (Mecp2KO) mice exhibit RTT-like abnormalities and provide a valid animal model of human RTT. Recovering wild-type (WT) MeCP2 in either neurons or microglia in Mecp2KO mice ameliorated RTT-like abnormalities, suggesting a pathological role of neuron-microglia interaction. CX_3CR1, a chemokine receptor expressed by microglia, mediates neuron-microglia interaction by binding its ligand CX_3CL1 expressed by neurons. While CX_3CR1-CX_3CL1 signaling regulates microglia activation in neuroinflammation, it plays an important role in synaptic pruning during development. Given that Mecp2KO microglia constitutively produce high levels of neurotoxic mediators such as glutamate and reactive oxygen species, we hypothesized that neuron-microglia interaction mediated by CX_3CR1-CX_3CL1 signaling may detrimentally affect neuronal and synaptic integrity in RTT. To test this hypothesis, we

determined the phenotype of Mecp2KO mice with CX_3CR1 ablation. We found that CX_3CR1 ablation significantly improved the RTT-like phenotype presented by Mecp2KO mice, including life span, body weight, the incidence of apneas, and motor coordination. These phenotypic improvements were associated with restorations of the number and morphological complexity of microglia, the production ofinsulin-like growth factor 1 by microglia, and the size of hippocampal CA2 neurons. Our results suggest a deleterious contribution of neuron-microglia interaction to RTT pathogenesis. CX_3CL1-CX_3CR1 signaling, therefore, could be a candidate therapeutic target for RTT.

Title: Misregulation of alternative splicing in a mouse model of Rett syndrome

Authors: R. LI[1], Q. DONG[2], C. CHIAO[3], H. LI[2], *Q. CHANG[4];
[1]CMB Training Program, [2]Waisman Ctr., [3]Univ. of Wisconsin-Madison, Madison, WI; [4]Genet & Neurol, Univ. Wisconsin-Madison, Madison, WI

Abstract: Mutations in human MECP2 gene cause Rett syndrome (RTT), a severe neurodevelopmental disorder that predominantly affects girls. Despite of decades of work, the molecular mechanism underlying how mutations of this methylated DNA binding protein leads to disease is still largely unclear. To systematically understand the molecular function of MeCP2, we performed coimmunoprecipitaton (Co-IP) on the cortex of FLAG-tagged Mecp2 knock-in mice followed by mass spectrometry to identify physiologically relevant MeCP2-interacting proteins. Gene ontology analysis showed that proteins identified were enriched with transcriptional factors and splicing regulators. MeCP2 has been well-characterized as a transcriptional regulator while its role in regulating splicing is less well defined. Therefore we focused our studies on these novel MeCP2-interacting splicing regulators. Further validation demonstrated that MeCP2 physically interacted with more splicing regulators than previously

appreciated. To illustrate the functional consequence of loss of MeCP2 on alternative splicing, we performed deep RNA sequencing and found that hundreds of splicing events were mis-regulated in Mecp2 null cortex. We are currently in the process of validating some of these changes by independent methods. In order to understand how MeCP2 regulates alternative splicing, we will perform chromatin immunoprecipitation (ChIP) to examine whether MeCP2 binds to these exons and recruits some of its interacting splicing regulators to modulate splicing. We will also test the hypothesis that MeCP2 might regulate alternative splicing through slowing down the progression pace of PolII and hence facilitating the inclusion of the alternative exon. Taken together, we are pursuing to understand better the role of MeCP2 in regulating alternative splicing through interacting with multiple splicing factors.

Abstract: The molecular mechanisms that lead to typical autism spectrum disorder (ASD) are unknown. Study of single gene disorders (Rett syndrome, Fragile X syndrome, tuberous sclerosis complex, PTEN mutation syndromes) characterized by autistic features, may contribute to the understanding of ASD. Rett syndrome (RTT), an X-linked dominant neurological disorder caused by mutation of the Mecp2 gene, is characterized by stereotyped hand movements and autistic features. We have created a mouse model (MeCP2 A140V "knock-in" mutant) expressing a human Mecp2 mutation linked to an X-linked mental retardation phenotype/Rett syndrome. The major neuropathological findings in the A140V mouse are (a) increased cell

packing density and small soma size), and (b) reduced dendrite branching (3). This exactly recapitulates the key pathological findings in Rett syndrome patients. Molecular evidence suggests that MeCP2 acts as a global transcriptional repressor but emerging evidences indicate that they also activate gene expression. In this study, we explored global gene expression in wild-type and Mecp2 A140V mutant mice and identify the signaling pathways that are affected by Mecp2 mutation. mRNA profiling was performed using affymetrix mouse expression array in layer 4/5 cortical pyramidal neurons of 2-week old male mice (MeCp2 A140V & WT). Changes in transcript levels were assessed by microarray analysis on an individual basis and the molecular pathway network analysis was done using GeneGo Pathways Software. The results of the microarray analyses indicated less dramatic changes in the transcription level of many genes in Mecp2 A140V mice compared to wild type. We observed that among the list of altered expression, 56 percent genes were found to be up-regulated compared to 44 percent down regulation. In addition, our preliminary analysis with gene length in 2 week old mutant mice found that increased expression of small group of long genes related to synaptic function. Gene ontology analysis revealed a significant alteration of multiple pathways in Mecp2 A140V mice comparing to control mice. Genes involved in pathways such as neurogenesis, neuronal differentiation and development were significantly altered. Interestingly, of the several hundred genes with altered expression levels in the mutants, we found that IGF-1 pathway genes implicated in the pathogenesis of Rett syndrome are significantly downregulated. This result suggests that MeCP2 A140V mutation leads to moderate gene expression changes affecting neuro developmental pathway and synaptic function, which may be associated with the phenotypic changes observed.

Title: Alterations in the novel object recognition circuit following MeCP2 deletion from cholinergic neurons

Authors: *E. BALLINGER[1], C. SCHAAF[2], D. TALMAGE[1], H. Y. ZOGHBI[2], L. W. ROLE[1]; [1]SUNY At Stony Brook, Port Jefferson Station, NY; [2]Baylor Col. of Med., Houston, TX

Abstract: Rett Syndrome (RTT) is an autism spectrum disorder that affects approximately 1 in 20,000 girls and is caused by mutations in the gene encoding methyl CpG binding protein 2 (*MeCP2*). The cholinergic system appears to be particularly important in RTT, as decreases in cholinergic markers have been correlated with increased clinical severity in patients with RTT. Schaaf and Zoghbi have developed a powerful transgenic mouse model, whereby *MeCP2* is selectively deleted in cholinergic neurons only, to facilitate study of the contribution of this cholinergic lesion to the overall phenotype of RTT. Interestingly, this model exhibits a selective deficit in recognition memory, a form of declarative memory that has been shown by lesion and electrophysiological studies to be dependent upon cholinergic signaling in the perirhinal cortex (PRH). This memory deficit may map onto the intellectual disability seen in patients with RTT, however, its circuit level electrophysiological underpinnings are unknown. We use *in vivo* electrophysiology to compare baseline firing characteristics of PRH neurons in both mice in whom *MeCP2* has been selectively deleted in cholinergic neurons (*MeCP2* sKO) and control. We also use optogenetics to selectively activate cholinergic neurons in the Nucleus Basalis of Meynert, the cholinergic source nucleus that innervates the PRH, while simultaneously recording the effects of this selective activation to evaluate the cholinergic response profile of the PRH in each genetic condition. The network consequences of this altered responsiveness are evaluated using genetic markers of activity to map the recognition memory engram in both controls and *MeCP2* sKO. We have shown that PRH units of control mice exhibit long time course correlations which are absent in PRH units from *MeCP2* sKO mice, in whom PRH unit firing is more stationary. Given the role of ACh as a neuromodulator, this change may represent deficient modulation of firing. Our recognition memory engram mapping shows that 3-6 times as many PRH cells are activated during exposure to a novel object than are activated during recognition of a familiar object, which is consistent with prevailing models suggesting that recognition is dependent upon modulation of PRH unit excitability. The deficient cholinergic modulation of PRH unit firing that we have observed among *MeCP2* sKO mice may thereby impair encoding of the recognition memory engram and lead to the observed behavioral deficits. These results will further understanding of the role of ACh in encoding recognition memory and of the circuit level perturbations that may underlie cognitive phenotypes seen in patients with RTT.

Title: Chronic forniceal deep brain stimulation recuses the impairment of contextual fear memory and hippocampal LTP in Rett syndrome mice

Authors: *S. HAO[1,2], Z. WU[1,2], B. TANG[1,2], Y. SUN[2,3], H. ZOGHBI[1,2,3,4,5], J. TANG[1,2]; [1]Dept. of Pediatrics, Baylor Col. of Medici, Houston, TX; [2]Jan and Dan Duncan Neurolog. Res. Abstract: Rett syndrome (RTT) is a postnatal neurodevelopmental disorder, which is caused by loss-of-function of X-linked gene encoding methyl CpG binding protein 2 (MeCP2). Cognitive deficit is one of the most reproducible and reliable outcome measures among RTT mouse models. Deep brain stimulation (DBS) serves as an established therapy for several neurological disorders, and recently it has shown promise for ameliorating cognitive deficits as well. Studies in AD patients and in amnestic rats have demonstrated that DBS in the fimbria-fornix, the region that appears to regulate hippocampal activity, reduces memory decline and improves cognitive function. Accordingly, we hypothesized that stimulation of the fimbria-fornix will improve cognitive function in RTT mice. We studied the effects of chronic forniceal DBS in both wide type (WT) and female MeCP2+/- mice, a well-characterized RTT model with impairment of hippocampal memory and synaptic long-term potentiation (LTP). We found that two-week chronic DBS enhanced contextual, but not cue, fear memory in both WT and RTT mice compared with sham controls, respectively. In parallel, forniceal DBS enhanced *in vivo* LTP in the perforant path - dentate pathway in RTT mice and WT littermates. Forniceal DBS boosted contextual memory and LTP in RTT mice to the levels of WT sham controls. As a result, DBS rescues the impairment of contextual memory and hippocampal LTP. These results suggest that chronic forniceal DBS may improve hippocampus-dependent cognitive dysfunction in MeCP2+/- mice via modulation of the hippocampal synaptic plasticity. Stimulating the neural circuits that underlie learning and memory may serve as a therapeutic intervention to enhance cognitive function of developmental neurological diseases.

Title: Bidirectional homeostatic synaptic plasticity is impaired in cultured hippocampal neurons from Mecp2 knockout mice

Authors: ***X. XU**, L. POZZO-MILLER;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Rett syndrome (RTT) is a progressive autism spectrum disorder caused by loss-of-function mutations in the gene encoding methyl-CpG-binding protein 2 (MeCP2). Numerous studies in animal models of RTT have revealed dysfunctions of neuronal and network excitability in Mecp2 deficient mice. Negative-feedback homeostatic synaptic plasticity (HSP), also known as synaptic scaling, maintains the global synaptic strength of individual neurons in response to sustained alterations in neuronal activity. Since the excitation/inhibition balance is impaired in the hippocampus of Mecp2 knockout (KO) mice (Calfa et al. 2015), and thought to be maintained by homeostatic mechanisms, we examined the role of MeCP2 in HSP. HSP was induced by either silencing with tetrodotoxin (TTX) or over-excitation with bicuculline (Bic) for 48hs in hippocampal cultures from male Mecp2 KO and WT littermate pups. Numbers of excitatory synapses and the surface levels of postsynaptic GluA1 were determined by triple color immunocytochemistry of VGLUT1-expressing presynaptic terminals on dendritic spines of GFP-expressing neurons. Here we show that Mecp2 KO neurons have fewer excitatory synapses, higher surface GluA1 and presynaptic VGLUT1 levels than WT neurons. TTX induced an increase whereas Bic induced a decrease of GluA1 and VGLUT1 levels in WT neurons, without changes in the numerical density of GluA1/VGLUT1 puncta. Chronic silencing of Mecp2 KO neurons didn't show scaling-up of GluA1 and VGLUT1 levels; and their over-excitation failed to scale-down GluA1 levels. Intriguingly, Bic scaled-down VGLUT1 levels in Mecp2 KO neurons, as observed in WT neurons. To directly measure synaptic scaling, we recorded miniature

excitatory postsynaptic currents (mEPSC) in pyramidal WT and Mecp2 KO neurons. We found mEPSC are larger, more frequent, and with higher channel conductance in Mecp2 KO neurons than in WT neurons. Chronic silencing of WT neurons increased the amplitude, frequency, and channel conductance of mEPSCs, whereas their over-excitation decreased mEPSC amplitude and the number of channels. On the other hand, TTX failed to scale-up mEPSC amplitude and channel conductance, whereas Bic failed to scale-down mEPSC amplitude and the number of channels in Mecp2 KO neurons. Intriguingly, TTX scaled-up mEPSC frequency in Mecp2 KO neurons, as observed in WT neurons. These findings demonstrate that both pre and postsynaptic homeostatic synaptic plasticity at excitatory synapses are impaired in Mecp2 KO neurons, providing proof-of-principle that restoring HSP may ameliorate neurological deficits in RTT.

Title: CDKL5 is required for spine maintenance during synaptic plasticity

Authors: *D. LI, C. YANG, Z. XIONG;
Inst. of Neurosci., Shanghai, China

Abstract: The X-linked gene cyclin-dependent kinase-like 5 (CDKL5) is associated with severe neurodevelopmental diseases including Rett-like syndrome and early onset seizure. However, the role of CDKL5 in synaptic plasticity remains unknown. Here we find that CDKL5 is tightly regulated by neuronal activity during synaptic plasticity. In cultured hippocampal neurons, the synaptic level of CDKL5 decreases in NMDA-induced chemical LTD (NMDA-LTD) and increases in glycine-induced chemical LTP (glycine-LTP); meanwhile, the dendritic microtubular accumulations of CDKL5 are enhanced in both forms of the plasticity. The

p150glued subunit of the microtubular dynein-dynactin motor is identified as a CDKL5 protein partner. Co-immunoprecipitation assays show that both the interactions of CDKL5 to postsynaptic PSD-95 and to microtubular p150glued are regulated in NMDA-LTD and glycine-LTP, which are consistent with activity-induced CDKL5 translocations. In addition, shRNA knockdown experiments reveal that CDKL5 is essential for activity-dependent spine maintenance. Together, these evidences suggest a critical role of CDKL5 in connecting activity-dependent cargo-specific vesicular trafficking and PSD-95-mediated spine remodeling, thus to maintain spine stability during synaptic plasticity. Our data not only give a hint to uncover the mechanism of activity-dependent vesicular trafficking in synaptic plasticity, but also provide a molecular basis to understand the pathogenesis of CDKL5-related disorders.

Title: Consequences of hippocampal hyperactivity in the medial prefrontal cortex of Mecp2 knockout mice, a model of the autism Rett syndrome

Authors: *M. PHILLIPS[1], W. LI[2], L. POZZO-MILLER[2];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Civitan Intl. Res. Ctr., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The balance between excitation and inhibition (E/I) in the central nervous system is crucial for normal brain function. This balance has been found to be altered in numerous brain regions in mouse models of Rett syndrome, a neurodevelopmental, syndromic autism spectrum disorder caused by mutations in the X-linked Methyl-CpG Binding Protein (MECP2) gene. E/I imbalance results in altered network activity levels, causing them to be either hyper or hypoactive. Here, we describe network activity levels in the hippocampus and anterior medial prefrontal cortex (mPFC) of symptomatic male Mecp2 knockout (KO) mice as compared to age-matched wildtype (WT) littermates. We previously demonstrated that the ventral hippocampus

(vHipp) network is hyperactive in Mecp2 KO mice, with increased spontaneous activity of pyramidal cells and reduced synaptic inhibition (Calfa et al. J Neurophysiol 2011, Hippocampus 2015). Consistently, the number of cFos-positive neurons is higher in all vHipp areas and the dentate gyrus of Mecp2 KO mice. In addition, the intensity of EGR1 (zif268) immunolabeling is higher in areas CA1 and CA3 of Mecp2 KO mice. Simultaneous electrophysiology and voltage-sensitive dye (VSD) imaging in acute brain slices confirmed that the vHipp network is hyperactive, as evidenced by the amplitude and spatiotemporal spread of VSD signals in area CA1 during single excitatory postsynaptic potentials evoked by Schaffer collateral stimulation. In contrast, the spatial spread of VSD signals evoked by layer 5 stimulation is smaller in mPFC slices from Mecp2 KO mice, even though their amplitude were comparable to those observed in WT slice (Bregma 1.5:2.0). Consistent with this hypoactivity of the mPFC network, the number of cFos-positive neurons and EGR1 levels are both lower in the mPFC of Mecp2 KO mice. Current studies are focusing on the influence of the vHipp on the prelimibic and infralimbic regions of the mPFC, testing the hypothesis that increased activity of vHipp long-range projections causes heightened feed-forward inhibition in the mPFC, resulting in the hypoactivation of the mPFC network. Such cortical inhibition may contribute to cognitive impairments and autistic features in RTT individuals.

Title: The balance between excitation and inhibition of cortical GABAergic interneurons is altered in both Mecp2 and Cdkl5 knockout mice

Authors: N. MORELLO[1], R. SCHINA[1], R. PIZZO[1], E. CALCAGNO[1], M. PHILLIPS[2], M. SASSOÈ-POGNETTO[1], L. POZZO-MILLER[2], *M. GIUSTETTO[1];

Abstract: Rett syndrome (RTT) is an X-linked progressive neurodevelopmental disorder. While most RTT patients show mutations of the methyl-CpG-binding protein 2 (MECP2) gene, recently a variant of RTT syndrome was shown to be associated with mutations in the cyclin-dependent kinase-like 5 (CDKL5). Recent published data showed that conditional mouse mutants where Mecp2 or Cdkl5 were selectively ablated in cortical interneurons (INs) recapitulate many RTT features, indicating that GABA (γ-aminobutyric acid)-releasing cells might be a prominent cellular substrate of the disease. However, how the organization of synaptic connectivity of cortical INs is impacted in RTT is still poorly understood. To shed light on this issue, we used immunofluorescence and confocal microscopy to evaluate the density and localization of both excitatory and inhibitory synapses on cortical INs in male Mecp2 knockout (KO) mice at 4 and 8 weeks of age, corresponding to presymptomatic and symptomatic stages of the pathology. Likewise, excitatory connectivity on cortical INs was studied in adult Cdkl5 KO mice. We found a significant increase of VGlut1-positive puncta on the dendrites of parvalbumin (PV) INs in mutant mice of both ages. In contrast, VGlut1 contacts on the dendrites of calretinin (CR) INs were increased only in symptomatic mutants. Moreover, we found that the density of VGAT-positive inhibitory synapses was significantly reduced on the dendrites of PV INs at both ages. To assess possible functional consequences of this altered synaptic connectivity, we performed voltage-sensitive dye (VSD) imaging in acute slices from the primary somatosensory cortex of symptomatic Mecp2 KO mice. The spatial spread of VSD signals during single excitatory postsynaptic potentials evoked by afferent stimulation was smaller in Mecp2 KO slices, consistent with increased inhibitory drive in the mutant neocortex. The analysis of VGlut1-positive puncta in the cortex of Cdkl5 mutant mice showed an increased density of excitatory terminals targeting the dendrites of both PV+ and CR+ subclasses of INs. Moreover, PV+ INs established an increased density of synapses on the soma of L5 pyramidal neurons. Our data suggest that in both models of RTT, the cortical GABAergic inhibitory system is hyperfunctional due to synaptic modifications that alter the excitation/inhibition balance (E/I), thus supporting the hypothesis that RTT might arise from a deregulated E/I ratio in the cerebral cortex.

Langevin, ESPCI ParisTech, PSL Res. university, Paris, France

Abstract: Absence epilepsy seizures consist in bilateral spike-and-wave discharges occurring in the thalamocortical circuit. In genetic rat models seizures emerge from the somatosensory cortex. A vascular correlate has been described both by NIRS and fMRI experiments, suggesting that localized and/or anticipatory vascular events coincide with EEG discharges. We sought to reveal these events with improved sensitivity and spatiotemporal resolution, using functional ultrasound imaging (fUS). We scanned through the brain of epileptic rats, to address the heterogeneous alterations in neuro-metabolic coupling during hypersynchronous seizure activity. Spontaneous generalized absence seizures were recorded from bilateral cortical electrodes in Genetic Absence Epilepsy Rats from Strasbourg (GAERS). The ultrasound acquisition sequence consisted in alternating 200ms to generate one compound mfUS image followed with 2.8s of processing. Multiple imaging planes were scanned for 10-15min each. In order to test the effect of the imaging procedure, we quantified both the relative time spent seizing and seizure duration, and found no significant difference between control and imaging conditions. Hemodynamic changes in seizure-associated areas ranged from -10% to +20%. We found distinct patterns of correlation across structures along the antero-posterior axis. Hyper-perfusion in the somatosensory cortex and thalamus was concomitant with hypo-perfusion in the Caudate Putamen and no variation in the hippocampus. Although absence seizures are generalized throughout neocortex, vascular alterations showed spatial compartments, and lateralization in the frontal primary sensory cortex

perfusion was observed in half of the animals. Furthermore, consecutive seizures with a similar bilateral cortical EEG profile could display distinct bilateral or unilateral perfusion course. Comparing the dynamics of cortical and thalamic areas coupled to seizure revealed synchronous oscillations in the perfusion pattern. Thus, the responses we observed across anatomical structures are compatible with EEG-fMRI experiments that found inversed electrographic-hemodynamic coupling between the cortex and CPu, and with time-resolved EEG-NIRS experiments that indicate blood flow fluctuations around seizures initiation. With the best of time and spatial resolution of these two techniques, fUS further points to cortical decoupling between electrographic activity and perfusion, with both static and transient components, in naturally occurring seizures.

Abstract: Acquired epilepsy is characterized by the development of spontaneous recurrent convulsive seizures following a precipitating insult, including traumatic brain injury, *Status Epilepticus*, and Febrile seizures. Initial brain trauma is followed by a highly variable seizure free “latent” period lasting months to years. While this behaviorally silent period is thought to involve progressive neural network changes leading to hyperexcitability, very little is known about the underlying etiology. This study uses a well-established chemoconvulsive animal model of acquired epilepsy combined with 24/7 video EEG recording and an external auditory stimulus to passively monitor and actively probe the hippocampus for changes in excitability. Passive

EEG monitoring indicates increases in pre-Ictal discharges (used diagnostically in epileptic patients) prior to the development of spontaneous seizures. Actively probing the hippocampus demonstrated reproducible, progressive and archetypal alterations in hippocampal excitability that were predictive of the forthcoming epileptic state. Together, these two mechanisms provide for a temporally accurate electrographic biomarker of epilepsy risk that identifies novel phases of epileptogenesis and emerging windows for therapeutic intervention, as well as providing a much needed tool for the understanding of the basic mechanisms underlying acquired epilepsy.

Title: Comparison of F-18-fluorethyltyrosine and F-18-fluordesoxyglucose positron emission tomography in chronically epileptic rats

Authors: *J. P. BANKSTAHL[1], P. BASCUNANA[2], I. LEITER[2,3], F. M. BENGEL[2], M. BANKSTAHL[3];
[2]Nuclear Med., [1]Hannover Med. Sch., Hannover, Germany; [3]Pharmacol., Univ. of Vet. Med., Hannover, Germany

Abstract: Rational In the epileptic focus of patients suffering from chronic epilepsy changes in glucose metabolism are well described and used for pre-surgical diagnostics. Investigation of protein metabolism might add valuable additional information concerning epilepsy-associated brain pathology. In this study, we evaluated positron emission tomography (PET) *in vivo* imaging using a marker for protein metabolism, F-18-fluorethyltyrosine (FET), in comparison to the standard marker for brain energy metabolism, F-18-fluordesoxyglucose (FDG), in chronically epileptic rats. Methods Control animals (n=4) and chronic epileptic animals (lithium-pilocarpine model, n=5) were dynamically PET scanned twice under isoflurane anesthesia after injection of FDG (16.5±1.9 MBq) or FET (19.1±0.5 MBq), respectively, and glucose blood levels were obtained. PET images were analysed by calculating influx rate Ki and metabolic rate

MRglu (Patlak plot for FDG) and volume of distribution Vt (two-compartment model, image-derived input function from arteria carotis for FET) of brain regions obtained by applying a VOI template map to the images (amygdala, piriform cortex, hippocampus, thalamus, cerebellum). Results With FDG, epileptic animals showed generalized reduction in Ki in all analysed brain regions of up to 35% (p=0.001), whereas MRglu was only reduced in hippocampus (25.14±0.24 vs. 21.56±1.00 mmol min-1 100ml-1, p=0.017). FET modelling resulted in a tendency for reduced Vt only in the hippocampus (0.62±0.03 vs. 0.50±0.04 ml cm-3, p=0.065), but not in other investigated brain regions. Correlation analysis between FDG MRglu and FET Vt in the hippocampus revealed a Pearson correlation coefficient r of 0.69 (p=0.041). Conclusion Our data reveal that metabolic underperformance in the epileptic focus is not limited to brain energy metabolism but also present for protein metabolism. This is reflected also by correlation between FDG MRglu and FET Vt values and might serve as an additional marker for pre-surgical evaluation of the epileptic focus.

Title: Retrograde tracing reveals changes in monosynaptic inputs onto neonatal- vs. adult-born dentate granule cells in a rodent model of temporal lobe epilepsy

Authors: *X. DU[1,2], H. ZHANG[2], E. WOLF[2], J. PARENT[2,1];
[1]Neurosci. Grad. Program/MSTP, [2]Dept. of Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Adult neurogenesis in the hippocampal dentate gyrus (DG) is potentiated by seizures. In rodent temporal lobe epilepsy models, however, dentate granule cell (DGC) neurogenesis is aberrant and adult-born DGCs generated after status epilepticus (SE) develop abnormal connections that are postulated to contribute to pathophysiology. To understand how SE affects

the integration of adult-born DGCs, we use a dual-viral tracing approach to identify and compare inputs onto neonatal- versus adult-born DGCs. A retrovirus (RV-Syn-GTR) driven by the human Synapsin1 promoter and expressing GFP, an avian retroviral receptor (TVA), and the rabies glycoprotein (Rgp) is used to selectively infect dividing cells in the rat DG at either postnatal day (P) 7 or P60 to birthdate either neonatal- or adult-born DGCs, respectively. Rats undergo pilocarpine-induced SE at P56 and then receive bilateral injections of an avian envelope protein (EnvA)-pseudotyped rabies virus, with Rgp replaced by mCherry (RbV-mCh) 10 weeks later. RbV-mCh selectively infects RV-Syn-GTR transduced neurons through EnvA binding to its cognate receptor, TVA. RbV-mCh then complements with Rgp provided by Rv-Syn-GTR and retrogradely crosses synapses, labeling first-order presynaptic neurons with mCh. As traced presynaptic inputs lack Rgp, RbV-mCh cannot spread further. Animals were euthanized 7 d post RbV-mCh injection. Control animals received saline injections rather than pilocarpine. We identify 'starter' DGCs as GFP+/mCh+ and their first-order inputs as mCh+/GFP-. We found mCh+ inputs onto both neonatal and adult-born DGCs from the DG hilus, entorhinal cortex (EC), septum, and supramammillary nucleus (SMN) in both SE and control animals. Surprisingly, we also observed a significant amount of mCh+/GFP- inputs from CA2, CA3, CA1, as well as subiculum in both P7 and P60-injected SE animals. Inputs from these areas were present in both P7 and P60-injected control animals, but to a much lesser degree than in SE animals. Triple-labeling also revealed decreased inhibitory input from parvalbumin (PV)+ and somatostatin (SST)+ interneurons onto adult-born DGCs after SE as compared with controls. Together, these finding suggest that adult-born DGCs receive decreased inhibitory inputs and new inputs from areas that were previously not known to project to the DG. Ongoing experiments are aimed at identifying whether there are changes in inhibitory inputs onto neonatal-born DGCs after SE and also whether excitatory inputs from DGCs and mossy cells onto other DGCs also change after SE.

Title: Identifying propagation and source of epileptiform activity in the hippocampus in transgenic mice with voltage-sensitive fluorescent proteins

Authors: *C.-C. CHIANG[1], L. E. GONZALEZ-REYES[2], R. SHIVACHARAN[2], D. M. DURAND[2];
[1]Biomed. Engin., [2]Case Western Reserve Univ., Cleveland, OH

Abstract: There is increasing interest in propagation and foci identification of epileptiform activity recently. Although the epileptiform activity can be spatially recorded by means of electrode array or voltage-sensitive dye, they are limited to the low spatial resolution or low signal-to-noise ratio. A voltage-sensitive fluorescent protein can provide solutions with higher spatial resolution and sensitivity to low voltage change for observing the epilepiform activity in the larger areas. In this manuscript, we study the propagation and source of the epileptiform activity detected by optical recordings in the hippocampus. We used transgenic mice with a voltage-sensitive fluorescent protein, called VSFP-butterfly 1.2, which enables optical recordings of the pyramidal cells in the hippocampus. The longitudinal hippocampal slices were prepared and epileptiform activity was induced by immersing the slice in the aCSF with 100μM 4-aminopyridine solution. The fluorescent change induced by intrinsic neuronal activity was detected through a fluorescent microscope with emission filters (542 nm and 590 nm) and an excitation filter (483 nm) and a high speed camera was used to acquire image sequence at 100 frame rate. A glass pipette electrode was also used to record local field potential for the comparison. The result shows that the fluorescent change around the glass pipette electrode is related to the field potential and the similar changes were also observed in the whole cellar layers and dendrites regions of the longitudinal hippocampal slice. By analyzing the image sequence, the result shows that the epileptiform activity could propagate through the longitudinal hippocampal slice. The speed of propagation of the epileptiform activity is around 0.05-0.1 m/s which is similar to our previous results detected by electrode array. Furthermore, the source of epileptiform activity could be differentiated from the spike of epileptiform activity and avoid the problem which the source and spike were interfered when using electrode array to record. A source of the epileptiform could be observed during the period of propagation and a very slow change of the source pattern is detected during the period of propagation. In summary, optical imaging could identify the propagation of the epileptiform activity and the change of the source pattern.

Title: Increased CA1 hippocampal excitability in Na, K-ATPase α3 subunit mutant (D801N) knock-in mice

Authors: *A. S. HUNANYAN[1], A. HELSETH[1], S. ADIL[1], M. LINABARGER[1], E. AREHART[1], L. CHUNG[2], M. MIKATI[1,2];
[1]Pediatrics Neurol., [2]Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Na, K-ATPase dysfunction involves in many neurological disorders including epilepsy and alternating hemiplegia of childhood (AHC). AHC is a disorder that manifests intermittent hemiplegias, dystonia and epileptic seizures (Mikati et al. 2000). Recently we have developed a knock-in mouse (Mashl+/-) that bears the most common mutation (D801N; mutation in Na/K pump α3 subunit) causing AHC (Hunanyan et al. 2015). Using extracellular recordings from hippocampal CA1 pyramidal cell body layer recently we have found that mutant mice exhibited increased excitability in response to 1Hz repetitive electrical stimulation of Schaffer collateral (Hunanyan et al. 2015). To elucidate the cellular mechanisms of increased hippocampal excitability in this study we performed whole-cell patch clamp recordings from individual CA1 pyramidal cells and compared intrinsic properties of CA1 pyramidal cells in wild-type littermates (WT) and Mashl+/- mice. Sagittal hippocampal slices (300 μm) were prepared from 21-30 day old mice (males and females). CA1 pyramidal cells were identified using upright Zeiss Axioskop microscope with DIC and IR-1000 videocamera. We obtained whole cell recordings in current clump mode (Multiclamp 700B and Axoclamp 2B) using glass microelectrodes (4-6MΩ resistance). Resting membrane potential of Mashl+/- mice CA1 pyramidal cells were significantly depolarized compared with WT littermates (Mashl+/-: -63.5 ± 0.8mV, n = 11mice/41cells vs WT: -59 ± 0.4mV, n = 6mice/36cells; p = 0.001). Rheobase (a minimum current to induce AP) was significantly smaller in Mashl+/- mice (18.3 ± 2.5pA, n=6/32cells) compared with WT littermates (37.5 ± 6.4pA, n = 8/24cells; p = 0.026). There were no significant difference in input resistance (Mashl+/-: 170.3 ± 9.4MΩ, n = 6/21cells vs WT: 149.8 ± 10.2MΩ, n = 8/32cells, p = 0.180), AP amplitude (Mashl+/-: 77 ± 2.1mV, n = 6/32cells vs WT: 76 ± 3mV, n = 8/24cells; p = 0.691), after hyperpolarization amplitude (Mashl+/-: 3.5 ± 0.2mV, n = 6/32cells vs WT: 2.7 ± 0.4mV, n = 8/24cells; p = 0.121) and Sag amplitude (Mashl+/-: 6.2 ± 0.4mV, n = 6/32cells vs WT: 8.3 ± 1.1mV, n = 8/24cells; p = 0.140). We

conclude that depolarized resting membrane potential and decreased rheobase in Mashl+/-mice CA1 pyramidal cells could be one of the causes of increased excitability in Mashl+/- mice hippocampal slices. Currently we are performing voltage clamp experiments to record spontaneous and evoked IPSPCs/EPSCs to find out which neurotransmitter(s) could be involved in increased excitability.

Title: Increased sensitivity to chemoconvulsant in Akt3 transgenic mice is improved by RAD001 treatment

Authors: *S. M. MCTIGHE[1], S. J. NEAL[1], A. J. GRAY[1], K. CAPRE[1], S. L. LEGARE[1], D. S. BURDETTE[2], J.-C. DODART[1];

Abstract: Genetic data indicate that mutations resulting in hyperactivation of the mTOR pathway are associated with brain overgrowth, seizures and autistic-like behaviors. Preliminary clinical data also suggest that Everolimus (RAD001 - mTOR inhibitor) reduces seizure frequency in patients with tuberous sclerosis. AKT is activated upon phosphorylation by mTORC2, and among other downstream effectors is hypothesized to signal through activation of mTORC1 leading to phosphorylation of S6 (P-S6). A mouse model expressing a gain of function mutation in the Akt3 gene has been reported to show reduced seizure threshold by both electroconvulsive treatment (ECT) and on pentylenetetrazol (PTZ; chemoconvulsant) administration. Here we investigate the effects of subchronic RAD001 treatment on seizure severity in this Akt3 transgenic mouse model. Data reported here from a full dose response of PTZ treatment indicate that Akt3 transgenic mice are hypersensitive to acute PTZ treatment as compared to wild-type littermate controls. Subchronic RAD001 dosing (30 mg/kg, PO, BID for 5 days) robustly inhibited the downstream mTOR pathway activity marker, S6 phosphorylation, while also significantly reducing PTZ-induced seizure severity in Akt3 transgenic mice. This

study suggests that the altered seizure threshold in Akt3 transgenic mice may be mediated by hyperactivated mTOR signaling.

Title: Electrophysiological and molecular characterization of a neonatal pilocarpine model

Authors: *C. WORMUTH, C. HENSELER, K. BROICH, M. WEIERGRÄBER, A. PAPAZOGLOU;
Federal Inst. For Drugs and Med. Devices, Bonn, Germany

Abstract: Epilepsy is a neurological disorder that is characterized by involuntary spontaneous seizures. Temporal lobe epilepsy (TLE) is a complex partial epilepsy in which patients experience recurrent epileptic seizures emerging mainly from the hippocampus and amygdala of the uni- and/or bi- lateral temporal lobes of the brain. Bromide is a cheap and easy to use antiepileptic drug (AED) that is administered to children only as a tertiary AED. Interestingly, administration during childhood does not lead to the severe side effects that can be observed in adults. The pilocarpine model is very common in adult rats and induces chronic epileptic seizures in the already consolidated brain. It mimics both the underlying aetiology and symptoms of TLE. This includes: i) seizure foci in the hippocampus; ii) a latent period as a seizure-free time before phenotype manifestation iii) hippocampal sclerosis. In order to investigate the different effect of bromide in adults and children, we developed a neonatal pilocarpine rat model with childhood onset. Epilepsy was induced in rat pups at different ages, with variable treatment durations as well as different pilocarpine and diazepam doses. Based on survival rates and seizures incidents, a protocol was selected for further validation. EEG was recorded 28, 49 and

112 days after treatment in the hippocampal CA1 and motor cortex M1 region for 4-7 days and seizures were analyzed with a Seizure Detection Module (Neuroscore, DSI). Furthermore, literature suggests that voltage activated calcium channels are likely to be predominant candidates for calcium elevation during most epileptiform activity. Therefore, we studied molecular changes in the neonatal epileptic rat hippocampal system using quantitative Real Time PCR analysis. In conclusion, our model is easy to use and yields the desired outcome. Mortality rates are as low as 10-20% while 70-90% of the survival animals present an epileptic phenotype. It presents seizures in the hippocampus and motor cortex on a reproducible manner and proofs the distinct role of voltage-gated calcium channels in epileptogenesis.

Title: Cholinergic status epilepticus induces widespread brain damage in postnatal day 7 rat pups

Authors: D. TOROLIRA[1], L. SUCHOMELOVA[1], *J. NIQUET[1,2], C. WASTERLAIN[1,2]; [1]Epilepsy Res. Lab., VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [2]Neurol., UCLA, Los Angeles, CA

Abstract: Status Epilepticus (SE) is common in neonates and infants, and is associated with adverse developmental outcomes. Newborn humans are treated in neonatal ICUs, and many survive with brain damage. However, the role of neonatal SE in this injury is uncertain. Until now, we have lacked an animal model in which seizures induces neuronal injury in rodent models at ages below postnatal day 12 (P12) unless seizures are combined with inflammatory stressors such as lipopolysaccharide (Auvin et al 2007). In this present study, we developed an animal model of SE in P7 rats, which are developmentally close to human neonates. Rat pups were injected ip with high dose lithium (5 mEq/kg) on post-natal day 6, and the next morning with very high dose pilocarpine (320 mg/kg), plus methylscopolamine to reduce secretions (1

mg/kg). This model was designed to mimic the seizures induced by 1.6/2 x LD50 of soman in adult rats (Tetz et al, 2006), and was adapted by us for use in P7 pups. Pups were kept in a special warming chamber to maintain their normal temperature (34-35°C). EEGs were recorded in selected animals and showed continuous seizures for 59.4 ± 6.3 min. O_2 saturation was measured non-invasively from tail probes in selected animals, and our results showed no significant hypoxemia. A third group of animals was perfused with 4% phosphate-buffered paraformaldehyde 6 or 24 hrs after SE. We examined the severity of neuronal injury on coronal sections using fluoro-jade B (FJB) and an antibody against caspase-3. A few FJB stained cells were found in the hippocampal formation and in extrahippocampal structures of sham control pups. Six hrs after SE onset, neuronal injury (FJB staining) was significantly different from controls in neocortex, thalamus, dorsal CA3 and dorsal dentate gyrus. Twenty-four hrs after SE onset, significant neuronal injury was observed in CA1/subiculum, CA3, dentate gyrus, thalamus, neocortex, amygdala, piriform cortex, lateral entorhinal cortex, hypothalamus, caudate putamen, globus pallidus, ventral pallidum, nucleus accumbens. At 24 hrs post-SE, caspase-3a IR was significantly increased in CA1/subiculum, thalamus, and neocortex compared to sham. These caspase-3a-IR neurons have distinct changes such as fragmented nuclei, suggesting that SE triggered an irreversible form of cell injury. In conclusion, we have developed a model of cholinergic SE in P7 rat pups, which combines high survival (70% survival at 24hrs) and widespread brain injury. These studies show that the immature brain is vulnerable to severe forms of SE.

Title: Pharmacological and genetic inhibition of protein kinase Cδ alleviates hippocampal neurodegeneration induced by trimethyltin

Authors: T.-H. T. TU[1], Y. NAM[1], H.-Q. TRAN[1], J. JEONG[2], *E.-J. SHIN[1], H.-C. KIM[1]; [1]Col. of Pharmacy, Kangwon Natl. Univ., Chunchon, Korea, Republic of; [2]Col. of Medicine, Chung-Ang Univ., Seoul, Korea, Republic of

Abstract: We investigated whether protein kinase C (PKC) is involved in trimethyltin (TMT)-induced neurotoxicity. Treatment with TMT resulted in a significant increase of PKCδ out of PKC isozymes (i.e., α, βI, βII, δ, and ζ) in the hippocampus of wild-type (WT) mice. Consistently, treatment with TMT resulted in significant increases in cleaved PKCδ expression. Genetic or pharmacological inhibition (PKCδ knockout or rottlerin) was less susceptible to TMT-induced seizures than WT mice. TMT treatment increased glutathione oxidation, lipid peroxidation, protein oxidation, and levels of reactive oxygen species. These effects were more pronounced in the WT mice than in PKCδ knockout mice. In addition, the ability of TMT to induce nuclear translocation of Nrf2, Nrf2 DNA binding activity and upregulation of γ-glutamyl cysteine ligase was significantly increased in the PKCδ knockout mice and rottlerin-treated WT mice. Furthermore, neuronal degeneration (as shown by nuclear chromatin clumping and TUNEL-staining) in WT mice was most pronounced 2 d after TMT. At the same time, TMT-induced inhibition of phosphoinositol 3-kinase (PI3K)/Akt signaling was evident, thereby decreasing phospho-Bad, expression of Bcl-xL and Bcl-2, and the interaction between phospho-Bad and 14-3-3 protein, and increasing Bax expression and caspase-3 cleavage were observed. Rottlerin or PKCδ knockout significantly protected these changes in anti- and pro-apoptotic factors. Importantly, the protective effects (i.e., Nrf-2-dependent glutathione induction and pro-survival phenomenon) of rottlerin were counteracted by the PI3K inhibitor LY294002. Therefore, our results suggest that down-regulation of PKCδ and up-regulations of Nrf2-dependent glutathione defense mechanism and PI3K/Akt signaling are critical for attenuating TMT neurotoxicity.

Title: Evoked lateral amygdala neuron activity in rats with acquired sound-induced seizures

Authors: H. K. ANDERSEN, D. M. GIANGRASSO, A. J. ROSSI, K. L. PATTERSON, D. E. COBB, *M. C. ZRULL;
Psychol, Appalachian State Univ., Boone, NC

Abstract: In reflex epilepsy, an inherited or acquired progressive disorder, an external stimulus evokes abnormal neural activity that can include generalized convulsive seizures. Rodent models feature a neural network that processes sound abnormally and promotes audiogenic seizures (AGS); most research on the network and its physiology is based in genetically epilepsy prone rats (GEPRs). For AGS in GEPRs, abnormal neural activity begins in the midbrain and spreads to the forebrain via the lateral amygdala (LA). Long-Evans rats are resistant but can be primed for AGS, and it is assumed that the same neural network supporting AGS in GEPRs mediates seizures in these rats with acquired reflex epilepsy. We examined seizure-induced neural activity in the LA and basolateral amygdala (BLA) of rats with acquired AGS using the activity marker c-fos. On postnatal day (pnd) 18, Long-Evans rats (n=12) were primed for AGS (120 dB, 10 kHz pips, 8 min). Age-matched rats (n=12) served as controls. Primed rats were tested for AGS susceptibility (120 dB noise) between pnd 32 and 62. On pnd 32 after an AGS induction for primed rats, 4 AGS and 4 control rats spent 60 min in the quiet and dark to allow expression of c-fos protein and were then sacrificed. Brain tissue was processed for c-fos immunohistochemistry. The protocol was repeated on pnd 46 for 4 more primed rats after a 6th sixth AGS induction and 4 more age-matched controls and on pnd 62 after the 12th AGS induction for the last 4 primed rats and 4 controls. Counts of c-fos positive neurons were made for LA and BLA across the groups using a digital camera, light microscope, and stereological techniques. For LA, a single AGS produced no more evoked activity than seen in control brains; however, on pnd 46 after 6 inductions, LA in the AGS brain exhibited nearly 1000% more c-fos positive neurons than in control LA ($p<.01$). On pnd 62, after 12 AGSs for primed rats, the LA contained 794% more activated neurons than in age-matched controls ($p<.01$). Within primed rats, the increase in LA neural activation from 1 to 6 or 12 inductions was 343% ($p<.01$). Fos-positive neuron counts from sampling frames in BLA were minimal for both primed rats after 1, 6 or 12 inductions and age-matched controls. On average, counts of activated neurons ranged from 1.0 (SD=1.1) to 2.4 (SD=1.7) for AGS brains and averaged 1.0 (SD=0.5) for controls across pnd 32, 46 and 62 cohorts. The data suggest neural activity allowing sound-induced seizures to generalize in primed and GEPR models of reflex epilepsy is the same, at least in terms of the role of LA as an important relay nucleus from brain stem to forebrain structures, reinforcing the likelihood of similar networks for acquired and inherited AGS in rat.

Title: Failure of synaptic transmission may contribute to seizure propagation

Authors: *A. BHANSALI, W. VAN DRONGELEN, A. K. TRYBA;
Univ. of Chicago, Chicago, IL

Abstract: Epilepsy is one of the most prevalent neurological diseases, affecting about 1% of the world population, but the mechanisms underlying seizure initiation, propagation and termination are not well understood. For neurons embedded in an active network, it is generally assumed that there are straightforward linear or sigmoidal relationships between net synaptic input and neuronal firing. However, due to the extreme conditions during a seizure, such a straightforward input-output relationship may vanish. For example, a paroxysmal depolarization shift (PDS) can occur, in which a neuron undergoes high-amplitude suprathreshold synaptic depolarization while it fails to generate action potentials. The PDS burst, a cellular hallmark of epilepsy, represents a neuronal activity-driven depolarization block that affects transmission within the network and may contribute to counterintuitive emergent behavior during seizures. In order to investigate the effect of PDS bursts on synaptic transmission, we performed whole-cell patch-clamp recordings of synaptically coupled rat hippocampal neurons in dissociated culture. Depolarizing current injections were used to determine the minimal amount of current required to induce action potential firing or a PDS-like burst. Current clamp (n=8) and voltage clamp measurements (n=3) revealed that PDS depolarization block led to failure of synaptic transmission in both inhibitory (n=2) and excitatory (n=8) neurons. Importantly, the amount of current needed to evoke a PDS-like burst was ~40% less in inhibitory than excitatory neurons, which suggests that inhibitory neurons enter depolarization block more readily than excitatory neurons. At the cellular level, our studies demonstrate that PDS depolarization block can create a counterintuitive relationship, such that MORE excitatory input generates LESS synaptic output. In addition, PDS bursts can lead to failure of inhibitory synaptic transmission before excitatory output is affected, which may explain the collapse of inhibitory signaling that precedes seizure propagation, an observation that supports our group's recent modeling work (Meijer et al., 2015).

Title: Online measurement of glutamate levels during pentylenetetrazole-induced epileptiform activity using a high temporal resolution technique and simultaneous EEG recording

Authors: *K. PARDO, A. MORALES-VILLAGRÁN, L. MEDINA-CEJA;
Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Online measurement of glutamate levels during pentylenetetrazole-induced epileptiform activity using a high temporal resolution technique and simultaneous EEG recording Pardo-Peña Kenia*, Morales-Villagrán Alberto and Medina-Ceja Laura Laboratory of Neurophysiology and Neurochemistry. Department of Molecular and Cellular Biology, CUCBA, University of Guadalajara, Jalisco, México. The study of neurotransmitters could describe the mechanisms and the progression of neurological diseases. Dynamic measurement of glutamate concentration is valuable for understanding neuronal communication under physiological and pathological conditions such as epilepsy. Microdialysis is a popular method for such measurements, but its use is hampered by its considerably slow temporal resolution in comparison with many dynamic processes in the CNS, with time sample collection varying from 1 to 30 min. In this study, a new approach is presented for measuring the recovery and quantification of glutamate during epileptiform activity every 200 ms. This method consist on mixing hippocampus microdialysate with an enzymatic reactor composed by glutamate oxidase, and Amplex Red which in presence of horse radish peroxidase generates a derivate (resorufin) that fluoresces at 590 nm when excited at 560 nm. Excitation was induced with a laser beam and the fluorescence intensity was determined with a CCD detector, the signal intensity was proportional to the glutamate concentration. We applied this novel technique to relate glutamate level with epileptiform activity induced by PTZ (75mg/kg, i.p) using a deep microelectrode implanted in hippocampus. The basal concentration of glutamate was 7.1±0.42 μM, detected before PTZ injection. The data showed an increase in glutamate level of 15.83 μM (122%) during the first seizure induced by PTZ, the latency to first epileptiform discharge was 2.5±0.35 minutes after injection, however glutamate concentrations increased even more when epileptiform activity was constant, reaching a value of 24.37 μM (243%) and this increase remained high throughout seizures before the death of animals. In contrast, glutamate levels observed after infusing a high potassium solution was 8.63 μM that represents a small increase of 21%. With respect to electrical activity frequency remained without significant changes in any period (2 Hz) but with significant changes in amplitude during seizures (452% compared with

baseline before PTZ injection). These data support the use of this novel technique for neurochemical studies *in vivo* to obtaining more specific information with high temporal resolution on mechanisms that occur in pathological conditions.

Title: Interleukin-1β augments neuronal cell death induced by status epilepticus in the developing dentate gyrus by a mechanism independent of IL-1RI activation

Authors: *L. LOPEZ-MERAZ[1], J.-S. MEDEL-MATUS[2], C. RINCÓN-LÓPEZ[3], A. TLAPA-PALE[3], L. BELTRÁN-PARRAZAL[1], C. PÉREZ-ESTUDILLO[1], C. MORGADO-VALLE[1]; [1]CICE, UNIVERSIDAD VERACRUZANA, XALAPA, Mexico; [2]Dept. of Pediatrics, Neurol. Div., UCLA, Los Angeles, CA; [3]Facultad de Química Farmaceútica Biológica, UV, Xalapa, Mexico

Abstract: Interleukin-1beta (IL-1β) has been associated with neuronal cell death induced by acute seizures in the mature and developing brain. However, the role of this inflammatory cytokine on neuronal cell death induced by status epilepticus (SE) in the immature hippocampus is still under study. The goal of this research was to analyze the participation of IL-1β and its receptor IL-1RI on the dentate gyrus (DG) neuronal cell death induced by SE in fourteen days-old (P14) rat pups. Pups (both sex) were given 3 mEq/Kg lithium chloride i.p. on the day before the induction of SE, which was carried out at P14 by subcutaneous injection of 100 mg/Kg pilocarpine hydrochloride. Six h after SE, IL-1β was injected in the right ventricle at different concentrations [0 (vehicle), 0.3, 3, 30 and 300 (n=6 per group) ng/µl]; other experimental groups were injected with the IL-1β receptor natural antagonist IL-1Ra (30 ng/µl) alone or in combination with IL-1β (3 ng/µl) (n=6 per group). Neuronal cell death was evaluated by hematoxylin and eosin staining 24 h post-SE. Data were analyzed by a one-way ANOVA for independent groups followed by a Tukey test. Results showed a significant increase in the number of cells with eosinophilic cytoplasm and fragmented nuclei (suggestive of apoptotic morphology) in the DG granule cell layer ipsilateral to the injection of 3 ng/µl (72.5±10.7) and

300 ng/µl of IL-1β (69 ±9.8), as well as contralateral to the injection of 3 ng/µl (65.9±9.5), when compared to the vehicle group (26.2±3.2, $p<0.05$ and 24.7±3.6, $p<0.05$, respectively); IL-1Ra did not avoid the effect of IL-1β on neuronal cell death ($p>0.05$). Our findings suggest that IL-1β increases neuronal cell death caused by SE in DG granule cell layer by a mechanism independent of IL-1RI activation.

Abstract: Gene expression can be regulated by microRNAs and they are important in many key biological functions. It has been demonstrated that different microRNAs may have different expression pattern in different brain regions. The hippocampus is functionally highly heterogeneous and it is likely to present different pattern of gene expression in different subfields. RNAseq-based transcriptome analyzes offers the possibility of accurate profiling global gene expression. The aim of this study was to analyze and correlate microRNA and transcriptome profiles in different regions of the hippocampus: Dentate Gyrus (DG), CA1, CA2 and CA3 subfields. Five male Wistar rats were euthanized and the brains were processed for laser microdissection using Zeiss PALM LCM. DG, CA1, CA2 and CA3 were collected from each rat, total RNA was extracted, and libraries were prepared for total RNA and small-RNA sequencing in an Illumina Hiseq platform. Sequences were aligned and quantified with the TopHat/DESeq2 pipeline for total RNA and bowtie/DESeq2 for smallRNA. Gene Onthologies, molecular networks and gene interactions were analyzed with the MetaCore® software. The miRNA target was analyzed by miRWalk® software. A total of 63 miRNAs and 4693 genes

were found to be differentially expressed ($p<0,05$) when comparing CA1 with DG. In CA2, 131 miRNAs and 5819 genes were differentially expressed in comparison with DG. In CA3, 96 miRNAs and 6331 genes were found to be differently expressed. Furthermore, when comparing CA2 to CA1, 54 miRNAs and 2645 genes were differentially expressed; CA3 to CA1, 48 miRNAs and 4096 genes were differentially expressed; and CA3 to CA2, 38 miRNAs and 1744 genes were differentially expressed. Enriched gene ontology categories identified miRNAs involved in p53 signaling, immune response IL-10 signaling pathway, microRNA-dependent inhibition of epithelial to mesenchymal transition. For transcriptome data, gene ontology categories identified networks involved in receptor-mediated axon growth repulsion, epidermal growth factor receptor signaling pathway, synaptic vesicle fusion and recycling in nerve terminals. Overall, the most activated genes were regulated by miR- 204, 205, 652, 187, 204, 532-3p, 873, 652, 34b and 375. These miRNAs were significantly down-regulated in our miRNAseq analysis. The present data indicates a large spatial heterogeneity in gene and microRNA expression in the rat hippocampus subfields. A better understanding of such variability may improve our interpretation of the molecular mechanisms involved in normal and pathological conditions related to the hippocampus, such as epilepsy and Alzheimer´s disease.

Title: Role of adult neurogenesis in the generation of ectopic neurons in the dentate gyrus and their role in epileptogenesis

Authors: ***A. BELMADANI**[1], D. REN[2], R. J. MILLER[3];
[1]Dept Molec Pharmacol & Biolog Chem, Northwestern Univ., Chicago, IL; [2]Phamacology, [3]Northwestern Univ. Chicago, Chicago, IL

Abstract: Ectopic placement of granule cells (EGCs) in the dentate gyrus (DG) of the hippocampus is a commonly observed feature in epilepsy and some psychiatric diseases. EGCs may cause aberrant network excitability in the dentate gyrus, an important step in the process of epileptogenesis. While most research on adult hippocampal neurogenesis has focused on the sub-granular zone (SGZ) as the local neurogenic source for EGCs, we suggest that the sub-hippocampal zone (SHZ), a region of the dorsal surface of the adult hippocampus, may also be important. Specifically, we showed that SHZ cells display properties of neural stem cells, including expression of the chemokine receptor CXCR4, GABA (A) currents and neurosphere formation when cultured ex-vivo. These cells migrate to the hippocampus along a unique migratory stream (CMS) involving the meninges which express the CXCR4 ligand SDF-1/CXCL12 and can contribute to restoration of the DG and SGZ morphology following their destruction by inflammation. We further showed that upon deletion of CXCR4, some of these cells prematurely differentiate into ectopic neurons in the DG. Our observations indicate that the SHZ is a neurogenic zone in adult mice through migration of NSCs in the CMS. Regulation of CXCR4 signaling in these cells may be involved in repair of the DG and may also give rise to ectopic granule cells in the DG in the context of neuropathology. In keeping with this hypothesis, using a model of epilepsy induced by intrahippocampal injection of kainate, we observed significant changes in CXCR4/SDF-1 signaling accompanied by strong migration of SHZ cells towards the DG, where some became ectopically placed in the hilus and expressed markers for granule neurons. Further investigation of the role of these neurons in the generation of epileptiform activity may identify new therapeutic targets for the control of epileptogenesis

Title: Serial preclinical C-11-PK11195-PET imaging reveals the time course of microglia activation during insult-induced epileptogenesis

Authors: *M. BRACKHAN[1], P. BASCUÑANA[1], F. TWELE[2], F. M. BENGEL[1], M. BANKSTAHL[2], J. P. BANKSTAHL[1];
[1]Nuclear Med., Hannover Med. Sch., Hannover, Germany; [2]Dept. of Pharmacology, Toxicology and Pharm., Univ. of Vet. Med., Hannover, Germany

Abstract: Objective: Accumulating evidence suggests that brain inflammation, triggered by epileptogenic injuries, may contribute to seizure development. Non-invasive nuclear imaging of brain inflammation in animal models of epileptogenesis may identify inflammatory processes as predictive biomarkers that hold potential for translation into the clinic. In this study, we investigated microglia activation indicative of neuroinflammation using C-11-PK11195-PET and immunohistochemical analysis. Methods: As epileptogenic insult, a status epilepticus (SE) was induced in rats by lithium-pilocarpine and interrupted after 90 min by diazepam. Rats (n=4-8 per time point) were subjected to 60 min PET scans followed by a CT for co-registration before SE, directly after SE interruption, 1, 2, 5, 7, 14 , and 22 days, and 14-16 weeks post SE. For data evaluation, brain regions (thalamus, hippocampus, amygdala, entorhinal cortex, cerebellum) were outlined by co-registration with a standard rat brain atlas, and % injected dose/cc and binding potential (simplified reference tissue model) were calculated. For immunohistochemical evaluation, additional rats were decapitated without and 48 hours, 5 or 14 days post SE. Brain sections were stained for CD11b, GFAP, and NeuN and analyzed semi-quantitatively. Results: Following SE, increases in C-11-PK11195 uptake and binding potential (BPnd) occurred in epileptogenesis-associated brain regions, but not in the cerebellum, first appearing 48 hours after SE and peaking between 7 and 14 days after SE (up to 2.09-fold increase in uptake, $p < 0.001$). Uptake and binding potential remained above baseline values up to 3 weeks after SE and were subsequently decreasing until at least 14-16 weeks after SE. Immunohistochemical evaluation revealed microglia and astroglia activation as well as neuronal cell loss in epileptogenesis-associated brain regions at all investigated time points. The time profile of microglia activation corresponded to that demonstrated by C-11-PK11195-PET. Conclusion: The revealed peak in neuroinflammation 1-2 weeks after epileptogenic brain insult enables improved timing of inflammation-targeting antiepileptogenic pharmacotherapy.

Title: Evoked population spike of *in vitro* rat hippocampal brain slice assay for assessment of proconvulsant liability of mGluRs ligands

Authors: *J. ZHAI, A. LAGRUTTA, H. ZENG, Y.-Y. ZHOU, F. SANNAJUST;
Dept. of Safety & Exploratory Pharmacology, SALAR Division, Merck Res. Lab., Merck & Co., West Point, PA

Abstract: Glutamate is a major excitatory neurotransmitter widely distributed in the CNS and modulates the synaptic response via activation of ionotropic and metabotropic glutamate receptors (mGLuRs). Activation of mGluR1 & 5 (group I) and inhibition of mGluR2 & 3 (group II) or some of mGluR4, 6, 7, and 8 (group III) as well as some positive allosteric modulator (PAM) of mGluRs have been shown to induce seizures in animal models following i.c.v. administration, in genetically seizure-prone rats, and or by analysis of spontaneous ictal discharges *in vitro*. Having previously demonstrated the utility of an *in vitro* assay measuring evoked population spikes (PS) in rat hippocampal brain slices to detect seizure liability of ~20 receptor ligands, we explore if the assay can detect the seizurogenic activity of diverse mGluRs ligands associated with epileptic seizures in animals. Ligands including group I mGluRs agonists and group II and III mGluRs antagonists were investigated. PS was electrically evoked at 30-s intervals from Schaffer collateral synaptic pathway and recorded in the cell soma of CA1 pyramidal neurons in brain slices prepared from adult Wistar rats. PS area and PS number were quantified to observe changes in PS morphology by the tested ligands at selected concentrations correlated with *in vivo* studies. DHPG concentration-dependently enhanced both PS number and PS area. The effect was reversed by antagonist DL-AP3. Consistently, (S)-3-HPG and CHPG, selective agonists of mGluR1 and mGluR5, respectively, significantly increased evoked PS like DHPG. Ro 01-6128 and VU 29, PAM of mGluR1 and mGluR5, respectively, could not increase either PS area and or PS number. Surprisingly, LY341495, mGluR2 & 3 antagonist, had no effect on PS at nanomolar concentrations (0.01-1 μM), but increased the PS at micromolar concentrations (3-30 μM). Highly selective group II antagonists, Eglu and APICA at 10-300 μM, could not induce seizures-like multiple PS, suggesting that seizure liability of LY341495 at high concentrations might not result from blockade of group II mGluRs. Finally, either PS area and/or PS number were increased by MSOP and MPPG, group III antagonists, respectively. In conclusion, this *in vitro* rat hippocampal brain slice assay can recapitulate seizure risk liability of majority of mGluRs ligands detected by *in vivo* rodent models. The absence of seizures-like activity from some of mGluR2 & 3 ligands or PAM could be related to the limited distribution of specific receptor subtypes within the CA1 neuronal pathways, or absence of active metabolite(s) as compared to *in vivo* experimental conditions.

Title: Neocortical organotypic slices show spontaneous epileptiform activity and a developmental decrease in neuronal Cl^- concentration

Authors: *J. C. GLYKYS, K. STALEY;
Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: Neocortical acute slices show a progressive decrease in neuronal intracellular Cl^- concentration ($[Cl^-]_i$) during early development. However, some neurons with high $[Cl^-]_i$ could result from slicing trauma in this model. The murine hippocampal organotypic slice develops spontaneous seizure activity after a few days *in vitro,* yet it is unknown if this happens in neocortical organotypic slices. Thus, we aimed to develop a neocortical organotypic slice to study if spontaneous epileptiform activity also occurs in this preparation, if there is a developmental decrease in $[Cl^-]_i$ and if diazepam's effect is correlated with the neuronal $[Cl^-]_i$. We addressed these questions with field potential recordings to study epileptiform activity, and with multi-photon imaging of Cl^-, to study neuronal $[Cl^-]_i$, in neocortical organotypic slices from wild type and transgenic mice expressing a Cl-sensitive fluorophore (Clomeleon). We found: 1) neocortical organotypic slices at days *in vitro* 5 (DIV5) have spontaneous epileptiform activity and the duration of the events decrease with development. 2) There is a progressive decrease in $[Cl^-]_i$ during development, similar to the acute neocortical slice. 3) Diazepam was ineffective in decreasing epileptiform activity at DIV5-6, but effective at DIV9-10 and DIV15. Interestingly, at DIV5-6, diazepam worsened epileptiform activity in 50% of the slices. We conclude that neocortical organotypic slices are a good model to study spontaneous epileptiform activity and that there is a decrease in $[Cl^-]_i$ during early development, not associated with slicing trauma. Finally, diazepam effectiveness is correlated with neuronal $[Cl^-]_i$, which can worsen epileptiform activity during very early development in 50% of the cases (when $[Cl^-]_i$ is high). These results

can explain the reported induction of epileptic activity such as myoclonus by benzodiazepines in some human neonates.

Title: Alterations of neurovascular coupling in rats with focal epilepsy

Authors: ***Y. SONG**[1], S. GARCIA[1], Y. FROMETA[1], R. A. TORRES[1], J. BAE[1], A. DESHMUKH[1], W.-C. LIN[1], Y. ZHENG[2], J. J. RIERA[1];

Abstract: Neurovascular couplings (NVCs) in epilepsy have been investigated on preclinical models with either acute or chronic seizures. However, these studies failed to quantitatively verify whether dysfunctions of NVCs exist in epileptic cortex. The answer to this question could have tremendous impacts on the interpretations of neuroimaging data applied in clinical practice, which could result in improving the surgical outcome. In this study, a metabolic-coupled balloon model was employed to study the NVCs both in epileptic (n=4) and normal (n=5) Wistar rats. Chronic epilepsy model was established following a “double-hit” protocol. Spontaneous seizure activities were observed during the intracranial recordings of these epileptic rats, and used as neuronal events in the subsequent analysis. Forepaw stimulation was conducted on normal rats as control. A 16-channel microelectrode array was inserted in corresponding cortical areas to record local field potentials (LFPs). Cerebral blood flow (CBF) was monitored by the laser Doppler flowmetry. In addition, intrinsic optical imaging (IOI) was performed in combination with LFP recordings. Modified Beer-Lambert law was applied on the IOI data to estimate the cerebral blood volume (CBV) and relative deoxy-hemoglobin concentration ([dHb]). LFP, CBF and [dHb] were included in the model to estimate parameters that quantify the relationships between the neuronal activity and the hemodynamic responses: 1) ε is the parameter links the neuronal activity to the CBF response; 2) κ uncovers the relationship between the neuronal activity and [dHb]. Significant increases in CBF were found to be associated with epileptogenesis and forepaw stimulation. Reflections of such neuronal activity within the optical field of view usually resembled an increase of CBV and a decrease of [dHb] with an epicentric origin followed by a

peripheral propagation (Fig A-B). However, parameter ε during epileptic activity and forepaw stimulation were significantly different (P<0.001) (Fig F), which indicated an alteration in NVC exists in epilepsy.

Title: Dentate gyrus-CA1 hippocampal interneuron desynchronization in chronically epileptic mice running on a virtual linear track

Authors: ***T. SHUMAN**[1], M. JAVAHERIAN[1], C. C. KABA[1], D. J. CAI[1], K. CHENG[1], R. MANAVI[1], N. RAO[1], J. DANESHRAD[1], A. A. FARIBORZI[1], J. LOU[1], S. E. FLORES[1], C. YANG[1], S. GHIAEE[1], M. STRAHMAN[1,2], K. I. BAKHURIN[1], S. C. MASMANIDIS[1], P. GOLSHANI[1];
[1]UCLA, Los Angeles, CA; [2]Salk Res. Inst., La Jolla, CA

Abstract: Interneurons in the hippocampus gate the processing and flow of information through the trisynaptic and temporoammonic pathways. Because there is dramatic reorganization of GABAergic interneuron connectivity in epilepsy, we hypothesized that this is likely to cause profound deficits in hippocampal interneuron synchronization to ongoing theta and gamma oscillations in epileptic mice. To test this hypothesis we used high density silicon probes with 128 recording sites to simultaneously record single units and local field potentials throughout dorsal CA1 and dentate gyrus in head-fixed mice running through a virtual linear track. Pilocarpine-treated epileptic animals showed reduced gamma power in dentate gyrus as well as reduced theta and gamma coherence between CA1 and dentate gyrus indicating reduced synchronization between these regions. We also found a reduction in theta-gamma cross-frequency coupling in epileptic animals. We further examined this synchronization deficit by examining the phase-locking of dentate gyrus interneurons to ongoing theta oscillations and found that while the magnitude of phase-locked firing in individual dentate gyrus interneurons was comparable to control animals, the preferred phase of these cells as a group was more dispersed and shifted to a later phase of theta. Together, these findings indicate a clear desynchronization between dentate gyrus and CA1 regions of the hippocampus of epileptic mice. These changes may contribute to cognitive deficits in chronic epilepsy. Future studies will gauge the efficacy of interneuron replacement therapies on restoring synchrony in dentate gyrus and CA1.

Title: Early life seizures in rodents can disrupt the preference for social novelty unrelated to increased emotionality

Authors: *R. M. CYSNEIROS, I. S. LEITE, A. S. S. CASTELHANO;
Univ. Presbiteriana Mackenzie, Sao Paulo, Brazil

Abstract: We previously demonstrated that male rats subjected to neonatal status epilepticus (SE) displayed social play impairment, deficit in social discrimination, anxiety like behavior and stereotyped behavior with no changes in motor activity. Taking into account the bi-directional relationship between social interaction impairment and the degree of anxiety, this study aimed to evaluate whether the reduction of state of anxiety could minimize the impaired social interaction. Male Wistar rats (PN9) were subjected to SE by pilocarpine administration (380mg/kg) and the controls received saline. Each group received saline or diazepam (1mg/kg) before each behavioral testing. Behavioral tests started from 60 days of postnatal life. The data was analyzed by Mixer Anova using condition (object x unfamiliar rat or familiar rat versus social novelty) as within-subjects factor and groups (EXP versus CTR) and treatment (saline x diazepam) as between-subjects factors. In the social approach phase, both groups spent more time in the compartment with unfamiliar rat as compared with the one with object ($F(1,48) =61,52$; $P=0,000$), but no effect was noted neither for groups ($F (1,48) = 1,075$, $P = 0,305$), treatment ($F(1,48) = 0,67$; $P = 0,417$) nor interaction between the factors (compartment x treatment, $F(1,48) = 0,42$; $P = 0,838$), (compartment x groups x treatment, $F(1,48) = 1,538$; $P = 0,221$) or (groups x treatment, $F(1,48) = 0,066$; $P = 0,799$), suggesting that both groups regardless treatment displayed preference for the social stimulus. In the social novelty phase, for time spent with familiar and novel rat, significant differences was noted between compartments ($F=(1,48) = 8.262$; $P=0.006$) and for interaction between compartment x groups ($F= (1,48) = 4.793$; $P= 0.033$), suggesting that control animals exhibited preference by social novelty and that experimental animals displayed deficit in social discrimination unaffected by the treatment with diazepam. In the elevated plus maze (EPM), for time spent in the open arms, significant effects of interaction between factors treatment x groups ($F(1,48) = 9,873$, $P =0,003$) and between groups ($F(1,48) = 4,859$, $P=0,032$) were observed. For total of entries, significant effects of interaction between factors treatment x groups ($F(1,48) = 8,188$ $P=0,0062$) and the treatment ($F(1,48) = 4,412$; $P=0,0062$) were noted. The EPM results suggest that experimental group exhibited anxiety related behavior reverted by the treatment with diazepam. The results suggest that the neonatal SE in male rats produces deficit in social discrimination unrelated to emotionality, being probably caused by social memory impairment. Title: Epilepsy induced depression and memory deficit: Intricacies of Serotonergic System

Authors: ***A. MISHRA**[1,2], R. K. GOEL[2];
[1]Pharmacol. and Toxicology, Natl. Inst. of Pharmaceut. Educ. & R, Raebareli, India; [2]Dept. of Pharmaceut. Sci. and Drug Res., Punjabi Univ., Patiala, India

Abstract: Serotonergic interplay (with different receptor subtypes) in the cortex and hippocampus appears to be one of the important common neurochemical interplay leading to epileptogenesis, depression, learning and memory impairment. Role of different receptor subtypes of serotonin has long been implicated in epileptogenesis, depression, learning and memory impairments, but their role in epilepsy induced comorbidities is still unexplored. Therefore this study was envisaged to evaluate the role of different 5- HT receptors (5-HT 1A/2A/2C/3) in kindling induced depression learning and memory deficit. In this study male Swiss Albino mice were kindled using subconvulsive dose of PTZ (35 mg/kg). Once the animals were kindled they were treated with vehicle, 8-OH-DPAT (1 mg/kg/day), WAY-100635 (0.3 mg/kg/day), WAY 100635 + 8-OH-DPAT, DOI (1 mg/kg/day), olanzapine (2 mg/kg/day), olanzapine + DOI, ondansetron (1 mg/kg/day; i.p.), m-CPBG (1 mg/kg/day; i.p.) and ondansetron + m- CPBG for 20 days. Seizure severity score, depression like behavior, learning and memory was evaluated on day 5, 10, 15 and 20. After the behavioral evaluations on day 20, animals were sacrificed to estimate different neurotransmitters in discrete brain parts (by HPLC-FD method), nitrite level and AChE activity (microplate reader method). Ondansetron treatment significantly reduced the seizure severity score and improved the depression like behavior, learning and acquisition performance as compared to vehicle treated kindled animals. The effect of ondansetron was reversed by m-CPBG co-treatment. The neurochemical changes in the cortex and hippocampus also supported the behavioral outcome of the study. This study substantiates the role of $5HT_3$ receptor in epilepsy associated depression like behavior, learning and memory deficit in mice. This study creates a rational to explore the use of more selective 5-HT_3 receptor

ligands for comprehensive management of depressive behavior and memory impairment in patients with epilepsy.

Title: The effects of an acute flurothyl seizure on associative learning and memory

Authors: ***A. J. HOLLEY**[1], J. N. LUGO, Jr.[2];
[1]Psychology and Neurosci., [2]Psychology & Neurosci., Baylor Univ., Waco, TX

Abstract: Introduction: Past studies that utilized the flurothyl model of seizure induction have demonstrated impairment of spatial learning and memory in both neonatal and adult rats. However, these studies focused on inducing several seizures and much later examining the effects on learning and memory. The impact of a single acute seizure on learning and memory has not been investigated in mice. **Methods:** In this study, we placed an adult male 129SvEvTac mouse in an inhalation chamber. We then exposed the animal to the inhalant flurothyl (infusion rate of 50 μL/min) until a behavioral seizure (wild running with tonic-clonic seizure) was induced. We ran parallel control subjects in an inhalation chamber for the same time as the seizure mice. Either one hour or six hours later we examined associative learning and memory in delay fear conditioning. In delay fear conditioning the animal was first placed in a fear conditioning chamber. We then presented 20s of 80-dB white noise, which was immediately followed by a 0.7-mA footshock (unconditioned stimulus). We administered two presentations of the sound (conditioned stimulus) and shock pairings. We then examined the acquisition of the associative conditioning by testing the mice 24 hr post-seizure. During this testing period we made changes to the fear conditioning chamber to introduce a novel context. We then placed the mice in the testing chamber and measured their freezing behavior in the new context for 3 min. We also measured freezing during presentation of the white noise CS. **Results:** We found that mice that had experienced a single seizure 1 hr prior to training showed a significant impairment

in associative conditioning to the conditioned stimulus compared to controls 24 hr later $t(1,13) = 2.54$, $p < 0.05$. However, the seizure mice were no different in their freezing behavior in the new context compared to controls $t(1,13) = 1.6$, $p = 0.14$. Mice that had experienced a seizure 6 hr prior to training did not show any significant difference in freezing behavior compared to controls 24 hr later when presented with the conditioned stimulus $t(1,9) = 0.81$, $p = 0.44$ or in the new context $t(1,9) = 0.76$, $p = 0.67$. 0.91. **Conclusions:** These findings suggest that a single acute flurothyl seizure induced 1 hr but not 6 hr prior to associative learning impairs long term fear memory. These findings have implications for understanding the acute effect of seizures on acquiring new knowledge.

Title: Cardiorespiratory dysfunction due to hippocampal seizure propagation into the brainstem

Authors: T. SALAM[1], W. NUWISAIT[1], G. MONTANDON[2], R. GENOV[3], J. PEREZ VELAZQUEZ[4], M. DEL CAMPO[1], *P. L. CARLEN[1];
[1]Toronto Western Hosp, Toronto, ON, Canada; [2]Physiol., [3]Electrical Engin., Univ. of Toronto, Toronto, ON, Canada; [4]Neurosci., Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Background: Cardiorespiratory dysfunction with seizures is the leading cause of death in patients with epilepsy. Clinical evidence suggests that respiratory arrest or prolonged apnea may be the initial cause of the cardiorespiratory dysfunction leading to death. We propose that this is caused by convulsive activity spreading from the cerebrum to cardiorespiratory network in the brainstem. Methods: Eleven rats underwent successful craniotomy for custom-made microelectrode array implantation into the cortex, hippocampus and brainstem. These rats were divided randomly into three groups: (i) control (n=3), (ii) low-dose 4-AP (n=5), and (iii) high-dose 4-AP (n=5). The control group (3 rats) were monitored for 2 - 3 months; the weekly

baseline EEGs were recorded to monitor the impact of implantation damage (especially in brainstem) on the EEG and long-term stability of the recording system. The other groups received an intrahippocampal dose of 4-AP (1 to 5 μL at 40 mM). The 4-AP experiments were repeated in 2 more rats without brainstem implantation. Results: The basal iEEG recordings indicated long-term stability of the recording system. The low-dose group (5 rats) was injected with 1 μl of 4AP (40mM) into the right hippocampus and exhibited local electrographic seizures without spread to the brainstem, which suggested that a higher dose was required. The third group (5 rats) received 5 μl of 4AP (40mM). Three of these rats had several electrographic seizures in the hippocampus and this seizure activity spread into the brainstem within 30 minutes. Sometimes seizures originated in the brainstem prior to being apparent in the cerebrum. Brainstem seizure activity was associated with violent motor seizures followed by dyspnea and respiratory arrest along and with cortical EEG flattening. Two more rats who did not undergo brainstem implantation, had similar seizure-related respiratory difficulties following the same higher dose of (40mM) 4AP. Conclusion: These studies show that seizure activity originating in a cerebral hemisphere can spread into the brainstem and cause death by impairing the cardiorespiratory network. Also cortical EEG flattening could be a marker for subsequent respiratory arrest as noted in both the animal model and in human cases.

Title: Characterization of neonatal ultrasonic vocalization behavior and neurodevelopmental signaling after kainate-induced seizures in mice

Authors: *C. REYNOLDS[1], G. SMITH[2], T. JEFFERSON[1], J. LUGO[1,2];
[1]Dept. of Psychology & Neurosci., [2]Inst. for Biomed. Sci., Baylor Univ., Waco, TX

Abstract: Seizures during early development are known to cause long-term deficits in social behavior, learning, and memory. However, less is known regarding the acute behavioral impacts due to early-life seizures. Ultrasonic vocalizations (UVs) are one tool to measure early

behavioral changes and have frequently been used to examine early communication deficits in mice. On postnatal day (PD) 10 we administered single intraperitoneal injections of 2.5 mg/kg kainic acid to male and female mice to induce continuous seizures (status epilepticus). On PD11 and PD12 seizure and control mice were separated from their dams for 5 minutes, and the quantity and duration of isolation-induced UVs were recorded. We ran a separate cohort of animals with the same seizure induction method then dissected hippocampi to examine protein changes through western blotting on PD 12. On PD11, we did not observe any significant differences in vocalization behavior. However, on PD12 we found that early-life seizures cause suppression of the quantity and duration of UVs emitted only at the 50 kHz range, $p< 0.05$. Western blotting studies on PD12 also revealed a significantly increased ratio of phospho-S6 protein and decreased phospho-FMRP in the seizure group, $p< 0.05$. These studies enhance existing evidence that neonatal vocalizations indicate selective impairments of early communication behavior in mice. In addition, the western blotting data provides new evidence that the mammalian target of rapamycin (mTOR) intracellular signaling pathway may play a role in this early behavioral alteration after seizures.

Title: Effect of age and sex on seizure responses in mice

Authors: *T. N. FERRARO[1], G. G. SMITH[3], R. J. BUONO[2];
[1]Dept Psychiatry, [2]Dept Biomed. Sci., Cooper Med. Sch. of Rowan Univ., Camden, NJ; [3]Res. Service, VAMC, Coatesville, PA

Abstract: The age of onset for Epilepsy in humans is highly variable. Infants and children are recognized as being particularly vulnerable to the development of epilepsy but risk falls for this group after about age 10. Epilepsy risk rises again in mid-life and it continues to increase as people grow older. The influence of sex is less pronounced but overall men appear to be at a slightly greater risk for developing epilepsy compared to women. In order to address age- and sex-dependent mechanisms underlying development of epilepsy, we studied seizure responses in

mice using an electroconvulsive shock paradigm. Male and female mice with a C57BL/6 (B6) genetic background were colony bred, weaned at 3 weeks of age and group-housed by sex. Throughout the study they were maintained under standard environmental conditions (12h/12h light dark cycle) with free access to food and water. Mice of various ages between 3 and 18 months were studied (total N = 286; 182 females and 104 males). Seizure responses were tested using a single electrical stimulus delivered from a constant current electroshock unit (model No. 7801, Ugo Basile, Varese, Italy). Stimulus parameters were 60 mA current at 60 Hz with a 0.4 ms pulse width and a 0.2 second stimulus duration. Seizures were scored as generalized tonic-clonic or as progressing to tonic extension of hind limbs. Data were analyzed using ANOVA. Results showed a sex-specific influence of age on seizure expression. Between the ages of 3 and 6 months, male and female mice exhibited a similar seizure response profile with two-thirds of each group expressing tonic-clonic seizures and one-third expressing more intense tonic hind limb extension seizures. At later developmental time points, a significantly greater number of female mice showed tonic hind limb seizures compared to both younger females and to males of the same age. A significantly smaller number of older male mice also expressed tonic hind limb seizures than younger male mice. These results document age- and sex-specific seizure responses in B6 mice and help to establish a model for subsequent elucidation of underlying mechanisms.

Title: Effects of adolescent cannabinoid exposure on adult seizure susceptibility and lethality

Authors: *H. H. LOPEZ[1], M. SPRING[2], K. SCHOOLCRAFT[2];
[1]Psychology, Skidmore Col., Saratoga Spgs, NY; [2]Neurosci., Skidmore Col., Saratoga Springs, NY

Abstract: There is substantial evidence that the endocannabinoid system (ECS) is involved in regulating seizure activity. Pharmacological manipulation of the ECS affects seizure intensity and susceptibility in numerous animal models. The current study explored whether chronic administration of cannabinoids during adolescent development increases subsequent, adult seizure susceptibility. 60 male Wistar Kyoto rats were treated with either the synthetic cannabinoid, CP55,940 (0.4 mg/kg, one treatment per day), or vehicle between 35-45 days old.

Subjects were then allowed to mature to adulthood. At 68-69 days of age, subjects were tested for seizure susceptibility using the pro-convulsant, pentylenetetrazol (PTZ). Subjects received an acute injection of either 35 mg/kg or 50 mg/kg PTZ immediately prior to a 30-min behavioral seizure test. PTZ doses were chosen to produce low-moderate levels of seizure activity in control subjects. There were no significant differences between treated and control subjects in: median seizure severity, % who displayed any seizure activity, % who displayed tonic-clonic seizure, or mean latency to first seizure. However, treated subjects had a higher mortality rate (20%) compared to controls (7%), suggesting that adolescent cannabinoid exposure may increase the lethality of severe seizures experienced in adulthood.

Title: The effect of elevated temperature on seizures and anxiety in GABRG2+/Q390X knockin epilepsy mouse model

Authors: *T. A. WARNER, J.-Q. KANG;
Neurol., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Febrile seizures and extended syndromes are frequently associated with gene mutations, especially those mutations in *SCN1A and GABRG2.* It has been demonstrated that elevated temperature alone can induce seizures in the $SCN1A^{+/-}$ mouse model associated with epileptic encephalopathy Dravet syndrome. $Gabrg2^{+/Q390X}$ knockin is a novel mouse model associated with epileptic encephalopathy. The objective of the study was to further explore the effect of elevated temperature on genetic mutations associated with febrile seizures using $Gabrg2^{+/Q390X}$ knockin mice and their wild-type littermates. A heat lamp was used to elevate body temperatures of the mice. A temperature probe and controller were used together to monitor the mouse core body temperature and to regulate heating. Pentylenetetrazol (PTZ)

treatment, a reliable method to induce seizures, was used for comparison to evaluate the effect of heat. Electroencephalography (EEG) was simultaneously evaluated to objectively measure seizure-related events induced by elevated body temperatures or PTZ treatment (50mg/kg). Other measures such as temperature change and levels of anxiety were also observed. Compared to the wild-type mice, *Gabrg2*$^{+/Q390X}$ knockin mice were more susceptible to heat-induced myoclonic jerks as well as generalized tonic clonic seizures, but the seizure frequency and mortality associated with seizures were lower than the PTZ treatment. Additionally, the core temperature of *Gabrg2*$^{+/Q390X}$ knockin mice increased more quickly upon heating. The *Gabrg2*$^{+/Q390X}$ knockin mice also engaged in greater jumping bouts in response to the excessive heat, which may suggest heightened anxiety. These findings suggest elevated temperature alone is a provoking factor for seizures in patients associated with *GABRG2* mutations.

Title: Impaired gabaergic neurotransmission in amygdala and anxiety phenotype in GABRG2+/Q390X knockin epilepsy mouse model

Authors: *C.-Q. ZHANG[1,2], B. MCMAHON[1], T. WARNER[1], R. MACDONALD[1,3], J.-Q. KANG[1,3];
[1]Dept. of Neurology,, Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Dept. of Neurosurgery,Xinqiao Hosp., Third Military Med. Univ., Chongqing, China; [3]Vanderbilt Brain Inst., Nashville, TN

Abstract: Epileptic encephalopathies have high comorbidity with other neuropsychiatric disorders such as anxiety and are frequently associated with ion channel gene mutations like

SCN1A and GABRG2. However, the molecular underpinnings of the comorbidities of epileptic encephalopathies have never been addressed. GABRG2(Q390X) is a mutation in the GABAA receptor γ2 subunit that is associated with epileptic encephalopathy in two independent pedigrees. The amygdala plays the central role in the CNS in processing afferent and efferent connections related to emotional functioning and is the site of perception of anxiety. We have recently characterized the Gabrg2+/Q390X knockin mouse, which phenocopies the major features of the epileptic encephalopathy Dravet syndrome. In this study, we used live brain slice recordings, biochemistry, immunohistochemistry and confocal microscopy, elevated zero maze and open field test to characterize the anxiety phenotype and its underlying molecular mechanisms. With live brain slice recordings, the pyramidal-like neurons in basolateral amygdala (BLA) had reduced peak amplitude of GABAergic mIPSCs in the Gabrg2+/Q390X mice. With immunohistochemistry and biochemistry, the wild-type γ2 and α1 subunits were reduced in amygdala. In elevated zero maze test, the heterozygous Gabrg2+/Q390X knockin mice spent increased time in the closed arm, decreased time in the open arm and decreased entries into the open arm. With the open field test, the mice had increased distance traveled and spent less time in the center. Future studies will test the GABAergic neurotransmission in the central amygdala medial sector (CeM) of Gabrg2+/Q390X mice and determine if treatment with diazepam, a positive allosteric modulator of GABAA receptors, can rescue the anxiety phenotype.

Title: Competition between the brain and testes for selenium utilization: insights into gender differences in selenium metabolism and risk of neurodevelopmental disease

Authors: *M. W. PITTS[1], P. M. KREMER[1], A. C. HASHIMOTO[1], D. TORRES[1], C. N. BYRNS[1], C. S. WILLIAMS[2], M. J. BERRY[1];

[1]Dept. of Cell and Mol. Biol., Univ. Hawaii, Honolulu, HI; [2]Dept. of Med. and Cancer Biol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Selenium is essential for both brain development and male fertility. Male mice lacking two key genes involved in Se metabolism (*Scly*$^{-/-}$*Sepp1*$^{-/-}$ mice), selenoprotein P (Sepp1) and Sec lyase (Scly), develop severe neurological dysfunction, neurodegeneration, and audiogenic seizures that manifest beginning in early adulthood. We demonstrate that prepubescent castration of *Scly*$^{-/-}$*Sepp1*$^{-/-}$ mice rescues maturation of GABAergic inhibition, prevents behavioral deficits, attenuates neurodegeneration, and increases brain selenoprotein levels. Moreover, castration also yields similar neuroprotective benefits to *Sepp1*$^{-/-}$ and wild-type mice challenged with Se-deficient diets. These studies provide evidence for a competition between the brain and testes for Se utilization that has concomitant effects on neurodevelopment and neurodegeneration.

Title: Increased susceptibility to 6-Hz-induced acute seizures and corneal kindling in a triple-transgenic mouse model of Alzheimer's disease

Authors: *M. BANKSTAHL[1], J. P. BANKSTAHL[2], W. HÄRTIG[3];
[1]Univ. of Vet. Med. Hannover, Hannover, Germany; [2]Nuclear Med., Hannover Med. Sch., Hannover, Germany; [3]Paul Flechsig Inst. for Brain Res., Univ. of Leipzig, Leipzig, Germany

Abstract: Rationale: Patients suffering from Alzheimer's disease (AD) have an increased risk of developing seizures and epilepsy, but it is not known how the degree of AD neuropathology influences this interaction. In this study, triple-transgenic (3xTg) mice of different ages, which progressively develop both hallmarks of AD, ß-amyloidosis and tau hyperphosphorylation (Oddo et al. 2003), were investigated for their seizure susceptibility as well as changes in epileptogenesis. Methods: Groups of 4- and 12-months old 3xTg mice (n=16, each) harboring three mutant human transgenes (presenilinM146V, APPSwedish mutation and tauP301L) and age-matched wild type (WT, n=17 and n=14, respectively) mice of both sexes were used. Mice underwent a behavioral test battery (modified Irwin screen, activity cage, elevated plus maze)

and, thereafter, were stimulated via corneal electrodes (6 Hz, 0.2 ms rectangular pulse width, 3 s duration) to determine CC50 via staircase method. Furthermore, mice were kindled by twice daily corneal stimulation (3 mA, 3 s, 50 Hz) for 17 days. Seizure severity was scored according to a modified Racine scale. Results: Irwin screen revealed increased activity and spatial locomotion in 12-months old 3xTg mice compared to corresponding WT mice. Both, 4- and 12-months old 3xTg mice were hyperexcitable (response to touching and elevation at the tail) compared to age-matched WT mice. Increased activity as well as increased horizontal (time spent in and number of visits to the center) and vertical (number of and time spent rearing) explorative behavior was found in 12 months old 3xTg mice compared to corresponding WT mice. Elevated plus maze test did not reveal differences between WT and 3xTg mice. CC50 for 6-Hz-induced seizures was lower in 4-months old (10.5 vs. 17.4 mA, p=0.00002) as well as 12-months old (11.1 vs. 17.8 mA, p=0.00027) 3xTg mice compared to age-matched WT mice. Moreover, the kindling process was age-independently accelerated in 3xTg mice. Conclusion: Mice exhibiting AD neuropathology show hyperactive and hyperexcitable behavior, which is currently discussed as a potential preclinical biomarker for an increased risk to develop epilepsy. Strikingly, increased seizure susceptibility and accelerated epileptogenesis exist already at a pre-plaque age, indicating other underlying mechanisms than only the degree of neuropathological burden.

Title: A novel behavioral approach to examining spatial learning and social interaction in a mouse model of temporal lobe epilepsy

Authors: L. D. ORMISTON[1], S. ANGELIDES[1], A. BARTH[1], *I. MODY[2];
[1]Univ. of California at Los Angeles, Los Angeles, CA; [2]Dept Neurol., UCLA Sch. Med., Los Angeles, CA

Abstract: Temporal lobe epilepsy (TLE) is the most common form of acquired epilepsy and is often associated with deficits in learning and memory, in addition to depression and anxiety. Neurological insults, including status epilepticus (SE), often induce epilepsy after a period commonly referred to as the latent period, during which epileptogenesis occurs. Here we

examine behavior associated with the epileptogenic period in a unilateral suprahippocampal kainic acid (KA) injection mouse model of SE-induced TLE. We have previously found that post-SE mice demonstrate anxiety-like behavior in an open field before the onset of spontaneous recurrent seizures (SRS). However, many traditional spatial and non-spatial learning tasks are limiting because they may not sufficiently engage the interest or interaction of the individual mouse. We have now developed a novel behavioral task to examine social interaction and both spatial and non-spatial learning and memory in mice. Using a novel odor-familiarizing housing protocol, we test the animal's interaction with familiar (social interaction), moved (spatial change), and novel (non-spatial change) mice separated within social interaction chambers. We compare post-SE mice to sham controls at multiple time points to characterize behavioral deficits associated with epileptogenesis and those apparent after development of SRS. We found that post-SE animals demonstrate diminished recognition of spatial and non-spatial changes compared to sham controls. Observed behavior differences may potentially be used as biomarkers for development of TLE in post-SE populations, as early test results may signal later development of spontaneous recurrent seizures. This novel test offers unique information about mouse interaction and memory behaviors, providing insights not limited to models of epilepsy.

Title: A head-fixation protocol allowing electrophysiological, hemodynamic and behavioral measurements in a polygenic rodent model of absence epilepsy

Authors: *C. P. MCCAFFERTY[1], A. KUNDISHORA[1], J. SAMPOGNARO[1], E. JOHNSON[1], N. SMITH[1], Y. SI[1], P. ANTWI[1], A. MORAWU[1], H. BLUMENFELD[2];
[1]Neurol., [2]Neurology, Neurobiology, & Neurosurg., Yale Univ., New Haven, CT

Abstract: Absence seizures (AS), consisting of behavioral arrest and concurrent EEG spike-and-wave discharges, are the most common seizure type of generalized epilepsy syndromes. They are the defining symptom of childhood and juvenile absence epilepsy, syndromes which are associated with learning difficulties, behavioral disorders and other cognitive impairments. The

neural activity underlying AS has yet to be comprehensively characterized, a development that is imperative given the lack of improvement in first-line therapeutics over the past 50 years. Experimental AS have hitherto been studied primarily in anesthetized or neurolept-sedated animals, introducing a difference in arousal state from the clinical condition that may explain discrepancies observed in hemodynamic responses. Consequently, the establishment of a protocol allowing electrophysiological, hemodynamic and behavioral measurements during unadulterated AS is a priority. At the same time, recent evidence suggesting inter-seizure variation in the degree of behavioral arrest calls for a protocol allowing controlled investigation of arousal and the behavioral correlates of consciousness during experimental AS. We have developed a training program to gradually introduce and habituate Genetic Absence Epilepsy Rats from Strasbourg (GAERS) to head fixation within a stereotaxic frame. The method uses incremental familiarization with restraint, minimizing stress to the GAERS in order to facilitate AS expression within the apparatus. A water restriction regime allows the provision of a reinforcing reward for cooperation in each stage, and also primes the animal for stimulus detection and discrimination training concurrently with the fixation habituation. We found that the protocol achieved linear improvement, over a total training period of 1 month, in measures of task cooperation (percentage of time in correct position, duration of training sessions) and decreases in adverse events (escape attempts, biting) and signs of stress (grooming, defecation, urination) (n = 6 rats). Session length, determined by the willingness of the animal to remain stationary within the apparatus, increased from <1 min to >20 min. These results suggest that sessions of sufficient duration for multi-modal electrophysiological and hemodynamic measurements can be achieved while keeping rats in an unstressed condition, providing an opportunity to investigate the physiological and hemodynamic mechanisms of AS in an awake behaving animal model.

Title: Sleep state and circadian time dependent respiratory consequences of seizures and seizure-induced death

Authors: *G. F. BUCHANAN[1,2], K. I. CLAYCOMB[2], M. A. HAJEK[2];
[1]Neurol., Univ. of Iowa, Iowa City, IA; [2]Neurol., Yale Sch. of Med., New Haven, CT

Abstract: Sudden unexpected death in epilepsy (SUDEP) is the leading cause of death in patients with refractory epilepsy. SUDEP tends to occur at night, but whether this is a coincidence, or whether this speaks to a specific sleep state-dependent or circadian-dependent mechanism is unknown. Respiratory and cardiac arrest are the most probable etiologies for SUDEP. Control of both breathing and cardiac function is subject to sleep state-dependent and circadian regulation. Seizures themselves are modulated in a sleep state- and circadian-dependent manner. Here we set out to determine whether there are state- and/or circadian-dependent effects of seizures on cardiac and respiratory function that contribute to seizure-related death. EEG, EMG and EKG electrodes were implanted in adult male mice. Seizures were induced with maximal electroshock (MES; 50 mA, 200 ms, 60 Hz) during wakefulness, non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep during mid-day and mid-night and EEG, EMG, EKG, and breathing were assessed. Vigilance state was determined on-line in real time based on EEG and EMG characteristics using standard parameters. Seizures that occurred during sleep were more likely to be fatal, especially those induced during REM, and those induced during the daytime. In all instances, death ensued due to primary respiratory arrest. Non-fatal seizures induced during NREM were associated with longer duration post-ictal respiratory suppression, reduced ventilation, and increased respiratory rate variability compared to those induced during waking. All mice died when seizures were induced during REM sleep, therefore this analysis could not be conducted. In addition, there was increased baseline variability in the respiratory rhythm in mice that died compared to those that survived. These data indicate that seizures that occur during sleep can have detrimental effects on breathing which may contribute to increased seizure related death.

Title: Characterization of Cacna1a knock-in mice as a model for sudden unexpected death in epilepsy

Authors: *E. A. TOLNER[1], I. C. M. LOONEN[2], M. B. HOUBEN[3], M. SCHENKE[2], R. D. THIJS[3], R. A. VOSKUYL[2], M. D. FERRARI[3], A. M. VAN DEN MAAGDENBERG[4]; [2]Human Genet., [3]Neurol., [4]Human Genet. and Neurol., [1]Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Sudden Unexpected Death in Epilepsy (SUDEP) is a devastating complication of epilepsy and difficult to study in humans. Risk factors and mechanisms for SUDEP are largely unknown. In recorded SUDEP cases, post-ictal generalized EEG suppression (PGES) is seen prior to death, more often for seizures occurring during sleep when neuronal inhibition is enhanced. In *Cacna1a* knock-in mouse mutants carrying a severe S218L gain-of-function mutation, fatal seizures closely resembling SUDEP were observed. Here we aimed to characterize the relationship of fatal and non-fatal seizures with PGES in the *Cacna1a* mouse model carrying S218L or the milder R192Q knock-in mutation resulting in enhanced excitatory, and presumed intact inhibitory, neurotransmission. Simultaneous EEG and multi-unit activity recordings were performed from somatosensory cortex in awake *Cacna1a* knock-in mice. Video-recording allowed parallel EEG and behavioral analysis of seizures in relation to fatal outcome in homozygous *Cacna1a* S218L mice. In homozygous R192Q and heterozygous S218L mice with a less severe phenotype, epileptic afterdischarges were evoked by electrical stimulation (15s, 8 Hz) of the somatosensory cortex. Up to 3 weeks of brain activity was recorded in freely behaving *Cacna1a* R192Q and S218L mutant mice, as well as in wild-type mice without mutations. Spontaneous seizures were recorded only in the severer S218L *Cacna1a* mutant mice; the majority died from a fatal seizure. All deaths were preceded by suppression of cortical activity, resembling PGES. The occurrence and duration of seizure-related suppression of brain activity were compared between fatal and non-fatal seizures and related to time-of-day and sleep-wake state. Evoked seizures in wild-type, homozygous R192Q and heterozygous S218L mice were

associated with strong EEG suppression and occurrence of cortical spreading depression in mutants. In conclusion, the spontaneous occurrence of fatal seizures typically followed by PGES in homozygous S218L mutants makes *Cacna1a* knock-in mice uniquely suited to investigate SUDEP mechanisms. Comparison of evoked seizure-PGES characteristics among wild-type, R192Q and S218L mice allows to assess gene-dosage effects and provide insight in the role of excitation-inhibition balance for PGES.

Title: Increased anxiety and cognitive impairments in a rat model of absence epilepsy: effects of the T-type calcium channel blocker Z944

Authors: *W. N. MARKS[1,2], M. E. CAVANAGH[2], Q. GREBA[2], L. AN[2], S. M. CAIN[3], T. P. SNUTCH[3], J. G. HOWLAND[2];

Abstract: Genetic Absence Epilepsy Rats from Strasbourg (GAERS) are a commonly used rodent model of childhood absence epilepsy. In addition to the occurrence of absence seizures in 100% of GAERS, research suggests that the animals also display characteristics of psychiatric disorders including heightened anxiety and increased sensitivity to dopamine agonists. However, a detailed behavioural assessment of the strain has yet to be completed. Therefore, we tested male and female GAERS and Non-Epileptic Control (NEC) rats on a battery of anxiety and cognitive tests relevant to psychiatric disorders. Similar to previous research, we found that GAERS showed increased anxiety-like behavior in the elevated plus maze and increased startle to an acoustic stimulus. In a battery of recognition memory tests, GAERS performed similarly to NEC rats on tactile recognition memory; however, their performance was impaired on a visual recognition test with a one hour, but not five minute, delay. The GAERS strain also showed a

profound disruption of crossmodal memory (tactile-to-visual memory) when compared to the NEC strain. The male, but not female, GAERS were also impaired in visual discrimination and reversal learning assessed using an automated task in touchscreen-equipped operant chambers. In a classical fear conditioning paradigm, GAERS showed normal learning and memory to an auditory conditioned stimulus but impaired extinction and reinstatement. Acute administration of the T-type calcium channel blocker Z944 (3 and 10 mg/kg; i.p.) reversed the crossmodal memory deficit in the GAERS rats while impairing memory in NEC animals (10 mg/kg dose). These results suggest that the GAERS strain is useful for studying the comorbidities related to absence epilepsy as well as the cognitive symptoms of some psychiatric disorders. Experiments with Z944 reveal that altered T-type calcium channel activity may underlie certain cognitive deficits in the GAERS strain.

Title: Role of RBFOX3/NeuN in epilepsy and cognitive impairment

Authors: *H.-S. HUANG, H.-Y. WANG, P.-F. HSIEH, D.-F. HUANG, P.-S. CHIN; GIBMS, Col. of Medicine, NTU, Taipei, Taiwan

Abstract: Epilepsy is a neurological disorder characterized by epileptic seizures and its prevalence rate is 7 out of 1,000 people. Cognitive impairment is a mental disability characterized by poor global intellectual performance and its prevalence rate varies from 3% to 29% due to differences in diagnostic criteria and sample characteristics. It is still unclear about the exact causal mechanism for epilepsy and cognitive impairment. RBFOX3 (NeuN) is a neuron-specific alternative splicing regulator and its disruption has been identified in patients

with epilepsy and cognitive impairment. RBFOX3 promotes neuronal differentiation through alternative splicing of Numb pre-mRNA during brain development. Despite the importance of RBFOX3 in brain development and its relevance in human brain diseases, its physiological role in brain remains unclear. To address this critical question, we decided to further explore RBFOX3 in the hippocampus of mice. Our studies may provide molecular and cellular mechanisms underlying RBFOX3-related human brain diseases such as epilepsy and cognitive impairment.

Title: A historical and critical overview of the contributions of the wistar audiogenic rat (war) strain to neuroscience. Challenging complexity and transdisciplinarity

Authors: *N. GARCIA-CAIRASCO[1,2], E. H. L. UMEOKA[2];
[1]Ribeirao Preto Sch. Med., Ribeirao Preto, Brazil; [2]Neurosci. and Behavioral Sci., Ribeirão Preto Sch. of Med. - Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Twenty-five years ago the Wistar Audiogenic Rat (WAR) strain was introduced to the neuroscience community. The WARs, a genetically-selected reflex model susceptible to audiogenic seizures (AS), mimicks acutely tonic-clonic seizures, and chronically (audiogenic kindling, AK) temporal lobe epilepsy. Here we present an overview of historical highlights of the

WAR strain. Seminal Neuroethological, EEG, cellular and molecular data support the WAR strain as a suitable animal model of epileptology. Epilepsy comorbidities, a hot topic in epilepsy research, bring new potential to the use of WARs in fields such as neuropsychiatry, memory/learning, neuroendocrinology and cardio-respiratory autonomic regulation. Behavioral studies with naïve WARs, showed endogenous anxiety, when compared to Wistars, with reduced exploration in the elevated plus maze and the open field. Also, when compared to age-paired Wistars, WARs are smaller, with hyperplasic adrenal gland and higher levels of corticosterone after exogenous ACTH injection. Furthermore, restrained WARs showed corticosterone-dependent (tested with GR and MR antagonists) higher seizure severity during AK, than unstressed animals. WARs have also potential for studies of compulsive behavior, because, when compared to Wistars microinjected into amygdala with oxytocin, a model of compulsion, naïve WARs displayed significant higher grooming behavior. Those neuroendocrine alterations contribute to the higher blood pressure and altered autonomic regulation of the cardiovascular system found in WARs. At the same time, brainstem 5-HT nuclei, associated to respiratory control, are highly compromised in WARs. Such combination of endocrine/autonomic factors is supportive of increased risk factors for sudden unexplained death in epilepsy. The Morris Water Maze test revealed an impairment of reference memory in young WARs, whereas the Novel Object Recognition test indicated a significant deficit in short-term memory in middle age WARs. The detection of altered β-amyloid protein and phosphorylated-Tau in the brain of WARs, together with the above mentioned memory dysfunctions in WARs, encourage the validation of WARs as a model of Epilepsy-Alzheimer disease comorbidities. Collectively, pioneer and recent findings reinforce the complexity associated to WAR alterations, consequent to their genetically-dependent background and seizure experience. We are currently developing more powerful EEG, molecular and behavioral methods, combined with computational neuroscience/network modeling tools to further increase the WAR strain contributions to contemporary neuroscience.

Title: The effects of early life immune programming on outcomes in a rodent mild traumatic brain injury model

Authors: *S. A. CANDY[1], R. MYCHASIUK[2], H. HEHAR[1], I. MA[1], Q. PITTMAN[1], M. J. ESSER[2];
[1]Univ. of Calgary, Calgary, AB, Canada; [2]Alberta Children's Hosp., Calgary, AB, Canada

Abstract: Mild traumatic brain injuries (mTBI) account for 70-90% of brain injuries and are most common in young children and adolescence. Although most symptoms are acute, approximately 10 -15% of children have impaired recovery and may develop long lasting symptoms. Even in cases where the force and type of the injury are similar it is unclear what renders some individuals more vulnerable than others. This would suggest that there are underlying factors that influence the differential outcomes between individuals. In this respect, peripheral inflammation during critical periods of development has been shown to cause long-term changes in brain excitability, as well as increased susceptibility to later-ischemia induced cell death. As neuroinflammation is thought to play an important role in TBI, early inflammatory exposure and immune programming may be one of the contributing factors to the variation in mTBI outcomes. The goal of this study was to determine whether an early life inflammatory event would modulate the behavioural outcomes subsequent to a mTBI in a rat model. In-house bred male and female Sprague Dawley pups from 8 separate litters, were given an intraperitoneal injection of either LPS (100µg/kg) or saline (SAL) on P10, followed by a mTBI or sham injury on P30. One group of rats was sacrificed at 24 hours after injury (*n=32*) and serum and brain tissue were collected to examine acute effects after the mTBI. Another group of rats (*n=60*) underwent a behavioural test battery including: beam-walking, open field, play behaviour and novel context mismatch. Results from the study were consistent with previous mTBI findings and showed some drug and injury interactions. Rats that experienced LPS and TBI had greater impairments in social interactions. The LPS and mTBI group also showed altered working memory, characterized by a poor preference for the object in the novel environment. Brain tissue and serum samples are currently being analyzed for differences in inflammatory markers. These results highlight that some behaviors' might be more susceptible to modulation by early life inflammation and subsequent brain injury. Future studies will attempt to further understand the role of pre-injury inflammation by altering the dosage of LPS and include fear conditioning testing in the behavioural battery after mTBI.

Title: Expression pattern of interleukin (IL)-6, 7 and 10 in the CNS of mice

Authors: *P. SZOT[1,3], A. FRANKLIN[1], D. F. LATTEMANN[2,3], M. RASKIND[1,3], E. PESKIND[1,3];
[1]MIRECC, [2]BSLRD, Puget Sound Hlth. Care Syst., Seattle, WA; [3]Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: Inflammation of the CNS has been implicated as an important component in several disorders of the brain including traumatic brain injury (TBI). Neuroinflammation is an initial and complex response with the release of various cytokines, chemokines and growth factors from various cell types. At the Northwest Network Mental Illness Research, Education, and Clinical Center (MIRECC), Seattle, a sample of Iraq/Afghanistan combat Veterans who experienced blast trauma mild traumatic brain injuries (mTBI) (median yrs post last blast TBI=4; median number of blast incidents=13) had elevated CSF IL-7 compared with deployed Veterans and civilian samples with no lifetime history of TBI. CSF IL-6 levels were elevated in deployed Veterans both with or without mTBI. Interleukins have been implicated in the response to TBI, but whether their expression is beneficial or harmful to brain tissue remains unclear. Since the interleukins are involved in the response to TBI, it is important to understand where in the CNS these cytokines and their receptors are expressed and what their contribution may be to the long-term response to TBI. To begin to address these questions, we are determining where IL-6, 7 and 10 are expressed in normal mice. Preliminary measurement of IL-7 mRNA expression with *in situ* hybridization indicates a limited pattern of expression, with stronger levels expressed in the central grey, lateral hypothalamus, and medial thalamic nucleus; this expression pattern differs from that of IL-6 mRNA. Data from CNS mapping studies of IL-6, 7, and 10 (and their receptors) will be presented.

Title: Exposure of rats to a mild blast traumatic brain injury: the galanin system

Authors: *L. KAWA[1], S. BARDE[1], U. ARBORELIUS[1], E. THEODORSSON[2], D. AGOSTON[3], M. RISLING[1], T. HÖKFELT[1];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Linköpings universitet, Linköping, Sweden; [3]Uniformed Services Univ., Bethesda, MD

Abstract: The incidence of traumatic brain injury (TBI) in the combat setting is increasing due to exposure to blast related mechanisms. The literature reports exposure to the primary blast wave alone can result in a mild blast TBI (mbTBI). The rapid changes in pressure as a consequence of the blast wave impact the head and transmit an initial burst of energy to the brain. This type of injury is very distinct to the TBI literature in the civilian population, which are most commonly due to falls and motor accidents. The underlying mechanisms of mbTBI have yet to be characterized due to the 'invisible' nature of this disease. Structurally the brain appears normal, but 15-30% of patients positive for a mbTBI go on to develop, and suffer persistent cognitive and emotional impairments. Post-traumatic stress disorder (PTSD) is one of the most commonly reported anxiety/mood-disorder in veterans, and is symptomatically highly related to mTBI. PTSD is a psychological consequence of exposure to traumatic events, and can manifest itself with or without injury. The peptide galanin is found co-expressed with the monoaminergic neurons in the brain regions where we have previously reported changes in the monoamine systems, following exposure to a blast wave. Galanin is also implicated to play a role in stress and mood disorders. Thus we sought to ascertain its role in the pathobiology of mbTBI using a rodent model of blast TBI. Anaesthetized rats were placed in a rigid metallic holder, which limited acceleration movements of the head and protected the animals' torso, and thereafter exposed to a single blast wave. Our findings indicate significant upregulation in the galanin transcript levels in the locus coeruleus (LC) and dorsal raphe nucleus (DRN), as evaluated by *in situ* hybridization and confirmed by qPCR. In regards to the receptors, galanin receptor 1 is upregulated in the DRN at 1 and 7 d post-exposure, while in the same region galanin receptor 2 is decreased at the later time point. Increases in the galanin transcript levels were also seen in a number of forebrain regions at the earlier time point. We also analyzed levels of the peptide itself, and found at 3d post-exposure increased galanin in several brain regions

including the amygdala and LC. While, at 7d post-exposure the peptide was decreased in the DRN and amygdala. Taken together, the galanin peptide system appears to play a role in the pathobiology of mbTBI and could present a promising target.

Title: Temporal profile of chronic motor and cognitive deficits in a rodent model of penetrating ballistic-like brain injury (PBBI)

Authors: *K. L. CAUDLE, R. C. PEDERSEN, J. A. SUN, S. A. BUSGANG, Y. DENG-BRYANT, A. M. BOUTTÉ, L. LEUNG, F. C. TORTELLA, D. A. SHEAR;
Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Traumatic brain injury (TBI) remains one of the largest causes of death and disability in the United States resulting in over 2 million emergency room visits per annum, and as many as 15-50% of patients surviving TBI will experience long-term disabilities. Clarification of pathophysiological mechanisms underlying progressive neurobehavioral deficits as well as other co-morbidities associated with severe TBI is required for targeted therapeutic development. This study sought to characterize the long-term recovery profile of neurobehavioral and neuropathological outcomes in a rodent model of severe penetrating ballistic-like brain injury (PBBI). PBBI was induced by stereotactically inserting a perforated steel probe through the right frontal cortex of an anesthetized rat and rapidly inflating the probe's elastic tubing into an elliptical shaped balloon to 10% of total rat brain volume causing temporary cavitation. Motor performance testing was conducted using the rotarod task at sub-acute (1 and 2 weeks) and chronic (1, 3 and 6 months) post-injury periods (sham n=8, PBBI n=12). Cognitive performance was assessed in separate cohorts of animals using a modified Morris water maze (MWM) task (two trials per day) at 1, 3 and 6 months post-PBBI (sham n=10, PBBI n=12). Rotarod testing revealed significant injury-induced deficits beginning at 7 days post-injury and persisting through 6 months with average latencies to fall reduced by 57±7% (PBBI vs. sham; $p < .05$)

across all assessment time points. Similarly, MWM results revealed significant injury-induced deficits in spatial learning performance across all three assessment post-injury periods, with the average latency to find the hidden platform increased by 115±16% (PBBI vs. sham; $p < .05$). Additionally, PBBI-injured rats spent significantly less time searching in the platform target area and significantly greater time in the perimeter (thigmotaxic swimming behavior) during the MWM missing platform trials. Overall, the results of the current study indicate that the PBBI model produces clinically relevant functional deficits which persist into the chronic phase post-injury. Furthermore, our repeated measures behavioral testing paradigms produce the robust gap in performance abilities between injured and sham animals necessary to evaluate putative neuroprotection therapies.

Title: Granule cells born during post-traumatic neurogenesis functionally integrate into the hippocampus

Authors: *E. SCHNELL[1], L. E. VILLASANA[2], K. N. KIM[1], G. L. WESTBROOK[3]; [1]Portland VA Med. Ctr., Portland, OR; [2]Anesthesiol. and Perioperative Med., OHSU, Portland, OR; [3]Vollum Inst., Portland, OR

Abstract: Traumatic brain injury (TBI) increases hippocampal neurogenesis, which may contribute to cognitive recovery after injury, but it is unknown whether TBI-induced adult-born neurons functionally integrate into the hippocampal network. We assessed the generation, morphology and synaptic integration of new hippocampal neurons after a controlled cortical impact (CCI) injury model of TBI. TBI-induced newborn neurons were labeled using transgenic expression of fluorescent marker proteins. TBI increased the generation, outward migration, and dendritic complexity of neurons born during post-traumatic neurogenesis. However, these cells had profound alterations in their dendritic structure, with increased dendritic branching proximal to the soma and widely splayed dendritic branches. These changes were apparent during early dendritic outgrowth, and persisted as these cells matured. Whole-cell recordings from neurons generated during post-traumatic neurogenesis demonstrated that they are excitable and functionally integrate into the hippocampal circuit. However, despite their wider dendritic fields, we found no differences in the rate of their electrophysiologic maturation, or their overall degree of synaptic integration when compared to age-matched adult-born cells from sham mice. Our results suggest that cells born after TBI participate in information processing, and receive an apparently normal balance of excitatory and inhibitory inputs. However, TBI-induced changes in their anatomic localization and dendritic projection patterns could result in maladaptive network properties. We are currently investigating the mechanisms driving these changes, with the goal of manipulating levels of post-traumatic neurogenesis to better determine its functional significance.

Title: Experimental Traumatic Brain Injury in rats results in a marked increase of translocator protein 18 kDa (TSPO) binding in the vicinity of the brain contusion

Authors: *C. K. DONAT[1], K. GABER[2], J. MEIXENSBERGER[2], P. BRUST[3], L. H. PINBORG[1], J. D. MIKKELSEN[1];
[1]Neurobio. Res. Unit, Copenhagen Univ. Hospital, Rigshospitalet, Copenhagen, Denmark;

[2]Dept. of Neurosurg., Leipzig Univ. Hosp., Leipzig, Germany; [3]Inst. of Radiopharmaceutical Cancer Research, Res. Site Leipzig, Helmholtz-Zentrum Dresden-Rossendorf, Leipzig, Germany

Abstract: Traumatic brain injury (TBI) can cause long-term disability by several secondary injury mechanisms. Inflammation in the nervous tissue is a crucial process in the injury response and therefore a potential target for treatment and molecular imaging. TSPO, a protein in the mitochondrial membrane, is robustly upregulated by the inflammatory response in the brain, making it a suitable biomarker. We investigated the response of TSPO over time with the selective and clinically relevant radioligand [^{123}I]CLINDE in a rat model of TBI. Male adult Sprague-Dawley rats were randomly assigned to four groups (survival time: 6, 24, 72 h and 28 d). Animals were anaesthetized and subjected to either sham injury, craniotomy or mild-to-moderate (2 mm depth, 4 m/sec) controlled cortical impact injury (CCI). Drug/surgery-naïve animals were included as additional controls. Representative coronal sections were cut and TSPO binding was assessed with *in vitro* autoradiography in the vicinity of the contusion (M1 motor cortex, bregma +3.5 mm posterior, +4.0 mm lateral). [^{123}I]CLINDE binding was nearly uniform in the brains of naïve and sham-operated animals and displaceable (10 µMol/L PK11195) in all groups. At 24 h, injured animals exhibited a significant increase in binding in the whole ipsilateral hemisphere (49%) as well as in the M1 ipsilateral (201%) and contralateral (38%) cortex. [^{123}I]CLINDE binding was maximally increased at 72 h after CCI in the whole ipsilateral (368%) and contralateral (29%) hemisphere and M1 ipsilateral (1076%) and contralateral (32%) cortex. Surprisingly, craniotomy without TBI produced a significant increase in TSPO at 24 h in the ipsilateral M1 cortex (42%) and at 72h in the ipsilateral hemisphere (232%) and M1 cortex (598%). Binding was not significantly different between the groups at 6 h and 28 d. These data strongly suggest [^{123}I]CLINDE to be a suitable radiotracer for the assessment of brain injury after TBI and the monitoring of anti-inflammatory (pharmaco)therapies.

Title: Two-dimensional unfolded maps for the study of the location, distribution and extent of the cortical lesion following lateral fluid-percussion injury

Authors: *X. E. NDODE-EKANE, I. KHARATISHVILI, A. SIERRA LOPEZ, R. J. IMMONEN, O. H. J. GRÖHN, A. PITKÄNEN;
A.I.V. Institute, Univ. of Eastern Finland, KUOPIO, Finland

Abstract: Information on the anatomical specificity of the cortical lesion following traumatic brain injury (TBI) is useful for understanding the post-traumatic functional outcome. Thus, there is the need for effective techniques in delineating and quantifying the extent of the cortical lesion. The aim of this study was to use the two-dimensional unfolded map technique to identify the anatomical location, distribution and extent of the cortical lesion following TBI in rats, as a first step in understanding its relationship to the post-traumatic functional deficits. Traumatic brain injury was induced in rats using the lateral fluid-percussion injury (LFPI). To visualise the acute lesion, the rat brains were scanned using the T2 weighted MRI at 3 d post-injury. AT 14 d post-injury, the rats were sacrificed and the brains processed for histological assessment of the lesion. To analyse the extent and distribution of the cortical lesion along the anterioposterior axis, several images of the brain in the coronal plane was collected from the T2 weighted MRI (8-9 slices, 1mm thick) (MRI lesion) and the thionin-stained histological sections (12-15 sections, 30um thick) (histology lesion). The length of the lesion was outline on the surface of the cortex on every image using the ImageJ® software and charted onto an unfolded map of the rat cortex. To reveal the lesion boundaries, the edges of the lesion on every slice/section was then connected with each other. The unfolded MRI and histology lesions revealed that, following LFPI, the lesion spread more laterally than medially and extends caudally involving cortical regions such as the ectohinal, perirhinal and entorhinal cortices. Furthermore, the maps showed that the most implicated cortical regions was the visual,parietal, auditory and somatosensory cortices. An estimate of the lesion size showed that MRI lesion was larger than the histology lesion (21.47 ± 1.53 mm2 vs. 13.15 ± 1.46 mm2, $p<0.001$), probably due to the resolution of the acute post-injury oedema. This data suggested that an unfolded map of the cortical lesion following TBI can be used to obtain precise anatomical information on the distribution and extent of the lesion in the different cortical region.

Title: Concomitant increase in cognitive behavioral deficits and white matter injury markers over time in a gyrencephalic animal model of traumatic brain injury

Authors: *S. C. SCHWERIN[1], E. HUTCHINSON[2], K. RADOMSKI[1], C. PIERPAOLI[2], S. L. JULIANO[1];
[1]Anatomy, Physiol. and Genet., Uniformed Services Univ., Bethesda, MD; [2]NIH, Bethesda, IL

Abstract: Rodent models of traumatic brain injury (TBI) provide important insight into mechanisms of damage and plasticity following injury, however the low volume of white matter and lissencephalic cortex of the rodent reduce their relevance to study human pathology. The ferret is the smallest mammal with a convoluted brain and the ratio of white to gray matter is comparable to humans. This suggests that the biomechanical response to impact is comparable to human injuries. We investigated injury progression (MRI and immunohistochemistry) and resulting behavioral changes following a mild controlled cortical impact (CCI) in ferrets. We used fifteen adult (5-8 month old) male ferrets; 12 CCI animals were randomly divided into 4 survival time-points (24 hour, 1 week, 4 week, 16 week) and 3 control animals that survived 16 weeks. *In vivo* MRI scans were acquired at baseline and at 1 day post injury (DPI), 7 DPI, 4 weeks post injury (WPI) and 16 WPI. T1 weighted SPGR scans (TE/TR=3.5/16ms) and T2W RARE scans (TE=10, 20, 30 and 40 ms, TR=8s) were acquired with 0.5mm isotropic resolution for visualization of anatomy and detection of volumetric and T2W abnormalities. All brains were also imaged *ex vivo*. Behavioral tests (motor: open field, beam walk, righting reflex, gait analysis; cognitive: T maze and novel object recognition) were conducted at baseline, 6 HPI, 1 DPI, 7 DPI, 4 WPI and 16 WPI. Immunohistochemical staining included markers to demonstrate glial fibrillary acid (GFAP), microglia (Iba1), myelin oligodendrocyte glycoprotein, and microtubule-associated protein . With longer survival times increased GFAP and Iba1 staining persisted strongly at the lesion site and at 1-2 mm from the lesion focus. T2 imaging detected abnormalities in the cortex at all time-points. FA was unremarkable, whereas axial diffusivity may be sensitive to chronic white matter changes. Cortical abnormalities were observed with the Trace map and orientation abnormalities using DEC maps weighted by linear anisotropy co-localized with immunolabeling. Immunohistochemical staining revealed a longitudinal increase in microglia, astrocyte and myelin staining in cortex as well as underlying white matter, which was strongest at 16 WPI. Concomitantly, memory impairment seemed to worsen with time (4 WPI and 16 WPI) on the novel object recognition and the T maze tests. Motor impairment was mild immediately (6 HPI and 1 DPI), but recovered with time. CONCLUSIONS. This gyrencephalic animal model of TBI demonstrated an evolution of injury that correlated with

worsening cognitive function and an increase in injury markers in the white matter, strengthening its translational capabilities.

Title: Mild traumatic brain injury enhances acquisition and impairs retention of fear learning

Authors: *C. LIN, C. WEISS, J. E. PITT, C. CHAN, J. F. DISTERHOFT;
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: Mild traumatic brain injury (mTBI) affects 1.5 million Americans annually, with half of them experiencing an acute loss of consciousness, memory loss, and confusion following the injury. Injury can result from multiple different traumas, including a sports-related impact or from the blast of an improvised explosive device (IED), as experienced by military personnel. mTBI is a known risk factor for Alzheimer's disease (AD) and is also linked to post-traumatic stress disorder (PTSD) among veterans. Despite the growing awareness to these detrimental effects of mTBI, the neuropathology underlying these specific repercussions is still relatively unknown. In order to elucidate these mechanisms, we adopted a model for closed head mTBI using a high-pressure pneumatic cannon to simulate the high-pressure blast experienced by individuals in the military. mTBI was induced in male B6SJLF1 mice by blasting the top of the head with an overpressure of 20 psi lasting 1-2 ms. Blasted mice exhibited a longer time to wake than sham-blasted mice. Following one day of recovery after the blast, the mice were trained on trace fear conditioning. After conditioning, the mice were tested daily for memory of context and cue retention for five days. Blasted mice acquired fear-conditioning more robustly than sham-blasted mice, as determined by percent freezing. Sham-blasted mice, however, retained the contextual memory of the fear conditioning better than blasted mice. Both groups exhibited equivalent cued fear responses. The enhanced acquisition of the fear conditioning by blasted animals, which has not previously been demonstrated in a mouse model of mTBI, is indicative of more fear-like behavior and correlates with symptoms of PTSD in humans. The poorer retention

of contextual memory is in accordance with previous data showing memory disturbance following mTBI. Studies are currently ongoing to investigate the effect of mTBI on a mouse model of AD (5xFAD mouse model) in fear conditioning to understand the convergence of mTBI and AD pathology on PTSD-like behavior. We hypothesize that mTBI will exacerbate the amyloid pathology and result in more severe learning and memory deficits in blasted mice. The results of this study will aid ongoing research in establishing therapeutics for those suffering from the consequences of mTBI.

Title: An investigation into the role of the nucleus accumbens in mild traumatic brain injury and impulsivity

Authors: *H. HEHAR[1], B. KOLB[3], K. YEATES[2], M. J. ESSER[2], R. MYCHASIUK[2]; [1]Room 274, [2]Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Children characterized as impulsive often engage in risky behaviours that may place them at greater risk for the acquisition of concussions. In addition, parents often report that their children display increased impulsivity and decreased attentional processing following concussion. Studies related to addictions have demonstrated that altered functioning of the nucleus accumbens (NAc) is associated with impulsive behaviour. The purpose of this study was to investigate the effects of a concussion on the NAc, with the primary focus being impulsivity and attentional processing, before and after the injury. This was supplemented with neuroanatomical (Golgi-Cox) and epigenetic (qRT-PCR) analysis. Juvenile Sprague Dawley rats from two distinct cohorts (Impulsive and Standard) were trained in the 5-Choice Serial Reaction (5-CSR) paradigm on the Go/No-Go task for 18 consecutive days. On postnatal day 45 (P45) rats

were tested in the Go/No-Go task and then received a mTBI or sham injury. Animals returned to daily Go/No-Go training from P47-P61, which was followed by extinction testing from P62-P64. Rats in the impulsive cohort were significantly more impulsive than rats in the standard cohort in the Go/No-Go task at both testing points (P45; before the injury, and P61; after the injury). In the standard group, the mTBI increased impulsivity at P61. Sex differences were found in response to the mTBI for the impulsive cohort. Female rats in the impulsivity group exhibited similar increases in impulsivity to that of standard rats following the injury, but there were no changes in impulsivity between males groups. In addition, there were no differences in the number of correct Go-responses completed by any of the groups at the pre-injury test period. However, at the post-injury test, all animals with an mTBI obtained significantly fewer correct Go-responses when compared to their sham cohorts, suggesting a deficit in spatial attention. Furthermore, rats in the impulsive cohorts and mTBI groups were significantly impaired on the extinction task. Golgi-cox analysis of the medium spiny neurons in the NAc showed that all rats with a mTBI had increased dendritic branching and decreased spine density. Sex differences were found for dendritic length whereby the mTBI increased length in females but decreased dendritic length in males. Analysis of expression levels of key genes involved in the reward pathway (DRD2, DRD3, DAT, Comt-f) extracted from the NAc is currently under investigation. Underlying differences in the NAc between the impulsive and standard cohorts, in conjunction with the mTBI induced modifications, may be contributing to their impaired behavioural performance.

Title: Variation in the return-to-exercise time interval following pediatric concussion: effects on behavioural and molecular outcomes

Authors: *R. M. MYCHASIUK[1], H. HEHAR[2], I. MA[2], M. J. ESSER[2];
[1]Neurosci., [2]Fac. of Med., Univ. of Calgary, Calgary, AB, Canada

Abstract: Similar to most brain injury research, the ultimate goal for studies on concussion is effective therapeutics. Literature has shown that exercise has positive effects on neuroplasticity, and brain health, suggesting that it may be an important therapeutic resource for recovery from concussion. Unfortunately, the current return-to-play guidelines were established and implemented with little empirical evidence and significantly limit exercise and activity. These guidelines have recently been called into question and the purpose of this study was to investigate their validity by (1) determining the optimal time-to-return to exercise following the injury, and (2) investigating the efficacy of exercise in amelioration of post-concussion symptomology. At postnatal day 21 (P21) Sprague Dawley rats were randomly assigned to live in sex-matched cages of 4; some of which were equipped with running wheels and some were standard cages. On P30 half of the rats received mTBI using the lateral impact device and the other half received sham injuries. The cages with running wheels were randomly divided into 3 groups; (1) had their running wheels returned immediately after the injury (IMD), (2) had their running wheels returned 3 days post-injury (3-Day), (3) had their running wheels returned 7 days post-injury (7-Day). This generated 6 groups; a) sham + Exercise, b) sham + No Exercise, c) mTBI + IMD, d) mTBI + 3 Day, e) mTBI + 7 Day and f) mTBI + no Exercise. Animals were then run through a behavioural test battery that included beam-walking, open field, elevated plus maze, novel context mismatch, and forced swim. At P46 animals were sacrificed and tissue from the prefrontal cortex (PFC) and hippocampus (HPC) was extracted and RNA was used for qRT-PCR. Expression levels of 8 genes were investigated, (Bdnf, Creb, Dnmt1, Fgf2, Mapt, Pgc1-α, Sirt1, and Tert) in both brain regions. Results from the behavioural battery demonstrated that the optimal recovery time for return-to-exercise was dependent upon the task examined and the sex of the rat. For tasks such as beam-walking and novel context, the earlier the rat returned to exercise, the better their performance was. Conversely, for tasks such as the elevated plus maze and forced swim, the optimal time to return-to-exercise was later, at 3 or 7 days post-injury. Results from the qRT-PCR analysis revealed similar outcomes; effects were sex-, injury-, and exercise-dependent. These findings further demonstrate the complexity of concussion research and emphasize that best-practices going forward may require more personalized treatment strategies based upon an individual's sex, pre-existing characteristics, and symptomology tendencies

Title: Does acutely placed embryonic neural stem cell therapy induce restoration of function following cortical contusion impact in adult rats reared in an enriched environment?

Authors: *K. MEERSCHAERT, I. HIATT, M. SEARLES, J. SMITH;
Saginaw Valley State Univ., University Center, MI

Abstract: Traumatic brain injury (TBI) is one of the leading causes of disability and mortality, and each year approximately 1.7 million individuals sustain a TBI. Currently, no effective clinical treatments have been found to combat functional and cognitive deficits that occur from TBI. Recent research has found that enriched environment (EE) aids in functional recovery following TBI. Embryonic neural stem cells (eNSC) express neuronal characteristics and have been shown to survive, migrate after transplantation, and improve recovery after functional loss. Furthermore, recent data from our lab shows that combining EE and eNSC therapy improves functional recovery from TBI and appears to increase the survival rate of eNSCs. The purpose of the current study was to examine the effect that acute transplantation of eNSCs, post-injury, may have on eNSC survival, neuroplasticity, and overall functional recovery following a medial frontal cortex (MFC) contusion in rats reared in EE. Thirty, twenty-five day old male Long-Evans rat pups were reared in EE housing. After ninety days in EE, twenty animals received a MFC contusion injury. Seven days post-injury, ten of the injured animals were transplanted with ~100,000 eNSCs in two locations near the lesion. Behavioral analysis was then conducted using the open field task (OFT), Barnes maze (BM), Morris water maze (MWM), rotor-rod (RR), elevated-plus maze (EPM), and the forced-swim task (FST). Following behavioral testing, the animals were euthanized, perfused, and their brains were extracted. The tissue was embedded in paraffin, sectioned, and underwent hematoxylin and eosin staining. Stereological analysis was performed to quantify the number of surviving cells and total cortical volume. That data suggests that injured animals who received eNSCs performed better during the MWM task, when compared to injured animals that didn't receive eNSCs. For the RR task, the data shows no difference between the treated and non-treated animals, although both were significantly impaired compared to intact controls. The data for the EPM shows that intact animals spent significantly more time in the closed arms and significantly less time in the open arms than both injured groups. Although there was no significant difference between the injured groups, the treated animals spent more time in the closed arms and less time in the open arms than the non-treated group. The current data suggests that timing of placement into EE may affect the performance of eNSC therapy and should be explored further.

Title: Abnormalities in coherence of local field potential oscillations in medial prefrontal cortex are linked to lasting perseverative depression and fear following mild traumatic brain injury in a mouse model

Authors: *D. H. HECK[1], Y. LIU[1], M. G. HONIG[1], S. HELDT[1], N. DEL MAR[1], N. H. GULEY[1], W. BU[1], B. M. MOORE[2], A. J. REINER[1];

Abstract: Mild traumatic brain injury (mTBI) typically results from a closed-head insult after a primary blast shock wave, blow to the head, or head acceleration - deceleration during a collision. It is a frequent occurrence during military combat, sports, recreational activities, and vehicular accidents, and can result in psychological health problems. The brain regions disrupted by mTBI so as to cause neuropsychiatric deficits have not been determined. We used an air-blast mouse model of mTBI [1] to study the link between functional abnormalities in medial prefrontal cortex (mPFC) and fear perseveration and depression, two of the more disabling neuropsychiatric sequelae of mTBI, for which there is currently no treatment. We focused on the coherence of neuronal oscillations because this measure is likely to reflect integrity of network connectivity and function. We used multi-electrode recordings to measure coherence of local field potential oscillations in the mPFC, somatosensory cortex (SSC) and hippocampus (HC). We found that deficits in coherence within the mPFC network but not in the SSC or HC, strongly correlated with behavioral measures of depression and fear at all tested times, up to one year after the mTBI event. By contrast, mice that had experienced a subconcussive air blast or sham treatment showed normal mPFC coherence and no depression or perseverative fear. We have

previously reported that treating mice with a novel drug SMM-189 (a cannabinoid type-2 receptor inverse agonist) ameliorates fear and depression after mTBI [2]. Our electrophysiological data showed that SMM-189 also restored coherence in the mPFC to normal. Our findings thus suggest that coherence of neuronal oscillations in mPFC is tightly associated with and thus possibly causal to the persistent depression and fear after mTBI. The defect in mPFC coherence may act by perturbing signaling between mPFC and other brain regions linked to fear memory and mood, such as amygdala and nucleus accumbens. Our finding that the rescue of mTBI-related fear and depression by SMM-189 is associated with normalization of neuronal coherence in the mPFC suggests that treatments targeting mPFC coherence may be beneficial for ameliorating neuropsychiatric consequences of mTBI. 1.Heldt, S.A., et al., A novel closed-head model of mild traumatic brain injury caused by primary overpressure blast to the cranium produces sustained emotional deficits in mice. Title: What can the next generation of diffusion MRI methods offer TBI research?

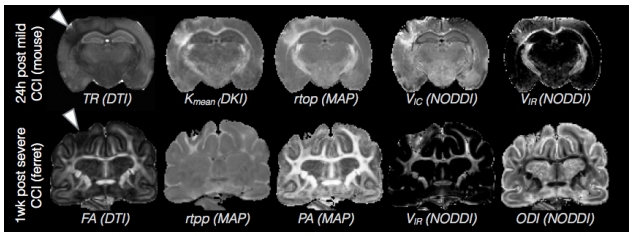
Authors: *E. B. HUTCHINSON[1], A. AVRAM[2], S. SCHWERIN[3], S. JULIANO[3], C. PIERPAOLI[2];
[1]NICHD, Natl. Inst. of Hlth., Bethesda, MD; [2]NICHD/NIH, Bethesda, MD; [3]Uniformed Services Univ., Bethesda, MD

Abstract: Introduction: A new generation of diffusion MRI tools have begun to emerge with promise to provide novel and meaningful imaging markers for traumatic brain injury research

and clinical use. These new MRI tools extend the more standard DWI and DTI methods to measure non-Gaussian features of water movement in tissue as a proxy for the physical manifestations of tissue changes following trauma. The objective of this study was to collate the metrics from several non-Gaussian frameworks calculated using identical diffusion data taken from tissue regions of post-traumatic abnormality. Methods: Brain tissue was evaluated from both mice and ferrets taken during the acute and chronic time periods after induced focal trauma by CCI. Ex-vivo diffusion MRI was acquired for each brain with high spatial resolution and comprehensive sampling of diffusion space. Three imaging frameworks were implemented for these data sets: diffusion kurtosis imaging (DKI), mean apparent propagator (MAP) MRI and neurite orientation dispersion distribution imaging (NODDI). Results: Several important non-Gaussian imaging markers were identified, reproduced and compared with DTI metrics. These results may be seen in the included figure, which reveals heterogeneous metric profiles of abnormalities in spatially distinct subdomains of cortical and white matter tissue.



Metrics abbreviations: TR - trace, FA - fractional anisotropy, Kmean - mean kurtosis, rtop(rtpp) - return to the origin(plane) probability, Vic - intracellular volume fraction, Vir - restricted volume fraction, PA - propagator anisotropy, ODI - orientation dispersion index Conclusions: Each of these new technologies has novel index maps with unique strengths for probing tissue injury that were quantitatively compared with more standard DTI index maps of anisotropy and diffusivity. These new metrics may be used as MRI “stains”, each with strengths and limitations, to better understand the spatio-temporal course of brain changes following trauma.

Title: Validation of mouse traumatic brain injury model with behavioral and MRI end-points

Authors: *E. LATONUMMI, L. TOLPPANEN, P. PIRINEN, K. K. LEHTIMÄKI, T. AHTONIEMI, A. NURMI;
Charles River Discovery Services Finland, Kuopio, Finland

Abstract: Traumatic brain injury (TBI) is a leading cause of mortality and survivors of TBI frequently experience long-term disabling changes in cognition and sensory-motor function. Animal models have been developed to replicate the various aspects of human TBI to better understand the underlying pathophysiology and to explore potential treatments. The aim of the current study was to validate cortical contusion injury in mice with behavior assays for functional recovery and T2-MRI imaging. Validation of mouse model will also allow later combination of TBI with transgenic animals and creation of double hit models for TBI research. In order to generate TBI, a computer controlled cortical PinPoint impact was carried out according to Bilgen M. with modifications (Bilgen M, Neurorehabil Neural Repair, 2005). The mice were anesthetized with isoflurane and temperature was maintained at 37.0°C ±1.5°C with a homeothermic blanket system. Cortical contusion was induced in a stereotactic frame. Briefly, a unilateral craniectomy of 3 mm in diameter was performed with the dura kept intact and impact was done with a 2,5-mm-diameter tip traveling at a velocity of 3 m/second and creating a 2 mm-deep deformation. Thereafter the wound was closed with sutures and mice were allowed to recover in homeothermic cages with post-operative care. Functional recovery was monitored with behavioral assays including adhesive tape test, body curl index and rotarod. Lesion volume, edema and tissue viability (T2-relaxation time) were measured with T2-MRI. TBI mice exhibited clear functional deficits and later functional recovery in the behavioral assays for sensory-motor performance. Non-invasive imaging with T2-MRI provided information on the lesion size, edema and tissue viability showing clear lesions as well as increased edema and T2-relaxation time. The validated mouse TBI model offers a tool to study TBI in mice allowing combination with various transgenic lines and making it a valuable model for TBI research and drug discovery.

Title: Long-term cognitive deficits induced by traumatic brain injury in rats are exaggerated by pre-exposure to life-threatening stress

Authors: ***M. O. OGIER**[1,2,3], A. BELMEGUENAI[2,3], S. BOUVARD[2,3], T. LIEUTAUD[2,3], L. BEZIN[2,3];
[1]French Armed Forces Biomed. Res. Inst., Bretigny-sur-Orge Cedex, France; [2]TIGER Team (Translational and Integrative Group in Epilepsy Research), Lyon Neurosci. Ctr. - CRNL, Bron, France; [3]Inst. For Epilepsy - IDEE, Bron, France

Abstract: In the military, traumatic brain injury (TBI) is often sustained under extremely stressful circumstances. However, the influence of such stress on the outcome of TBI has been overlooked. Here, using a rat model, we aimed at determining if behavioral and cognitive outcomes after TBI are affected by prior exposure to life-threatening stress. Adult male Sprague-Dawley rats were stressed by exposure to predator odor 2- 4- 5-trimethyl- 3- thiazoline (TMT) for 7 minutes or were exposed to water (WAT) instead of TMT; exposure was repeated 8 times at irregular intervals over a 2-week period. Two days after the last exposure, rats were subjected to either bilateral mild-to-moderate fluid percussion brain injury (LFP) or Sham surgery. In our 4 experimental groups (Sham-WAT, Sham-TMT, LFP-WAT, LFP-TMT), we measured motor activity and anxiety- like behaviors at 1, 2 and 6 weeks post- trauma, spatial learning and hippocampal long- term potentiation (LTP) at 1 month post- trauma, and basal activity and restraint-stress-induced activation of the hypothalamic-pituitary-adrenal (HPA) axis at 2 months post-trauma. Compared with Sham-WAT rats, LFP-WAT rats exhibited transient signs of motor hyperactivity but no sign of anxiety at 1 week post- trauma, minor spatial learning and hippocampal LTP deficits, and, finally, lower basal activity of the HPA axis with slightly stronger reactivity to restraint-stress. Exposure to TMT had negligible effects on Sham rats, whereas it exaggerated all deficits observed in LFP rats except for motor hyperactivity. Hence, these data suggest that pre-exposure to stress can aggravate long-term deficits induced by TBI.

Title: The crustacean central nervous system in focus: nitric oxide induces a specific innate immune response

Authors: *P. CHAVES DA SILVA[1], D. B. PINHEIRO-SOUSA[2], C. CORRÊA[1], S. L. CARVALHO[1], S. ALLODI[1];
[1]Univ. Federal Do Rio De Janeiro, Rio de Janeiro, Brazil; [2]Univ. Federal do Maranhão, São Luis, Brazil

Abstract: The activation of innate immune system after CNS injury is not widely explored in invertebrates. Among few clues available are the results published by our group reporting the recruitment of microglia-like cells expressing inducible nitric oxide synthase (iNOS) 24 h after traumatic injury and secondarily, the recruitment of hyalinocytes - considered immature blood cell - to the lesion site during subacute phase. Glial cells were clearly activated in both stages (Chaves da Silva et al., 2010, 2013). In vertebrates, blood cells and microglia are potentially able to produce nitric oxide (NO) and are important components that integrate the nervous and immune systems during inflammatory processes after injuries to the nervous tissue. Here, we aimed to investigate the cellular/molecular strategy employed 24 and 48 h following ablation of the protocerebral tract (PCT) in animals treated with an inhibitor of iNOS. Adult male crabs Ucides cordatus were injected with L-NIL (dihydrochloride), a specific iNOS inhibitor, 4 h before the unilaterally ablation of eyestalks (in order to cause degeneration of the distal stump of the PCT) to study the contribution of NO to the cell recruitment. L-NIL was also injected 8 h and 20 h after lesion. Using light and electron microscopy, immunohistochemistry and flow cytometry techniques we observed remarkable features in the crustacean CNS. By flow cytometry, we observed a significant decrease of circulating blood cells, especially granular hemocytes, in injured animals treated with L-NIL 24 h after the lesion onset - similar to the control without lesion - when compared with no-treated animals with lesion. By immunohistochemistry, the activation of glial cells and the iNOS expression were also decreased in the lesion site 48 h after L-NIL injections. By immunohistochemistry, light and electron microscopy we also studied and characterized the hematopoietic tissue, which showed cells - hyalinocytes - with similar morphology of those attracted to the lesion site 48 h after lesion, reinforcing the hypothesis that these cells could be immature blood cell migrating to the lesion.

We suggest that iNOS released from granulocytes in the acute phase (24 h) may be responsible to attract other cell types as well as activate glial cells in the subacute phase (48 h). The importance of our study resides in the characterization of cellular and biochemical strategies peculiar of the neurodegeneration in invertebrates. Such events are worth studying in crustaceans because in invertebrates this issue may be addressed with less interference from complex strategies resulting from the acquired immune system.

Title: *Drosophila* melanogaster as a model for blast-induced traumatic brain injury

Authors: *K. R. BARBER[1], A. M. BUCKLEY[1], B. E. HAWKINS[2], D. S. DEWITT[2], Y. P. WAIRKAR[1];
[1]Neurol., [2]Anesthesiol., The Univ. of Texas Med. Br., Galveston, TX

Abstract: Traumatic brain injury (TBI) is a high priority medical and public health concern, especially veterans. Among veterans deployed to Iraq and Afghanistan, 10-20% suffer deployment related TBI, majority associated with blast exposure (The CDC et al., 2013). Blast-induced traumatic brain injury (bTBI) patients have been diagnosed later with chronic traumatic encephalopathy (CTE), which is characterized by behavior and cognitive impairments including dementia (Goldstein et al., 2015). However, it is unclear why not all TBI patients develop CTE suggesting a genetic component. Postmortem diagnosis of TBI-associated CTE patient´s brain revealed the presence of neurodegenerative disease markers such as hyperphosphorylated tau protein (p-Tau), neurofibrillary and astrocytic tangles, and clustering of neurites around the blood vessels (Mckee et al., 2015). We are using the fruit fly *Drosophila* melanogaster as a model system to unravel the genetic pathway underlying TBI-linked neurodegeneration in CTE. The fruit fly D. melanogaster has been widely accepted as powerful model organism to dissect

the genetic pathway underlying the pathogenic mechanism of various protein aggregations and neurodegenerative diseases. Intriguingly, fruit flies have feature such as an exoskeleton, hemolymph, and glia that represent the human brain and is therefore amenable to TBI. Our preliminary results provide evidence that bTBI reduces lifespan parallel to what is observed in humans after blast injury. To build a successful model we hope to observe p-Tau neurofibrillary tangles and results from D. melanogaster brain sections will be presented. Our preliminary data is promising and suggests bTBI-linked CTE can be modeled in D. melanogaster and it can be very useful to identify the genetic pathway underlying the mechanism of progressive neurodegeneration.

Title: Electron microscopy of delayed axonopathy following traumatic brain injury

Authors: *C. A. WILEY[1], G. MURDOCH[2], M. SUN[3], J. FRANKS[3], D. B. STOLZ[3], C. E. DIXON[4], G. A. WANG[2], S. J. BISSEL[2], P. M. KOCHANEK[5];
[1]Univ. Pittsburgh, Pittsburgh, PA; [2]Pathology, [3]Cell Biol., [4]Neurolog. Surgery, [5]Critical Care Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) is associated with acute tissue destruction at the site of contusion. However, many patients experience a delayed injury of uncertain etiology. Using a murine model of controlled cortical impact (CCI) and sensitive silver staining, we delineated the nature and extent of injury up to 4 weeks after CCI. Cortical damage at the site of impact varied in severity but followed a stereotypical tissue reaction. More distal neuroanatomically connected sites demonstrated a delayed pathology. This diaschisis consisted of silver positive neuritic processes broadly distributed throughout cortical (e.g. contralateral cortex) and subcortical (e.g. thalamic) sites, beginning as early as 7 days after injury and extending out to 4 weeks. Astrocytic and microglial reaction in these regions was document by immunohistochemistry for GFAP and IBA1 respectively. To further characterize these lesions we developed a novel technique using successive sections to examine the ultrastructure of the silver positive regions. Rather than observing aberrant neurofilamentous structures at the EM level, silver positive neurons and

neurities demonstrated hydropic degeneration. Cellular membranes were preserved despite the loss of mitochondria and cytoskeletal structures including neurofilaments and microtubules. Staining of thalamic regions with Nissl showed "dropout" of identifiable neurons, but electron microscopy showed persistence of the neuronal cell bodies. The morphological preservation of neurons and neuritic processes raises the possibility of reversing the diaschisis and preventing secondary neurodegeneration.

Title: Effects of mild whole-body blast wave trauma to the vestibular receptor organs, nuclei, and VOR in mice

Authors: *S. LIEN[1], S. AJLUNI[2], Z. MRIDHA[1], H. ARNSON[1], N. LEFELDT[1], D. DICKMAN[1,2];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Psychology, Rice Univ., Houston, TX

Abstract: The increased use of close range explosives has led to higher incidence of exposure to blast-related head trauma. Exposure to primary blast waves is a significant cause of morbidity and mortality. Active service members who have experienced blast waves report high rates of vestibular dysfunction, such as vertigo, oscillopsia, imbalance, and dizziness. Accumulating evidence suggests that exposure to blast wave trauma produces damage to both the peripheral and central vestibular system; similar to previous findings that blast-induced damage of auditory receptors. Here we examined the vestibular receptor, central nuclei, and vestibulo-ocular reflex (VOR) behavior in mice after exposure to mild whole body blast wave trauma. Mice were implanted with a head stability post, and the VOR was then measured using a horizontal rotation stimulus (0.5 - 2 Hz; 20 deg/s). Next, each animal was exposed to a single air blast wave overpressure of 55, 75, or 95 kpa while anesthetized and suspended inside a rigid tube. Following blast exposure, animals were allowed to survive for periods of 1, 7, 14, or 28 days. At each survival time point, the VOR was again measured after which the animal was euthanized

and perfused for histological analyses. Vestibular receptors and central nuclei were histologically prepared and the following measures quantified: stereocilia hair bundle counts, density of hair cells (both type I and type II) in the central and peripheral zones, density and size of otoconia in central and peripheral zones, axon density and diameter beneath the stroma. Ongoing measurements also include number and length of axonal initial segment, terminal innervation patterns of calyx, dimorph, and bouton afferents. The medial and lateral central vestibular nuclei were measured for the density of neurons at the caudal, central, and rostral regions of each of these nuclei. The VOR gain and phase of the eye movement responses were compared for the normal (pre-blast) and the blast exposed animals. To date, we have observed a reduction in horizontal VOR gains and stereocilia loss in the highest, 95, kPa blast wave exposed animals. These results suggest that blast-wave exposure can lead to peripheral vestibular damage (possibly central deficits as well) and provides some insight into causes of vestibular dysfunction in blast-trauma victims.

Title: Efficacy of motor cortical stimulation following experimental TBI is frequency dependent

Authors: *E. R. CLAYTON[1], D. A. KOZLOWSKI[2], T. A. JONES[3], D. L. ADKINS[1]; [1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Biol. Sci., DePaul Univ., Chicago, IL; [3]Inst. of Neurosci., Univ. of Texas, Austin, Austin, TX

Abstract: In humans and animal models, electrical and magnetic brain stimulation can improve motor function following stroke, especially when paired with rehabilitative training (RT). Previously, we found that following experimental stroke in rats that epidural electrical cortical stimulation (CS) of the ipsilesional sensorimotor cortex (SMC) combined with forelimb RT enhanced motor function and motor cortical plasticity. We also have reported that following experimental traumatic brain injury to the SMC in rats, induced via a controlled cortical impact (CCI), the stimulation parameters previously used in our stroke models improved motor

recovery, but sub-optimally. We have since reported that 100Hz Bipolar epidural stimulation combined with eight weeks of impaired forelimb reach training improves skilled reaching performance compared to Cathodal or Anodal stimulation concurrent with RT. The primary focus of the current study was to determine a more optimal frequency of stimulation. Adult rats that reached criterion on a single-pellet reaching task received a unilateral CCI to the SMC contralateral to the animal's preferred reaching limb. RT was delivered daily for eight weeks alone or concurrently with 25Hz, 50Hz, 100Hz or 350HZ. Animals were also tested in other motor behavioral tasks. We found that 350 Hz Bipolar stimulation combined with RT significantly enhanced motor recovery when compared to RT alone.

Title: Differential abundance of amyloid beta peptides in brain tissue and biofluids after delayed recovery from a subacute penetrating ballistic-like brain injury

Authors: *A. M. BOUTTE, B. N. ABBATIELLO, S. F. GRANT, J. S. GILSDORF, D. W. JOHNSON, C. M. CARTAGENA, F. C. TORTELLA, D. A. SHEAR;
Neurosci. and Psychiatry, Walter Reed Army Inst. For Res., Silver Spring, MD

Abstract: Introduction: Severe traumatic brain injury (TBI) is a risk factor for dementias, such as Alzheimer's disease (AD). The degree to which severe TBI produces Aβ pathology remains to be elucidated. Further, the role of Aβ peptides as TBI biomarkers remains debated. This preliminary study sought to determine the effect upon several Aβ peptides and their ratios in a rat model of penetrating ballistic-like brain injury (PBBI). Methods: For PBBI and sham/craniotomy controls, ipsilateral frontal cortex (FC), CSF, plasma, and serum were each collected 1-2 weeks (wks) post-injury (defined as our subacute window of recovery). Aβ38, 40, and 42 quantitation of clarified FC lysate or biofluids was conducted in duplicate using modified ELISAs (Mesoscale, Rockville, MD, USA). Analyte content is displayed as the fold change vs. Sham per time-point. Comparisons between PBBI and Sham groups are discussed ($p \leq 0.05$, 1-tailed t-Test).

Results: In the FC, Aβ40 increased 1.7x after 1wk and Aβ38 increased 1.2x after 2wks. Aβ42 was unchanged. The Aβ42/40 ratio was decreased to 0.56x, but the Aβ40/38 ratio was increased by 1.8x at 1 wk compared to Sham. CSF Aβ38 increased marginally by 1.1x at 1wk, but decreased to 0.85x of sham after 2 wks. Both Aβ40 and 42 increased by 1.3-1.33x 1wk post-PBBI. Interestingly, both of these peptides were reduced to 0.41-0.49x of Sham controls after 2 wks. CSF peptide ratios Aβ 40/38, Aβ 42/38, and Aβ 42/40 were all reduced to 0.48-0.78x compared to Sham levels. Although there was little effect 1wk after PBBI, serum Aβ38, Aβ40, and Aβ42 increased by 2.3x, 1.6x, 3.9x, respectfully, 2 wks after PBBI. In addition, the Aβ42/38 ratio was increased by 3.0x compared to controls at this time-point. Plasma Aβ38 and Aβ40 also increased 2 wks post-PBBI, by 1.2x and 1.1x, each. The plasma Aβ42/38 ratio was 1.3x higher 1 wk after PBBI (but not significant). In contrast, the ratio of Aβ42/40 in plasma was slightly decreased to 0.92x of Sham 2wks after PBBI compared to Sham controls. Overall, Aβ38, 40 and 42 peptides and their inter-peptide ratios were affected in brain tissues and biofluids over time, and the increase within tissues or blood was somewhat proportional to the decreases in CSF during the subacute injury time-frame. Conclusions: The relationship between Aβ38, 40, 42 and their inter-peptide ratios may be key indicators of pre-AD mechanisms in brain tissues affected by TBI. Furthermore, peptide quantitation and their ratios may serve as novel biomarkers of TBI that are (1) detectable during the subacute injury period wherein therapeutic strategies may be stratified and monitored and (2) highly relevant to AD risk. The role of Aβ peptides in TBI warrants further investigation.

Title: Traumatic brain injury in mice induces chronic hyperesthesia

Authors: J. WU[1], Z. ZHAO[1], X. ZHU[1], N. WARD[1], S. ZHAO[1], *A. I. FADEN[2];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Anesthesiol., Univ. of Maryland Med. Ctr., Baltimore, MD

Abstract: Clinical studies indicate that traumatic brain injury (TBI) patients frequently experience chronic post-traumatic pain, particularly vascular-type headache. Although headache

descriptions predominate, patients may also experience allodynia, hyperesthesia, or spontaneous pain. Periorbital and extra-cephalic (paw) mechanical allodynia have been reported in rodent models of TBI, which may persist for weeks after injury. However, there has been little research devoted to understanding the pathobiology to such hyperesthesia. The present study characterized post-TBI sensory changes in mice with mild, moderate or severe controlled cortical impact injury (CCI) by testing mechanical/thermal allodynia, as well as presence of spontaneously face pain. C57BL/6 male mice were subjected to mild, moderate, or severe CCI and mechanical/thermal allodynia as well as mouse grimace scale (MGS) test, a measure of spontaneous pain, were evaluated before and after TBI. The von Frey hair force was significantly decreased on the left hindpaw of mice subjected to moderate or severe TBI when compared to sham operated mice. On the right hindpaw, a significant decreased force was observed in the mice with moderate TBI. The threshold for hot plate temperature was decreased in a severity-dependent manner. The threshold for cold plate was significantly increased in the mice subjected to all grades of TBI severity at early time points (week 1 and 2) but returned to baseline level at 4 weeks post-injury. MGS based on ear position, orbital tightening, and nose bulge was transiently increased at post- TBI day 1 for all groups. Sham and mild TBI group returns to the baseline level at week 1. However, moderate and severe TBI mice showed extended increases of MGS. The present study characterizes the time course of hyperesthesia after TBI of varying severity. These observations indicate that more generalized hyperesthesia and pain, as well as vascular-like headaches, may occur after TBI, and may serve as a model to characterize the pathobiology and potential therapies for such pain.

Title: Development and validation of an organotypic brain slice model for studying chronic traumatic encephalopathy

Authors: C. A. BERG, S. GHAISAS, N. KONDRU, H. JIN, V. ANANTHARAM, A. KANTHASAMY, *A. G. KANTHASAMY;
Biomed Sci, Iowa Ctr. for Advanced Neurotoxicology, Iowa State Univ., Ames, IA

Abstract: Chronic traumatic encephalopathy (CTE) is a progressive neurodegenerative condition that occurs as a long-term consequence of repetitive mild traumatic brain injury (TBI). Pathologically, this disease is characterized by abnormal deposition of phosphorylated tau and 43-kDa TAR DNA binding protein (TDP-43), cerebral atrophy and white matter degeneration. Currently, there are multiple *in vitro* and *in vivo* TBI models for studying CTE. However, the lack of consensus on what constitutes an appropriate TBI animal model not only hinders reproducibility but also impedes our understanding the disease mechanisms, which is critical to identifying novel treatment strategies. As an *ex vivo* model that maintains many organ-specific features, organotypic brain slice cultures offer an excellent platform for dissecting the pathophysiology of brain diseases. In the present study, we have established an organotypic brain slice culture model of CTE by subjecting coronal mouse brain slice cultures to repeated mild traumatic brain injury with a Stretch Injury Controller device that delivers pulses of compressed air at a precise rate, resulting in a reproducible blast wave shock injury reminiscent of mild traumatic brain injury. We first compared tissue viability with two different slice culture conditions. Brain slices cultured on the Bioflex membrane possess better cell viability than those on Millicell cell cultures. Next, we cultured brain slices on Bioflex membranes, subjected them to single-blast TBI (4.6 psi) and assessed the neuronal damage. The single TBI induced severe neuronal cell death in cortico-striatal organotypic slices, as determined by propidium iodide uptake assay. We further examined whether repeated mild TBI (mTBI) could induce accumulations of phosphorylated tau and TDP-43 proteins in cortico-striatal organotypic slice cultures. Interestingly, Western blot analysis demonstrated increased phosphorylated tau and TDP-43 in slice homogenates 24 hours after triple-blast exposure. In addition, we confirmed the mTBI-induced gliosis in cortico-striatal organotypic slice cultures by Western blots for the glial markers Iba-1 and GFAP. Together, these results demonstrate that our organotypic brain slice culture recapitulates some key pathological features of CTE in humans and will be amenable for studying the pathophysiological mechanisms as well as for testing potential pharmacological agents for the treatment of CTE (DoD, W81XWH1110700).

Sch. of Med., Detroit, MI

Abstract: Individuals with mild traumatic brain injury (mTBI) often develop affective changes such as anxiety, depression or symptoms resembling posttraumatic stress disorder (PTSD). It is not clear how mTBI results in PTSD-like symptoms, although studies show changes in activation in brain regions associated with fear learning such as prefrontal cortex (PFC), amygdala (AMY), and hippocampus (HC). Here, we used a mouse model of mTBI to examine the effects of contextual fear conditioning (FC) combined with mTBI compared to the effects of mTBI only. Anesthetized male C57BL/6 mice (10-12 wk) were subjected to either a mild, concussive impact over the sagittal suture of the intact skull, surgery alone, (sham), or handling only (naïve). At 14 d post-injury mice were assessed for fear response (freezing) to FC or left undisturbed. The FC paradigm consisted of 5 distinct phases: habituation, acquisition, extinction, reinstatement, and reinstatement recall. Brains were harvested for proton magnetic resonance spectroscopy (1H-MRS) analysis *ex vivo* at 11.7 T at 25 d post-injury for neurochemical assessment. Naïve and sham groups did not differ on any measures and so were combined to form one group (controls). Mice with mTBI demonstrated increased freezing during acquisition and extinction trials compared to controls. At 25 d post-injury, dorsal HC (dHC) and PFC demonstrated decreased GABA/creatine and GABA/glutamate with mTBI/FC versus mTBI alone, while AMYG showed increased GABA/creatine with mTBI/FC versus mTBI alone. The increased acquisition and slower extinction of conditioned fear observed in mTBI mice resemble facets of FC reported in PTSD patients and observed in those with mTBI. Decreased GABA/creatine in the dHC and PFC, and decreased GABA/glutamate in dHC may reflect reduced inhibitory neurotransmission in these regulatory regions when mTBI is combined with FC, compared to mTBI alone. The increase in GABA/creatine in the AMYG may reflect greater inhibitory neurotransmission when FC is added to mTBI versus mTBI alone. These changes in excitatory/inhibitory tone are also unlike that expected with FC alone, suggesting an interaction between mTBI and FC in the

delayed post-mTBI period that may influence top-down control in the fear learning circuit and affect PTSD-like symptoms.

Title: From biomechanics to behavior: an end-to-end investigation of blast-induced traumatic brain injury causes and consequences

Authors: ***N. RACE**[1,2], B. ZIAIE[1], W. TRUITT[2], E. BARTLETT[1], Z. LIU[1], R. SHI[1];
[1]Purdue Univ., West Lafayette, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The rising incidence of blast-induced traumatic brain injury (bTBI) from terrorist activity, sectarian violence, and military efforts has sparked intense interest in the increasingly prominent public health issue of post-bTBI neurological dysfunction. Linked to neurodegenerative diseases and mental health disorders, bTBI's visibility has grown dramatically over the past decade, garnering substantial coverage in both public news media and the scientific community. A particularly alarming feature of bTBI is its ability to cause brain damage in absence of acutely observable symptoms. So-called mild bTBI have been labeled "silent killers" which preclude early diagnosis and treatment due to their subclinical nature. Numerous instigators and mediators of bTBI damage have been proposed, but mechanistic links between acute biomechanical events during blast exposure and delayed development of behavioral alterations have yet to be established. At present, there have been few reports of the initial consequences of bTBI on brain structure and function and, further, no successful attempts to mechanistically link blast injury mechanics, brain alterations, and ensuing behavioral abnormalities. This precludes well-targeted investigations of novel preventative, diagnostic, and therapeutic measures from being conducted. To this end, we present a rat model and approach

for mechanistically interrogating all stages of bTBI from the injurious insult to eventual behavioral abnormalities. We have obtained real time recordings of brain deformation *in vivo* during bTBI as well as histological and biochemical evidence of mechanical damage to neurons and microvasculature. Further, we have integrated a noninvasive urine biomarker and neurophysiological monitoring via evoked potentials and functional magnetic resonance imaging into our study and demonstrate an ability to distinguish injured from uninjured rats non-invasively. Finally, we have made long-term assessments of behavior and discovered that mild bTBI in our model can recapitulate key end outcomes that transfer to the human post-bTBI clinical presentation including potentiation of Parkinson's disease development and instigation of mental health alterations observed as psychosocial deficits. Further study within this model continuing simultaneous exploration of mechanistic linkages between incident injury, interceding changes in brain morphology, biochemistry, and function observed through neuroimaging and evoked potentials, and eventual behavioral changes will yield new insight capable only when multiple disciplines are utilized together as presented here.

Title: Studies of repetitive mild TBI: animal model of sports-related head impact

Authors: *D. BRIGGS[1,2], M. ANGOA-PÉREZ[1,2], D. KUHN[1,2];
[1]Wayne State Univ., Detroit, MI; [2]John D. Dingell VA Med. Ctr., Detroit, MI

Abstract: Background: Approximately 1.7 million traumatic brain injuries (TBIs) occur yearly, 80-85% of which are classified as mild. Repetitive mild TBI (rmTBI) has gained worldwide attention for its contribution to higher rates of psychiatric illness, cognitive impairment, and neurodegenerative disease. Chronic traumatic encephalopathy (CTE) is a disease resulting from rmTBI and is believed to contribute to its cognitive and psychiatric manifestations. Three known cellular markers of CTE are GFAP, TDP-43, and p-tau. **Objectives**: Current animal models of TBI are not appropriate for delivering multiple head impacts to the same subject, and the

development of successful therapeutics is contingent upon their translational validity. Current animal models do not fulfill the biomechanical or bio-kinetic requirements to model rmTBI. We have developed a novel method to model sports-related head impact as seen in athletes. To characterize this method, we have assessed selected neuropathological, psychiatric, and cognitive correlates of rmTBI that are known to occur in humans. **Methods**: C57BL/6 male mice are lightly anesthetized with isoflurane and placed under a vertical tube. A weight is pulled upward to a drop height of 1 m and released. Immediately upon impact, the mouse falls onto a foam cushion through a traversable platform. In this arrangement, the impact-induced acceleration and fall always involve a 180° horizontal rotation of the mouse body and free movement of the head upon impact. Mice received a total of 30 head impacts (one per day for 30 consecutive days) with either a 75 g or a 95 g weight. Control animals were anesthetized with isoflurane once per day for 30 consecutive days. Following the final head impact, mice underwent 7 weeks of behavioral testing. Upon completion of behavioral testing, mice were sacrificed and their brains were post-fixed. Immunohistochemistry was used to assess the development of CTE- like neuropathology. **Results**: Mice are delayed in recovering the righting reflex following head impact. Mice show increases in GFAP, Iba-1, p-tau and TDP-43 immunoreactivity following rmTBI. These increases manifest predominantly in the corpus callosum and optic tract. Mice subjected to rmTBI also develop learning and memory impairments and exhibit depression- like behavior. **Conclusions**: We report presently the development of a mouse model that faithfully reflects sports-related head injury in form and outcome. Our method overcomes the limitations of other models while causing the neuropathological and cognitive deficits seen in athletes exposed to multiple head impacts. This neuropathology is seen post-mortem in humans having suffered rmTBI.

Title: Tamoxifen improves locomotor recovery after spinal cord injury: establishing a therapeutic window for this condition

Authors: *J. M. COLON[1], A. I. TORRADO[1], J. M. SANTIAGO[2], I. K. SALGADO[1], A. CAJIGAS[3], Y. ARROYO[2], J. D. MIRANDA[1];

Abstract: Mechanical trauma after spinal cord injury (SCI) initiates a series of cellular and molecular events that lead to necrosis, apoptosis, ischemia, excitotoxicity, gliosis and demyelination. The acute and chronic damage results in loss of sensory-motor function in areas caudal to the lesion epicenter. In the clinical setting, patients arrive at the hospital minutes to hours after the initial insult, which suggests the need to evaluate the effects of a delayed therapeutic intervention. In addition, gender differences exist regarding the outcome after SCI reinforcing the need to establish sex-related differences regarding recovery and response to treatment. We propose the use of Tamoxifen (TAM), a Selective Estrogen Receptor Modulator (SERM) as a therapeutic intervention after SCI. This study aims to determine the beneficial effects of TAM after SCI and the therapeutic window available to administer this treatment. We hypothesized that a continuous TAM administration will improve locomotor function up to 24 hrs after SCI. A laminectomy at the T9-T10 level was performed on adult male and female Sprague Dawley rats (~250 g), which received a moderate contusion to the spinal cord using the NYU impactor. In order to assess a clinically relevant window, TAM pellets (15 mg) were placed subcutaneously at t=0, 6, 12 and 24 hrs for a continuous drug release. Locomotor recovery (BBB Open field test, grid-walk and beam crossing test) was assessed weekly for 35 days post injury (DPI). Male and female TAM-treated rats showed significant functional locomotor improvement after SCI. Delayed TAM administration up to 6 hrs in male rats and 24 hrs in female rats resulted in a significant locomotor improvement after SCI. To establish the mechanism of TAM neuroprotection, a protein expression profile for regenerative, anti-apoptotic and, pro-apoptotic proteins will be determined. Our results suggest that TAM administration activate neuroprotective mechanisms in a clinically relevant setting, which could provide valuable information for the translational properties of this drug into the SCI setting.

Title: Combined lithium and noggin treatment regulates differentiation of endogenous neural progenitors and promotes functional recovery after spinal cord injury through down-regulation of p300

Authors: *H. K. YIP[1], Y. DAI[2], M. P. L. CHEUNG[2];
[2]Anat., [1]Univ. Hong Kong Fac Med., Hong Kong SAR, China

Abstract: Background: LiCl and noggin inhibits astrogliogenesis through inhibition of GSK-3β/STAT3 and BMP/Smad pathway respectively. We have recently shown that LiCl and noggin promotes neuronal and oligodendroglial differentiation of endogenous neural progenitors (NPCs) and simultaneously inhibited astrocyte differentiation. p300 co-transcription factor bridges between STAT3 and Smad1 leading to an increase in GFAP transcription. Objectives: To examine: (1) the effect of combined LiCl + noggin treatment on the spinal cord (SC)-derived NPC differentiation, astroglial scar formation, axonal regeneration and functional recovery in the chronically injured adult mouse SC, and (2) to investigate the role of p300 in the synergistic effects of the combined treatment. Methods: NPCs were isolated from 4-week-old nestin-GFP transgenic mice and differentiated with LiCl + noggin for 7 days. Four weeks after contusion injury, osmotic minipumps delivering LiCl ± noggin or vehicle were implanted onto the injured SC for 2 weeks. p300 siRNA was injected to the SC tissue in the epicenter. Two weeks later, SC segments were collected for tissue analyses. BDA was injected into the motor cortex to trace the corticospinal tract. BMS test was conducted to examine the locomotor function every week post-SCI. Results: Combined treatment increased the NPC differentiation along neuronal and oligodendroglial lineage while decreased astroglial differentiation. It reduced the size of astroglial scar, decreased GFAP and CSPG expression, promoted axonal regeneration and enhanced BMS scores after chronic SCI. Moreover, combined treatment decreased pSTAT3, pSmad and p300 expression and p300 immunoprecipitated with pSTAT3 and pSmad. p300 siRNA showed a stronger effect than that of the combined treatment on the promotion of oligodendrocyte differentiation and the inhibition of astrocyte differentiation in NPC culture. Knockdown of p300 in injured SC had a similar effect as the combined treatment on NPC differentiation and enhanced remyelination and functional recovery. Conclusions: Combined LiCl and noggin treatment showed a synergistic effect on promoting neuronal and oligodendroglial differentiation of endogenous adult SC- derived NPCs, and concomitantly inhibited astroglial differentiation. These results indicate that combined treatment of LiCl and

noggin after contusive SCI may have significant neurorestorative effects mediated at least partially via p300 down-regulation. Our results suggest the possibility of modulating the expression of p300 as a novel therapeutic strategy to enhance or suppress the formation of astrocytic scar for the treatment of CNS disorders.

Abstract: Strategies using stem cells have demonstrated significant promise for treating and repairing spinal cord injuries (SCI). Most cell therapies aim to either replace lost neural tissue, or preserve tissue from further necrosis during secondary injury cascades, creating a divide between the functional benefits obtained from using neural stem cells and mesenchymal stem cells (MSC) for treating SCI. The goal of the present project was to enhance the migration of neuronal tissue, including endogenous neuronal stem cells, towards the lesion cavity by inducing a gradient of the known chemotaxic protein, stromal derived factor-1 (SDF-1). In addition to examining the migration of neuronal stem cells and axonal projections into or around the transplant site, another aim of this project was to identify the effects of MSC treatment on major histological landmarks, including gliotic scaring, the expression of inhibitory chondroitin sulfate proteoglycans, reduction in inflammation, as well as white matter sparing at seven weeks post injury. Behavioral outcomes were characterized using the Basso Beattie and Bresnahan scale for locomotor recovery, with a novel modified cylinder task to characterize weight-supporting abilities in this severe SCI model. Results suggest that SDF-1 expressing MSC transplants may have potential as a therapeutic option for treating SCI, but further work is needed to increase the potential efficacy

of this approach. Support for this study was provided by the Office of Research and Sponsored Programs at CMU, the College of Medicine, and the Field Neurosciences Institute and John G. Kulhavi Professorship.

Title: Enbrel treatment promotes transplanted donor human mesenchymal precursor cell survival following spinal cord injury

Authors: *S. LOVETT[1], A. R. HARVEY[1], G. W. PLANT[2], S. I. HODGETTS[1];
[1]Univ. of Western Australia, Crawley, Australia; [2]Stanford Univ., Stanford, CA

Abstract: Immediately following spinal cord injury (SCI), pro-inflammatory cytokines such as tumour necrosis factor alpha (TNFα) and interleukins 1β and 6 (IL-1β, IL-6) are released from damaged cells and other resident cells within the spinal cord. This cytokine release is involved in the inflammatory response to injury and the extensive and persistent spread of secondary damage following SCI. Activation and infiltration of immune cells into the spinal cord contributes to ongoing secondary damage with increased death of neurons and glia, demyelination of intact axons and cyst formation at the injury site. This leads to the development of an adverse environment at the injury site that is inhibitory to axonal regeneration. We have previously shown marked improvements in functional (locomotor) and morphological (tissue sparing, cyst size) outcomes in host tissue following transplantation of adult human mesenchymal precursor cells (hMPCs) into the contused spinal cord in Nude rats. However, donor hMPCs do not survive beyond 4 weeks post transplantation, most likely due to a host immune response. Modulation of pro-inflammatory cytokine levels and immune cell activity immediately following injury may lead to decreased secondary degeneration and increased donor hMPC survival, potentially leading to greater improvement in functional and morphological outcomes. Enbrel is a TNFα antagonist that can have neuroprotective effects following SCI by reducing immune cell

activation, apoptosis and tissue damage. Nude rats were given a moderate contusive SCI and treated with hMPCs alone or in combination with anti-inflammatory Enbrel. Enbrel treatment immediately after SCI improved donor cell survival in all Enbrel+hMPC treated animals, with at least some hMPCs still present in the spinal cord 4 weeks post-transplantation (c.f. two thirds of hMPC only treated animals). These hMPCs were located at the border of the injury and did not appear to migrate from the injection site. Although transplanted hMPC survival was increased, there were no statistically significant improvements in functional recovery at 5 weeks post-injury for any treatment groups. Also, combined Enbrel + hMPC treatment did not further reduce cyst size compared to hMPC transplantation alone. Enbrel may have a moderate impact on SCI repair alone by reducing secondary damage, and may be useful in combinatorial clinical applications to enhance donor stem cell survival in transplantation based therapies.

Title: Inhibiting cortical PKA activity in spinal cord injured rats enhances corticospinal tract plasticity and rehabilitative training efficacy via EPAC

Authors: *K. FOUAD, D. WEI, C. HURD, D. GALLEGUILLOS, J. SINGH, K. K. FENRICH, C. WEBBER, S. SIPIONE;
Univ. of Alberta, Edmonton, AB, Canada

Abstract: Elevated levels of the cellular messenger molecule cAMP have frequently been associated with the ability of neurons to sprout and extend neurites, even in the growth inhibitory environment of the central nervous system. A prominent downstream target of cAMP that has been associated with neurite outgrowth is Phosphokinase A (PKA). Here we attempted to demonstrate that also the neuroplasticity promoting effect of rehabilitation training following spinal cord injuries is mediated via PKA activation. However, when we inhibited cortical PKA using Rp-cAMPS during the phase of rehabilitation in spinal cord injured rats to prove this principal, we found the opposite effect. In two independent experiments we discovered that blocking cortical PKA in parallel to rehabilitative training, increased functional recovery and

corticospinal tract sprouting. When we evaluated the effects of the PKA inhibitor *in vitro*, we found that increasing cAMP levels still resulted in increased phosphorylation of a prominent downstream target (i.e., CREB). This however was not found when instead of increasing cAMP a specific PKA agonist was utilized, suggesting that an alternate cAMP dependent pathway was involved. This was proven in an *in vitro* neurite outgrowth essay, where blocking PKA once more increased outgrowth, however when this was combined with an inhibitor for another downstream target of cAMP (EPAC), outgrowth was significantly reduced. It appears that by blocking PKA activity, higher cAMP levels are available for EPAC to increase neurite outgrowth. In conclusion this study shows that although PKA and EPAC act synergistically to translate rehabilitative training induced neuronal plasticity, the increase in EPAC activation is a key to enhanced plasticity. This finding offers new specific pharmacological gateways to boost rehabilitative training.

Title: Optimization of trophic support for neural stem cell grafts in sites of spinal cord injury

Authors: J. ROBINSON[1], L. GRAHAM[1], D. WU[1], Y. WANG[1], M. TUSZYNSKI[1,2], *P. P. LU[1,2];
[1]UCSD, La Jolla, CA; [2]VA-San Diego Healthcare Syst., San Diego, CA

Abstract: Previously we reported that neural stem cells (NSCs) embedded in fibrin matrices containing 9 growth factors and an anti-apoptotic agent, survived and completely filled sites of spinal cord injury. In the current study, we examine whether the number of factors can be reduced while optimizing NSC survival and filling of the lesion site. NSCs derived from embryonic day 14 F344 rat spinal cord (expressing green fluorescent protein, GFP) were

embedded in fibrin matrices containing a defined growth factor cocktail (1 to 4 factors among BDNF, bFGF, VEGF and calpain inhibitor, or original 10 factor combination). Grafts were made into a C5 lateral hemisection of wild-type adult F344 rats two weeks post-injury (N=3-6 per group, total 9 groups). Graft survival was assessed 2 weeks post-grafting. A 4 factor cocktail resulted in graft survival, neuronal differentiation, and filling of lesion site that was equivalent or superior to the 10 factor cocktail. The use of fewer than 4 growth factors, including single growth factors, also frequently but less consistently resulted in NSC survival and fill of lesion site. The effect of fewer growth factors on axon extension from the graft into the host cord is currently under analysis. Collectively, these findings suggest that excellent neural stem cell engraftment and survival can be achieved with a reduced growth factor cocktail, enhancing clinical practicality.

Title: A potent time-dependent suppression of muscle spasticity by spinal-intrathecal delivery of glycine transporter 1 inhibitor (sarcosine) in rat complete thoracic 9 transection model

Authors: *T. YOSHIZUMI, K. KAMIZATO, A. PLATOSHYN, J. STRNADEL, J. A. CORLETO, A. M. ALAMRI, M. R. NAVARRO, J. GIESSINGGER, S. MARSALA, M. MARSALA;
ANETHESIOLOGY, UNIVERSITY OF CALIFORNIA SAN DIEGO MARASALA LAB, LA Jolla, CA

Abstract: Loss of spinal segmental glycinergic inhibition is believed to play a role in the development of spinal injury-induced muscle spasticity. In our previous studies we have characterized the potency of spinal GlyT2 inhibition/silencing in modulating tactile stimulus-evoked spasticity and have demonstrated a paradoxical and time-dependent anti- and pro-spastic effect after a long-term GlyT2 silencing. In our current study, the anti-spastic potency of intrathecal (IT) treatment with glycine transporter 1 inhibitor (sarcosine) in thoracic 9 (T9)

complete transection model of chronic spasticity rat was studied. Adult Sprague-Dawley (SD) rats were used to perform a T8 laminectomy followed a complete T9 transection of the spinal cord. At 2-3 months after transection animals with fully developed muscle spasticity were selected and implanted with a chronic intrathecal catheter placed into lumbar IT space after a partial L5-L6 laminectomy. To measure muscle spasticity EMG response recorded by surface EMG electrodes from gastrocnemius was used and analyzed after applying a progressively increase paw pressure using Von Fray filaments. After baseline spasticity measurement animals received intrathecal bolus injection of: 1) normal saline (10µl), 2) sarcosine 0.25mg, or 3) sarcosine 1mg (in 10µl of saline). After drug or saline delivery the EMG response after paw tactile stimulation was measured at 30, 60, 90, 120 min and at 24 hours. A potent dose-dependent suppression of muscle spasticity was measured after sarcosine administration. Injection of 1mg sarcosine led to a near complete loss of EMG response and this suppressive effect continue for minimum of 120 min after treatment. At 24 hrs the spasticity response returned back to pre-treatment baseline. Saline injection had no detectable anti-spasticity effect. These data demonstrate that pharmacologically-induced spinal GlyT1 inhibition is associated with a potent but transient anti-spasticity effect. Accordingly the spinal GlyT1 system may represent a therapeutical target to ameliorate spinal neuronal hyper-excitability states associated with several spinal neurodegenerative disorders including spinal injury, chronic pain or multiple sclerosis. (Support: SCRM Porcine Center Grant)

Title: NSAID treatment for whole body vibration-induced pain: effects on behavioral symptoms & spinal activity

Authors: M. ZEEMAN[1], *S. KARTHA[2], B. WINKELSTEIN[1];
[2]Bioengineering, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Warfighters, pilots, and industrial workers exposed to whole body vibration (WBV) report chronic pain, the severity of which is associated with factors related to the vibration exposure. WBV can cause neck pain, particularly due to loading along the long-axis of the spine. Although there is growing evidence that WBV induces long lasting pain, neurotrophin upregulation in spinal tissues, and inflammation in the spinal cord, effective treatment remains difficult. Even a single vibration exposure at the resonant frequency of the spine produces persistent hyperalgesia, increased PKCε expression in the DRG, and increased CGRP expression and glial activation in the spinal cord. Since ketorolac, a non-steroidal anti-inflammatory drug (NSAID), is an effective analgesic if given after spinal joint pain is established, this study used a rat model to determine if ketorolac, given after WBV exposure, can reduce pain and/or spinal neuronal activity that typically develop. WBV was imposed at 8Hz for 30 minutes under inhalation anesthesia (n=4 rats). Sham rats were exposed only to anesthesia for that same period (n=3). A separate group of rats received ketorolac (10mg/kg i.p.) at 6 hours after the same WBV exposure (n=5). Mechanical hyperalgesia was assessed in the forepaws and hind paws before and 1 day after exposure. On day 1 after behavior testing, electrophysiological recordings were made extracellularly in the C6-C8 spinal dorsal horn under pentobarbital anesthesia (45mg/kg). Evoked neuronal firing was recorded with a carbon fiber electrode for both noxious (10g, 26g) and non-noxious (1.4g, 4g) von Frey stimuli applied to forepaws and analyzed with Spike2. WBV induced hyperalgesia in both the forepaws and hind paws, with significantly lower paw withdrawal thresholds from baseline ($p<0.04$) at day 1; there was no change in threshold after sham or ketorolac treatment with WBV. In fact, on day 1, the ketorolac treatment returned withdrawal thresholds to sham levels, with both paws exhibiting significantly higher withdrawal thresholds than the WBV group ($p\leq0.004$). In general, all stimuli evoked greater numbers of spikes after WBV (31 neurons) than either sham (25 neurons) or NSAID treatment (44 neurons), which were similar to each other. After painful WBV the spike counts were as much as 2.4-fold greater than with NSAID treatment or sham for noxious stimuli and between 1.3 and 1.95 times greater than WBV for non-noxious stimuli. These findings suggest that when given after a painful vibration injury, ketorolac can reduce pain. Additional studies are needed to determine the duration of this effect and the specific effects on spinal neuronal responses and inflammation.

Title: Exogenous factors contributing to neuropathic pain after SCI

Authors: *B. MURATORI[1], G. ACOSTA[2], S. M. VEGA ALVAREZ[2], J. PAGE[2], R. SHI[3]; [1]Weldon Sch. of Biomed. Engin., West Lafayette, IN; [2]Dept. of Basic Med. Sci., [3]Weldon Sch. of Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Neuropathic pain (NP) is a debilitating consequence of SCI which is resistant to current analgesic therapies and can greatly degrade the quality of life for SCI victims beyond paralysis. The mechanisms of NP have been widely investigated but are still not well understood. Although most research has been focused on endogenous causality, it is possible that external factors may also contribute to NP which could give insight to the pathogenesis and persistency of NP after SCI. There have been several studies linking cigarette smoking, a known serious threat to human health, to an increase in NP in SCI patients, but no animal study has been attempted to study this further. Acrolein, a neurotoxin present in high quantities in cigarette smoke, has been shown in several animal studies to exist in elevated concentrations in the days to weeks after SCI and also plays a critical role in the degradation of lipids, DNA, and proteins, and consequently, the functionality of neurons in the CNS after injury. In addition, acrolein has been shown to be involved in pathogenesis of NP post SCI. Previous studies with FDA-approved acrolein scavengers have shown that these agents have a neuroprotective effect after SCI in rats by increasing motor function and decreasing NP. In the current study, the inhalation of acrolein at a level equivalent to that emitted from tobacco smoke was shown to exacerbate NP behaviors by up to 60% over the course of two weeks in rats post-SCI. After cessation of acrolein inhalation, pain thresholds returned to the baseline level. The increase in pain coincided with an up-regulation of TRPA1 mRNA expression in the spinal dorsal horn and DRG of animals. TRPA1 is a nociceptor on c fibers of sensory neuron, for which acrolein is a direct agonist. Further, an increase in an acrolein metabolite, 3-HPMA, in urine was shown during the inhalation period, indicating a systemic accumulation of acrolein. This data indicates that cigarette smoke can contribute to neuropathic pain after SCI and that taking measures to reduce smoke-borne acrolein could mitigate post SCI pain. Additionally, and perhaps more importantly, these results further support the mechanistic hypothesis for a key role of acrolein, from both endogenous and exogenous sources, in the genesis of NP after SCI. The ability of acrolein to up-regulate and activate TRPA1 channels indicates that acrolein is a multiple threat in propagating NP, increasing not only activation, but also the sensitivity of TRPA1 to acrolein. Taken together, these data suggest that acrolein may be a novel and effective therapeutic target to alleviate neuropathic pain resulting from both endogenous and exogenous factors after SCI.

Title: Two-week administration of neuropathic pain medications fails to prevent the development of cutaneously evoked autonomic dysreflexia after high thoracic spinal cord transection in rats

Authors: *K. E. TANSEY, J. CHUNG, H. J. LEE;
Neuro & Physiol/SCI Clin., Emory Univ/Atlanta VA, Atlanta, GA

Abstract: In uninjured, pentobarbital anesthetized Long Evans rats, electrical stimulation of thoracic segmental dorsal cutaneous nerves (DCNs) generates a stimulation frequency and nociceptive afferent subtype specific cardiovascular response. To varying degrees, depressor blood pressure (BP) responses and heart rate (HR) increases are seen. We previously found that cervical (C7) spinal cord crush/incomplete injury gives rise to 3 different pathophysiological BP responses to DCN stimulation at 2 weeks, a normal-like depressor response evoked by all DCNs, a dysautonomia response where mixed depressor and pressor effects are evoked from different DCNs, and a pressor response like autonomic dysreflexia (AD) evoked by all DCNs. In all 3 injury groups, the HR increases evoked by DCN stimulation showed prolonged elevation. We also found that the severity of BP pathology is positively correlated with the extent of DCN C fiber sprouting in the dorsal horn and that the prolonged HR responses are correlated with increases in DCN A fiber sprouting there. We have now used a complete T2 spinal cord transection model to produce consistent pressor BP and increased HR responses to stimulation across all DCNs. In this model, we have continuously (twice daily for 2 weeks following injury)

administered 3 neuropathic pain medications commonly used clinically in spinal cord injury (SCI). We used an opioid (Buprenorphine, 0.05 mg/kg), a non-steroidal anti-inflammatory drug (Meloxicam, 1 mg/kg), and an anti-epileptic medication (Gabapentin, 50 mg/kg) to test the hypothesis that continuously treating "pain" could perhaps limit the development of nociception induced autonomic dysfunction after severe high thoracic SCI. Following injury and treatment, segmental DCN stimulation still generated AD cardiovascular responses with pressor BP and increased HR effects in all 3 drug groups. Buprenorphine generated even greater BP increases with caudal (T12, L1) DCN activation. We are currently evaluating whether A and C fiber sprouting in the dorsal horn of these animals tracks with our physiological findings.

Title: Cell cycle activation contributes to development and maintenance of neuropathic pain following spinal cord injury

Authors: ***J. WU**[1], Z. ZHAO[2], C. L. RENN[3], S. G. DORSEY[3], A. I. FADEN[2];
[1]Dept. of Anesthesiol. & Ctr. for Shock, Trauma and Anesthesiol. Resea, Univ. of Maryland, Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Univ. of Maryland Sch. of Nursing, Baltimore, MD

Abstract: In addition to causing sensorimotor deficits, spinal cord injury (SCI) also results in posttraumatic neuropathic pain in a majority of patients. Chronic pain after SCI may present as hyperalgesia, allodynia, and/or spontaneous pain and is often resistant to conventional pain therapy. Identifying better interventions to manage SCI-PAIN requires improved understanding of the pathophysiological mechanisms involved. After SCI, a key pathophysiological mechanism appears to be cell cycle activation (CCA). We have shown previously that central or systemic early administration of a selective CCA inhibitor reduced CCA, glial changes, and limited SCI-

induced hyperesthesia. Here we compared the effects of early versus late treatment with pan-CDK inhibitor flavopiridol on allodynia as well as presence of spontaneously face pain. Adult C57BL/6 male mice subjected to moderate SCI were treated with daily IP injections of flavopiridol (1 mg/kg), beginning 3 h or 5 weeks after injury and continually for 7 days, mechanical/thermal allodynia as well as mouse grimace scale (MGS) test, a measure of spontaneous pain, were evaluated. We showed that the von Frey hair force, thresholds response to thermal stimulation, and locomotor function were significant improved in early flavopiridol-treated mice when compared to vehicle group. MGS based on ear position, orbital tightening, and nose bulge was transiently increased at day 1 post-injury for all groups. The mice with SCI showed robust and extended increases of MGS up to 3 weeks. Early administration of flavopiridol significantly reduced MGS at week 1 and returned to the baseline level at week 2. Late flavopiridol injection significantly limited hyperesthesia at 7 days after treatment with no effects on locomotion. Thus, our data suggest that cell cycle modulation may provide an effective therapeutic strategy to improve reduce both hyperesthesia and motor dysfunction after SCI. These findings would also markedly expand the potential therapeutic window for such pain.

Title: Anti-inflammatory compound curcumin and mesenchymal stem cells improved recovery from spinal cord injury by altering immune responses in rats

Authors: *J. RUŽICKA[1], L. MACHOVÁ URDZÍKOVÁ[2], A. KLOUDOVÁ[2], C. SHANNON[4], K. KÁROVÁ[2], J. DUBISOVA[2], Š. KUBINOVÁ[2], R. MURALI[4], E. SYKOVÁ[3], M. JHANWAR-UNIYAL[4], P. JENDELOVÁ[2];
[1]Inst. of Exptl. Medicine, ASCR, Praha 4 - Krc, Czech Republic; [2]Neurosci., [3]Inst. of Exptl. Medicine, ASCR, Prague, Czech Republic; [4]Neurosurg., New York Med. Col., Valhalla, NY

Abstract: Spinal cord injury (SCI) is a result of direct injury to the spinal cord, a consequence of which are secondary injuries that cause local subsequent edema and ischemia and hinder the recovery process. The activation of signaling pathways associated with pro-inflammatory cytokines, such as IL-1, IL-6 and IL-15, presents a major obstacle for spinal tract reinervation. Recent studies have suggested that stem cell therapy provides a better option for the treatment and recovery of SCI. Furthermore, the naturally-occurring compound Curcumin longo, an active component present in the spice turmeric, possesses a potent anti-inflammatory property which helps SCI recovery. The objective of this investigation was to use mesenchymal stem cell (MSC) therapy in conjunction with curcumin for an improved and faster recovery from SCI. Methods: Balloon induced spinal cord compression was performed in rats and MSCs (5x 105/50ml) were administered intrathecally seven days after SCI at the site of injury. Curcumin (0.5 mmol/kg or 60 mg/kg) was then given via epidural injection or IP injection with or without MSCs. BBB score, flat beam test and plantar test were used for functional analysis. Secretary inflammatory cytokines (MIP-α, IL-4, IL-1β, IL-2, IL-6, IL-12p70, TNF-α and RANTES) were evaluated at 1, 3, 7, 10, 14 and 28 days post SCI with and without treatments. Results: Recovery from SCI was noticeably greater in curcumin treated rats. All treated animals (curcumin, MSC, curcumin + MSC) showed significant improvement in locomotor behavior in comparison with the saline treated group. The combined treatment of MSCs with curcumin showed a synergic effect in improving locomotor function. Notably, thermal hyperalgesia diminished following treatment with curcumin alone, or in combination with MSCs. Curcumin or MSC treatment preserved white matter and the combination of curcumin and MSCs influenced tissue sparing in the central part of white mater and in the cranial part of gray matter in the injured spinal cords. The levels of cytokines displayed a biphasic effect, where levels of IL-6 and IL-12p70 increased robustly at 28 days, while remaining lower at early stages of injury. In contrast, TNFa showed an increase at day 7, but increased noticeably at day 28 in curcumin and MSC treated groups, along with IL-4, IL-2 and MIP1a. Conclusions: These results provide evidence that curcumin synergistically enhances recovery from SCI when given with stem cells by discretely modulating the immune response at different phases of SCI recovery.

Title: Curcumin decreases secondary damage and improves function following spinal cord injury

Authors: S. ABU HUSSEIN[1], H. ATTIA[3], *A. A. ABDELLATIF[2];
[1]Biology, SSE, American Univ. in Cairo, New Cairo, Egypt; [2]Biology, SSE, American Univ. in Cairo, New York, NY; [3]Anat. Dept., Alazhar Univ. Fac. of Med., Damietta, Egypt

Abstract: Altering the inhibitory micro-environment in the spinal cord that results from the secondary damage following Spinal Cord injury (SCI) has been a major challenge. In the current study we show that Curcumin -a naturally occurring food substance- can provide antioxidant activity that decreases the inflammatory changes and improves functional recovery following a hemi-section SCI model in rats. Our preliminary results show inhibition of the pro-inflammatory cytokine TNF-a and functional improvement on the Grid walk, inclined plane and beam walk functional recovery tests in the treatment group when compared to control groups. Our data support a role for antioxidant food supplements e.g. Curcumin in SCI treatment in combination with other treatment strategies.

Title: The effect of bone marrow stromal cells on blood spinal cord barrier stabilization after spinal cord injury

Authors: *G. J. RITFELD[1], G. VOLPEDA[2], M. OUDEGA[1];
[1]The Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL; [2]Univ. of Pittsburgh, PITTSBURGH, PA

Abstract: Bone marrow stromal cell (BMSC) transplantation is a promising strategy for repair of the injured spinal cord. BMSCs have been shown to elicit neuroprotection associated with functional recovery. The exact mechanism behind this BSMC-mediated neuroprotective effect is unknown, but paracrine effects of the numerous growth factors secreted by BMSCs are believed to, at least in part, mediate tissue protection. Among the factors secreted by BMSCs are angioprotective molecules, including vascular endothelial growth factor (VEGF) and angiopoietin-1 (ANG1). Previously, we have shown that BMSCs transplants elicit an angiogenic response. These newly formed blood vessels may mediate the observed neuroprotective effects, but may also contribute to inflammation due to an immature blood-spinal cord barrier and associated blood vessel leakage. In the present study, we studied the effects of BMSC transplants on blood vessel stabilization after spinal injury. We used female adult Sprague-Dawley rats to elicit a moderately severe spinal cord contusion at the ninth thoracic level. Three days later 5 x 10e5 BMSCs were injected in the contusion epicenter and spinal cords were collected at 4 days, 8 days, 17 days, and 4 weeks post contusion. The blood-spinal cord barrier was analyzed structurally with antibodies against occludin and SMI-1 and functionally by quantifying blood vessel leakage after systemic perfusion with Evan's Blue. Our data provides detailed information about BMSCs' effect on blood vessel stabilization after spinal cord injury. Future studies will focus on genetically enhancing Angiopoeitin-1 expression by BMSCs to accelerate blood-spinal cord barrier maturation to enhance tissue repair. This work was funded by the Craig H. Neilsen foundation.

Abstract: Spinal Cord Injury (SCI) is a highly incapacitating condition for which there is still no treatment. Cellular therapies are seen as a promising tool for SCI repair. From the myriad of cells currently being tested, Adipose Tissue Stem Cells (ASCs) secrete factors that promote neuronal proliferation; in addition, Olfactory Ensheathing Cells (OECs) are characterized by promoting neuronal regeneration and guidance. Interestingly, our group has previously shown that OECs present positive paracrine interactions with ASCs [1]. In this sense, we intend to combine ASCs and OECs, testing their effects on: 1) an *in vitro* model of axonal regeneration, using dorsal root ganglia explants (DRGs); and 2) an *in vivo* hemisection rat model of SCI. DRGs were co-cultured with ASCs/OECs during 4 days, after which axonal outgrowth was measured. *In vivo*, 80.000 cells of a mixture of ASCs and OECs was injected rostral and caudally to the injury site. Animals without treatment were used as controls. The behavioral evaluation included the BBB test, activity box test and average velocity on water. *In vitro* results revealed that OECs alone or in co-culture with ASCs promote the highest increase of neurite outgrowth. Moreover, rats treated with ASCs/OECs presented improved locomotor scores on the BBB scale. Histological analysis revealed a lower inflammatory profile of animals treated with the transplantation of cells. No major alterations were observed in astrogliosis and axonal organization. Overall, these results support the use of these cells as a therapeutic approach for SCI. References [1] Silva NA, Gimble JM, Sousa N, Reis RL, Salgado AJ. Title: Sox9 knockdown promotes reactive sprouting and locomotor recovery in spinal cord injured mice by reducing CSPG levels

Authors: *T. HRYCIW[1], W. M. MCKILLOP[1], N. M. GEREMIA[1], E. M. YORK[2], L. RUBINGER[1], T. LIU[1], K. XU[1], A. BROWN[3];

Inst. and Dept. of Anat. and Cell Biology, Western Univ., London, ON, Canada

Abstract: Chondroitin sulfate proteoglycans (CSPGs) are upregulated by reactive astrocytes both at the glial scar and distal to the lesion following spinal cord injury (SCI). This response may limit plasticity during recovery from injury. We have previously identified the transcription factor SOX9 as a key regulator of CSPG production, and demonstrated that conditionalSox9 ablation leads to decreased CSPG levels and improved recovery of hind limb function after SCI. We now demonstrate increased neural input onto spinal neurons caudal to the lesion in SCI Sox9 conditional knockout mice as indicated by increased levels of the presynaptic markers synaptophysin and VGLUT1. Whereas retrograde tract-tracing studies failed to provide evidence for increased axonal sparing or long-range regeneration in the Sox9 conditional knockout mice, anterograde tract-tracing experiments demonstrated increased reactive sprouting from the corticospinal tract caudal to the lesion after SCI. Finally, inhibiting CSPG degradation in Sox9 conditional knockout mice by administration of an MMP inhibitor prevented the improvements in locomotor recovery observed in untreated Sox9 conditional knockout mice, suggesting that improved locomotor function in these mice after SCI is due to increased reactive sprouting secondary to reduced CSPG levels distal to the lesion. Using computational chemistry we have recently identified Z02 as a putative small molecule inhibitor of SOX9. Z02 reduces SOX9 target gene expression in primary astrocyte cultures. The effects of Z02 on gene expression and locomotor recovery after spinal cord injury in the rat will be presented.

Title: A pericyte origin of stromal scar tissue following multiple different types of lesions to the central nervous system

Authors: *Y. KELAHMETOGLU[1], D. DIAS[1], J. TATARISHVILI[3], C. PEREZ ESTRADA[2], A. ERNST[1], L. BRUNDIN[2], Z. KOKAIA[3], O. LINDVALL[3], J. FRISÉN[1], C. GÖRITZ[1];

Abstract: Central nervous system (CNS) lesions often lead to long lasting functional deficits due to poor regeneration. One major obstacle is the formation of scar tissue that represents a permanent barrier to regenerating axons. We recently showed that in the injured mouse spinal cord, a discrete subpopulation of perivascular cells lining the microvasculature, termed type A pericytes, are the primary source of stromal cells that form the core of the chronic CNS scar. This study aims to analyze whether type A pericytes are a general source of stromal tissue in various pathologies and throughout the CNS. Using inducible *in vivo* lineage tracing of type A pericytes in combination with different lesion models of the CNS, we compared the contribution of type A pericytes to scar formation. Our results show that type A pericytes contribute similarly to stromal scar tissue formation after a corticostriatal stab lesion in the brain as is seen after spinal cord injury (SCI). We furthermore compared the type A pericyte recruitment in response to transient middle cerebral artery occlusion (MCAO), a model of cerebral ischemia, experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis (MS) and the GL261 glioblastoma model that mimics the human Gliablastoma Multiforme. In all lesion models we observed vascular modulation that led to a change in vessel density and pericyte coverage. Type A pericytes detach from the blood vessel wall and contribute to stroma formation in all models but MCAO, while the extent of recruitment was lesion specific. Our findings reveal pericyte-derived stroma formation in different parts of the CNS and in response to several different lesions and propose type A pericytes as a novel target to interfere with stroma formation.

Title: Effects of reduction of suppressors of cytokine signaling-3 (socs3) expression on dendritic outgrowth and demyelination after spinal cord injury

Authors: K. PARK, C.-Y. LIN, K. LI, *Y.-S. LEE;
Neurosci, Cleveland Clin., Cleveland, OH

Abstract: Suppressors of cytokine signaling-3 (SOCS3) is associated with limitations of nerve growth capacity after injury to the central nervous system. Although genetic manipulations of SOCS3 can enhance axonal regeneration after optic injury, the role of SOCS3 in dendritic outgrowth after spinal cord injury (SCI) is still unclear. The present study investigated the endogenous expression of SOCS3 and its role in regulating neurite outgrowth *in vitro*. IL-6 induces SOCS3 expression at the mRNA and protein levels in neuroscreen-1 (NS-1) cells. In parallel to SOCS3 expression, interleukin-6 (IL-6) induced tyrosine phosphorylation of signal transducer and activator of transcription 3 (STAT3) in NS-1 cells. Lentiviral delivery of short hairpin RNA (shSOCS3) (Lenti-shSOCS3) to decrease SOCS3 expression into NS-1 cells enhanced IL-6-induced tyrosine phosphorylation of STAT3 (P-STAT3 Tyr705) and promoted neurite outgrowth. In addition, we determined if reduction of SOCS3 expression by microinjection of Lenti-shSOCS3 into spinal cord enhance dendrite outgrowth in spinal cord neurons after SCI. Knocking down of SOCS3 in spinal cord neurons with Lenti-shSOCS3 enhanced complete SCI-induced P-STAT3 Tyr705. Immunohistochemical analysis showed that complete SCI induced a significant reduction of microtubule association protein 2 (MAP-2) positive (MAP-2+) dendrites in the gray and white matter at 1 and 4 weeks after injury. The SCI-induced reduction of MAP-2+ dendrites was inhibited by infection with Lenti-shSOCS3 in areas both rostral and caudal to the lesion at 1 and 4 weeks after complete SCI. Furthermore, shSOCS3 treatment enhanced up-regulation of growth associated protein-43 (GAP-43) expression, which co-localized with MAP-2+ dendrites in white matters and MAP-2+ cell bodies in gray matters, indicating Lenti-shSOCS3 may induce dendritic regeneration after SCI. Moreover, we demonstrated that Lenti-shSOCS3 decreased SCI-induced demyelination in white matter of spinal cord both rostral and caudal to the injury site 1 week post-injury, but not rostral to the injury at 4 weeks. Collectively, these results suggest that SOCS3 has negatively regulatory

effects on dendritic regeneration, at least in part by inhibition of dendritic loss, through negative regulation of STAT3 signaling after SCI.

Title: Differential activation and effects of the PERK, ATF6, and IRE1 arms of the ER stress response after spinal cord injury

Authors: ***S. R. WHITTEMORE**, S. MULLINS, K. R. ANDRES, A. S. RIEGLER, M. HETMAN, S. SARASWAT OHRI;
Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Spinal cord injury (SCI) initiates a cascade of secondary cell death mechanisms in most resident cells. These pathophysiologic responses have been shown in non-CNS cells to initiate the endoplasmic reticulum stress response (ERSR). We addressed the extent to which and in what cell types, the ERSR was initiated after contusive thoracic SCI in adult mice. All three signaling branches are rapidly up regulated as early as 6 hours post-SCI and remained elevated until 72 hours post-SCI as detected by both PCR and immunohistochemistry. CHOP expression was observed in neurons and oligodendrocytes, but not in astrocytes at 72 hours post-SCI. In CHOP null mice, the ERSR was attenuated and hindlimb locomotor function significantly improved. At both acute (72 hours) and chronic (6 weeks) times after SCI, oligodendrocytes were significantly spared. Thus, blocking the pro-apoptotic aspects of the ERSR in oligodendrocytes was one mechanism underlying behavioral recovery. To explore if pharmacological enhancement of the homeostatic arm of PERK signaling was similarly therapeutically protective after SCI, mice were treated with salubrinal, which inhibits the dephosphorylation of eIF2α by both PPP1R15A/GADD34 and PPP1R15B/CReP, the stress-inducible and constitutive eIF2α phosphatases, respectively. Salubrinal treatment resulted in similar ERSR attenuation, oligodendrocyte sparing, and locomotor recovery. Guanabenz, an

FDA approved, specific inhibitor of PPP1R15A/GADD34 promoted the survival of OPCs treated with tunicamycin *in vitro* and enhanced eIF2α phosphorylation after SCI. However, guanabenz treatment of wild type mice after SCI (or SCI in GADD34 null mice) showed differential attenuation of the ERSR and no locomotor improvement. ATF6 null mice also show attenuation of the ERSR after SCI, but no enhanced recovery. Conditional deletion of XBP1, an effector downstream of IRE1, in oligodendrocytes did not enhance functional recovery after SCI. The pro-homeostatic aspects of the ERSR appear to be the most attractive therapeutic target after CNS injury.

Title: Role of autophagy in oligodendrocyte survival and functional recovery after thoracic SCI

Authors: *S. O. SARASWAT, A. BANKSTON, A. MULLINS, A. METZ, M. HETMAN, S. WHITTEMORE;
Neurolog. Surgery, Univ. Louisville, Louisville, KY

Abstract: Autophagy is a basic catabolic mechanism that involves cell degradation of unnecessary or dysfunctional cellular components through the action of lysosomes. During this process, targeted cytoplasmic constituents are isolated from the rest of the cell within autophagosome, a double-membraned vesicle. Autophagosomes mature by fusing with the lysosome to form the autolysosome, leading to degradation of the inner membrane and cargo and recycling of the products to the cytoplasm. Autophagosome complex formation involves the PI3K Vps34, Beclin-1, Ambra1 and two ubiquitin-like conjugation systems: 1) conjugates of Atg12 ligated to Atg5 to form oligomers with Atg16L and 2) lipidation of cleaved LC3 (Atg8) by addition of phosphatidyl ethanolamine, converting LC3-I to LC3-II. Induction of autophagy has been observed in response to starvation, endoplasmic reticulum (ER) stress, and apoptosis.

Recent data showed that acute manipulation of the ER stress response (ERSR) pathway after thoracic contusive spinal cord injury (SCI) improved functional recovery and identified oligodendrocytes as uniquely sensitive to ERSR. Interestingly, ERSR genes remain elevated at the injury epicenter for at least 6 weeks. Our preliminary data indicate that: 1) the mRNA levels of key autophagy markers, Atg5, Beclin1 and Ambra1 are dysregulated acutely after T9 contusive SCI, remain disrupted at least until 6 weeks and correlate with the ERSR data. 2) The levels of LC3, an unequivocal marker of autophagy, remain elevated for at least 2 weeks post-injury. 3) Blocking autophagy in oligodendrocyte precursor cells (OPCs) exposed to ER stress resulted in enhanced survival. 4) Differentiated oligodendrocytes (OLs) show enhanced autophagic flux, especially in the processes compared to OPCs. 5) Protein levels of MBP, LC3B, Atg5 and beclin1 are enriched in purified myelin fractions of contused day 8 post-SCI tissue suggesting autophagy is active in remyelination after SCI. These preliminary data suggest that the complex autophagic mechanism is distinct in OPCs vs. OLs and that the timing of modulating autophagy after SCI will be critical. Importantly, the results identify a window(s) of opportunity to manipulate autophagy for a therapeutic benefit after SCI. Ongoing studies are examining the effects of genetically and pharmacologically manipulating autophagy after SCI. Supported by NS073584 and GM103507.

Title: Crosstalk between endoplasmic reticulum stress response and autophagy pathways in CNS endothelial cell survival

Authors: *S. A. MYERS[1], A. E. RIEGLER[2], K. R. ANDRES[2], S. SARASWAT-OHRI[2], T. HAGG[3], S. R. WHITTEMORE[2];

[1]Univ. Louisville, Louisville, KY; [2]Univ. of Louisville, Louisville, KY; [3]East Tennessee State Univ., Johnson City, TN

Abstract: Following stress, endothelial cells (ECs) initiate the unfolded protein response (UPR) after endoplasmic reticulum (ER) stress sensors (XBP-1, PERK, and ATF6α) detect a high unfolded/misfolded protein to ER chaperone ratio. These stress sensors also initiate macroautophagic responses by promoting autophagosome vesicle nucleation and elongation. ER stress within ECs contributes to many diseases, including hypertension, atherosclerosis, diabetes, and bleeding disorders. We previously showed that genetic deletion of the ER stress pro-apoptotic protein C/EBP homologous protein (CHOP) improved vascular sparing and enhanced locomotor recovery following moderate spinal cord injury. We hypothesized that inhibiting signals upstream of CHOP may similarly reduce ER stress-induced apoptosis and improve sparing of primary, CNS-derived ECs. Deletion of the eIF2α kinase PERK, however, actually increased CHOP expression and apoptosis. This increase appears, in part, due to a compensatory overexpression of XBP-1 signaling. Deletion of the ER associated degradation (ERAD) protein ATF6α led to similar increases in ER stress-induced cell death, in part due to a compensatory overexpression of XBP-1 and PERK mRNA. Targeted deletion of XBP-1 had little long-term effects on ER stress-induced apoptosis. We further observed that when ER stress-induced autophagy was blocked by PI3 kinase inhibition, the extent of ER-localized misfolded proteins as well as CHOP expression was reduced, suggesting that inhibition of autophagy further reduces ER stress responses in ECs. These data implicate signals regulating both ER stress and macroautophagy as potential targets for therapeutic intervention within diseases exacerbated by vascular dysfunction. Future experiments will explore whether these interactions are synergistic. Supported by NS045734, NS073584, and GM103507.

Title: Inhibition of RNA-polymerase-1 protects oligodendrocytes against endoplasmic reticulum stress

Authors: *E. KILANCZYK;
Dept. of Neurolog. Surgery, Univ. of Louisville, Louisville, KY

Abstract: Inhibition of RNA-polymerase-1 protects oligodendrocytes against endoplasmic reticulum stress Ewa Kilanczyk[1] Kariena R Andres[1], Scott R Whittemore[1,3] and Michal Hetman[1,2] [1]Kentucky Spinal Cord Injury Research Center and the Departments of Neurological Surgery, [2]Pharmacology&Toxicology and [3] Anatomical Science & Neurobiology, University of Louisville, Louisville, KY Recent work has documented that the conserved ER stress response (ERSR) is activated after contusive SCI. Genetic or pharmacological modification of the ERSR protects white matter, prevents oligodendrocyte apoptosis and improves functional recovery after trauma. The ribosome is the nexus of protein synthesis. Ribosomal biogenesis takes place in the nucleolus where RNA polymerase I (Pol1)-driven transcription of ribosomal RNA (rRNA) initiates that process. As cancer cells hijack ribosome biogenesis to fuel their growth, Pol1 became a target of novel anti-cancer drugs including the clinically tested CX-5461 or the recently identified BMH-21. Surprisingly, we found that ribosomal biogenesis is increased after moderate thoracic SCI and remains active in cultured oligodendrocytes precursor cells (OPC) that were challenged with ER stress inducers tunicamycin or thapsigargin. Importantly, transient, non-toxic inhibition of ribosomal biogenesis using CX-5461 or BMH-21 protected mouse or rat OPCs against ER stress toxicity. The protection was accompanied by enhancement of the pro-survival phosphorylation of the eIF2α and moderate modulation of ER stress-mediated inhibition of general protein synthesis. Induction of the ER stress-related killer transcription factor CHOP was unaffected by Pol1 inhibitors. Instead, these agents activated p53 whose pharmacological inhibition blocked the anti-ER stress protection. Most interestingly, *i.p.* treatment with BMH-21 inhibited ribosomal biogenesis in the mouse spinal cord and increased expression of oligodendrocyte markers following SCI. These findings suggest that the nucleolar disruption and the subsequent activation of p53 support OPC and/or oligodendrocyte survival under conditions of ER stress. Title: Autophagy regulates the final stages of CNS myelination

Authors: ***A. N. BANKSTON**, A. E. METZ, R. M. HOWARD, S. R. WHITTEMORE; Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Myelination of the central nervous system (CNS) is a tightly regulated process. Oligodendrocyte precursor cells (OPCs) proliferate and migrate to target axons, where they mature to myelinating oligodendrocytes (OL), the sole providers of CNS myelin. Many factors have been identified that regulate OL differentiation and myelination. However, few factors have been found that act specifically in myelin formation, and the mechanisms regulating myelin sheath wrapping and compaction are poorly understood. Here, we present evidence that autophagy, the targeted isolation of cytoplasm and organelles by the double-membrane autophagosome for lysosomal degradation, regulates myelin formation in mature OLs. Autophagy is critical for cell homeostasis, but recent evidence has shown that autophagy regulates OL survival and differentiation and morphogenesis of neurons and astrocytes in the brain. Our data show: 1) increased autophagosome formation, trafficking, and autophagic flux, especially in OL processes, during late stages of OL differentiation and myelin wrapping, 2) autophagy regulatory proteins co-localization with markers of the OL lineage during myelin development, 3) detection of key autophagy regulatory proteins in enriched myelin fractions from corpus callosum (CC) at the peak of myelination and immunostaining of DRG co-cultures, 4) time-lapse imaging demonstrates autophagosome movement from myelin to the OL soma in DRG co-cultures, 5) autophagy inhibition blocked and autophagy stimulation enhanced myelination, 6) increased autophagy activation during remyelination after cuprizone-induced demyelination. These results provide insight into novel functions of autophagy in OL and myelin development and identify autophagy as an attractive target to both promote OL survival and subsequent myelin repair after injury.

Title: Two PTP receptors for CSPG inhibitors use convergent and divergent signaling pathways in neurons

Authors: *Y. OHTAKE[1], D. WONG[1], P. M. ABDUL-MUNEER[1], M. E. SELZER[2], S. LI[1]; [2]Neurol., [1]SHPRC, Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: The extracellular matrix molecule chondroitin sulfate proteoglycans (CSPGs) are axon growth inhibitors that are highly upregulated by reactive scar tissues, forming a potent chemical barrier to axon regeneration after CNS injuries. CSPGs may mediate suppression of axon growth by several mechanisms, including binding and activating functional transmembrane receptors, sterically hindering growth-promoting adhesion molecules and facilitating inhibitory effects of chemo-repulsive molecules. In particular, recent studies support that the receptor protein tyrosine phosphatase σ (PTPσ) and its subfamily member leukocyte common antigen related (LAR) phosphatase act as the transmembrane receptors that mediate the growth inhibiting effects of CSPGs. Transgenic or pharmacological inhibition of either PTPσ or LAR receptor promotes significant regrowth of descending or ascending axons into and beyond scar tissues and functional recovery in adult rodents with spinal cord injury. However, the molecular basis for requirement of two similar PTP receptors by neurons is not clear, including the downstream signals that mediate the effects of these two receptors. In the present study, we performed the parallel *in vitro* experiments in cultures of the neuronal cell line N2A overexpressed with PTPσ or LAR and compared their intracellular downstream signaling pathways following CSPG stimulation. Our results indicate that PTPσ and LAR employ some signaling pathways in common, including RhoA, Akt, Erk and MAP1B, but also use distinct signaling pathways to mediate CSPG function. Activation of PTPσ by purified CSPGs selectively inactivated CRMP2, APC, S6 kinase and CREB. In contrast, activation of LAR by CSPGs selectively activated PKCζ and inactivated cofilin and LKB1. We thus proposed a model of the CSPG downstream pathways based on our experimental findings. The presence of both convergent and divergent downstream signaling pathways of PTPσ and LAR suggests that blocking both PTP receptors may have synergistic therapeutic effects in overcoming CSPG inhibitory effects of neuronal growth.

Title: The effects of a nt-3 persistent delivery gelatin sponge scaffold on mscs growth *in vitro* and spinal cord tissue regeneration in rats and canines

Authors: ***G. LI**[1], Y.-S. ZENG[2];
[2]Histology and Embryology,, [1]Sun Yat-Sen Univ., Guangdong, China

Abstract: Neurotrophin-3 (NT-3) plays an essential role in the development of nervous system. Our previous studies have demonstrated that Schwann cells overexpressing NT-3 could support sufficient nutrition for constituting an adult stem cell-derived neural network. In the present study, we evaluated the physiological effects of a new-developed NT-3/fibroin coated gelatin sponge (NF-GS) scaffold to establish a controlled artificial release system that may serve as a novel therapy of spinal cord injury (SCI). A lyophilization technique was used to immobilize NT-3/fibroin complex to gelatin sponge scaffold. The physical, chemical and physiological properties of the NF-GS scaffolds were tested by seeding bone marrow-derived mesenchymal stem cells (MSCs) *in vitro*. Then, NF-GS scaffolds were implanted into the injury site of rat and canine spinal cords to directly investigate the therapeutical effects *in vivo*. *In vitro* release test showed that the NF-GS was capable to generate a sustainable NT-3 release in 28 days. A 7-days culture indicated that MSCs could maintain high cell activity as well as excellent cell distribution and morphous. *In vivo* study showed that the total concentration of NT-3 in rat host spinal tissue was much higher in the NF-GS group than the control group 4 weeks after graft. Additionally, cavity areas within the injury/graft site of spinal cord were significantly reduced due to tissue regeneration and axon extension with myelinization in rats and canines. The results suggest that we establish a bioactive scaffold to persistently release NT-3 *in vitro* and *in vivo*. This scaffold will greatly facilitate our future experiments loading or attracting stem cells for repairing SCI.

Title: microRNA mediated augmentation of therapeutic effects of synthetic bororetinoid in mono-culture and co-culture models of spinal cord injury

Authors: *S. K. RAY[1], M. CHAKRABARTI[1], B. C. DAS[2];
[1]Dept Patho Micro & Immuno, Univ. SC Sch. Med., Columbia, SC; [2]Kansas Univ. Med. Ctr., Kansas City, KS

Abstract: Spinal cord injury (SCI) is a complex neurological problem that begins with a rapid mechanical injury or breakup of the spine. A severe SCI can cause paralysis and even death. Primary injury to the spinal cord initiates progressive secondary injury processes such as calcium overload causing cell death that spans over time to the rostral and caudal regions. The only recommended therapy for SCI is methylprednisolone (MP) that shows poor efficacy and its use in SCI is now highly controversial. So, new therapeutic agents for targeting secondary injury pathways must be developed for neuroprotection in spinal cord in the SCI patients. Recent investigations show that retinoids at lower doses are promising therapeutic agents for inhibiting apoptosis, augmenting autophagy, and reducing expression of various pro-inflammatory cytokines. In current investigation, we examined therapeutic efficacy of our synthetic bororetinoids in cell culture models of SCI. We found that all-trans retinoic acid, a natural retionoid, at a low dose (1 μM) caused significant cell death while each of our synthetic bororetinoids (BIT-5, BIT-6, and BIT-7) even at 10 μM did not induce significant cell death in ventral spinal cord 4.1 (VSC4.1) motoneurons. In a mono-culture model of SCI (exposure of VSC4.1 motoneurons to 200 nM A23187, a calcium ionophore (CI), for 24 h) induced significant neuronal death but 10 μM BIT-5 most significantly prevented the CI induced neuronal death. Our real-time quantitative reverse transcription-polymerase chain reaction (qRT-PCR) experiments indicated decreases in expression of six neuroprotective microRNAs (miRs) such as miR-34a, miR-138, miR-184, miR-96, miR-98, and miR-133b in VSC4.1 motoneurons after CI insult. Notably, expression of miR-96 was most significantly decreased in the CI insulted motoneurons. So, we hypothesized that overexpression of miR-96 could augment

therapeutic efficacy of BIT-5 in cell culture models of SCI. Our cellular and molecular results indicated that induction of autophagy, a survival mechanism, in CI exposed VSC4.1 motoneurons was suppressed due to treatment with MP but increased due to treatment with combination of miR-96 and BIT-5. Also, in a co-culture model of SCI (VSC4.1 motoneurons and C6 astroglial cells exposed to CI), we found that combination of miR-96 and BIT-5 was the most effective treatment in preventing apoptosis, promoting autophagy, and inhibiting pro-inflammatory molecules in both neuronal and astroglial cells. Collectively, our studies demonstrated that miR-96 augmented therapeutic effects of BIT-5 in both mono-culture and co-culture models of SCI. This work was supported in part by SC SCIRF and USC SOM RDF.

Title: Differential intensity-dependent effects of magnetic stimulation on the longest neurites and shorter dendrites in neuroscreen-1 cells

Authors: *C.-Y. LIN[1], K. LIN[1], V. LIN[2], Y.-S. LEE[1];
[1]Neurosci, [2]PM&R, Cleveland Clin., Cleveland, OH

Abstract: Magnetic stimulation (MS) is a potential treatment for neuropsychiatric disorders. This study investigates if MS-regulated neuronal activity can translate to specific changes in neuronal arborization and thus regulate synaptic activity and function. To test our hypotheses, we examined the effects of MS on neurite growth of Neuroscreen-1 (NS-1) cells over pulse frequencies of 1, 5 and 10 Hz at field intensities controlled by machine output (MO). Cells were treated with either 30% or 40% MO and received either maximal or minimal MS-induced current density. Due to the nature of circular MS coils, the center region of the gridded coverslip (zone 1) received minimal (~5%) electromagnetic current density while the remaining area (zone 2) received maximal (~95%) current density. Plated NS-1 cells were exposed to MS twice per day for 3 days and then evaluated for length and number of neurites and expression of brain-derived

neurotrophic factor (BDNF). We show that MS dramatically affects the growth of the longest neurites (axon-like) but does not significantly affect the growth of shorter neurites (dendrite-like). Also, MS-induced changes in the longest neurite growth were most evident in zone 1, but not in zone 2. MS effects were intensity-dependent and were most evident in the bolstering of the longest neurite outgrowth, mainly seen in the 10 Hz MS group. Furthermore, we found that MS-increased BDNF expression and secretion was also frequency-dependent. Taken together, our results show that MS exerts distinct effects when different frequencies and intensities are applied to the neuritic compartments (longest neurite versus shorter dendrite(s)) of NS-1 cells. These findings support the concept that MS increases BDNF expression and signaling, which sculpts longest neurite arborization and connectivity by which neuronal activity is regulated. Understanding the mechanisms underlying MS is crucial for efficiently incorporating its use into potential therapeutic strategies.

Hospital, Natl. Hosp. Organization, Osaka, Japan; [5]Dept. of Pathology, Tokyo Metropolitan Children's Med. Ctr., Tokyo, Japan

Abstract: [Purpose] Transplantation of neural stem cells (NSCs) is now considered to be a promising treatment for various central nervous system disorders. In countries where fetal NSCs are not allowed to use due to ethical issues, iPS cells are a potential cell source of NSCs for cell therapy. Especially in Japan, an iPS cell bank is planned to be established from peripheral blood mononuclear cells (PBMCs). To apply these cells to clinic, we developed three Good Manufacturing Practice (GMP) grade protocols to induce PBMC-derived iPSCs into NSCs. We compared its characteristics *in vitro*, and *in vivo*, and investigated useful markers to distinguish

safe NSCs for clinical use. [Methods] Two feeder-free iPSC lines established from human adult PBMCs were used (1210B2, 1231A3). First, the karyotype of the iPSCs was checked. Next, the iPSCs were induced into NS/PCs by three different protocols: (ProA, B, and C). Neural phenotypes, multipotency, and cellular heterogeneity of induced NS/PCs were evaluated by immunocytochemistry, qRT-PCR, and flow cytometry (FACS). Microarray analysis was also performed to compare the quality of each NSC lines. To assess cellular behavior *in vivo*, intracranial or spinal xenograft models were used. For intracranial xenograft models, 1x10^6 NS/PCs were injected into each side of the striatum of intact NOG mice. For spinal xenograft models, 5x10^5 NSCs were transplanted into the spinal cord of NOD/SCID mice 9 days after contusion injury. Their histologically examined 13-26 weeks after transplantation to see the *in vivo* characteristics of the transplants. [Results] *In vitro*, karyotype analysis revealed that the frequency of copy number variation (CNV) was higher in 1231A3-iPSCs than in 1210B2-iPSCs. All three neural induction protocols had the potential to induce PBMC-derived iPS cells into NSCs. FACS analysis revealed that there were more subtypes of neural crest stem cells (NCSCs) in ProC-NSCs. Microarray clustering analysis also showed that ProA-NSCs and ProB-NSCs were more similar to fetal derived-NSCs than ProC-NSCs. *In vivo*, 1210B2-ProA-NSCs had the best integration to the host brain and also to the spinal cord. 1210B2-ProB-NSCs had a tendency to leak to the subdural space when transplanted into the spinal cord. 1231A3-ProA-NSCs revealed massive growth both in the brain and spinal cord. Bone formation was observed from 1210B2-ProC-NSCs 6 months after transplantation to the spinal cord. [Conclusion] 1210B2-ProA-NSCs had the best quality *in vitro* and *in vivo*. All of the analyses performed in this study were important. Further study should be performed to determine *in vitro* markers to set effective criteria to certify safe and useful NSCs.

Title: Pharmacological inhibition of clathrin mediated endocytosis and the effect of magnetic nanoparticles in the morphology of primary neurons

Authors: *R. AMMASSAM VEETTIL[1], T. MCALLISTER[2], S. GHOSH[2], S. SEBASTIAN[1], D. HYNDS[1];

Abstract: Traumatic central nervous system (CNS) injury leads to neuronal damage and results in varying levels of functional impairment. Nanomaterial-based drug delivery systems provide potential for axon regeneration from specific neurons by crossing blood brain barrier. From our previous experiments we found that -NH2 and -COOH surface functionalized nanoparticles were internalized through clathrin mediated endocytosis. In the present study we are using clathrin inhibitors to block the clathrin mediated endocytosis. This would confirm the definite mechanism through which the nanoparticles are endocytosed. We also used magnetic nanoparticles to study the time and dose dependant effects on neurite outgrowth in primary dorsal root ganglion (DRG) neurons from embryonic chick. We are treating dissociated DRG with different concentrations of magnetic nanoparticle for 72 hours. We will then look for any change in the number of neurites, branches and neurite length. We except to see no effect on the morphology of neurons after magnetic nanoparticle treatment. Together, these results will test the feasibility of MNP nanocarriers for targeted drug delivery to encourage axon regeneration following nervous system damage.

Title: Transdifferentiation of human keratinocytes into oligodendrocyte progenitors

Authors: *P. MOHAMMAD GHARIBANI[1], C. KERR[2], S. CHUA[3], A. ALL[1,3];
[1]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Recent reports show that somatic cells can be directly converted to other mature cell types by using combined expression of defined factors. Here for the first time, we show that the same strategy can be applied to human keratinocytes to be directly converted into induced-human oligodendrocyte progenitors (i-hOPs). Epigenetically unstable state was developed using the single transcriptional factor Sox2 in human foreskin fibroblasts for 1 week. Then, i-hOP induction was carried out by using FGF2, EGF and PDGF for 2 weeks. We successfully derived these cells and not only expanded them for 3 months but also, extensively characterized them by Immunocytochemistry (ICC), Fluorescence activated cell sorting (FACS) and Western Blot (WB). Interestingly, our *in vitro* experiment revealed that these i-hOPs expressed oligodendrocyte (OL) markers even after 3 months expansion. We stained the i-hOP cells with O4 and NG2 antibodies for the FACS experiment. The Oligodendrocyte marker O4 reacts with late OL progenitors as well as OLs that have entered terminal differentiation, while NG2 (Neural/glial antigen 2) is present only on the surface of developing oligodendrocyte precursor cells. Analytical FACS results showed that almost 80% of the i-hOPs express O4, while only 20% of the i-hOPs express NG2. This data reveals that our i-hOPs are mostly oligodendrocyte progenitor cells. ICC of i-hOPs has also confirmed that more than 70% of the i-hOPs are O4 positive. In addition, we have also shown that these cells express O1, a late marker of OL. WB has shown that these i-hOP cells do not express nestin, a marker of stemness. Olig-1 is a bHLH transcription factor that is expressed by oligodendrocytes in the brain where it promotes OL formation and maturation. WB on our i-hOPs showed Olig-1 expression. In additional tests, the level of expression of MAG (Myelin Associated Glycoprotein) and MOG (Myelin Oligodendrocyte Glycoprotein) in i-hOPs after 3 months showed the potential of these cells to carry out myelination *in vitro*. Most importantly, the absence of K5, a marker of keratinocytes, in our i-hOP cells revealed that the proposed direct conversion of foreskin fibroblasts into OPs was successfully done without keratinocyte differentiation. This is a significant milestone, since these i-hOPs were derived directly from the transformation of adult human fibroblasts without an intermediate pluripotent state, which helps to avoid all limitations of using iPS derived cells. At the same time, these i-hOP cells will be patient-specific and optimal for a time-sensitive pathology like spinal cord injury, since these cells can be obtained in a shorter time with a higher yield and purity.

Title: Eugenol exhibits anxiolytic activity in diabetic encephalopathic rats

Authors: *J. KHAN, D. GARABADU, S. KRISHNAMURTHY;
Indian Inst. of Technol. (BHU), Varanasi, India

Abstract: Diabetic encephalopathy is considered as one of the most prevailing complication in type-2 diabetic population. Several synthetic drugs such as thiazolidinediones, dipeptidyl peptidase 4 (DPP-4) inhibitors, biguanides are used for type-2 diabetes mellitus (T2DM)-induced encephalopathic condition. However, their use is limited because several adverse effects such as hypoglycemia, weight gain and gastrointestinal symptoms are associated with them. Therefore, there is need to develop drugs for management of T2DM-induced neurological complications. Eugenol is a phenylpropanoid with several pharmacological activities including anti-stress activity. Therefore, we evaluated the neuroprotective effect of eugenol in T2DM-induced diabetic encephalopathy. In the present study, streptozotocine (45 mg/kg, i.p.) and nicotinamide (110 mg/kg, i.p.), at a time lag of 15 min, were injected to induced T2DM in male rats. After confirmation of diabetes in terms of plasma glucose level on day-7 after streptozotocine injection, the animals were treated with vehicle or metformin (25 mg/kg, p.o.) or eugenol (12.5, 25.0 and 50.0 mg/kg, p.o.) for four consecutive weeks. On the last day of the experiment (i.e. day-31), eugenol (50 mg/kg) exhibited anxiolytic activity in terms of increase in the T2DM-induced decrease in percentage in the entries and time spent into open arm in EPM test. The highest dose of eugenol also mitigated anxiety in diabetic encephalopathic rats in hole-board test in terms of increase and decrease in the number of head-dip and edge-sniff. Eugenol (50 mg/kg) attenuated hyperglycemia and hyperinsulinemia along with the improvement in insulin resistance and beta-cell function in T2DM-induced diabetic encephalopathic rats. Eugenol at the highest dose level also reversed the T2DM-induced mitochondrial dysfunction, integrity and oxidative stress (level of lipid peroxidation and activities of superoxide dismutase and catalase) in the amygdala. Hence, eugenol could be a potential candidate for the management of T2DM-induced diabetic encephalopathy.

Title: Metformin exhibits anxiolytic activity in experimental type-2 diabetic rats

Authors: *D. GARABADU, S. KRISHNAMURTHY;
Indian Inst. of Technol. (Banaras Hindu University), Varanasi, India

Abstract: Type-2 diabetes mellitus (T2DM) is mostly associated with several peripheral as well as central complications including anxiety. It has also been reported that the therapeutic regimen gains critical attention when there is a comorbid condition of T2DM and anxiety. Hence, it is necessary to investigate the pathophysiology of anxiety in T2DM condition. The insulin signaling glucose utilization pathway i.e., PI3K/Akt/GLUT-4 is deranged in T2DM condition along with mitochondrial dysfunction. However, there is no report on the cross-talk between PI3K/Akt/GLUT-4 signaling pathway and mitochondrial dysfunction in such comorbid condition. Therefore, the present study evaluated the relationship between PI3K/Akt/GLUT-4 signaling and mitochondrial dysfunction in T2DM-induced anxiety animals using metformin as standard drug. T2DM was induced in male rats by a single injection of nicotinamide (110 mg/kg, i.p.) and streptozotocine (45 mg/kg, i.p.) with a time lag of 15 min (day-1). Metformin (25 mg/kg, p.o.) was administered once daily for seven consecutive days from day-7. Metformin on day-13 exhibited anxiolytic activity by reversing the T2DM-induced increase in ambulation, rearing and percentage of time spent in the center during open-field test, decrease and increase in the number of head-dip and edge-sniff respectively and decrease in the ratio of head-dip to edge-sniff during hole-board test, and decrease in the percentage entries and time spent into open arm during elevated-plus maze test. Metformin showed anti-diabetic activity by mitigating the disturbed glucose homeostasis, beta-cell dysfunction and insulin resistance in T2DM rats. Metformin increased phosphorylated Akt level and translocation of GLUT-4 into the plasma membrane in amygdale of T2DM rats. Moreover, it mitigated T2DM-induced alterations in loss of mitochondrial integrity (mitochondrial membrane potential and level of expression of cytoplasmic cytochrome-C) and oxidative stress (lipid peroxidation) in amygdala. These observations suggest that there could be a direct relationship between derangement of PI3K/Akt/GLUT-4 signaling pathway and mitochondrial dysfunction in amygdale of T2DM-induced anxiety. Metformin was able to ameliorate these alterations in amygdale of these animals. Thus, metformin could be a therapeutic option in the management of co-occurring condition of T2DM and anxiety.

Title: Valosin-containing protein (VCP)/ p97 is a key mediator between autophagic cell death and apoptosis in adult hippocampal neural stem cells following insulin withdrawal

Authors: *B. YEO, C. HONG, S. JUNG, H. WOO, S.-W. YU;
Brain & Cognitive Sci., DGIST, Daegu, Korea, Republic of

Abstract: Programmed cell death (PCD) plays essential roles in regulation of survival and function of neural stem cells (NSCs). Abnormal regulation of this process is associated with aging and neurodegenerative diseases. However, the mechanisms underlying the PCD of NSCs remain largely unknown. Therefore, understanding the mechanism of PCD in NSCs is crucial for exploring therapeutic strategy for the treatment of neurodegenerative diseases. We have previously reported that adult rat hippocampal neural stem (HCN) cells undergo autophagic cell death (ACD) following insulin withdrawal without apoptotic signs despite their normal apoptotic capabilities. It is unknown how interconnection between ACD and apoptosis is mediated in insulin-deprived HCN cells. Valosin-containing protein (VCP) is known to be essential for autophagosome maturation in mammalian cells. In this study, we report that VCP regulates the rate of autophagic flux in HCN cells following insulin withdrawal, suggesting the novel roles of VCP at other steps of autophagy as well as maturation. Particularly, VCP is expressed abundantly in HCN cells compared to hippocampal tissue and neurons. Pharmacological and genetic inhibition of VCP significantly decreased ACD and autophagy markers, while apoptotic cell death was induced in insulin-depleted HCN cells. Taken together, these data demonstrate that VCP may play an essential role in completion of ACD and mediation of crosstalk between ACD and apoptosis in HCN cells following insulin withdrawal. Elucidating the mechanism by which VCP regulates the crosstalk of ACD and apoptosis will contribute to understanding the molecular mechanism of PCD in NSCs.

Title: Dual Leucine-Zipper Kinase (DLK) dependent regulation of the Integrated Stress Response contributes to neurodegenerative and neuroregenerative responses

Authors: *M. LARHAMMAR[1], S. HUNTWORK-RODRIGUEZ[1], A. SENGUPTA GHOSH[1], Z. JIANG[1], H. SOLANOY[1], J. EASTHAM-ANDERSON[1], J. S. KAMINKER[2], J. W. LEWCOCK[1], T. A. WATKINS[3,1];
[1]Neurosci., [2]Bioinformatics, [3]Phamacodynamic Biomarkers within Develop. Sci., Genentech Inc, South San Francisco, CA

Abstract: Characterization of the cellular pathways activated upon neuronal stress is essential for our understanding of the underlying mechanisms contributing to neurodegenerative diseases. Axonal damage triggers both regenerative and apoptotic responses, yet the molecular pathways mediating these divergent outcomes remain elusive. The ISR can be engaged by a variety of insults, from oxidative stress to viral infection, and has recently emerged as a putative mediator in neurological conditions. In the present study we employed a combination of molecular biology techniques, pharmacology and nerve injury models in transgenic mice to show that the Integrated Stress Response (ISR) is activated upon neuronal stress and influences transcriptional and functional outcomes *in vitro* and *in vivo*. We observed activation of the ISR-associated protein kinase R (PKR)-like endoplasmic reticulum (ER) kinase (PERK, EIF2AK3) and up-regulation of Activating Transcription Factor-4 (ATF4) protein following sciatic and optic nerve injuries in mice. Disruption of either ATF4 or PERK enhances axon regrowth from adult sensory neurons *in vitro*, and neuronal-specific deletion of PERK in mice improves survival of retinal neurons after optic nerve damage. Furthermore, we demonstrate that an essential regulator of MAP kinase neuronal stress response pathways, Dual Leucine-Zipper Kinase (DLK, MAP3K12), is also required for ISR activation and that inhibition or deletion of DLK reduces the ISR *in vitro* and *in vivo*. Taken together, our current findings imply that the ISR is a critical component of the broad DLK-mediated stress response and a significant contributor to neuronal fate, highlighting the clinical potential of targeting the ISR in disease.

Title: TCP and CPFO, the metabolites of CPF induce neurotoxicity in SH-SY5Y cells

Authors: *H. DAI[1], L. ZHAO[1], Y. DENG[1], J. ZHANG[2];
[1]Third Xiangya Hosp. of Central South Univ., Hunan, China; [2]Dept. of neurology, the Second Xiangya Hosp. of Central South Univ., Hunan, China

Abstract: Chlorpyrifos (CPF) is one of the most widely used organophosphate pesticides. CPF can be converted into its active neurotoxic metabolite chlorpyrifos oxon (CPFO) by cytochrome P450-dependent oxidative desulfuration. Both CPF and CPFO can be hydrolyzed to 3,5,6-trichloro-2-pyridinol (TCP) in a detoxification pathway. A large amount of research has proved that CPF exposure was associated with neurodevelopmental disorders. However, the mechanism of neurotoxicity of the metabolites remain a mystery although it has been reported that CPFO had toxic effect on nervous systems through inhibiting AchE. In present study, we tested the major metabolites TCP and CPFO in dopaminergic SH-SY5Y cells, and check their effects on cell morphology, proliferation and apoptosis and autophagy. Our results showed that both of the two metabolites could decrease SH-SY5Y cell viability,inhibit proliferation, produce excessive ROS and cause cell death via caspase-dependent pathway. Furthermore, we also found that TCP and CPFO can induce autophagy in dopaminergic cell as well as CPF. Interestingly, not only CPF but also its major two metabolites TCP and CPFO can produce excessive ROS. And further research showed only CPF itself can induce significant mitochondrial fragmentation and reduce the potential of mitochondrial membrane which suggested that there were some differences in mechanisms of neurotoxicity between CPF and its metabolites . In conclusion, metabolites TCP and CPFO is neurotoxity as well as CPF itself.

Title: Regulation of neuronal death and survival by interaction of pro and anti-death versions of Bcl-xL with the mitochondrial permeability transition pore

Authors: *H.-A. PARK[1], P. LICZNERSKI[1], P. MIRANDA[1], Y. NIU[1], S. SACCHETTI[1], K. N. ALAVIAN[2], E. A. JONAS[1];
[1]Yale Sch. of Med., New Haven, CT; [2]Imperial Col. London, London, United Kingdom

Abstract: ABT-737 is a pharmacological inhibitor of the anti-apoptotic activity of B-cell lymphoma-extra large (Bcl-xL) protein; it functions by occupying the BH3-binding domain, supporting apoptosis of cancer cells. We have shown that ABT-737 lowers neuronal metabolic efficiency by inhibiting ATP synthase activity. However, we unexpectedly found that ABT-737 protects brains from ischemic injury *in vivo*. We reported that ABT-737 inhibited formation of the pro-apoptotic, cleaved form of Bcl-xL, ΔN-Bcl-xL. In this study, we find that a high concentration of ABT-737 (1μM) blocks the effects of full length Bcl-xL but a low concentration of ABT-737 (10 nM) inhibits ΔN-Bcl-xL. We tested whether ABT-737 exerts neuroprotective properties by altering mitochondrial membrane permeability during cell death stimuli. We found that ΔN Bcl-xL levels are enhanced after glutamate-induced excitotoxicity. Pre-treatment of neurons with 1μM ABT-737 aggravated glutamate-induced death. We observed a loss of mitochondrial potential and a decline in ATP production in high ABT-737 and glutamate treated cells. In contrast, pre-treatment with 10nM ABT-737, a hundred fold lower concentration, rescued neurons from death and augmented mitochondrial potential and ATP production similarly to effects of Cyclosporine A (CsA) during glutamate challenge. Incubation of recombinant ΔN-Bcl-xL protein with isolated mitochondria significantly reduced mitochondrial potential, rescued by CsA or low ABT-737, suggesting involvement of the mitochondrial permeability transition pore. To confirm this, we depleted the c-subunit of the ATP synthase. We found that c-subunit depletion is neuroprotective against ΔN Bcl-xL accumulation in glutamate-exposed neurons. Our findings suggest that low concentrations of Bcl-xL inhibitors may promote

survival by preferentially binding to the pro-apoptotic form of Bcl-xL even as high concentrations potentiate cell death in malignant cells.

Title: Induced Mitophagy alters localization of TDP-43

Authors: S. ITAMAN[1], K. GAN[1], S. A. DAVIS[1], *M. A. GITCHO[1,2];
[1]Biol. Sci., Delaware State Univ., Dover, DE; [2]Delaware Ctr. for Neurosci. Res., Dover, DE

Abstract: TAR DNA binding protein (TDP-43) is a heterogeneous nuclear ribonucleoprotein (hnRNP) involved in mRNA stability and transport. While, TDP-43 is a major pathological protein in frontotemporal dementia and motor neuron disease, it also accumulates in ~50% of Alzheimer's disease (AD) cases. Besides TDP-43, dysfunctional mitochondria are one of the main underlying factors of neurodegenerative diseases. Studies have shown that overexpression of the full length TDP-43 and its C-terminal fragments activated mitophagy in a motor neuron cell line (NSC34). However, the relationship between TDP-43 and mitophagy is still unclear. We hypothesize that the induction of mitophagy causes the localization of TDP-43 from the nucleus to the mitochondria. We utilized carbonyl cyanide m-chlorophenyl hydrazone (CCCP) to disrupt the proton gradient established by the electron transport chain and subsequently are able to induce mitophagy in cells. We have found that TDP-43 localizes to the mitochondria following CCCP treatment in SH-SY5Y cells and primary cortical neurons. Further experiments are needed to delineate the role of TDP-43 in mitochondria metabolism particularly in neurodegenerative diseases.

Title: Pro-survival role of thioredoxin reductase under metabolic stress condition: interplay between autophagy and apoptosis

Authors: *N. PANDIAN[1], M. IQBAL[2], E. EFTEKHARPOUR[3];
[1]Physiol., Dept. of Physiology, Univ. of Manitoba, Winnipeg, MB, Canada; [2]Physiol., Dept. of Physiol. and Pathophysiology, Univ. of Manitoba, Winnipeg, MB, Canada; [3]Physiol. and Pathophysiology, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Autophagy is a cellular physiologic phenomenon for normal turnover of long-term proteins and organelles. Temporary shortage of nutrients enhances autophagy through inhibition of new protein synthesis which prompts the cells to use their organelles as energy source. Upon resumption of growth material autophagy will be scaled back and cells will continue their normal activities. While short term autophagy is necessary to ensure cell survival during the stress conditions, prolonged autophagy will result in cell death. Although apoptotic cell death is the most common studied form of cell death after neurotrauma and ischemia, increasing evidence indicates the involvement of autophagy as an undergoing but less investigated form of cell damage. Rationale for studying autophagy comes from reports of functional improvements after application of autophagy inhibitors or inducers in neurotrauma or ischemia. This warrants the need for understanding the molecular mechanisms of autophagy that may lead to identification of novel therapeutic tools for CNS treatment. Oxidative stress is a major inducer of cell death. Upregulation of oxidizing agents such as oxygen and nitrogen reactive species results in oxidation of many signaling molecules and induction of autophagy or apoptosis. Thioredoxin (Trx) system is a major regulator of protein oxidation and modulator of oxidative damage. Trx is

responsible for reduction of oxidized proteins but is oxidized in this process. Thioredoxin reductase (TrxR) reduces Trx and therefore maintains the reducing capacity of the cell. TrxR is upregulated under stressful conditions and its inhibition results in cell death. The exact role of TrxR in induction of autophagy or apoptosis has not been investigated. In this study we used neuroblastoma cell line (SH-SY5Y) to study autophagy and apoptosis under normal (10% serum) and metabolic stress (0% serum) conditions. TrxR was inhibited using pharmacological inhibitors, and gene-delivery approaches. We observed that inhibition of TrxR in normal growth conditions promotes apoptosis as indicated by upregulation of caspases. This was associated with upregulation of endoplasmic reticulum (ER) stress markers IRE1, and ATF6. Serum deprivation resulted in 40% cell death that was associated with upregulation of autophagy and apoptosis markers. Serum deprived SH-SY5Y cells were several folds more sensitive to TrxR inhibition and after inhibition of TrxR, apoptosis was the prevalent form of cell death. This is the first study to investigate the role of TrxR in normal and stressed conditions. Our observations further confirm the potential therapeutic capacity of Trx system for neuroprotection.

Title: The pro-survival role of cytosolic p53 in adult hippocampal neural stem cells

Authors: ***S. J. JUNG**, K. CHUNG, H. RYU, C. J. HONG, H. PARK, H. WOO, B. YEO, S.-W. YU;
DGIST, Daegu, Korea, Republic of

Abstract: Programmed cell death (PCD) of neural stem cells (NSCs) plays a critical role in the development and function of the central nerve system. Previously, we have reported that adult hippocampal neural stem (HCN) cells undergo autophagic cell death (ACD) following insulin withdrawal despite their intact apoptotic capabilities. Here, we demonstrate that p53 is involved

in regulation of HCN cell survivals. Basal p53 expression level is high in HCN cells, yet is degraded in response to cell death signals, such as insulin withdrawal and staurospourine (STS). Interestingly, p53 is degraded by autophagy following insulin withdrawal, whereas p53 degradation is mediated by ubiquitin proteasome system (UPS) in STS-induced apoptosis. p53 is transcriptionally inactive and localized mostly in the cytosol in HCN cells. Overexpression of p53 mutant targeted to the cytosol significantly reduced cell death after STS treatment. In summary, high expression level and cytosolic location of p53 and anti-apoptotic effects of cytosolic p53 suggest the interesting transcription-independent, pro-survival role of p53 in HCN cells. Understanding the role of p53 in response to cell death signals would help to understand the cell death mechanism of HCN cells.

Title: Amp-activated protein kinase contributes to zinc neurotoxicity in mouse cortical cultures via activation by lkb1 and induction of bim

Authors: J.-W. EOM[1], *Y.-H. KIM[2];
[1]Sejong university, Seoul, Korea, Republic of; [2]Sejong Univ., Seoul, Korea, Republic of

Abstract: Previously, we reported that zinc neurotoxicity, a key mechanism of ischemic neuronal death, was mediated by PARP over-activation and following NAD^+/ATP depletion in cortical culture. Since AMP-activated protein kinase (AMPK) can be activated by ATP depletion and some reports showed that AMPK plays a key role in excitotoxicity and ischemic neuronal death, we examined in this study, whether AMPK is involved in zinc neurotoxicity in mouse cortical neuronal cultures. Suggesting the essential role of AMPK, Compound C, a chemical inhibitor of AMPK, significantly attenuated zinc-induced neuronal death. Activation of AMPK was detected from 2 hr after the onset of 10 min exposure of mouse cortical neurons to 300 μM zinc. However, AMPK activation in zinc neurotoxicity may not be induced by the increase of intracellular AMP level, because the significant change of AMP level was detected from 4 hr

after zinc treatment in cortical neurons. As an upstream signaling pathway, we observed the involvement of Liver kinase B1 (LKB1) but not Ca^{2+}/calmodulin-dependent protein kinase kinase β (CaMKKβ). Although STO-609, a chemical inhibitor of CaMKKβ, significantly attenuated zinc neurotoxicity, zinc-induced AMPK activation was not affected by STO-609, suggesting the non-mediation by CaMKKβ of AMPK activation. In the case of LKB1, knock-down using the specific siRNA for LKB1 significantly reduced zinc neurotoxicity as well as zinc-induced AMPK activation, indicating the possible role of LKB1 as an upstream kinase for AMPK. In addition, we found that mRNA and protein level of Bcl-2 homology domain 3 (BH3)-only protein Bim, a pro-apoptotic Bcl-2 family member, was noticeably increased in zinc neurotoxicity in an AMPK-dependent manner. Consistently, caspase-3 activation in zinc neurotoxicity was also mediated by LKB1 and AMPK activation. These results suggest the possibility that AMPK is a key signaling molecule to induce zinc-induced neuronal death via up-regulation of Bim and resultant activation of caspase-3 in zinc neurotoxicity. **Keywords**: AMPK, brain ischemia, LKB1, Bim, caspase-3, neuronal death, zinc

Title: Modulation of mitochondrial dynamics by high-extracellular glucose in nerve growth factor (NGF)-differentiated PC12 cells

Authors: *A. E. SOSA ESCALANTE[1], R. DIAZ-ESCARCEGA[1], J. MANZO-DENES[2], C. MORGADO-VALLE[2], L. BELTRAN-PARRAZAL[2];
[1]Doctorado en Investigaciones Cerebrales, [2]Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstract: In the nervous system, high-extracellular glucose has been proposed as a cause of mitochondrial dysfunction, generating drastic changes in the mitochondrial dynamics, and

therefore damaging neurons. It is unknown whether high extracellular glucose affects directly the mitochondrial dynamics, or if it produces changes on other molecular mechanisms that affect indirectly the mitochondria. In the presence of high-extracellular glucose, there are changes in the rates of mitochondrial fusion and fission (Kumari et al, 2012). However, there is not information regarding the effect of high-extracellular glucose on mitochondria number and length, and how could this affect fusion and fission rates. Here, we used PC12 cells differentiated to sympathetic-like neurons by NGF as a model of peripheral axons to measure mitochondrial velocity in the presence of high-extracellular glucose. We tested a high-extracellular glucose concentration (75 mM) and compared with control concentration (25 mM). After incubation period, we dyed mitochondria with the specific marker MitoTracker Green. Using fluorescence microscopy, we acquired time-lapse videos and generated kymographs of mitochondria. Our data shows that high-extracellular glucose decreases significantly the mitochondrial velocity from 0.233 ± 0.074 μm/s in control conditions to 0.012 ± 0.012 μm/s in 75 mM glucose. We did not found significant differences in the total number of mitochondria in both conditions, however we found a significant decrease in the number of short mitochondria. Our results suggest the 75 mM extracellular glucose modulates mitochondrial transport and decreases mitochondrial velocity in PC12 cells differentiated to neurons.

Title: The effect of dichloroacetate on mitochondrial metabolism and brain injury after hypoxia ischemia in neonatal mice

Authors: ***T. LI**[1,2,3], Y. SUN[2,4], C. XIE[4,5], Y. ZHANG[4,3], K. ZHOU[4,5], K. BLOMGREN[4,5], C. ZHU[2,4];

Hosp., Stockholm, Sweden

Abstract: Background: Dichloroacetate (DCA) is a small molecule that crosses the blood-brain barrier and activates pyruvate dehydrogenase (PDH). DCA shows substantial efficacy in a variety of brain injury models, but there is no report yet on its efficacy in neonatal brain injury. **Objective:** To evaluate the therapeutic effectiveness of DCA treatment in neonatal mice after hypoxia-ischemia (HI). **Design/Methods:** Nine-day-old male mouse pups were subjected to unilateral HI, and 100 mg/kg DCA was injected intraperitoneally immediately after HI. Additional DCA injections were administered 24 h and 48 h after HI, and the extent of brain injury was evaluated 72 h after HI. Some pups were sacrificed 24 h after HI and the mitochondrial fraction was isolated. **Results:** Brain injury, as indicated by infarction volume, was reduced by 54.2% from 10.80 mm^3 ± 1.86 mm^3 in the vehicle-only control group to 4.94 mm^3 ± 1.05 mm^3 in the DCA-treated group 72 h after HI (p=0.008). Injury was reduced in the cortex, hippocampus, thalamus, and striatum, and the protective effect was greatest in the cortex and thalamus. Furthermore, treatment with DCA significantly reduced white matter loss analyzed by measuring the MBP-positive volume (p=0.018). Caspase-3 activity was increased dramatically 24 h after HI, and DCA treatment reduced caspase-3 activation significantly (p=0.0421). PDH activity in the mitochondria was decreased in the ipsilateral hemisphere after HI compared with the contralateral hemisphere (p=0.0037), and DCA treatment prevented the decrease in PDH activity. The amount of acetyl-CoA in mitochondria was significantly higher after HI with DCA than that of with PBS treatment (p=0.024). **Conclusion**: DCA treatment in neonatal mice reduced HI brain injury. This effect might be related to the activation of PDH and a subsequent reduction in lactate acidosis, caspase-3 activation and neuronal cell death.

Title: Gene expression profile in glioblastoma multiforme

Authors: *N. CARKACI-SALLI[1], J. M. SHEEHAN[2], J. W. BACCON[3], T. ABRAHAM[4], K. E. VRANA[1], R. E. HARBAUGH[2], M. GLANTZ[2];

Abstract: The most aggressive type of brain tumor is glioblastoma multiforme (GBM). Currently, temozolomide (TMZ), combined with radiation, is the most effective therapy for GBM, but chemoresistance, that occurs in tumors, limits the efficacy of this treatment. To understand the molecular and cellular processes that underlie temozolomide resistance in GBM tumors we investigated alterations in protein expression, gene expression in primary GBM tumors from patients with different survival phenotypes (primary tumors for which there was not tumor recurrence after TMZ treatment) and patient primary tumors for which there was tumor recurrence. After proteomics analysis 92 spots out of over 2200 protein spots were found to be differentially-expressed. Of these, 16 up-regulated proteins and 15 down-regulated spots were chosen for identification by mass spectrometry. Individual specimens subjected to gene expression analysis Gene expression of Vimentin (VIMA) (P=0.01)(1.8 fold decreased in proteomics), LIM and SH3 domain protein (LASP1) (P=0.01) (1.9 fold decreased in proteomics), AnnexinA2 (ANXA2) (p=0.01) (3.2 fold decreased in proteomics) and AnnexinA5 (ANXA5)(P=0.01) (4.4 fold increased in proteomics), Coactosin-like protein (COTL1) (0.05) (3.5 fold increased in proteomics) , S100 calcium binding protein A9 (S10A9)(P=0.04) (3.7 fold increased in recurrent patients' primary tumor in proteomic) were found significantly different. Multidrug resistance gene (MDR1) (P=0.02), UDP-glucose ceramide glucosyltransferase (UGCG) (p=0.02), C-X-C chemokine receptor type 4 (CXCR4)(P=0.04) gene expression elevated in the recurrent tumor specimens in the targeted genes. These results suggest that VIMA, LASP1, AnnexinA2, AnnexinA5, COTL1, S10A9, MDR1, UGCG and CXCR4 were significantly plays role on recurrence of GBM tumors.

Title: Cortical thickness in the contralesional hemisphere is related to survival length and tumor diffusivity in long-term survivors of glioblastoma multiforme

Authors: *C. DE LOS ANGELES, K. I. ALPERT, J. JACOBS, A. W. RADEMAKER, J. J. RAIZER, K. R. SWANSON, L. WANG;
Northwestern U Feinberg Sch. of Med., Chicago, IL

Abstract: Background: Patients with glioblastoma multiforme (GBM) provide a clinical population to study brain structural response to a lesion. GBM patients survive a median of 16 months with a small subset living longer than three years (reported rates: 3-10%). Some information exists about patient and tumor factors that relate to increased survival including younger age, higher Karnofsky Performance Status score, and certain tumoral gene mutations. Our study was concerned with identifying a neuroimaging marker of long-term survival using the presenting diagnostic magnetic resonance imaging (MRI) scan. This study assessed structural neural compensation by examining the contralesional (opposite hemisphere of tumor) hemisphere cortical thickness in GBM patients. Methods: We computed contralesional gray matter cortical thickness using the pre-treatment, diagnostic T1-weighted MRI. Cortical thickness was determined using Freesurfer. These structural measures were categorized as less than or greater than the population median. Days of survival was calculated from date of diagnosis until death. $\chi 2$ and logistic regression analyses were performed in SPSS. Patients who lived longer than three years were considered long term survivors. Results: In our preliminary studies, we found that in right-sided temporal lobe GBM patients (n = 39), cortical thicknesses within regions of the contralesional temporal lobe were associated with or showed a trend toward significance with long-term survival after controlling for age at diagnosis, sex, and tumor volume (entorhinal cortex $p = 0.040$; transverse temporal cortex $p = 0.074$). Moreover, cortical thicknesses in a region that was thicker in long-term survivors, the tranverse temporal cortex, positively correlated to patient tumor-specific diffusivity measures ($r = 0.626$, $p = 0.001$); more diffuse tumors displayed greater contralesional cortical thickness. Conclusions: In long-term survivors with GBM, increased contralesional cortical thickness is seen at diagnosis and related to tumor diffusivity, suggesting brain structural compensation. Work is ongoing to assess other

regions and to further understand the relationship between contralesional brain structural measures, tumor characteristics, and survival.

Title: RNA-seq expression profiling of ion channels in glioblastoma stem cells

Authors: *J. POLLAK[1], P. J. PADDISON[2], R. C. ROSTOMILY[3,4], J.-M. RAMIREZ[1,3]; [1]Seattle Children's Res. Inst., Seattle, WA; [2]Human Biol. Div., Fred Hutchinson Cancer Res. Ctr., Seattle, WA; [3]Dept. of Neurosurg., [4]Inst. for Stem Cell and Regenerative Med., Univ. of Washington, Sch. of Med., Seattle, WA

Abstract: Glioblastoma multiforme (GBM) is a prevalent and highly aggressive type of brain tumor. Glioblastoma stem cells (GSCs) play a major role in tumor formation and malignancy owing to their rapid self-renewal, invasiveness, and chemotherapeutic resistance. Evidence suggests that disruption of ion balance through ion channel and transporter perturbation within glioma cells contributes to malignant invasion and proliferation. Neural activity from surrounding brain regions may also augment glioma malignancy, suggesting a role for voltage- or ligand-dependent communication between glioma cells and surrounding neurons. To comprehensively assess the expression of multiple families of ion channels, transporters, and receptors that may contribute to glioma malignancy, we profiled the transcriptomes of patient-derived GSCs using RNA-seq analysis. Nineteen distinct lines of GSCs, which were derived from patient GBM tumors and propagated as stem cell cultures, were processed in triplicate for RNA sequencing. GSC samples were processed and analyzed in tandem with transcriptome data from human astrocyte and neural stem cell lines. Unique subsets of ion channels, transporters, and neurotransmitter receptors were identified by Gene Set Enrichment Analysis (Broad Institute) to be highly enriched across multiple lines of GSCs compared with astrocytes and neural stem cell controls. These results were compared with transcriptome analysis of bulk GBM tumor cells and normal brain tissue from The Cancer Genome Atlas in order to identify ion channels unique to GSCs. Based on their ion channel expression profile alone, GSC lines clustered without bias by GBM molecular subtype classification, and expression levels of

individual ion channels significantly correlated with molecular subtype. Real-time PCR analysis confirmed expression of genes of interest across multiple GSC lines. These data suggest that candidate ion channels and transporters may be unique identifiers of glioblastoma stem cells compared with other neural and tumor cell types and may play an important role in GSC malignant properties; the functional implications of these findings will be discussed.

Title: Cisplatin (CDDP) modifies the protein expression of IP3R and RYR as well as interacts with Ca^{2+} -ATP-ase dependent calcium management of SH-SY5Y neuroblastoma cells

Authors: *D. BUSSELBERG[1], A. SAYED[2], E. VARGHESE[2], A.-M. FLOREA[3]; [1]Weill Cornell Med. Col. In Qatar, Doha, Qatar; [2]WCMC-Q, Doha, Qatar; [3]Neuropathology, Univ. Dusseldorf, Dusseldorf, Germany

Abstract: Neuroblastoma is a childhood cancer with limited treatment options. While chemotherapy with cisplatin (CDDP) is used in current treatment schemes the underlying mechanisms behind successful anticancer treatment are yet not well understood. It is now accepted that CDDP modulates the intracellular calcium signal ($[Ca^{2+}]_i$) due to a facilitation of calcium entry from the extracellular space. Therefore, here we investigate whether CDDP treatment of neuroblastoma cells will result in changes of the protein expression of IP3R and RYR (ITPR1, ITPR3, RYR1, and RYR3) and whether the Ca^{2+} -ATP-ase dependent calcium management is changed after the application of CDDP. Confocal microscopy imaging of ITPR1, ITPR3, RYR1, and RYR3 show that only RYR1 has a nuclear localization however, due to CDDP treatment (2.5 or 5μM CDDP for 24h) it was found translocated into the cytoplasm of neuroblastoma cells. In the same experimental conditions, the FACS analysis of SH-SY5Y cells showed no significant changes in expression of RYR1, RYR3 and ITPR1, but was an increase in ITPR3 (from 32% to ~50%). To further explore the role of CDDP in Ca^{2+} release from SH-SY5Y, cells labeled with Fura2-AM were treated with CDDP (5μM) in calcium free media.

When CDDP was applied to neuroblastoma cells, after pre-treatment with thapsigargin, the time till the rise of calcium was observed increased by 7-9 times, and by 6-times when added before and after treatment with thapsigargin. The slope (time to reach the calcium peak) was doubled. Recovery was prolonged in a similar way. Overall, CDDP changes the expression and localization of IP3R and RYR and modulates the Ca^{2+} -ATP-ase dependent calcium management of neuroblastoma cells.

Title: Alterations in functional connectivity due to brain tumor growth in a mouse model of glioma

Authors: *I. ORUKARI[1], A. Q. BAUER[2], E. A. SLAT[3], J. B. RUBIN[3], J. P. CULVER[2]; [1]Radiology, Washington Univ. In St Louis, St Louis, MO; [2]Radiology, [3]Pediatrics, Washington Univ. in St Louis, St Louis, MO

Abstract: Background: Gliomas are known to cause significant neuropsychological deficits in humans. We assessed the effects of tumor growth on resting-state functional connectivity in a mouse model of glioma. The resting-state functional connectivity data was obtained using functional connectivity optical intrinsic signal (fcOIS). This technique allowed us to perform functional neuroimaging on the small mouse brain. Methods: Gliomas cells (10^5 U87) were stereotactically injected into the cortical region in between the motor cortex and hindpaw and forepaw somatosensory cortex of adult nude mice. A plastic cover slip was affixed to the exposed skull of the mice for serial OIS imaging. OIS imaging was performed following our previously published protocol [1]. Seed based functional connectivity analysis was performed on the OIS images to monitor how brain tumor growth affects functional brain networks. Bilateral functional connectivity maps - maps of the correlation value between a pixel and the corresponding pixel in the contralateral hemisphere - were obtained as a metric of functional network disruption. Results: The region of decreased bilateral functional connectivity increased in size with time (Figure 1). Conclusions: We have shown that fcOIS is capable of detecting

alterations to brain function due to brain tumor growth. Our data show that tumor tissue becomes functionally disconnected from the contralateral hemisphere. Ongoing studies are incorporating bioluminescence to independently track the number of tumor cells to provide an improved estimate of the tumor size. A better understanding of the role brain tumors play in the development of functional brain deficits may lead to improved outcomes after neurorehabilitation. Abstract: Glioblastoma multiforme (GBM) is one of the most aggressive and infiltrative primary tumor formations of the central nervous system. Current therapies are ineffective in eradicating this deadly type of tumor. In fact, the resurgence of GBM is almost inevitable and patient outcome following diagnosis remains dismal. Therefore, a novel and efficacious therapy is desperately needed to prevent tumor resurgence and improve patient outcome and quality of life. Mesenchymal stem cells (MSCs) have recently become a very popular avenue for the delivery of a variety of molecules and substances, and of particular interest to this project is their ability to release endogenous anti-inflammatory cytokines, such as interleukin-10 (IL-10). Importantly, solid tumors often secrete pro-inflammatory cytokines in an effort to increase angiogenesis and nutrient support to promote further proliferation. Specifically, the MSC therapy utilized in this study aimed to diminish this pro-inflammatory effect and ultimately slow and eradicate tumor progression. To these ends 24 rats were randomly placed into three groups: SHAM controls (n=8) received only vehicle treatments; the F98 group (n=8) received only a transplantation of F98 tumor cells; and the F98+MSC group (n=8) received a transplantation of MSCs seven days post-F98 transplantation. Stem cell grafts were placed adjacent to the tumor bed in order to promote the optimal release of anti-inflammatory signaling molecules. All animals were euthanized 21 days following F98 transplantations and histological analyses were performed to compare tumor size and inflammatory response between each group. Results indicated that the ipsilateral MSC treatment was unable to affect the inflammatory response produced by the tumor, nor significantly mitigate tumor growth. However, current studies aim to investigate the optimization of the stem cell graft to tumor cell ratio as well as the utilization of stem cells over-expressing these endogenous signaling molecules and their effects on tumor proliferation. Support for this study was provided by the Office of Research and Sponsored Programs at CMU, the College of Medicine, and the Field Neurosciences Institute and John G. Kulhavi Professorship.

Title: Activation of a putative membrane androgen receptor increases the efficacy of the chemotherapeutic agent, temozolomide, in a human glioblastoma cell line

Authors: C. A. BROCK, A. BADEAUX MCGILVRAY, *M. SINGH;
Pharmacol. & Neurosci., Univ. North Texas Hlth. Sci. Ctr-Ft. Worth, Fort Worth, TX

Abstract: Glioblastoma Multiforme (GBM) is a form of brain cancer with very poor prognosis such that the life expectancy of a person with this disease is about one year after diagnosis. Moreover, current treatment regimens are only able to extend the life span by mere months. Based on recent studies from our lab that identified a putative membrane androgen receptor (mAR), which when activated is capable of promoting cell death, we investigated whether exploitation of this receptor could increase the efficacy of current chemotherapeutic agents to combat this deadly and invariably lethal cancer. Using the human glioblastoma cell lines, A172 and T98G, our studies have shown that activation of the mAR (using testosterone or dihydrotestosterone conjugated to bovine serum albumin) not only sensitized the glioblastoma cells to temozolomide (TMZ), the current standard chemotherapeutic agent for GBM, but also suppressed the phosphorylation of Akt, a known survival-promoting factor. Further, in T98G cells that express high levels of O6-methylguanine DNA methyltransferase (MGMT), a DNA repair protein, activation of the mAR suppressed the expression of MGMT. Our data also suggest that these mechanisms may not be mutually exclusive such that inhibition of Akt phosphorylation in and of itself led to a reduction in MGMT expression. Collectively, our data support the targeting of a putative membrane androgen receptor as complementary treatment for glioblastoma.

Title: Selective inhibition of survival of malignant astrocytoma by conjugated linoleic acid. Implication in anti-glioma therapy

Authors: A. S. SILVA-RAMIREZ[1], H. M. GONZALEZ-SANCHEZ[2], C. G. CASTILLO[2], A. ROCHA-URIBE[1], M. M. GONZALEZ-CHAVEZ[1], S. F. ALI[3], E. RANGEL-LOPEZ[4], A. SANTAMARIA[4], *C. GONZALEZ, V[1];

Abstract: Glioblastoma multiforme (GBM), a fast-growing glioma that develops from astrocytes, is the most aggressive brain tumor in adults due to the rapid spread and failed treatments. Current chemotherapeutic agents are known to have a low therapeutic index in brain tumors, first due to the inability of anticancer agents to reach the brain tissue and secondly by their low selectivity towards cancer cells. Synthetic agonists of peroxisome proliferator-activated receptor-gamma (PPARγ) have shown decrease the viability of malignant astrocytoma cells without affecting the viability of primary astrocytes through a PPARγ independent pathway. Conjugated linoleic acid (CLA) is a natural PPARγ-agonist which cross blood-brain barrier and induce anti-tumor activity on glioblastoma cells; however, neither the mechanisms of action involved in the anti-glioma effect of CLA nor its toxicity on primary astrocytes has been elucidated. The aim of this study was to evaluate if CLA induced a selective cytotoxicity mediated by ROS or NO production on GBM without affecting primary astrocytes. Primary astrocytes isolated from male and female newborn Wistar rats and C6 glioma cells (rat GBM) were exposed for 24 or 72 hours to CLA (5, 10, 25, 50 and 100 uM) obtained by chemical synthesis assisted by microwave irradiation. Cell viability was measured by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Cytotoxicity was determined by lactate dehydrogenase (LDH) test. The decrease in mitochondrial membrane potential (MMP) in apoptotic cells was associated with a reduction in the uptake of 3,3' dihexyloxacarbocyanine iodide (DiOC6(3)). Reactive oxygen species (ROS) were monitored using a 2',7'-dicholofluoroscein diacetate (DCFH-DA) assay and nitric oxide (NO) levels were determined using the Griess reaction. The PPARy involvement in cell signaling was assessed using the antagonist Bisfenol a diglicidil eter (BADGE). CLA treatments, since 24 hours, resulted in a significant decrease in cell viability of GBM without affecting primary astrocytes. The PPARy antagonist did not block the anti-glioma effect induced by CLA, indicating that the receptor is not involved in the mechanism of action. No significant changes in extracellular LDH or NO levels were detected. Data indicate that CLA exposure activates oxidative stress pathways, interferes with the mitochondrial electron transport chain and induces apoptosis, suggesting that CLA may represent a novel adjuvant therapeutic alternative in the treatment of GBM without causing adverse side effects. However, additional experiments are needed to determine the mechanism of action involved.

Title: Effects of irinotecan nanoparticles on viability rates of glioblastoma multiforme and neurons

Authors: ***H. AHMET**[1], A. TAGHİZADEHGHALEHJOUG[2], U. OKKAY[2], N. TASPINAR[2], K. NALCI[2], M. TASPINAR[5], M. CETIN[3], A. UYANIK[4], S. BUTUNER[2];

Abstract: Introduction: It is crucial to development of technology based, efficient tumor cell-targeted therapies for treating GBM. Polymeric nanoparticles (PNPs), especially poly-(DL-lactic-co-glycolic) acid (PLGA), have been used as an anti-tumor drug delivery vehicle which carries drug into the targeted tumor cells by their unique biodegradable properties, controlled release and intrinsic encapsulated empty area. Irinotecan, a semi-synthetic competitive analogue of topoisomerase-I enzyme, is an important and affective chemotherapeutic. It shows high activity against a wide spectrum of malignancies, including GBM. It has been reported that irinotecan loaded liposome useful for colorectal cancer (1). Matherial and method: For this study ethical permission is taken with the number 36643897-13. Brain cortex were obtained from 6 Sprague Dawley Rat which were one day old. U87MG culture were obtain from Van Yuzuncu Yil university. Cell cultures were performed. 100 Sprague Dawley Rats (250±10 gr) were chosen and performed GBM model using U87MG cell line. 8×105 cells were injected stereotactically into the brain; 1mm anterior to bregma, 2.5mm left to bregma and 4mm below into the nigrostriatal region. 15 days after injection drugs were injected directly into cancer region. From sections in pathology, the tumor areas were measured using cavalier principle. Results and

Discussion: Irinotecan was found effective on cancer cells. PLGA didn't give any damage alone. PLGA+irinotecan can be used for GBM therapy *in vivo*. PLGA didn't decrease the activity of irinotecan. Irinotecan + PLGA doses found more effective on cancer cells. We can postulate that slower releasing *in vivo* may be more effective on cancer cells. References: 1-Park, J., H. V. Pham, K. Title: Expression patterns of multiple antigens evaluated by immunochemistry in individual glioblastoma patient samples

Authors: *M. E. BARISH[1], L. WENG[2], Y. ZHAI[2], M. D'APUZZO[3], B. BADIE[4], S. J. FORMAN[5], C. E. BROWN[2];

Abstract: Cellular heterogeneity is a hallmark characteristic of ostensibly similar cell populations occurring during neural and glial development, and during tumorigenesis and tumor progression. For the latter case, large collections of formalin-fixed paraffin embedded (FFPE) clinical specimens are a valuable resource for evaluating gene expression across large study cohorts. Many of these patient samples consist of serial tumor sections each stained for a single antigen by chromogenic immunohistochemistry (IHC), as is standard clinical pathology practice. Quantifying multiple tumor related antigens in the context of GBM tissue is an essential step towards understanding the fundamental biology of these tumors as well as developing novel targeted therapies. Towards this end, we have developed methods for combining semi-quantitative analysis of IHC processed tumor sections with regional annotation by a clinical pathologist. This has allowed us to consider patterns of antigen co-expression as well as spatial relationships with tumor structures and physiological status. We will present observations on expression of tumor-associated antigens IL13Rα2, HER2 and EGFR, and associations with proliferation as indicated by Ki67 expression and the vasculature as marked by the endothelial cell marker CD34.

Title: Enhancement of human neuroblastoma cell apoptosis by combined treatment with valproic acid and interferon-β

Authors: *S. DEDONI, M. C. OLIANAS, P. ONALI;
Univ. of Cagliari, Dept Biomed. Sci., Cagliari, Italy

Abstract: Type I interferons (IFNs), including IFN-α and IFN-β, possess antitumoral activity and have been proposed to be potentially useful in the treatment of neuroblastoma. We have previously shown that IFN-β causes cell death of human SH-SY5Y neuroblastoma cells by inducing apoptosis through the intrinsic mitochondrial pathway (Dedoni et al. J. Neurochem. 115,1421-1433, 2010). As valproic acid, an histone deacetylase inhibitor (HDACi) has been reported to enhance the antitumoral effects of type I IFNs, in the present study we have examined the effects of this drug on IFN-β-induced apoptosis of neuroblastoma cells. We found that prolonged exposure (24 h) of SH-SY5Y cells to therapeutic concentrations of valproic acid (0.6-1 mM) had no effect on cell viability. However, when combined with IFN-β, valproic acid markedly enhanced cell apoptosis induced by the cytokine, as demonstrated by the increase in annexin V staining, caspase activation and poly-(ADP ribose) polymerase (PARP) cleavage. Acetylation of histone 2B at Lys5 was markedly enhanced by valproic acid, but this response was not affected by co-treatment with IFN-β. Conversely, valproic acid enhanced the IFN-β-stimulated Tyr-phosphorylation of STAT1, which is crucial for cytokine-induced apoptosis. Sodium butyrate (1 mM), another HDACi, elicited similar potentiating effects on IFN-β-induced apoptosis and STAT1 phosphorylation, whereas valpromide (1 mM), which did not enhance histone acetylation, had no effects. MYCN-amplified human LAN-1 neuroblastoma cells displayed no sensitivity to the pro-apoptotic activity of IFN-β, but underwent apoptosis when treated with either valproic acid or sodium butyrate. Co-treatment of LAN-1 cells with IFN-β and HDACi, but not valpromide, resulted in a significant increase in cell apoptosis. These data show a synergistic interaction of IFN-β and valproic acid in promoting neuroblastoma cells apoptosis, which appears to be related to enhancement of histone acetylation.

Title: MMPs facilitate perivascular glioma cell invasion

Authors: *E. G. THOMPSON, H. W. SONTHEIMER;
Neurobio., The Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Primary brain tumors, gliomas, have thus far evaded effective treatment making them a tremendous challenge clinically. This is due in part to the aggressive, invasive nature of glioma cells to infiltrate the surround brain away from the main tumor mass, making complete surgical resection impossible. Glioma cells primarily invade using pre-existing secondary structures such as white matter tracts or blood vessels. It has recently been shown that as glioma cells co-opt the vasculature, astrocytic endfeet are displaced leading to breakdown of the blood-brain barrier. Matrix metalloproteinases (MMPs), a large family of zinc-dependent endopeptidases, function in normal physiological settings to remodel the extracellular matrix (ECM). For example, they are critical in the wound healing process. MMPs have also been implicated in many disease states, of which gliomas are included. Glioma cells express MMPs-2, 3, & 9 and the ability of tumor cells to digest the ECM by secreting enzymes has been shown to correlate with their invasiveness. While MMPs have long been believed to contribute to the migration of glioma cells away from the main tumor mass, the role that MMPs play in perivascular glioma cell invasion, specifically whether MMPs mediate the cleavage of astrocytic endfeet anchoring proteins has yet to be explored. We hypothesized that perivascular gliomas release MMPs that digest basement membrane components responsible for anchoring astrocytic endfeet to the vascular surface. Using a clinically relevant mouse model of glioma and quantitative immunohistochemistry, we confirmed the expression of MMPs in and around glioma cells associated with the vasculature. In addition, we identified substrates for these released MMPs—components of the basement membrane and the endfoot anchoring complex. Using confocal time-lapse microscopy of acute slice glioma invasion preparations we were able to compare rates of perivascular glioma invasion with and without broad-spectrum MMP inhibitor batimastat (BB-94), to conclude that MMPs are essential for perivascular glioma invasion. Finally, we utilized a human glioma cell line that stably expresses a recombinant GPCR (RASSL), which activates Ca^{2+} signaling in response to a synthetic ligand, and genetically encoded Ca^{2+} sensor GCaMP3. This cell line used in conjunction with our acute slice glioma invasion preparation allowed for the determination that MMP release from perivascular glioma cells is a Ca^{2+} dependent process. Taken together, our data suggests that MMPs are essential for perivascular glioma cell invasion and help to mediate the displacement of astrocytic endfeet from the vascular surface.

Abstract: Accumulation of DNA lesions, due to defects in DNA repair mechanisms, can have a profound effect on development and induce mutagenic events that ultimately lead to cancer. We have developed mouse models targeting specific factors involved in DNA repair and telomere maintenance with which to assess the impact of genome instability towards tumorigenesis in the brain. DNA double-strand breaks (DSBs) are repaired by two distinct pathways, non-homologous end joining (NHEJ) or homologous recombination (HR). These pathways have been disabled in the mouse by brain region-specific deletions of DNA ligase IV (Lig4) or BRCA2, respectively. We also developed models in which normal regulation of topoisomerase-1 was compromised via inactivation of ATM or TDP1. Finally, telomere maintenance was disrupted by inactivation of Pot1a, a protein essential for proper telomere capping. Importantly, these factors are all known to underpin specific human cancers, including brain tumors. Loss of these factors during development has a cumulative effect on genome stability, resulting in a high frequency of tumor formation. These tumors were high-grade gliomas (HGG) and showed oligodendroglial and/or astrocytic morphology or mixed glial and primitive neuroectodermal tumor-like phenotypes. To understand the molecular basis of these tumors, we undertook RNA and exome sequencing. Sequencing of the transcriptome revealed alterations in gene expression that resulted in a heterogeneous set of HGG. Gliomas exhibited molecular signatures of all subtypes of the disease, suggesting transformation can occur in various cells of origin. Importantly, we identified both novel and previously described gene fusions and translocations involving potent oncogenes such as Met, Pdgfrα, Alk, and B-Raf. Exome sequencing also revealed tumor-specific somatic mutations in chromatin remodeling factors and the serine/threonine kinase B-Raf. Significantly,

the mutation observed in B-Raf corresponds to the V600E mutation observed in many human cancers, including some primary nervous system tumors. These new models will provide important tools to uncover the key genetic events that drive gliomagenesis in the context of neural development.

Title: The effect of pharmacological modulation of calcium signaling on the viability of human neuroblastoma cells

Authors: ***A. M. FLOREA**[1], G. REIFENBERGER[1], D. BÜSSELBERG[2];
[1]Heinrich Heine Univ. Düsseldorf, Uniklinikum, Düsseldorf, Germany; [2]Weill Cornell Med. Col. in Qatar, Doha, Qatar

Abstract: Neuroblastoma is a childhood cancer that urgently needs improved treatment schemes especially for the high-risk forms of the disease. Current treatment strategies include application of platinum complexes (CDDP, carboplatin), DNA alkylating agents and topoisomerase I inhibitors (e.g. TOPO). In this study we tested whether an array of calcium signaling modulators that target specific sites involved in calcium signaling are able to modify cell viability of SH-SY5Y, IMR32 and NLF human neuroblastoma cells. We tested the effect of (1) SERCA ATP-ase inhibitors: Thapsigargin (THAPS), Cyclopiazonic acid (CPZ); (2) IP3R inhibitor 2APB; (3) L-type calcium channel inhibitors verapamil (VERA) and nifedipine (NIFE); (4) mitochondrial transition pore inhibitor and calcineurin inhibitor Cyclosporine A (CYCLA); (5) RyR modulators Dantrolene (DANTR) and Ryanodine (RYA). The results show that in SH-SY5Y cells THAPS (0.02-2μM) was able to significantly reduce cell viability in a time and concentration dependent manner; highest cytotoxicity was observed after 72h time of exposure. Cyclopiazonic acid (0.2-20μM) was also cytotoxic in SH-SY5Y cells in a time and concentration dependent manner, but at a concentration 100-fold higher than THAPS. The IP3R inhibitor 2APB (2-100μM) was

cytotoxic in SH-SY5Y cells in a time and concentration dependent manner, but only the highest concentrations were cytotoxic after 72h of exposure. Cyclosporine A was also an effective cytotoxic drug in SH-SY5Y cells, with concentrations of 0.2-20μM showing reduced cell survival in a time and concentration dependent manner. The other modulators such as VERA (0.2-20μM), NIFE (0.2-20μM), DANTR (0.2-20μM), RYR (0.02-2μM), did not show cytotoxicity at the concentrations tested. When we compared the cytotoxicity of these inhibitors for the 72h time of exposure in SH-SY5Y, IMR32, NLF human neuroblastoma cells, we observed differential effect in regard to the cytotoxicity. For instance, THAPS (0.02-2μM) had highest cytotoxicity in NLF cells (20% cell survival), while THAPS cytotoxicity in IMR32 cells was between 80 % (0.2μM) to 60% (2μM) cell survival, and in SH-SY5Y 80% cell survival. CPZ was cytotoxic at the highest concentration tested (20μM) in SH-SY5Y and NLF cells but not in IMR32. Furthermore, the 100μM 2APB as well as CYCLA were cytotoxic in all three neuroblastoma cell lines tested. Overall, our *in vitro* data indicate that SERCA ATP-ase inhibitors as well as IP3R antagonists and mitochondrial/calcineurin modulators demonstrate cytotoxic activity against neuroblastoma cells.

Title: Insights into HuR multimerization in glioma

Authors: ***N. FILIPPOVA**[1], X. YANG[1], A. SOROCHINSKY[2], Z. GENTRY[3], L. B. NABORS[1];
[1]Neurol., Univ. of Alabama At Birmingham (UAB), Birmingham, AL; [2]VHHS, Birmingham, AL; [3]Vanderbilt Univ., Nashville, TN

Abstract: HuR is the mRNA binding protein (ELAV family) which is overexpressed in different types of cancer cells, including brain tumors. HuR overexpression and strong cytoplasmic localization in tumor tissue are associated with an aggressive tumor phenotype, chemoresistance, and pure patient outcomes. In our current report, we performed a comparison of HuR nuclear/cytoplasmic localization in an array of brain tumor samples (grades i-iv) and control brain tissue. We confirmed a mostly nuclear HuR localization in control brain tissue compared to HuR nuclear/cytoplasmic localization in brain tumors samples with an increase of HuR

cytoplasmic localization and intensity with increasing tumor grade. The analysis of HuR protein in the non-denatured condition Western blot revealed strong HuR protein multimerization in the cytoplasmic fraction of tumor samples. We found that HuR multimerization is stable in the presence of RNase treatment and could be partially decreased by the reducing condition. HuR protein multimerization in the cytoplasmic fraction was observed also in samples of patient derived xenolines (PDGx) and established glioma cell lines. We developed several assays including split Firefly Luciferase assay (N and C terminals parts of Firefly luciferase were attached to the C terminal end of HuR constructs), bioluminescence energy transfer (BRET) assay (between HuR-Renilla Luciferase and EGFP-HuR or HuR-EGFP constructs) to analyze HuR multimerization in U251 cells and to map HuR domains which come in close proximity during multimerization. In split Firefly Luciferase assay we were able to detect the luminescence signal from full length HuR constructs, HuR constructs truncated at 198 residue (before hinge region) and HuR constructs truncated at 244 residue (after hinge region), suggesting that the C-terminal edge of RM2, hinge region, and the C terminal edge of RM3 may come in close proximity as homo-oligomers during HuR multimerization and could affect the HuR multimerization conformation. This data was confirmed in BRET assay between HuR-Renilla Luciferase and HuR-EGFP constructs. The disruption of the HuR multimerization process in cell-based assays by targeting HuR protein redox state, or the hinge region function or RM3 domain were associated with a decrease of tumor cell proliferation and enhanced sensitivity to chemotherapeutic treatment. In summary, we provide evidence of HuR multimerization in cancer cells and propose possible pharmaceutical pathways for specific inhibition of HuR multimerization for cancer cells based on differentiation of targeted domains involved in multimerization.

Title: Morphological effects of curcumin on A172 cell line of human astrocytoma

Authors: ***M. B. GARRIDO ARMAS**[1,2], M. SALAZAR-GARCIA[3], S. OROZCO-SUAREZ[5], F. ARENAS-HUERTERO[4];

[1]Patologia experimental, HOSPITAL INFANTIL DE MEXICO FEDERICO GOMEZ, Ciudad DE Mexico, Mexico; [2]UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, Mexico city, Mexico; [3]Dept. de Biología del Desarrollo y Teratogénesis Exptl., [4]Lab. de Investigacion en Patología Exptl., Hosp. INSTITUTO MEXICANO DEL SEGURO SOCIAL, MEXICO CITY, Mexico

Abstract: Morphological effects of curcumin on a172 cell line of human astrocytoma Cell death is a crucial physiological process that controls many vital functions, including development, morphogenesis, tissue homeostasis and defense against pathogens. Tumor cells can be sensitive or resistant to cell death. Many tumors initially respond to treatment with drugs and eventually develop multiple resistances due to the increase in drug injection mechanisms, or increase the capacity of DNA repair. These challenges have been stimulated interest in finding other cell death pathways that could be used to eliminating tumor cells, which have created the resistance phenotype. Various forms of cell death have been described, based on morphological criteria. Curcumin is a polyphenol compound extracted from *Curcuma longa* plant, which is commonly used in the preparation of oriental food, as well as mustard and curry. This kind of yellow spice has been used for thousands of years as traditional medicine in Asia, for the treatment of acne, psoriasis, dermatitis, among others. It is a molecule with pleiotropic effects and suppresses the transformation targets, proliferation and metastasis of malignant tumors. We found in our laboratory that Curcumin at 100 μM induces cell death and specific morphological characteristics on human astrocytoma cell line A172. Results show increase in size, presence of translucent accumulated vesicles in the cytoplasm, some with fusion, which produces the cytoplasmic membrane rupture. The vacuolization response started at 14 minutes of curcumin exposure, the cells were evaluated 1, 3 and 6 hours and at these times the response was reversible. There is no evidence of nuclear fragmentation, that's why apoptosis and necrosis were discarded. To evaluate autophagy cell death, the cells were analyzed with LysoTracker green and this labeling didn't localize into big vesicles inside the cells. At 24 hours of treatment, the changes were irreversible and the cells dead at 85%. It seems methuosis-like response. This cell response comes from the Greek "methuo" which means "drinking to intoxicate". It is distinct from other non apoptotic deaths since it involves macropinocytosis combined with defects in traffic independent of clathrin endocytic vesicles, which results in the presence of large vesicles which alter the integrity of the cell membrane. This response is reported by other authors, with other natural compounds like chalcons.

Title: Soluble adenylyl cyclase(sAC) modulates cell proliferation and survival in glioblastoma

Authors: *L. MICCI[1], C. CARDENAS[2], R. G. CORREDOR[3];
[2]Neuroscience/psychiatry, [3]Neuroscience/Psychiatry, [1]Florida Intl. Univ., Miami, FL

Abstract: It is known that the second messenger cyclic adenosine monophosphate (cAMP) participates in cell proliferation and growth in the mammalian brain; however it is not clear how cAMP participates in glioblastoma, the most frequent, deadly and aggressive primary tumor of the central nervous system. Recently, a novel source of intracellular cAMP, the sAC, was identified. sAC is present in cytoplasm, nucleus and mitochondria of neurons and glia in the central nervous system, but contrary to transmembrane adenylyl cyclase , sAC is not activated by G-protein-coupled receptors (GPCR) but by intracellular calcium and bicarbonate, suggesting that sAC may be a critical modulator of cell metabolism. Although sAC has been shown to be present in some cancers like melanoma and prostate cancer, its potential role in cancer pathogenesis is still unknown. We investigated expression and function of sAC in four glioma-glioblastoma cell lines (H4, A172, U118 and U87) and found that western blot using two different anti-sAC antibodies targeting the sAC catalytic domain detects the protein at the molecular weight expected for the truncated form of sAC, but in addition, there is a characteristic unique band pattern identifiable for each cell line. Light microscopy allowed also for identification of characteristic cell behavior of cell lines in culture after sAC pharmacological inhibition with KH7. Cell quantification of the same cultures 5 hour and 24hour after sAC inhibition showed that sAC inhibition significantly impairs proliferation of glioblastoma cell lines in a dose-dependent manner where some cell lines are very sensitive to sAC inhibition compared to others. sAC-inhibition-mediated cell death was also observed with the most robust effect in H4 glioma cell line. These data suggest characteristic patterns of sAC expression for specific glioblastoma cell types and identifies a sAC-mediated cAMP signaling pathway as a potential target for diagnostic classification and treatment of glioblastoma.

Title: Additive effects of the combined expression of tGAS1 and PTEN-LONG reducing the viability of glioma cells

Authors: *L. SANCHEZ[1], J. HERNANDEZ-SOTO[1], P. VERGARA[1], R. O. GONZALEZ[2], J. SEGOVIA-VILA[1];
[1]CENTRO DE INVESTIGACION Y DE ESTUDIOS AVANZADOS, Mexico City, Mexico;
[2]UNIVERSIDAD AUTONOMA METROPOLITANA, Mexico City, Mexico

Abstract: When GAS1 (Growth Arrest Specific 1) is expressed in glioma cells it induces cell arrest and apoptosis. We have previously demonstrated that the apoptotic process set off by Gas1 is caused by its capacity inhibiting the GDNF-mediated intracellular survival signaling. Furthermore, PTEN antagonizes the action of PI3K, but there are cancers in which PTEN is not active. Thus, it is important to investigate the potential additive effect of the overexpression of GAS1 and PTEN inhibiting tumor growth. We have already observed that GAS1 and PTEN have an additive effect inducing cell death. Moreover, it has also been shown that soluble forms of GAS1 and PTEN (tGAS1 and PTEN-LONG) are effective reducing tumor growth. Hence, we made a lentiviral vector with a 2A peptide-enabled dual expression system, which allows us to generate the two proteins from the control of a single promoter. The co-expression of tGAS1 and PTEN-LONG in U87 human glioblastoma cells induced a decrease in the activity of both ERK and AKT and reduced the number of viable cells expressing the transgenes. These outcomes were also observed in independent cell cultures in which conditioned medium containing tGAS1 and PTEN-LONG was administered. These data indicate that tGAS1 and PTEN-LONG act in both autocrine and paracrine manners. These effects were stronger than when each protein was individually expressed. All this together suggests that the combined treatment with tGAS1 and PTEN-LONG is a potentially interesting therapeutic approach for the treatment of gliomas.

Title: Intratumoral modulation therapy for glioblastoma

Authors: M. COOPER[1], H. XU[2], C. DE OLIVEIRA[3], S. WHITEHEAD[3], S. SCHMID[3], *M. O. HEBB[2];
[1]Neurosci., [2]Clin. Neurolog. Sci., [3]Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: **Background:** Glioblastoma (GBM) is the most common and malignant primary brain tumor in adults. Median survival with current therapies remains dismal at 12-18 months and there is a critical need for innovative and effective treatment strategies. The clinical indications for neuromodulation therapy in the brain are rapidly expanding and this technique is now the standard of surgical care for select neurological diseases (e.g., Parkinson's Disease). It is well known that glia-originated tumors are vulnerable to perturbations of the electrochemical environment; however, direct neuromodulation techniques have not been exploited for glioma management. **Methods:** Our group has developed an *in vitro* model to deliver continuous, low voltage electric current directly into GBM cultures, a technique we call intratumoral modulation therapy (IMT). GBM cell lines as well as primary GBM cells derived from operative specimens were studied for vulnerability to IMT without and with temozolomide (TMZ) chemotherapy or oncogene targeting strategies. **Results:** These studies demonstrated a marked vulnerability of patient GBM cells, but not primary neurons, to IMT with parameters that align with those clinically used for deep brain stimulation to treat various neurological diseases, or with externally applied devices to deliver alternating electric fields across the cranium of GBM patients. GBM cells treated with IMT undergo enhanced caspase 3-activated apoptosis, and develop markedly heightened sensitivity to TMZ. Uptake and biodistribution of siRNA was enhanced in primary GBM cells, along with target gene knockdown and functional effect, in the presence of IMT. **Conclusions:** These studies follow on the heels of reported significant advances using externally applied alternating electric fields in GBM patients. The proposed use of minimally invasive implantable stimulation devices offers distinct advantages, including direct lesion targeting for delivery of continuous IMT, titratible stimulation settings to maximize benefit and lessen off-target effects and low maintenance, concealed hardware for improved self-perception and quality of life. Results from these investigations will guide further studies to evaluate the *in vivo* efficacy of IMT for GBM.

Title: Plexin-B2 signaling promotes tumorigenicity of glioblastoma stem-like cells through activation of STAT3

Authors: *Y. HUANG[1], R. TEJERO-VILLALBA[1], R. H. FRIEDEL[1,2], H. ZOU[1,2]; [1]Neuroscience, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Neurosurgery, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Glioblastoma harbors a subpopulation of stem-like tumor propagating cells termed glioma stem cells (GSCs). The signaling pathways that promote malignant potency of GSCs remain to be identified. Here, we show that Plexin-B2, a semaphorin receptor, is highly expressed in patient-derived GSCs. Plexin-B2 deletion slowed down GSC growth and self-renewal *in vitro* and attenuated tumor formation *in vivo* in orthotopic transplantation assays. Plexin-B2 remains expressed in differentiated progenies of GSCs, and its ablation affects differentiation phenotypes. Furthermore, we identified a novel link between Plexin-B2 signaling and activation of the STAT3 transcription factor, a central regulator of glioma cell phenotypes. Our analysis of patient gene expression data revealed that Plexin-B2 upregulation in glioblastoma is correlated with high expression of STAT3. Plexin-B2 deletion in both GSCs and their differentiated progenies leads to marked reduction in STAT3 activation. Consistently, downstream targets of STAT3 were decreased in Plexin-B2 deficient GSCs and their differentiated progeny. Our preliminary data indicate that STAT3 activation is required for Plexin-B2 mediated function in GSCs and is mediated through activation of Rho GTPases. Together, our study elucidates a novel signaling cascade in glioma cells from membrane receptor Plexin-B2 to a nuclear transcriptional response mediated by STAT3.

Title: Targeted delivery of histone deacetylase inhibitor for anti-glioma therapy

Authors: L. ZOU, J. D. RODRIGUEZ, T. THOMAS, *H. DOU;
Dept. of Biomed. Sci., Texas Tech. Univ. Hlth. Sci. Ctr. (TTUHSC), El Paso, TX

Abstract: Introduction: The fundamental difficulties of anti-glioma therapy are across the BBB and specifically target to the tumor to enhance therapeutic efficacy and minimize side effect. Nanoparticles (NPs) containing mixed lipid monolayer shell and rabies virus glycoprotein (RVG) peptide as brain targeting ligand were developed for brain targeted delivery of entinostat, a histone deacetylase inhibitor, to treat malignant glioma. Materials and Methods: NPs were prepared and sized by extrusion through 100 nm membranes. Then, entinostat was loaded by transmembrane pH gradient method and RVG was conjugated by thiol-maleimide specific reaction. Entinostat loaded NPs conjugated with RVG (RVG-entinostat-NPs) were characterized by AFM, DLS and HPLC to measure the shape, surface morphology, particle size and the drug loading content. Fluorescent rDHPE and DiSC3(5) were used to label RVG-entinostat-NPs. MTT test was conducted to examine anti-glioma activities. Live image and histological sections were employed to detect RVG-entinostat-NPs *in vivo*. Results: RVG-entinostat-NPs were successfully prepared with the desirable size (139nm), narrow size distribution, spherical shape and high entinostat loading content. *In vitro* study showed that RVG-entinostat-NPs exhibited poor uptake by neurons and selective targeting to the brain tumor associated macrophages (TAMs) with controlled release. The toxicity to U87 was obtained by treatment of RVG-entinostat-NPs at concentrations of 10-2mM and above. *In vivo* studies revealed that RVG-entinostat-NPs were significant across the blood-brain barrier (BBB) and specific targeting to the brain. Histological analysis revealed that RVG-entinostat-NPs were obviously accumulated in brain of the mice. Importantly, live animal imaging and tumor growth evaluation showed that RV- entinostat-NPs significantly prevent glioma growth. Conclusions: We have been successfully developed RVG-entinostat-NPs to deliver entinostat for treatment of glioma. RVG-entinostat-NPs combine the superb trans-BBB capability and the TAMs targeting specificity providing an effective anti-gloma delivery system for further clinic use.

Title: Mechanism of transport and intracellular target of GlioStem: novel technology for near-immediate detection of glioblastoma-derived stem cell-like cells

Authors: A. GRACIAS[1], B. MIGLIORI[1], N. GIOTOPOULOU[1], E. KAVANAGH[2], M. BÄCK[3], P. NILSSON[3], B. JOSEPH[2], *O. HERMANSON[1];

Abstract: Glioblastoma multiforme (GBM) is one of the most aggressive brain tumor types. Despite being one of the most well studied nervous system tumors, the median survival has not increased significantly and is 14.8 months with the best possible treatment including surgery, chemotherapy and radiation. One of the reasons for this poor prognosis is believed to be the existence of cancer stem cells. The GBM-derived stem cell-like cells (GSCs) have features of tumor-initiating cells (TICS) and can self-renew, leading to tumor formation. Previous studies from our lab have introduced a luminescent conjugated oligothiophene (LCO) named p-HTMI or GlioStem that specifically detects rat embryonic neural stem cells and GSCs, but not adult neural stem cells, differentiated cells of any kind, or other stem or cancer cells. By mere application to the cell culture dish, GlioStem labels in green more than 70% of the cells in populations of GSCs derived from three patients, within 10 minutes, a higher number when compared to CD133, a stem cell marker. The GlioStem-labeled cells overlapped with the more promiscuous marker CD271 (NGF receptor). The detection of human GSCs with GlioStem occurred without

triggering apoptosis or necrosis. GlioStem labeling was mostly cytoplasmic in embryonic neural stem cells as well as GSCs. Preliminary studies indicate an ER target of GlioStem. The side chain moiety is essential for its functionalization, and additional LCOs have been generated producing red fluorescence that currently is under verification for specificity and function. With regards to mechanism of uptake, our results indicated a passive uptake of GlioStem that required an intact cell membrane, verified using different permeabilization techniques. Its specificity, sensitivity, ease of use and detection by fluorescence microscopy and FACS suggests its potential clinical use in surgery. We are currently performing *in vivo* studies to verify GlioStem selectivity in GSCs when injected into NOD/SCID mice.

Title: Pharmacological inhibition of CLIC1 chloride channel impairs glioblastoma stem cell proliferation

Authors: R. WURTH[1], F. BARBIERI[1], M. TONELLI[1], G. GAUDENZI[2], M. PERETTI[2], G. VITALE[2], M. MAZZANTI[2], *T. FLORIO[1];
[1]Univ. of Genova, Genova, Italy; [2]Univ. of Milano, Milano, Italy

Abstract: Glioblastoma (GBM) is the most common primary brain tumor in adults showing an overall survival of only 14.6 months, even in the presence of aggressive treatments. Thus, the discover of new drugs is a compelling requirement. Chloride intracellular channel 1 (CLIC1) is involved in development of GBM, controlling cell cycle progression in tumor cells. Here we show that metformin, the first-line drug for type-2 diabetes that recently showed to possess antitumor properties, selectively inhibits CLIC1 activity in human GBM stem cells (GSCs), leading to tumor cell growth arrest. The inhibition of CLIC1 conductance induced by metformin reduces GSC proliferation, causing arrest in G1 phase of the cell cycle. This effect is time-

dependent, and prolonged treatments lead to antiproliferative effects for low, clinically achievable, metformin concentrations. Single point mutation in the putative CLIC1 pore region impairs metformin modulation of the channel activity, suggesting that metformin binding site is located on the extracellular portion of CLIC1. Metformin's effects were also shown *in vivo*, causing a significant inhibition of GSC invasiveness and metastatic diffusion. Interestingly, CLIC1 is not active in mesenchymal stem cells, and consequently these cells are not affected by the antiproliferative effects of metformin, highlighting that this drug seem to be GSC-selective. These results identify a completely new molecular target for the antiproliferative effects of metformin, which could be exploited to identify novel pharmacological approaches for GBM. Following this line we evaluated the antitumor activity, and the ability to inhibit CLIC1 ion conductance, of several known and novel biguanide derivatives. In particular, we identified novel compounds showing higher potency than metformin, but reproducing the same mechanism of action, representing promising candidates to be further developed in clinical settings. Since the lack of drugs affecting GSCs viability is the main cause of therapy failure and tumor relapse, the identification of novel and specific molecular targets and of drugs acting on it represents a needed pharmacological strategy to improve GBM treatment.

Title: Bioenergetic adaptation of invasive glioma: a complication to therapeutic targeting?

Authors: ***B. AHN**[1,2], Y. AHN[3], N.-H. DANG[1,2], A. WELJIE[4], J. RHO[3], D. SENGER[1,2]; [1]Dept. of Oncology, Univ. of Calgary, Calgary, AB, Canada; [2]Southern Alberta Cancer Res. Inst., Calgary, AB, Canada; [3]Dept. of Pediatrics, Univ. of Calgary, Calgary, AB, Canada; [4]Dept. of Pharmacol., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Patients with high-grade glioma or glioblastoma (GBM) have an average survival of only one year and existing therapies are palliative at best. Current therapeutic strategies include the exploitation of the tumor cellular metabolism and largely focuses on the higher rate of glucose consumption in the cancer cells as compared to the surrounding normal tissues, a phenomenon known as the Warburg effect. Recently, glioblastoma tumors have been shown, in

addition to glucose, to simultaneously oxidize acetate providing an explanation for the observed resistance of glioma cells to conventional metabolic drugs that target glycolysis. Herein, we provide evidence that the upregulation of glutamine metabolism can result in resistance to glycolytic pathway inhibitors (DCA, 2DG) or glucose oxidation targeting drugs (Metformin). Using previously established non-invasive (U87pc) and invasive (U87p75^{NTR}) human GBM cell lines, or patient-derived brain tumour initiating cells (BTICs), we found that highly invasive GBM cells are resistant to DCA, DG and Metformin, but not BPTES (an inhibitor of glutaminase). Moreover, we found that oxygen consumption (OCR; measure of oxidative phosphorylation) and extracellular acidification (ECAR; measure of cellular glycolytic activity) were higher in non-invasive GBM cells as compared to their invasive counterparts suggesting that invasive glioma cells are less dependent on glycolytic activity or oxidative phosphorylation. Conversely, metabolomic studies revealed that glutamine metabolism was elevated in the highly invasive GBM population, an observation that was associated with an increase in glutamine metabolism related genes. Consistent with this observation, the invasive glioma cells maintained the capacity to grow in the absence of glucose where the cells were shown to utilize glutamine as a metabolic substrate. These data highlight the bioenergetic diversity and adaptability of human glioma and provide data to support a role for glutamine metabolism in promoting resistance of the highly invasive population and thus identifies additional mechanisms for the development of therapeutic resistance.

Title: Differential tumor graft acceptance of 261 Glioblastoma Multitforme (GBM) cell lines between wild type C5Bl6, CD74 deficient, and Gamma Delta TCR deficient mice

Authors: ***S. MUKHERJEE**[1], L. DAO[1], R. TOBIN[1], G. DUSIO[2], E. FONKEM[4], M. NEWELL ROGERS[1,3];
[1]Surgery, Texas A & M, Temple, TX; [2]Surgery, [3]Scott and White Healthcare, Temple, TX; [4]Neurol., scott and White Healthcare, Temple, TX

Abstract: Background and Significance. Glioblastoma Multiforme (GBM) is a deadly and highly aggressive brain tumor with grim prognosis. At present none of the treatment strategies extend the life of most patients beyond a year. A contribution from the immune system in the control and/or growth of tumors is currently under intense investigation. However, the strategies GBM cells use to hide from the immune cells are poorly understood. Experimental Approach. To address this issue, we compared the tumor graft acceptance of 261 cells (mouse glioma cell line/derived from a tumor from a C5Bl6 strain background) into C5Bl6 mice with three genetic modifications (CD74, invariant chain knockout mice; gamma delta knockout mice; and control C5Bl6 mice). The 261 cells were injected stereotactically in the caudate nucleus and mice were observed for 4-6 weeks. Results. The data showed that the tumor acceptance in C5Bl6 mice was higher when compared to either CD74 deficient or Gamma Delta TCR deficient mice. In addition, C57Bl6 mice showed rapid tumor growth with robust neurological deficit as early as 4 weeks. No neurological deficit was observed in invariant chain deficient mice or gamma delta knockout mice. Conclusions. These data suggest a contribution from CD74 as well as gamma delta T cells in tumor graft acceptance. Further experiments are ongoing to determine the potential role of CD74 and/or gamma delta T cells in the progression of GBM.

Title: Glycolytic inhibition induces er stress and apoptotic cell death in patient derived glioblastoma stem-like cells

Authors: *S. S. SHAH[1,2], G. A. RODRIGUEZ[1], A. SANCHEZ[1], M. SCHECHTER[2], W. WALTERS[1], R. J. KOMOTAR[1], J. S. PRINCE[2], R. M. GRAHAM[1];
[1]Dept. of Neurolog. Surgery, Univ. of Miami Miller Sch. of Med., Miami, FL; [2]Dept. of Biol., UM Electron Microscopy Lab., Coral Gables, FL

Abstract: Background: Glioblastoma multiforme (GBM) is one of the most malignant and common primary brain tumors. Even with aggressive treatment, patient prognosis is dismal with a median survival time of 14.7 months. A subset of glioblastoma cells, glioblastoma stem cells (GSCs), is treatment resistant and implicated in disease recurrence. Currently, there is controversy regarding metabolic pathways GSCs employ_glycolysis versus oxidative phosphorylation. Therefore, we sought to perform transmission electron microscopic (TEM) analysis of GSC ultrastructure to determine metabolic preference, evaluate potential therapeutic targets, and propose mechanisms of action of novel treatments. Methods: GSCs were generated from patient-derived tumors, propagated in neurosphere media, and examined for stem-cell markers (Nestin, Musashi, Sox2, CD44, GFAP, BMI1) and ability to generate tumors in nude mice. Cellular morphology was evaluated by TEM. Effect of glycolytic inhibitors, 2-deoxyglucose (2-DG) and 3-bromopyruvate (3-BrPA), on cell viability was determined by MTS assay. Drug effect on cell signaling pathways was elucidated through Western Blot. Results: TEM analysis of multiple patient-derived GSCs confirmed a majority (>50%) of mitochondria exhibit either cristae loss or inner-fold polarization, indicating less available surface area for oxidative phosphorylation suggesting a metabolic dependence on glycolysis. Glycolytic inhibition significantly reduced GSC viability at 72 hours. 2-DG showed most consistent loss in viability compared to non-treated controls at clinically relevant concentrations (0.5mM = 52.1±10.3%; 1.0mM = 22.1±9.9%; 2.0mM = 8.1±5.0%). 3-BrPA showed similar dose dependent loss of GSC viability. In addition, 2-DG was found to up-regulate ER Stress markers (GRP78, CHOP) while also increasing apoptotic markers (cleaved PARP, cleaved Cas3). Conclusions: Targeting GSCs is vital in preventing tumor regeneration. EM provides a useful tool in developing experimental therapies. Our EM results indicate that oxidative phosphorylation is severely compromised in GSCs. Glycolytic inhibition proved effective in targeting GSCs and may represent an adjuvant therapy for a disease with minimal survival.

Title: The CXCL12/CXCR4 signaling axis in the pathogenesis and progression of neural stem cell derived glioblastomas

Authors: *A. CALINESCU[1], E. CARBALLO[2], D. B. ZAMLER[1], R. DOHERTY[1], D. TRAN[3], P. R. LOWENSTEIN[1,4], M. G. CASTRO[1,4];
[1]Neurosurg., [2]Med. Sch., [3]Sch. of Literature Sci. and Arts, [4]Cell and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: CXCL12 is a pleiotropic chemokine critical for the development and trafficking of immune cells, a key regulator of CNS development, neuronal survival and neurotransmission. Altered expression and function of CXCL12 is found in numerous infectious, autoimmune and malignant CNS pathologies like glioblastoma (GBM). In a screen of chemokines secreted by GBM cell lines we identified CXCL12 with highest expression in glioma cells derived from the malignant transformation of neural stem cells in neonatal mice. Tumors were induced with oncogenic DNA (NRAS and SV40-LgT) injected into the lateral ventricles of P1 mice. Transformed cells proliferate from the ventricles towards the brain parenchyma or travel alongside CXCL12 + vascular endothelial cells to form supra-tentorial tumors in the cortex, striatum or hippocampus. These tumors express the neural stem cell marker Nestin and the glioma stem cell marker Olig2 and render animals moribund within 30 days. Mature tumors harbor the histological hallmarks of human GBM (WHO grade IV): pseudo-palisading necrosis, nuclear atypias, microvascular proliferation and glomeruloid vascular abnormalities. Treatment with Plerixafor, a CXCR4 inhibitor, the cognate signaling receptor for CXCL12, extends the median survival of tumor bearing animals to 53 days ($p=0.0006$). Cell lines derived from these tumors show a 6-fold increase in expression of CXCL12 after 96 hours in culture, which is completely blocked by Plerixafor and correlates with decrease in cell cycle progression, expression of cyclin D1, cdk4 and cdk6. This is preceded at 72h by a decrease in Rb protein and increase in apoptosis. Within the tumor, expression of CXCR4 is maximal in tumor infiltrating myeloid derived suppressor cells (MDSCs), a heterogeneous population of immature bone

marrow (BM) derived cells which suppress the antitumor immune responses in numerous cancers. Treatment of BM cells with GBM conditioned media induces expansion of MDSCs which is dose-dependently inhibited by Plerixafor. Migration and invasion of MDSCs towards CXCL12 is completely blocked by Plerixafor. *In vivo* experiments currently underway explore the role of the CXCL12/CXCR4 signaling axis in tumor infiltrating MDSCs using a genetic mouse model in which CXCR4 is ablated in this population. Our data so far illustrate that in neural stem cells derived GBMs the CXCL12/CXCR4 axis operates via an autocrine positive feedback mechanism in which CXCL12 induces its own expression towards promoting survival and cell cycle progression. The increased survival of immunocompetent tumor bearing animals treated with the CXCR4 inhibitor may result from a concerted effect on tumor cells and MDSCs.

Title: Carnosol: a natural approach to control cancer stem cell in human neuroblastoma and glioblastoma

Authors: C. GIACOMELLI[1], M. L. TRINCAVELLI[1,2], S. DANIELE[1], A. BERTOLI[1], G. FLAMINI[1], A. BRACA[1,2], *C. MARTINI[1,2];
[1]Univ. of Pisa, PISA, Italy; [2]Ctr. Interdipartimentale di Ricerca "Nutraceutica e Alimentazione per la Salute", Univ. of Pisa, Pisa, Italy

Abstract: Carnosol is a naturally diphenolic diterpene found in rosemary that possess anti-inflammatory and anti-cancer effects, although the molecular mechanisms of its activity remain poorly investigated. Neuroblastoma (NB), an extracranial nervous system tumor, and Glioblastoma Multiforme (GBM), a glial tumor with a high proliferation rate and resistance to chemotherapy, are two aggressive cancer characterized by poor prognosis. Recently, several studies have shown the importance of a minor population of cells with stem-like properties (cancer stem cells, CSCs) for the etiopathogenesis and progression of brain tumors. This effect has been related to CSCs self-renewal capacity, tumorigenicity, and altered expression of

specific molecules such as the constitutive activation of signal transducer and activator of transcription 3 (STAT3) signaling (Magee et al., 2012; Zhou et al., 2014). Furthermore, they play a role as master regulators not only in the development of different cancer but also during the process of chemoresistance acquisition. Recently, it has been reported that carnosol is able to induce apoptosis in different tumor through the regulation of intracellular signaling pathways such as nuclear factor kappa B (NFκB), Akt/mTOR and STAT3 inactivation (Park et al, 2014). Herein, we investigate the effect of carnosol in survival of NB, GBM and the respective CSCs. Interestingly, the treatment caused a significant anti-proliferative effect on NB and GBM cells, and a reduction of the CSC proliferation. The effects were ascribed to both the induction of apoptosis and the blocking of cell cycle. Most importantly, carnosol produced synergic/addictive effects on cell apoptosis to the genotoxic action of temozolomide (TMZ) and reduced the ability of cells to recover cell growth. Globally, these data highlighted the potential use of natural diterpenes as starting point in the development of drugs for the treatment of NB and GBM. Moreover, carnososl could represent a promising natural approach to sensitize cancer stem cells to conventional chemotherapy (TMZ). Title: The role of neuropilin 1 in glioma associated microglia and macrophages

Authors: *J. MIYAUCHI[1], J. NISSEN[1], D. SELWOOD[2], S. TSIRKA[1];
[1]Dept. of Pharmacol., Stony Brook Univ., Stony Brook, NY; [2]Univ. Col. London, London, United Kingdom

Abstract: Malignant gliomas are the most commonly diagnosed tumors of the central nervous system (CNS). Despite management, median time of survival after diagnosis falls between 12 to 15 months. Current treatment modalities are suboptimal and there is a substantial need to develop more effective therapies. Modulation of the immune system is a promising strategy as innate and adaptive immunity play important roles in cancer progression. Neuropilin 1 (Nrp1), is responsible for amplifying pro-angiogenic signaling within the tumor microenvironment and its expression correlates with glioma malignancy. Nrp1 also signals via additional pathways and plays a role in the behavior of innate immune cells. Microglia, the resident macrophages of the CNS, can comprise over 30% of the cells in glioma biopsies. Gliomas secrete cytokines which suppress the anti-tumorigenicity of microglia, causing them to secrete factors that support the tumor's spread and growth. Some of the factors which are secreted by gliomas in high amounts signal via Nrp1 and its co-receptors. The objective of this research is to identify how Nrp1-mediated signaling in microglia affects glioma progression. Using a Cre-lox system, we generated mice which lack expression of Nrp1 in microglia and macrophages (MG/MPs). We demonstrate in an *in vivo* orthotopic glioma model, that tumors exhibit less vascularity, grow at a slower pace, and are populated by MG/MPs which exhibit a more anti-tumorigenic phenotype in mice that lack Nrp1 in MG/MPs or that are treated with a small molecule inhibitor of Nrp1. We conclude that ablation or pharmacologic inhibition of Nrp1 promotes an anti-tumorigenic shift in the phenotype of MG/MPs, effectively reducing tumor growth.

Title: Reduced functional connectivity and synchrony between spiking neurons in a primate model of schizophrenia

Authors: *J. L. ZICK[1,2], R. K. BLACKMAN[1,2,4], M. V. CHAFEE[1,4], T. I. NETOFF[3,1]; [1]Neurosci., [2]Med. Scientist Training Program (MD/PhD), [3]Biomed. Engin., Univ. of Minnesota, Minneapolis, MN; [4]Brain Sci. Center, VA Med. Ctr., Minneapolis, MN

Abstract: Disordered connectivity appears to be a key pathophysiological feature of schizophrenia. Measures of temporal correlation between regions of the brain are consistently reduced in schizophrenic patients upon functional imaging; however, evidence for functional disconnection at the synaptic level is limited. Here we describe a study in which we assessed functional connectivity between spiking neurons in a pharmacological nonhuman primate model of schizophrenia. Neural data were obtained from multielectrode recording arrays inserted into the parietal and prefrontal cortices of macaque monkeys while the animals performed a cognitive control task that measures a specific cognitive impairment in human patients with schizophrenia. Phencyclidine (PCP), an NMDA receptor (NMDAR) antagonist with well-described schizomimetic properties, was administered systemically on alternating days with injections of saline.To characterize changes in synaptic communication between neurons in the disease state, we first employed a Generalized Linear Model (GLM) approach to infer functional connectivity between neurons. Unlike traditional cross-correlation approaches used for inferring functional connectivity, GLMs parse out the proportion of variance in spike timing attributable to synaptic interactions between neurons from other sources of variance such as stimulus input, the intrinsic spike patterns of the cells, and the effects of other simultaneously-recorded cells in the network. After identifying functionally coupled pairs of neurons using GLMs, we evaluated the effects of PCP on functional coupling and synchrony between coupled cells. We found a dramatic decrease in the proportion of cells that were functionally coupled in the prefrontal cortex in the PCP condition as compared to the control condition. In order to investigate hypothesized alterations in spike timing in the disease state, we identified the distribution of interspike intervals between putative pre- and postsynaptic neurons. In our analysis we found a prominent “zero-lag” peak representing a large number of coincident (within 1 millisecond) action potentials between coupled cells in the saline condition, but not in the PCP condition. This suggests a change in the timing of action potentials which was apparent in the absence of a change in firing rates, precluding overall decreased activity as an explanation for reduced synchrony. In summary, these results suggest that PCP induces a functional disconnection between synaptically coupled cortical neurons which may be related to a Hebbian reduction in synaptic strength resulting from desynchronization of spiking activity.

Title: Ketamine induced chronic alterations of neural oscillatory amplitudes and cross-frequency couplings in the rat hippocampus: a translational model of schizophrenia

Authors: *T. I. MICHAELS, L. L. LONG, J. J. CHROBAK, C.-M. A. CHEN, C.-M. A. CHEN;
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Disrupted neuronal oscillations have been identified as a possible neural mechanism for the perceptual and cognitive symptoms of schizophrenia. Although findings from human research have focused on abnormalities in different frequency band oscillations, emerging evidences suggest that interactions between different frequency bands, cross-frequency coupling (CFC) serve an important role in integrating sensory and cognitive information and may contribute to the pathophysiology of schizophrenia. Animal studies have utilized ketamine as a pharmacological model of disrupted neuronal oscillations, but few studies have examined its effects on cross-frequency couplings. In the present study, we investigated the acute and chronic effects of ketamine (30 mg/kg i.p. each day) versus saline on changes in averaged amplitudes in different frequency bands (i.e., theta: 6-12 Hz, slow gamma: 25-50 Hz, and fast gamma: 65-100 Hz) and modulations in low-frequency phase (1 to 30 Hz) and high frequency amplitude (50 to 115 Hz) couplings in the rat hippocampus over a 14-day period. We hypothesize that there would be both acute and chronic ketamine effects on: 1) oscillatory amplitudes in theta and gamma frequency bands, and 2) CFC. Electrode recordings were conducted while the rats were running in a four-arm maze. Results indicate a significant drug-by-day interaction effect for both gamma ($F(2, 172) = 3.75$, $p = 0.03$) and theta ($F(2, 172) = 4.64$, $p = 0.01$) amplitude. Within the ketamine group, there was a gradual decrease in fast gamma amplitude from day 1 to day14 and an increase in theta amplitude from day 1 to day 7. Ketamine administration also induced acute and chronic alterations in the strength of phase-amplitude coupling that were not observed in the saline group. Our results demonstrate that chronic ketamine administration alters the interaction of low-frequency phase and high-frequency oscillations in the rat hippocampus. These findings are consistent with human studies and provide evidence that CFC may serve as an important neuronal mechanism for cognitive and perceptual processes known to be impaired in schizophrenia.

Title: Gut vagal afferents modulate schizophrenia-relevant behavioral functions

Authors: ***M. KLARER**[1], M. ARNOLD[1], J.-P. KRIEGER[1], W. LANGHANS[1], U. MEYER[1,2]; [1]Physiol. and Behavior Lab., ETH Zurich, Schwerzenbach, Switzerland; [2]Inst. of Pharmacol. and Toxicology, Univ. of Zurich-Vetsuisse, Zurich, Switzerland

Abstract: Vagal afferents are an important neuronal component of the gut-brain axis allowing bottom-up information flow from the viscera to the CNS. Impaired vagal signaling has been implicated in a number of neuropsychiatric disorders, including anxiety disorders, major depression and schizophrenia. We have recently shown that innate anxiety and learned fear are both subjected to visceral modulation through abdominal vagal afferent signaling (Klarer et al., 2014, J Neurosci 34:7067-7076). Here, we explored whether vagal afferents may further modulate behavioral functions relevant to schizophrenia and related psychotic disorders. To this end, we used a rat model of subdiaphragmatic vagal deafferentation (SDA), the most complete and selective vagal deafferentation method existing to date, to study the consequences of complete disconnection of abdominal vagal afferents on sensorimotor gating selective attention, and sensitivity to dopamine-stimulating drug challenge. We found that SDA-induced loss of vagal afferent signaling led to impairments in prepulse inhibition (PPI) of the acoustic startle reflex and latent inhibition (LI) in conditioned taste aversion. Compared with Sham controls, SDA rats also displayed increased stereotyped behavioral responses to systemic treatment with the indirect dopamine receptor agonist amphetamine (2 mg/kg, i.p.). Post-mortem immunohistochemical investigations revealed increased tyrosine hydroxylase densities in the dorsal (but not ventral) striatum of SDA rats relative to Sham controls. Our study demonstrates that gut vagal afferents modulate behavioral functions implicated in schizophrenia and related psychotic disorders, possibly via changing striatal dopaminergic signaling. These data are in line with the beneficial effects of vagus nerve stimulation against schizophrenia-relevant abnormalities (Perez et al., 2014, J Neurosci 34:9261-9267) and add further weight to theories

emphasizing an etiopathological role of impaired afferent visceral signaling in psychosis-related disorders.

Title: Sub-anesthetic ketamine-induced changes in resting state functional connectivity in conscious nonhuman primates

Authors: ***E. MALTBIE**[1], K. GOPINATH[1], N. URUSHINO[1], L. HOWELL[2];
[1]Emory Univ., Atlanta, GA; [2]Emory Univ., Atlanta, Georgia

Abstract: There is significant interest in the NMDA-receptor antagonist ketamine due to its efficacy in treating depressive disorders and its ability to induce psychotic-like symptoms that make it a useful tool for modeling psychosis. This study extends previous research using fMRI to determine ketamine-induced brain activation in conscious nonhuman primates as a translational model for evaluating antipsychotics. Five adult female rhesus monkeys received a bolus i.v. infusion of 0.345 mg/kg ketamine followed by continuous i.v. infusion of 0.256 mg/kg/hr ketamine. All subjects were responsive to tactile and auditory stimulation, indicating that dosing was well below the anesthetic range. Subjects were scanned in a Siemens Trio 3T magnet while laying prone in a custom built MRI cradle fitted to a transmit-receive volume head coil designed specifically for nonhuman primates. BOLD fMRI images were collected utilizing a whole-brain gradient echo single-shot echo planar imaging sequence (TR/TE/FA = 3000ms/32ms/90; 1.5mm isotropic resolution). Each subject underwent 3 separate scans: a 10-minute baseline scan and two ketamine infusion scans, with and without risperidone pretreatment (0.06 mg/kg) one hour prior to scanning. Ketamine-induced changes in functional connectivity were assessed by seed-based cross correlation analysis comparing each ketamine scan against the baseline scan. Spherical 3mm seed regions defined a priori were placed in the amygdala, subgenual cingulate, medial dorsal thalamus, dorsolateral and medial prefrontal cortex (dlPFC and mPFC), orbitofrontal cortex (OFC), anterior and posterior cingulate cortex (ACC and PCC), and ventral

striatum. Ketamine induced robust functional connectivity increases in limbic-cortical and cortico-striatal networks involved in emotional regulation, motivation, and executive function. The subgenual cingulate displayed increased connectivity with mPFC, dlPFC, inferior temporal gyrus, and amygdala. The amygdala showed increased connectivity with mPFC, OFC, and dorsal striatum. The ventral striatum displayed increased connectivity with mPFC and dlPFC. Pretreatment with the antipsychotic drug risperidone blocked ketamine-induced increases in each of these networks. These data are consistent with literature in humans showing that ketamine induces hyperconnectivity in the prefrontal cortex (early schizophrenia) and acutely modulates connectivity in networks implicated in mood disorders. The model employed has significant translational value in medications development.

Title: Knockout of NR1 receptors in the reticular nucleus of the thalamus impairs reversal learning and decreases sleep spindles

Authors: *T. E. BJORNESS[1], S. BIRNBAUM[2], J. LISMAN[3], R. W. GREENE[2];
[1]Psychiatry, Univ. of Texas, Southwestern Med. Ctr., Dallas, TX; [2]Univ. of Texas Southwestern, Dallas, TX; [3]Brandeis Univ., Boston, MA

Abstract: The reticular nucleus of the thalamus (nRT) receives widespread input from the cortex and the thalamus and in turn provides GABAergic inhibitory projections throughout the thalamus including thalamic relay neurons that project to the cortex. Activity in the nRT is thought to be important for sensory gating, a function impaired in schizophrenia. Additionally, spindle activity during sleep is dependent on burst firing of neurons in the nRT and is decreased in schizophrenics. Disruption of normal activity in the nRT has been posited as a possible source of schizophrenia-related symptoms. In the current experiment, NR1 NMDA receptors were locally knocked out through the use of AAV-Cre injections into the nRT of male floxed NR1 mutant mice. AAV-GFP injections into the nRT were used as a control. Briefly, approximately one microliter of AAV-Cre or AAV-GFP was injected bilaterally into the nRT using a Picospritzer

injection system. A subset of mice was also implanted with skull screw electrodes for electroencephalography and paddle electrodes into the nuchal muscle for electromyography. Mice were given at least 2 weeks for recovery from surgical procedures prior to the start of behavioral experiments, which consisted of Y maze reversal learning, nest building assessment, social transmission of food preference, fear conditioning, and polysomnography. For polysomnography, EEG and EMG signals were recorded under undisturbed baseline conditions for 72 hours, after which sleep state was assigned using standard criteria. Additionally, spindles were identified and counted using a custom Matlab module. Local knockdown of NR1 receptors in the nRT resulted in an impairment in reversal learning, while training and testing on the Y maze was not affected. Additionally, AAV-Cre injected mice showed a lack of normal nest building. Conversely, social transmission of food preference and fear conditioning were not different than controls. When we investigated the effect of NR1 knockdown in the nRT on sleep/waking behavior, we found that although there was a similar amount of time in sleep/waking states as compared to controls, frequency of peak EEG power during waking slowed from 8 Hz in the theta range to 4 Hz in the delta range. Furthermore, AAV-Cre injected mice showed a profound decrease in the number of spindles during SWS, along with a decrease in average spindle frequency. In sum, these results support a possible role for thalamic NMDA-related dysfunction in mediating some of the symptoms of schizophrenia, in particular that of impaired reversal learning and decreased spindle activity which has previously been reported in schizophrenics.

Title: The short- and long-term behavioural effects of chronic risperidone differ in adolescents and adults

Authors: *A. MOE[1], S. ALEXANDER[1], N. D. KURNIAWAN[2], X. CUI[1], T. H. J. BURNE[1,3], D. W. EYLES[1,3];
[1]The Queensland Brain Inst., St Lucia, Brisbane, Australia; [2]Ctr. for Advanced Imaging, Brisbane, Australia; [3]Queensland Ctr. for Mental Hlth. Res., Brisbane, Australia

Abstract: Adolescent brain undergoes major remodelling changes in several neural pathways, raising the possibility of vulnerability to exogenous pharmacological agents. Studies in adult humans and animals have shown that the maturing neurotransmitter systems of the adolescent brain such as dopamine systems and brain structure can be adversely affected by antipsychotic drugs (APDs). However, the dramatic rise in APD prescription to adolescents over the recent decades has not been accompanied by a parallel increase in knowledge on the APDs' effects on the adolescent brain, especially long-term outcomes. Our study tested the hypothesis that the adolescent brain is selectively sensitive to APDs, by examining the well-known effects of APDs on suppression of the conditioned avoidance responses (CAR) in adolescent and adult rodents. Male rats achieving ≥70% avoidance were subjected to chronic 21-day treatment with 1.3 mg/kg risperidone or vehicle either as adolescents (postnatal day (P) 35-55)) or as adults (P80-100). In both age groups, CAR was examined both during chronic treatment (day 1 and 17 of APD exposure) and after lengthy drug-free interval (at P118 for both age groups). At P120, the long-term effects on neural metabolites in nucleus accumbens and brain structures were examined with *in vivo* nuclear magnetic resonance spectroscopy (MRS) and structural MRI respectively, with all brain tissues collected at P127. Similar CAR responses were observed in adolescents and adults on day 1 of chronic treatment. On day 17, adolescent risperidone treatment induced less suppression of CAR and produced fewer escape failures and higher crossings, compared to the adult risperidone treatment. At P118, i.e. after drug-free interval, a long-term sensitization to the CAR-suppressive effects of risperidone was observed selectively in the adolescent risperidone-exposed rats. The underlying neurochemical and structural changes are still under active investigation. Our differential age-dependent behavioural responses both during chronic treatment and after drug washout suggest that the effect of risperidone on the immature adolescent brain is different from that on adult brain. More importantly, the finding that only adolescent-treated rats developed long-term sensitized response further suggests a higher sensitivity of the adolescent brain to risperidone's long-term effects. Differential neural adaptation changes following chronic risperidone exposure are speculated to occur in adolescents and adults during drug-free interval. Given risperidone is the most commonly used atypical APD in adolescents, our findings may have clinical implications.

Title: Nucleus reuniens regulation of ventral tegmental area dopamine neuron activity

Authors: *E. C. ZIMMERMAN[1], N. JAKOBOWSKI[2], A. A. GRACE[2];
[1]Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Dopamine (DA) neurons of the ventral tegmental area (VTA) mediate a wide variety of fundamental behaviors, ranging from reward to motivation and salience. Previous findings from our group and others have described a tripartite circuit composed of the ventral subiculum (vSub), nucleus accumbens (NAc), and ventral pallidum (VP), which governs the proportion of VTA DA neurons that are spontaneously active, ie "population activity." Burst firing is believed to be the behaviorally relevant output of the DA system. However, population activity is a key parameter of VTA activity, because DA cells can only exhibit burst firing if they are spontaneously active. Therefore, the population activity acts as the "gain" to the burst firing "signal." However, all of the regions that modulate population activity have not been fully characterized. Several anatomical studies have described dense, reciprocal connections between vSub and the nucleus reuniens of the midline thalamus (RE). This suggests that RE could be involved in controlling VTA DA neuron population activity, but physiological studies examining this possibility are lacking. To address this question, male Sprague-Dawley rats were anesthetized with chloral hydrate. We then infused NMDA or vehicle into RE, and performed *in vivo* extracellular single-unit recordings of spontaneously active VTA DA neurons. Three properties of identified DA neurons were measured: population activity, quantified as the average number of spontaneously active cells per electrode track, average firing rate, and percent of spikes occurring in bursts. We found that NMDA activation of RE increased population activity in VTA DA neurons without affecting firing rate or burst firing. These findings suggest that RE could play a key role in modulating hippocampal control of VTA DA neuron population activity.

Title: Identification of EEG biomarkers in mouse models of psychiatric disorders induced by NMDA antagonists

Authors: *V. DUVEAU, C. TOULLER, B. POUYATOS, C. DUMONT, C. BOUYSSIÈRES, Y. ROCHE, C. ROUCARD;
SynapCell, La Tronche, France

Abstract: EEG and related methodologies have emerged as powerful tools in both clinical and preclinical research programs for the identification of physiological and pathological biomarkers. Nowadays EEG endpoints are largely used in the clinic to identify and evaluate a pathological state and/or as surrogate biomarkers for clinical trials (depression, schizophrenia, autism, epilepsy ⋯). EEG biomarkers are easily translatable from human to rodent offering a unique opportunity to develop more efficient drug discovery programs. Two main types of EEG activities can be recorded: spontaneous and evoked. Spontaneous EEG activity is recorded continuously in behaving animals whereas evoked activities are recorded after sensory stimulations (auditory, visual etc⋯). In rodents, EEG responses evoked by auditory stimulation (AERPs) can be recorded in the cortex or the hippocampus. They are composed of a succession of positive and negative deflections of variable latencies corresponding to the treatment of information by the ascending auditory pathways. A second level of signal analysis can be performed by measuring the power of gamma oscillations evoked by the stimulations, as well as the inter-trial phase coherence (ITC) of this gamma response. The gamma band is of special interest in neurological and psychiatric disorders as it is linked to the integration and processing of information. In this work, we studied the alterations of AERP responses and the associated impairment in the gamma band power and ITC index in well-known mouse models of psychiatric disorders induced by NMDA antagonists (MK801 and ketamine). The goals of these recordings were (1) to define the EEG signatures of these animal models, and (2) to assess their use as potential biomarkers of these diseases. In C57Bl6 mice, the AERP response is typically composed of a positive deviation at 20-30ms (P1) followed by a prominent notch at 40-60ms (N1) and a late positive peak at around 100-200ms (P2). Ketamine and MK801 both altered the AERP responses, but with different patterns. While Ketamine induced dose-dependent decreases of the N1 and P2 amplitudes, MK801 caused both a decrease of amplitude and an increase of latency of both these deviations. These drugs left the P1 deviation unaffected. The evoked gamma power and ITC indexes were, for their part, impaired dose-dependently by the MK801 only. In this study, we identified functional biomarkers in mouse models of psychiatric disorders induced by NMDA antagonists using EEG and related methodologies. These specific biomarkers

could represent an important tool for the identification, selection and validation of new innovative therapeutics in psychiatric disorders.

Title: Chronic ketamine administration differentially alters parvalbumin expression as a function of age and time of sacrifice: evidence for dynamic protein expression

Authors: *J. A. CORRIVEAU, K. M. KEARY, III, V. M. KANIA, M. M. CHALUPARAMBIL, J. J. CHROBAK;
Psychology, Univ. of Connecticut, Storrs, CT

Abstract: A marked decrease in the expression of the calcium-binding protein (CBP) parvalbumin (PV) has been a consistent postmortem finding in schizophrenia. This reduction in CBP immunoreactivity is specific to PV, with alterations exclusively seen in the prefrontal cortex and hippocampus of patients. Rodent models of NMDA-receptor hypofunction utilizing non-competitive NMDA antagonist drugs (e.g. ketamine) to induce schizophrenic-like cognitive impairments show a comparable decrease in PV immunoreactivity, which is often considered a marker of underlying neuropathology. However, previous studies looking at the effects of chronic ketamine administration on cognitive impairment and concomitant changes in PV expression are contradictory, with findings suggesting decreased, increased, or even no change in PV expression. Upon examination of the procedures used across studies it is clear that there many inconsistencies, particularly with regard to the age of animals used, as well as the timeline of tissue collection. In order to better understand the possibility of methodological differences impacting PV expression, the present study examined the impact of age and time of sacrifice in behaviorally-naïve male Sprague-Dawley rats following chronic ketamine treatment (14 consecutive days of 30 mg/kg IP ketamine). Our findings suggest a dynamic interaction between age and time of sacrifice on prefrontal cortical and hippocampal PV expression based on treatment. Based on our data, we propose that PV expression is a highly dynamic marker, and

that changes in expression following NMDA antagonist treatment should be considered in the context of the age of the animals used, as well as the timeline of experimental procedures.

Title: Subcortical coherence changes induced by high-frequency stimulation in the thalamic reticular nucleus on a neonatal model of schizophrenia

Authors: *G. CONTRERAS-MURILLO[1], V. M. MAGDALENO-MADRIGAL[1], A. VALDÉS-CRUZ[1], R. FERNÁNDEZ-MAS[1], S. ALMAZÁN-ALVARADO[1], D. MARTÍNEZ-VARGAS[1], I. CAMACHO-ABREGO[2], J. V. NEGRETE-DÍAZ[2], G. FLORES[2];

Abstract: Schizophrenia is a chronic and disabling psychiatric disorder that is often refractory to treatment. The heuristic model most thoroughly characterized is the neonatal ventral hippocampal lesion (NVHL). With this model, brain oscillations changes have been reported similar to schizophrenic patients. Deep brain stimulation (DBS) is accepted as an alternative therapy to treat a variety neuropsychiatric disorders refractory to conventional treatments. In this study high-frequency stimulation (HFS) of the thalamic reticular nucleus (TRN) was performed in the NVHL model of schizophrenia. Fourteen female Sprague-Dawley rats were used. Lesions of the ventral hippocampus in pups with ibotenic acid were performed in seven rats. Left seven rats were sham-operated. At time of implantation the rats were 3-4 months old and weighted ~215-270 g. Bilateral stainless steel electrodes were implanted in TRN (AP -1.4, L 1.8, H 6.2) thalamic dorsomedial nucleus (DM) (AP 1.4, L 1.3, H 5.4) and prelimbic area (PrL) (AP 3.0, L 0.6, H 3.6). Rats were classified as follows: Sham group and NVHL group, both groups received

bilateral HFS in TRN during one hour (100 Hz, 100 microsec pulses, 200 microA). Intra- and inter-hemispheric EEG recordings were analyzed. All animals showed a sudden behavioral arrest accompanied by widespread symmetric bilateral paroxysmal-like EEG activity. The DBS-TRN induced a significant increase in the coherence power of TRN/PrL, TRN/DM and DM/Prl ($p< 0.001$) at 0-4Hz and in the 35-55Hz bandwidth frequencies of the Sham group of left and right hemispheres. The interaction between the TRN and the DM increased with the DBS-TRN at 0-4Hz bandwidth frequency. In addition, in the interaction between the TRN, the DM with the PrL a significant decrease was observed ($p< 0.001$) in NVHL group, whereas the interaction between the TRN and the DM increased with the DBS-TRN and the interaction between TRN and the PrL decreased at 35-55 Hz bandwidth frequency. Our results suggest that HFS in TRN may modify functional connectivity between different parts thalamo-cortical network of NVHL rats, and provide experimental support for the concept that this thalamic region may be a promising target for focal stimulation to treat the refractory schizophrenia disorder.

Title: Possible role for thalamic GAD67 in vacuous chewing movements

Authors: *S. E. BACHUS;
Psychology, George Mason Univ., Fairfax, VA

Abstract: We have previously found a significant negative correlation between levels of thalamic GABA-A alpha 1 mRNA and chronic haloperidol (HAL)-induced vacuous chewing movements (VCM), a rat model for tardive dyskinesia (Sharma et al., SfN Abstr. 2008). Thus, we have explored thalamic levels of GAD67 mRNA, as a presynaptic indicator of GABA function in thalamus. Group-housed male Long-Evans rats (starting wts 90-165 g) were monitored for 2 min samples weekly, under conditions in which environmental noise was not controlled for ("random noise"), over 7 wk, for baseline VCM, and then for 24 wk during chronic administration of HAL decanoate (28.5 mg/kg/ml, i.m., at 3 wk intervals; n=38) or vehicle (sesame oil; n=18), under random noise conditions, and subsequently also under

controlled quiet and noisy conditions. Upon completion of HAL, brains were frozen and cryosectioned onto slides for *in situ* hybridization with an oligoprobe complementary to GAD67 mRNA (or control probe) in diencephalic sections. Measurements of thalamic GAD67 mRNA levels were sampled from scanned and calibrated autoradiograms by a blinded observer. VCM were significantly higher under both random noise and noisy conditions, relative to quiet conditions, in the HAL-treated rats, with much higher variability occurring under the random noise condition relative to the noisy condition. There was a trend toward a reduction in thalamic GAD67 mRNA produced by chronic HAL ($t=1.89$, $p=.06$). Thalamic GAD67 mRNA was not significantly correlated with previously measured GABA-A alpha 1 mRNA in this cohort, among either controls or HAL-treated rats. Nonetheless, thalamic GAD67 mRNA was significantly positively correlated with VCM, specifically under the random noise condition ($r=.32$, $p=.025$), in which variability was highest. That is, the HAL-induced reduction in thalamic GAD67 occurred preferentially among the rats that were less sensitive to the enhancement of VCM by random noise. We conclude from this that effects of chronic HAL on thalamic GABA release may play a protective role against VCM, possibly via secondary upregulation of postsynaptic receptors.

Title: Longitudinal observations of neuro-metabolites in social isolation rearing model: 1H-MRS study at 9.4 T

Authors: *H. HEO, H. H. LEE, H. KIM;
Seoul Nat'L Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: The pathophysiology of schizophrenia is known to be associated with the imbalance between glutamate (Glu) and gamma-aminobutyric acid (GABA) levels. However, little is understood as to how this neuro-metabolic imbalance is initiated. In this study, Glu and GABA as well as other key brain metabolites were quantified *in vivo* in the left hippocampus of a group housing (GH) and a social isolation (SI) rearing rat models by using proton magnetic resonance

spectroscopy (1H-MRS) at 9.4T at the 6th, 10th and 14th week after the weaning period. SI models demonstrated diverse behavioral and neurochemical abnormalities that resembled the features of schizophrenia. The GABA to total creatine (tCr) ratio (GABA/tCr) and the N-acetylaspartate (NAA) to tCr ratio (NAA/tCr) were significantly lower in SI rats with respect to those of GH rats at the 10th and 14th week of isolation. However, Glu/tCr and Glu/NAA did not differ between the two animal groups regardless of the duration of isolation. In the subsequent partial least-squares discriminant analysis (PLS-DA), GABA/tCr and NAA/tCr were further proven to be important factors in the separation of the two animal groups. These data suggest that the neuro-metabolic imbalance between Glu and GABA levels in schizophrenic brain may be initiated with the alterations in the GABA levels.

Title: Network-level dysfunction induced by perinatal phencyclidine is rescued by D-serine treatment

Authors: *S. SESHADRI[1], D. PLENZ[2];
[1]NIMH, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Cognitive dysfunction in schizophrenia (SZ) is thought to arise from disturbances in cortical network functioning, such as impaired local and long-range synchrony. However, these disturbances have not been well characterized at the neuronal level. Here, we used *in vivo* 2-photon imaging of a genetically encoded Ca2+ indicator to record spontaneous spiking activity in local populations of layer 2/3 pyramidal neurons in a rodent model of SZ. Sprague-Dawley rats were treated with phencyclidine (PCP, 10 mg/kg s.c.), an N-methyl D-aspartate (NMDA) receptor antagonist, at postnatal days 7, 9, and 11. This model recapitulates several SZ-associated phenotypes, including reduced density of fast-spiking interneurons and impaired visual working memory, which we confirmed in our cohorts. To assess network-level dysfunction in our recordings, we compared activity cascade sizes between control and PCP treated rats, and found that PCP treatment caused a significant deviation from the expected scale-free, power-law distribution. Such distributions characterize networks organized at a critical point, where several aspects of cortical processing, including information capacity and dynamic

range, are optimized. This higher-order analysis was more sensitive to PCP treatment, and therefore to disrupted excitatory-inhibitory (E-I) balance, than first- or second-order measures (e.g. firing rate and pairwise cross-correlation). Furthermore, treatment with D-serine (800 mg/kg, i.p.), an NMDA receptor co-agonist, reversed this phenotype, in parallel with rescuing impaired cognitive functioning as assessed by a visual working memory test. These results have two important implications. First, that ongoing neuronal group activity at single-cell resolution shows critical dynamics and is sensitive to E-I disruption *in vivo*. Second, that the framework of criticality could characterize cortical dysfunction in schizophrenia, and potentially serve as a biomarker for diagnosis or drug screening.

Title: Developmental ethanol exposure disrupts attention performance and prefrontal neuron function in male mice

Authors: *E. L. LOUTH, W. BIGNELL, C. L. TAYLOR, C. D. BAILEY;
Dept. of Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Chronic prenatal exposure to ethanol can produce a variety of teratogenic effects known collectively in humans as Fetal Alcohol Spectrum Disorder (FASD). Although deficits in attention rank among the most common and persistent neurobehavioural components of FASD, mechanisms underlying this outcome are not known. The objective of this study was to determine effects of developmental ethanol exposure on attention behaviour and on prefrontal neuron function in adult male C57BL/6 mice. Mice were exposed to either ethanol (treatment) or sucrose (control) via oral gavage during the mouse equivalent of the human second and third trimesters. We first measured attention performance using the five-choice serial reaction time test. In these experiments, adult mice from the developmental ethanol treatment group performed with lower accuracy during initial training sessions and then exhibited a greater rate of omissions

under challenging training conditions when the light stimulus was presented for short time periods. Whole-cell electrophysiological recording of pyramidal neurons located within layer VI of the medial prefrontal cortex of these same mice found decreased intrinsic excitability and increased responses to excitatory neurotransmission in mice from the developmental ethanol treatment group. Comparison of behaviour and neuron physiology identified significant correlations between attention performance and nicotinic acetylcholine receptor function in layer VI neurons of control mice, which were not present for mice that had been exposed to ethanol during development. These findings suggest that the role of prefrontal nicotinic signaling to support attention behaviour may be disrupted following developmental ethanol exposure.

Title: The impact of prenatal ethanol exposure on fear memory recall and behavioral development in adulthood

Authors: *O. O. KOZANIAN, E. KORZUS, K. J. HUFFMAN;
Dept. of Psychology, UC Riverside, Riverside, CA

Abstract: *In utero* ethanol exposure produces developmental abnormalities in brain and behavior that often persist into adulthood. Fetal alcohol spectrum disorders (FASD) is an umbrella term used to describe a wide range of adverse developmental conditions caused by alcohol exposure during gestation. Children diagnosed with FASD suffer a wide range of phenotypes including growth retardation, facial dysmorphology, central nervous system anomalies and abnormal behavior and cognition. Previous research in mice suggests that abnormal cortical gene expression and circuitry may underlie reported disabilities of learning, memory, and behavior resulting from early exposure to alcohol (El Shawa et al., 2013). To further characterize behavioral deficits resulting from prenatal ethanol exposure (PrEE) in our mouse model of FASD, we conducted a series of studies to determine if behavioral deficits in sensory-motor integration and anxiety levels persist into adulthood on postnatal day (P) 50, and to evaluate the implications of PrEE on contextual fear memory recall in P50 and P70 mice. In the first study, the behavior of ethanol-exposed offspring was compared to control mice in early adulthood, extending our previous study in pre-adolescent mice (P20, El Shawa et al., 2013).

Results in P50 PrEE mice demonstrated long-term behavioral alternations that mirrored observations made previously in P20. Specifically, P50 mice performed poorly on behavioral tasks measuring sensori-motor integration and had increased anxiety compared to controls. In the second study, fear memory in PrEE mice was assessed at P50 and P70. PrEE significantly alters learning and memory of aversive stimuli at both time points in adulthood. Specially, PrEE mice showed significantly poorer performance on the fear memory recall task when compared to controls. Insight from this study will help provide new information on long-term behavioral effects of prenatal ethanol exposure and how learning and memory is impacted in people diagnosed with FASD.

Title: Delayed orbital frontal cortex recruitment allows for dorsal striatum to drive behavioral inflexibility in prenatal alcohol exposed mice

Authors: *K. L. MARQUARDT[1], J. CAVANAGH[2], K. CALDWELL[1], J. BRIGMAN[1]; [1]Neurosciences, BMSB 145, [2]Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: With a prevalence rate of 2-5% Fetal Alcohol Spectrum Disorders (FASD) are a leading cause of developmental disability in the US despite that prenatal alcohol exposure (PAE) is completely preventable. The social, learning and executive function deficits associated with PAE endure across the lifespan, preventing these individuals from thriving in a dynamic environment. FASD also has a high societal cost with estimates that as many as 46% of adolescents with FASD end up incarcerated and 29% end up being treated for alcohol and drug abuse by the age of 21. The inability of adolescents with FASD to alter their actions appropriately leads to repetitive maladaptive behaviors that can result in arrest, incarceration and substance use disorders. We have previously demonstrated that mice exposed prenatally to a clinically relevant (daily maternal BAC ~85 mg/dL) level of alcohol, during gestation, have

impaired behavioral flexibility, demonstrated by repetitive non-rewarded responses on a touch screen discrimination-reversal task. Targeted lesion, inactivation and immediate early gene expression studies have demonstrated that optimal performance of discrimination learning requires the dorsal striatum (dS) for formation of stimuli-reward associations, while the orbital frontal cortex (OFC) is critical for reward-updating during reversal. Here we integrated the well-established 'drinking in the dark' exposure model with *in vivo* electrophysiological recording during discrimination-reversal performance. Our results of single unit recordings in PAE mice suggest a delay of lateral OFC event-dependent recruitment during choice behavior in reversal and a concomitant over activation in the dS. Analysis of local field potential oscillations revealed differences in timing and power of dS and OFC low-frequencies in PAE animals during reward delivery or omission following correct and incorrect choices, respectively. These data suggest that in the FASD model, the OFC fails to properly update alterations in expected outcomes and exert regulatory control over dS activity during reversal. Ongoing studies are using dual region *in vivo* electrophysiology to analyze functional connectivity between OFC and dS to further elucidate circuitry dynamics between the two regions. The overall goal of these projects is to understand how dS over activation, due to improper recruitment of the OFC is driving behavioral inflexibility after PAE, and how these alterations may be prevented or reversed.

Title: Consequences of prenatal drinking in the dark (DID) and neonatal ethanol intubation on spatial learning and memory in mice

Authors: A. HAWKEY[1], W. XU[2], H. LI[2], L. FIELDS[1], M. CARTER[1], J. LUO[2], G. CHEN[2], *S. BARRON[1];
[1]Psychology Dept., [2]Mol. and Biomed. Pharmacol., Univ. Kentucky, Lexington, KY

Abstract: Fetal ethanol (ETOH) exposure is associated with a variety of behavioral and learning deficits. These effects are observed in both children with Fetal Alcohol Spectrum Disorders and a variety of animal models. The data presented here represents a new exposure model using C57BL/6J mice who are unique in that they will voluntarily drink ETOH when provided limited access during their dark cycle (referred to as "Drinking in the Dark" (DID)). Previous research has examined DID as a model of fetal ETOH exposure (Boehm et al., 2008) however, this work did not include ETOH exposure during the "3rd trimester" brain growth spurt which occurs after birth in mice nor did it examine spatial learning. The hippocampus undergoes considerable perinatal development and is particularly sensitive to ETOH induced teratogenesis. Therefore, the current study used the maternal DID model and a novel, combined pre/post-natal exposure to assess whether maternal DID produces long-term effects on spatial learning and whether adding "3rd trimester exposure" exacerbates these effects. For two weeks prior to breeding and throughout pregnancy, female mice were given access to a 20% ETOH solution daily for 4 hours during their dark cycle. After birth, a subset of ETOH-exposed pups received intubations (3g/kg ETOH, 2x day) on PND 4-10. Non-treated controls were also included. Offspring (PND 35-45) were tested daily to find a hidden platform in a fixed location for 4 trials/day for 4 days using a standard Morris Water Maze. Following acquisition, a probe trial and reversal learning was examined. ETOH-treated males (both prenatal and the combined pre and postnatal ETOH group) displayed deficits in acquisition of the task. Similarly the ETOH-treated females from both groups also displayed acquisition deficits although they eventually reached performance levels similar to controls. ETOH-exposed males also performed more poorly on the probe trial and reversal learning. There were no deficits observed when tested with a visible platform. These data suggest that there may be sex differences in sensitivity to perinatal ETOH exposure on performance in the Morris water maze in C57BL/6J mice. Furthermore, the DID model which uses voluntary consumption is a useful tool to study the consequences of prenatal ETOH exposure on spatial learning.

Title: Moderate *in utero* alcohol exposure results in sex-dependent inflammation in the developing rat brain

Authors: *L. S. TERASAKI, J. M. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Activation of the developing immune system can lead to changes in neural development and long-term neural function. Recent studies show alcohol can activate the immune system; however, the fetal neuroimmune response and long-term effects of *in utero* alcohol exposure are unknown. This project aimed to determine how prenatal alcohol exposure affects the fetal brain and long-term immune and cognitive function. Pregnant Sprague-Dawley rats were left undisturbed or gavaged with either water or 50% ethanol, twice daily on embryonic (E) days 10-16. This low dose of alcohol resulted in an approximate 0.08% blood alcohol concentration for 8 hours. Real-time PCR was used to analyze pro-inflammatory cytokines and chemokines in E17 pup brains. We found that alcohol exposure increased expression of TNF-alpha, TNF-SF13, and TNF-SF13B in the hippocampus-cortex of females, while alcohol-exposed males exhibited decreased expression of CCL2 and CCL20 chemokines in the hippocampus-cortex. Additionally, maternal serum samples were analyzed for cytokine and chemokine levels, but we found no significant changes based on treatment, indicating that this level of alcohol exposure did not have a significant effect in the peripheral immune response of the mother. In a second experiment, using the same paradigm, pups were raised to adulthood to examine long-term learning and immune function. Learning was assessed using a novel object recognition task (NOR) and context pre-exposure facilitation effect (CPFE). We found that alcohol-exposed males exhibited learning deficits in NOR following a second-immune challenge with lipopolysaccharide (LPS) immediately after pre-exposure to the objects. Additionally, alcohol-exposed males exhibited a stronger neuroimmune response to LPS in adulthood, which may precipitate cognitive deficits seen in the NOR. We also examined the effect of a second dose of alcohol during adulthood as a different type of neuroimmune challenge and then tested these rats' cognitive ability by using CPFE. These on-going studies will contribute to our understanding of the impact of *in utero* alcohol exposure on the developing brain and immune system.

Title: Neuroimmune consequences of postnatal ethanol exposure and the potential anti-inflammatory and pro-cognitive benefits of ibuprofen treatment

Authors: *M. J. GOODFELLOW[1], Y. SHIN[2], D. LINDQUIST[1];
[1]Psychology, [2]Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Fetal alcohol spectrum disorders (FASD) describe a range of physical and/or cognitive abnormalities that can occur in people exposed to alcohol during gestation (Streissguth, 2007). The present study utilizes a FASD rat model in which pups are administered ethanol in a binge-like manner (5 g/kg/day; 5E) via intragastric intubation across postnatal days (PD) 4-9. During this human 3rd trimester-equivalent period (Bayer et al., 1993), the developing forebrain is particularly sensitive to ethanol-induced neurotoxicity (Gil-Mohapel et al., 2010), which can cause enduring alterations in NMDA receptor subunit expression and forebrain-dependent learning and memory (e.g., trace fear conditioning or TFC, a cognitively-challenging Pavlovian conditioning task) in adolescent and adult rats (Goodfellow, Abdulla, & Lindquist, Submitted; Schreiber & Hunt, 2013; Samudio-Ruiz et al., 2010). Neuroinflammation (NIF), initiated by the interaction of ethanol with toll-like receptor 4 (Alfonso-Loeches et al., 2010), is proposed to contribute to changes in forebrain structure and function seen in FASD model animals (Kane et al., 2011; Pascual et al., 2011; Tiwari & Chopra, 2012). As a first step toward linking postnatal ethanol exposure, NIF, and observed impairments in learning and memory, we employ ibuprofen (IBU)- an anti-inflammatory drug that is commonly administered to premature human infants (Ohlsson, Walia & Shah, 2015)- to assess its ability to diminish NIF and improve TFC performance in adolescent (PD32) rats. In the current study, male and female 5E, sham-intubated (SI), and unintubated control (UC) Long-Evans rats were injected (s.c.) with IBU (100 mg/kg on PD4 followed by 50 mg/kg every 24h from PD5-20) or PBS. Pre-weanlings were euthanized (PD10 or 21) and forebrain tissue (hippocampus and medial prefrontal cortex) was analyzed via qPCR for expression of inflammatory (e.g., Ptgs2, Il1b, Tnf) and NMDA receptor subunit (Grin2A, Grin2B) genes. Preliminary data suggest postnatal ethanol exposure upregulates pro-inflammatory gene expression but that IBU may have an ameliorating effect. To examine the putative cognitive benefits of IBU treatment, separate 5E, SI and UC adolescent rats will be submitted to TFC. Reduced ethanol-induced NIF is predicted to improve TFC in 5E rats, suggesting IBU may improve forebrain-dependent cognitive function following 3rd trimester-equivalent binge-like ethanol exposure.

Title: Transgenerational effects of perinatal ethanol exposure: alcohol and sucrose consumption in two generations

Authors: *R. LAWRENCE[1], F. HOUK[1], V. STETTER[2];
[1]Biol., Viterbo Univ., La Crosse, WI; [2]Viterbo Univ., La crosse, WI

Abstract: Fetal alcohol spectrum disorders describe the various developmental deficiencies that result from *in utero* exposure to ethanol. Animal models have been helpful in understanding the effects of ethanol on humans. Prenatal ethanol exposure results in cognitive disabilities such as impairment in language, memory, and attention. Secondary defects in social behavior, impulsivity, inappropriate sexual conduct, and substance abuse also occur. Prenatal ethanol exposure characteristically results in higher risks of ethanol preference and addiction. Rattus norvegicus was used to simulate a human equivalent three-trimester ethanol exposure model. Rats were intubated prenatally to simulate the first and second human trimesters and the first ten days after birth to simulate the third human trimester. Ethanol preference across multiple generations was examined by using a two bottle choice test with solutions of ethanol and sucrose and sucrose. Ethanol exposure resulted in increased consumption of ethanol compared to controls whereas the F2 generation was characterized by significant reductions in alcohol consumption. However, offspring of those developmentally exposed to ethanol demonstrated a significant increase in maltose-dextrin consumption. D1R expression in the nucleus accumbens was also determined. This suggests an alteration in nucleus accumbens activity and rewarding aspects of ethanol following developmental exposure.

Title: Paternal alcohol imparts stress hyporesponsivity to male offspring

Authors: G. R. ROMPALA[1], A. FINEGERSH[2], *G. E. HOMANICS[2];
[1]Ctr. for Neurosci., [2]Anesthesiol., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Alcohol use disorder (AUD) is associated with dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis, the endocrine system critical for mounting an appropriate physiological response to stress. Adult men with a family history of alcohol abuse exhibit reduced HPA axis responsivity. Numerous studies have demonstrated that ancestral perturbations including exposure to stress or ethanol (EtOH) can impact subsequent generations via epigenetic mechanisms. In the present study, we tested the hypothesis that chronic paternal preconception EtOH exposure alters acute stress responsivity and stress-evoked EtOH drinking behaviors in offspring. Adult male mice were exposed to five weeks of intermittent vapor EtOH or control conditions and then mated with EtOH-naïve females to produce EtOH-sired (E-sired) and control-sired (C-sired) offspring. Paternal EtOH blunted corticosterone (CORT) responses to acute restraint stress selectively in male offspring. To assess stress-evoked EtOH drinking, adult E-sired and C-sired male offspring were exposed to chronic variable stress (CVS) (comprised of three days each of social defeat, forced swim, predator odor, and restraint stress exposures) over four weeks. Throughout the CVS period, mice were assessed for two-bottle choice EtOH (8% w/vol) drinking in the home cage. While we did not detect an effect of stress on EtOH consumption, C-sired males exhibited increased total fluid intake from baseline during CVS (polydipsia). In contrast, E-sired males were resistant to this stress-induced phenotype. Following CVS and 72 hours after cessation of EtOH availability in the home cage, mice were sacrificed for brain tissue collection and analysis of stress-responsive gene expression [i.e., corticotropin-releasing factor (CRF), glucocorticoid receptor (GR), and arginine vasopressin (AVP)] in the paraventricular nucleus (PVN) using rt-qPCR. CRF mRNA expression in the PVN was significantly reduced for E-sired vs C-sired males with no difference in AVP or GR expression. In addition, using bisulfite-treated DNA from the PVN and melt curve analysis, we detected significantly increased DNA methylation of the CRF promoter in E-sired vs C-sired male offspring. Levels of DNA methylation showed a significant inverse correlation with CRF gene expression. All together, we present endocrine, behavioral, molecular, and epigenetic findings suggesting that E-sired males are hyporesponsive to stress.

Title: The effect of early alcohol exposure on the brain and behavior in a third trimester equivalent animal model of fetal alcohol spectrum disorders

Authors: *P. C. SWART;
Human Biol., Univ. of Cape Town, Observatory, South Africa

Abstract: Introduction: Early alcohol exposure-induced changes in locomotor activity, learning and memory, neurotransmission and proteins were measured using an animal model of fetal alcohol spectrum disorders (FASD). It was also investigated whether a memory enhancing drug (Vinpocetine) could alleviate early alcohol exposure-induced changes. Hence providing insight towards the mechanisms behind FASD. Methods: A third trimester equivalent animal model of FASD was used in which Sprague-Dawley rats were administered 12 % ethanol (EtOH) solution (4 g/kg/day i.p.) or saline volume control from P4 to P9. From P25 to P31, randomly selected male rats were treated with Vinpocetine (Vinp) (20 g/kg/day i.p.) or DMSO vehicle control (saline+DMSO-; EtOH+DMSO- and EtOH+Vinp-treated rats) prior to undergoing behavioural testing in the Open Field and Morris Water Maze (MWM). All rats were decapitated on P31, after which the prefrontal cortex (PFC), dorsal hippocampus (DH) and striatum were removed. The striatum of untreated rats were used in an *in vitro* superfusion experiment to asses glutamatergic receptor and dopaminergic functioning using radioactively labelled [3H] Dopamine (DA). The rest of the dissected tissue from treated rats was stored in liquid nitrogen for later use in a BDNF ELISA, Western Blot and proteomic analysis. Results: Behavioural results show that EtOH+Vinp-treated rats learnt better during the acquisition trials of the MWM compared to EtOH+DMSO-treated rats on days 1, 2 and 4. However, during the probe trial no significant difference was observed in the time spent in the platform quadrant between experimental groups. Results from *in vitro* superfusion experiments showed no differences in [3H]DA release between saline- and EtOH-treated rats. BDNF was significantly decreased in the PFC of EtOH+Vinp-treated rats. MKP-1 was significantly increased in the PFC of EtOH+Vinp-treated rats. P-ERK was significantly decreased in the PFC and significantly increased in the DH of EtOH+DMSO-treated rats. An increase in P-GSK was observed in the DH of EtOH+Vinp-treated rats. Similarly, synaptophysin was increased in the DH of EtOH+Vinp-treated rats. Conclusion: EtOH induced learning deficits in the MWM during acquisition trials however, all animals were able to re-call the location of the platform during the probe trial. This indicates differential learning between groups however memory remains unaffected. EtOH did not affect glutamatergic receptor or dopaminergic function. Therefore, the behavioural results may be explained by differential protein expression between experimental groups in the PFC and DH.

Title: Magnetoencephalography study on multisensory integration in adolescents with fetal alcohol spectrum disorder

Authors: *A. D. BOLANOS[1,4], B. A. COFFMAN[4,5], J. F. L. PINNER[2], P. KODITUWAKKU[3], J. M. STEPHEN[4];
[2]Psychology, [3]Pediatrics, [1]Univ. of New Mexico, Albuquerque, NM; [4]The Mind Res. Network, Albuquerque, NM; [5]Psychiatry, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: It is now known that children exposed to alcohol *in utero* display a broad range of cognitive and behavioral deficits along with functional and structural neural anomalies. Children with fetal alcohol spectrum disorder (FASD) have impairments in sensory processing and executive functioning, suggesting atypical brain development. Here we measure brain responses using magnetoencephalography (MEG) during passive auditory (A - left and right monaural 1000 Hz tone), somatosensory (S- air puff stimulus to left and right index finger), and multisensory (synchronous auditory/somatosensory) stimulation from 19 adolescents with FASD and 23 age-matched, typically developing controls. A cross-hemisphere multisensory paradigm (left A/left S, LA/RS, RA/RS and RA/LS) was employed to assess hemispheric connectivity deficits in children with FASD. Based on the role of neural oscillations in multisensory integration, we hypothesized that neural oscillations would be altered in adolescents with FASD. Time-frequency analysis of the MEG data revealed a significant decrease in oscillatory power for six (LS, RS, RA/RS, RA/LS, LA/RS, and LA/LS) out of the eight conditions in the FASD group based on permutation testing of significant group differences. Gamma power was reduced in two multisensory conditions (RA/RS and RA/LS) in the FASD group relative to controls.

Also, an increase in beta and gamma band power was noted in the FASD group compared to the control group, for multisensory conditions associated with left auditory stimulation (LA/RS and LA/LS). Through one-sample t-tests corrected for multiple comparisons, we noted that between-group differences in multisensory conditions were accompanied by a significant within-group increase in oscillatory power relative to baseline in the control group and a decrease in the FASD group. Furthermore, results revealed that unisensory oscillatory power predicted multisensory oscillatory power more strongly in the control group than in the FASD group. Yet, oscillatory power only correlated with attention and impulsivity scores in the FASD group. The present results provide further evidence of abnormal gamma band oscillations in adolescents with FASD when responding to sensory stimuli. Differential response to left vs. right auditory stimuli may indicate hemispheric differences in neural activity related to prenatal alcohol exposure. These alterations in neural oscillations may contribute to the neurobehavioral deficits experienced by individuals with FASD by restricting their ability to respond properly to external stimuli during day-to-day interactions.

Title: Female rats exposed to moderate levels of ethanol during gestation display modified spatial navigation behavior

Authors: *C. M. MAGCALAS[1], D. BARTO[2], C. W. BIRD[2], S. DAVIES[3], D. D. SAVAGE[3], D. A. HAMILTON[4];

Abstract: Prenatal alcohol exposure (PAE) is associated with structural and physiological changes that impact the central nervous system and can result in persistent negative consequences in a broad spectrum of cognitive and behavioral domains including deficits in motor behavior, social behavior, and behavioral flexibility. Previous studies have characterized

the influence of PAE on spatial navigation and behavioral flexibility through various behavioral paradigms including the Morris water task (MWT). The current study focuses on examining the behavioral consequences of PAE on directional and place navigation through the use of the MWT. Pregnant rat dams voluntarily consumed saccharin (SAC) water containing 0% or 5% ethanol (EtOH) for 4 hours per day during the entire gestational period. The pups matured and 16 adult males and 16 adult females were tested in a variant of the MWT. In order to assess directional and place navigation the animals were tested in a 2-day hidden platform protocol and a 2-day cued platform protocol with a 2 week time period between sessions. Day 1 of the hidden protocol consisted of 12 training trials and 1 pool shift test. Day 2 consisted of 8 training trials, 1 pool shift test (opposite of the first test), 4 training trials, and 1 probe trial. The pool shift test consisted of moving the pool to a secondary position. The platform either moves with the pool to a relative location in the pool (directional navigation) or stays in the absolute location in the room (place navigation). Following a 2-week period the rats were tested in a cued variant of the MWT. The cued variant followed the same scheme as the hidden variant except that there were 8 preferred reversal trials added to the end of day 2. The reversal paradigm involved shifting the pool while the platform was placed in the opposite of the location that the animal showed preference to. There were no significant differences between PAE treatment or sexes in the hidden or cued training trials. In the hidden variant there was a significant interaction in the females between preference for the absolute or relative location and PAE. The SAC female rats displayed a preference for the relative platform location, which is consistent with previous findings, while EtOH female rats displayed a preference for the absolute location. These outcomes suggest that animals may have distinct search patterns that may be sex specific and can be influenced by PAE. [Supported by grant AA019462 to DH].

Title: Impact of postnatal 5-7-9 alcohol exposure and voluntary exercise on prefrontal plasticity and behavior

Authors: *G. F. HAMILTON, I. J. HERNANDEZ, C. P. KREBS, J. S. RHODES;
Univ. of Ilinois Urbana-Champaign, Champaign, IL

Abstract: Developmental alcohol exposure in humans can result in a wide range of deficits collectively referred to as Fetal Alcohol Spectrum Disorders (FASD). FASD-related impairments in cognition and learning persist into adulthood and are accompanied by structural changes in the prefrontal cortex (PFC). In animal models of FASD, neonatal alcohol exposure significantly altered medial PFC (mPFC) pyramidal neuron dendritic morphology. Basilar dendrites of mPFC neurons receive indirect connections from the mediodorsal nucleus of the thalamus via parvalbumin+ GABAergic interneurons. Therefore, in this experiment we examined the impact of a postnatal (PD) 5, 7 and 9 alcohol exposure on 1) the number of mPFC parvalbumin+ GABAergic interneurons and 2) behavioral performance on both the Rotarod and the Passive Avoidance tasks. Further, we explored the therapeutic role of aerobic exercise. Exercise consistently has been shown to improve hippocampal function and plasticity in the alcohol exposed brain, while its influence on the mPFC is much less established. In this experiment, animals received a treatment of either saline or a 20% ethanol solution at 5 g/kg split into two doses, two hours apart on postnatal day (PD) 5, 7, and 9. Animals were weaned on PD 23 and, beginning on PD 35, all animals received either a running or sedentary intervention for 48 days. Animals were perfused on PD 83 and the number of mPFC parvalbumin+ interneurons was measured. Preliminary data suggest that a PD 5, 7 and 9 alcohol exposure reduces the number of parvalbumin+ cells in the mPFC. The role of exercise on the number of parvalbumin+ interneurons is currently being determined. Neonatal alcohol exposure significantly impaired acquisition of the Passive Avoidance task, regardless of exercise intervention. On Day 2, exercise significantly increased retention of the Passive Avoidance task, regardless of postnatal condition. All runners remained on the rotarod significantly longer than did all sedentary animals. Overall, these data examine the long-term, possibly detrimental, influence of neonatal alcohol exposure and the potentially beneficial impact of voluntary exercise in the alcohol-exposed brain.

Title: Reduced agonistic behavior in male rats exposed to ethanol prenatally following blockade of GluN2B containing NMDA receptors in agranular insular cortex

Authors: *C. W. BIRD[1], D. BARTO[1], C. MAGCALAS[1], C. I. RODRIGUEZ[1], T. DONALDSON[1], S. DAVIES[2], D. D. SAVAGE[2], D. A. HAMILTON[1,2];

Abstract: Moderate exposure to alcohol during development leads to subtle neurobiolgical effects, which are diagnosed under the umbrella term fetal alcohol spectrum disorders (FASDs). Alterations in social behaviors are a frequently observed negative consequence of maternal drinking, as children with FASDs display inappropriate aggressive behaviors, have altered responses to social cues, and increased prevalence of conduct disorder. Rodent models of FASDs mimic the behavioral alterations seen in humans, with rats exposed to ethanol during development displaying increased aggressive behaviors, decreased social investigation, and altered play behavior. Prior work from our laboratory has observed increased agonistic behaviors in adult male rats following prenatal alcohol exposure (PAE), as well increased expression of GluN2B containing NMDA receptors in agranular insular cortex (AID), a frontocortical subregion specifically implicated in modulating social behaviors. This study was undertaken to determine if GluN2B antagonism has a significant effect on agonistic social behaviors in PAE rats. Using a voluntary ethanol exposure paradigm, rat dams were allowed to drink a saccharin sweetened solution of either 0% or 5% ethanol for 4 hours per day throughout gestation. Following parturition and weaning, rats from the same prenatal diet condition were pair-housed, and at 6-8 months of age were implanted with cannulae into AID. Animals were isolated for 24 hours before ifenprodil (1 μg), a GluN2B specific NMDA receptor antagonist, or vehicle was infused bilaterally into AID, and after 15 minutes they were recorded in a social interaction chamber. The following week animals were again isolated for 24 hours, then infused with the opposite drug treatment and observed again. A significant effect of ifenprodil infusion was observed on agonistic wrestling behavior in males, as PAE rats infused with vehicle displayed increased wrestling behavior compared to control rats that was normalized to controls following ifenprodil infusion. In female rats ifenprodil infusion increased agonistic wrestling behavior regardless of prenatal diet condition, mirroring previously observed sexually dimorphic effects of PAE exposure on social behaviors. Together, these data indicate that GluN2B containing NMDA receptors in AID play a role in social behavior and may underlie alterations observed in PAE animals.

Title: *In utero* ethanol exposure disrupts migration of glutamatergic neurons into the cortical plate

Authors: *L. C. DELATOUR, H. H. YEH;
Geisel Sch. of Med. At Dartmouth, Lebanon, NH

Abstract: Exposure to ethanol during fetal brain development is one of the leading causes of preventable, non-genetic intellectual disability. However, the mechanisms leading to the detrimental effects of *in utero* ethanol exposure on brain development are multifaceted and not fully understood. We have previously reported that exposure to ethanol *in utero* disrupts tangential migration of GABAergic cortical interneurons that occurs early in embryonic corticogenesis. Here we initiated an investigation into the effect of prenatal ethanol exposure on radial migration, involving radial glial cells (RGCs). These cells are critical not only to the development of cortical lamination and radial migration, but also to producing neurons directly as well as indirectly through intermediate progenitor cells (IPCs). During neurogenesis, the expression of transcription factors Pax6, Tbr2, and Tbr1 correspond to the progression from RGCs to IPCs, and to postmitotic glutamatergic neurons, respectively. We used a 3-day binge-drinking paradigm in which pregnant dams were exposed to ethanol (5% in liquid food) from embryonic day(E) 14.5 through E16.5, corresponding to a period of active neurogenesis and migration. In 30-µm coronal cryosections through the E16.5 embryonic telencephalon, we noted aberrant expression of both Tbr2 and Tbr1 in the ethanol-exposed cohort. In control animals, Tbr1 immunoreactivity was greatest in the cortical plate (CP). However, in the ethanol-exposed telencephalon, Tbr1 immunoreactive profiles were dispersed throughout both the CP and intermediate zone. Tbr2 expression also differed between control and ethanol-exposed animals. To investigate whether the observed changes in migration were due to a difference in neuronal proliferation, pulse-labeling experiments were conducted with BrdU, analyzed 2 hours post IP injection on E14.5. The results revealed a different pattern of migration of the BrdU+ cells prior

to entry into the cortical plate and a trend towards an increase in their overall number in the cortex of ethanol-exposed relative to control cohorts. Pyramidal neurons in the cortex are glutamatergic. The results of our immunostaining indicated that at least a subpopulation of them express Tbr1 at some point in their maturation. Our results thus far suggest that ethanol exposure *in utero* affects the radial migration of Tbr1- and Tbr2-expressing cells. Ongoing studies are examining (1) whether changes in the radial glial scaffolding could be affecting the migration of these glutamatergic neurons into the CP, and (2) the short- and long-term effects of *in utero* ethanol exposure on pyramidal cells in the cortex. *Supported by PHS NIH R01AA023410*

Title: Impaired production of oligodendrocyte lineage cells in a third trimester-equivalent mouse model of fetal alcohol spectrum disorder (FASD)

Authors: J. NEWVILLE[1], C. F. VALENZUELA[1], L. LI[1], L. JANTZIE[2], *L. A. CUNNINGHAM[1];
[1]Dept Neurosci, [2]Pediatrics, Univ. New Mexico Sch. Med., Albuquerque, NM

Abstract: Recent imaging studies have demonstrated white matter abnormalities in individuals with clinical FASD, but the underlying mechanisms are unknown. Here, we evaluated the impact of early postnatal alcohol exposure on the production of oligodendrocyte lineage cells using a third trimester equivalent preclinical mouse model of FASD, in which pups were exposed to alcohol during a critical period of rapid myelination. We utilized the Nestin-CreER^{T2}/YFP strain to distinguish between oligodendrocyte lineage cells derived from the postnatal subventricular zone (SVZ; Olig2^{+}/YFP^{+}) *vs.* those originating during embryonic development (Olig2^{+}/YFP^{-}). Nestin-CreER^{T2}/YFP pups received a single intraperitoneal injection of tamoxifen (33 mg/kg) at postnatal day 2 (P2) to label SVZ progenitors, and cages containing both mothers and pups were placed into inhalation chambers where they were exposed to ethanol vapors or air (control) for

four hours daily from P3 through P15 (3 litters/group). The mean daily pup blood alcohol concentration over the 13 days of exposure was 48 mM within a 24-84 mM range. Mice from each litter were sacrificed at P16 or P50 and the densities of $Olig2^+$ and YFP^+ cells within the septal region of the corpus callosum were quantified using immunofluorescence and confocal stereology. Although alcohol had no effect on the density of $Olig2^+/YFP^-$ cells at P16 (1547 $\pm$ 110 vs. 1335 $\pm$ 337 cells/mm^2, air vs. alcohol, n=4-5 mice/group), the density of $Olig2^+/YFP^-$ cells was significantly decreased by approximately 32% in alcohol exposed mice compared to controls at P50 (2424 $\pm$ 278 vs. 1546 $\pm$ 57 cells/mm^2, air vs. alcohol, p=0.0342, n=7-9). Interestingly, there was no effect of alcohol on the density of SVZ-derived oligodendrocyte lineage cells ($Olig2^+/YFP^+$) at either P16 or P50. SVZ-derived $Olig2^+$ cells comprised approximately 20% of the total oligodendrocyte lineage cells within the corpus callosum across all groups except the P50 alcohol exposed group (25%), due to loss of $Olig2^+/YFP^-$ cells at this age. These results indicate that third trimester equivalent alcohol exposure results in a delayed, long-term deficit in oligodendrocyte production that becomes manifest in early adulthood. Furthermore, these data suggest that the oligodendrocyte lineage cells derived from the postnatal SVZ are relatively insensitive to the effects of early postnatal alcohol exposure, but do not fully compensate for loss of non-SVZ derived cells.

Abstract: Maternal alcohol exposure during pregnancy is an environmental risk for disturbed brain function, causing impaired cognitive and social functioning in exposed offspring. Preclinical studies demonstrate that alcohol exposure during development effects multiple processes of brain development, though the underlying molecular mechanisms remain poorly understood. Here we present that developmental alcohol exposure impairs dendritic development via disruption of neuronal nitric oxide synthase (nNOS)-mediated *S*-Nitrosylation of nuclear distribution element-like (NDEL1). *S*-Nitrosylation of NDEL1 accelerates dendritic arborization in the cerebral cortex. This posttranslational modification is enhanced by NMDA receptor-mediated neuronal activity, a main regulator of dendritic formation. Importantly, dendritic deficits caused by alcohol exposure are rescued by up-regulation of NDEL1 *S*-Nitrosylation, suggesting that altered *S*-Nitrosylation of NDEL1 acts as a key pathological factor mediating neurodevelopmental abnormalities caused by maternal alcohol use.

Title: Bumetanide treatment mitigates ethanol-induced deficits in PFC-dependent behavior associated with interneuronopathy in a mouse model of FASD

Authors: *H. H. YEH, A. G. J. SKORPUT, V. P. GUPTA, P. W. L. YEH, J. T. WEISS, N. M. SIMINERI;
Physiol. and Neurobio., Geisel Sch. of Med. at Dartmouth, Lebanon, NH

Abstract: GABA, via GABAA receptors, regulates corticopetal migration of GABAergic cortical interneurons during corticogenesis. This GABA-mediated migration is accelerated *in vivo* by prenatal exposure to ethanol, a positive modulator of the GABAA receptor. GABAA receptor activation depolarizes these cells due to increased developmental expression of the Na+-K+-2Cl- cotransporter (NKCC1), maintaining [Cl-]i higher than [Cl-]e. We hypothesized that ethanol, in potentiating GABAA receptor function, surges chloride efflux, augmenting the GABA-induced depolarization and, thereby, boosting tangential migration. Here, we tested the corollary mechanistic hypothesis that bumetanide, an inhibitor of NKCC1 activity in the brain, mitigates the ethanol-induced aberrant tangential migration. In addition, ethanol-exposed young adult offspring exhibited enduring interneuronopathy in the medial prefrontal cortex as well as decreased behavioral flexibility. We report here on our ongoing investigations into bumetanide's ability to prevent ethanol-induced aberrant migration in the short-term and the behavioral deficit in the long-term. Nkx2.1Cre/Ai14 mice harbor tdTomato-fluorescent MGE-derived GABAergic interneurons. On E14.5, organotypic slice cultures prepared from Nkx2.1-tdTomato embryos were divided into 4 groups: Control; 50mM Ethanol; 20μM Bumetanide; 50mM Ethanol+20μM Bumetanide. Ethanol and/or bumetanide were added to the slice medium at t1hr. The slices were fixed at t25hr, and the number of tdTomato-fluorescent cells was analyzed for each group in a blinded fashion. Such analyses uncovered significantly higher numbers of tdTomato-flourescent cells in slices exposed to ethanol, as reported *in vivo*, indicating a greater degree of tangential migration into the neocortex. The number of migrating cells was near control levels in the group treated with ethanol+bumetanide, suggesting that bumetanide prevented the ethanol-induced heightened tangential migration. Cell counts were similar in slice cultures treated with and without bumetanide alone. With binge-type gestational ethanol exposure *in vivo* (5% w/w in food, E13.5-E16.5), bumetanide prevented the ethanol-induced increase in Nkx2.1+ cells. Young adult offspring treated daily with bumetanide during the period of binge-type ethanol exposure did not exhibit the increase in perseverative error upon reversal of a spatial navigation task, as was seen in ethanol-exposed offspring. These results suggest that bumetanide treatment may have therapeutic benefits in decreasing cortical dysfunction associated with interneuronopathy in the pathophysiology of FASD.

Title: Embryonic alcohol exposure increases apoptosis in the zebrafish brain; a strain comparison

Authors: *S. MAHABIR[1], D. CHATTERJEE[2], R. GERLAI[2];
[1]Univ. of Toronto Mississauga, Mississauga, ON, Canada; [2]Psychology, Univ. of Toronto Mississauga, Toronto, ON, Canada

Abstract: Fetal alcohol spectrum disorder (FASD) is the term used to describe children that have been exposed to alcohol in the womb. Individuals that are affected display a range of severe to mild central nervous system (CNS) abnormalities. The severity of this disorder varies depending on the dose and time of exposure and genetic background of the individual. The biological mechanisms that underlie how alcohol exerts its deleterious effects in vertebrates are complex and poorly understood. The zebrafish has been a popular model for developmental biology, and recently has also started to be employed for FASD research. When exposed to low concentration of alcohol during embryonic development, zebrafish show long lasting behavioural alterations that persist in adulthood. These alternations are correlated with changes in the dopaminergic and serotonergic systems. One potential mechanism that embryonic alcohol may be acting on is programmed cell death or apoptosis. The present study investigates the effects of embryonic alcohol exposure on apoptosis and two proteins in the signaling pathway leading to apoptosis. We used 3 different zebrafish strains AB, TU and TL. Zebrafish embryos were exposed to ethanol (EtOH) at 24 hours post-fertilization (hpf) for 2 hours using three external bath concentrations, 0.00%, 0.50% or 1.00% EtOH (vol/vol%). The embryos were analyzed for apoptosis, pro and anti apoptotic proteins Bax and Bcl2 at 26 hours post-alcohol exposure. Results show that embryonic alcohol increases apoptosis in fish of the AB and TL strains but not in fish of the TU strain. Moreover, AB and TL zebrafish also show an increase in pro-apoptotic protein Bax and no change in anti-apoptotic protein Bcl2 in the alcohol-exposed group. TU strain fish, on the other hand, did not show any change in pro apoptotic and anti apoptotic proteins in response to embryonic alcohol exposure. We conclude that apoptosis induced by embryonic alcohol exposure is mediated by Bax and Bcl2 proteins and that characterization of zebrafish strains may allow one to discover potential protective mechanisms. Given the translational

relevance of the zebrafish, our studies may help us further understand the biological mechanisms underlying FASD in humans.

Title: Third trimester-equivalent ethanol exposure causes micro-bleeds in the rat cerebral cortex

Authors: J. WELCH, J. MAYFIELD, *C. F. VALENZUELA;
Dept Neurosci, Univ. New Mexico HSC, Albuquerque, NM

Abstract: Exposure to ethanol during fetal development causes a wide range of alterations in many organs and systems, including the brain. It is known that ethanol exposure results in a number of molecular pathologies; however, experimental evidence also suggests that ethanol can indirectly affect brain development by altering maternal and fetal vascular development. Spontaneous hemorrhage has been documented in the cerebral cortex of developing rats, suggesting that immature cortical capillaries are susceptible to rupture (Pavlik and Mares, *Neuroscience Letters*. 141 (1992) 177-180). In this study, we examined whether ethanol exposure during the rat equivalent to the 3rd trimester of human pregnancy causes bleeding in the developing brain. Pregnant Sprague-Dawley dams were exposed with their pups to air or ethanol on postnatal days 3, 4, and 5 from 10 am-1 pm daily using vapor inhalation chambers. This paradigm results in peak ethanol levels near 75 mM in the pup serum. Brains were examined at postnatal day 6 and, as expected, demonstrated spontaneous micro-bleeds in the surface of the cerebral cortex of air exposed control pups (1.6 ± 0.08 bleeds/brain; n = 4). In brains from ethanol exposed pups, the number of bleeds per brain was significantly increased to 23 ± 0.08 (n = 7; p = 0.006 by Mann-Whitney test). Coronal brain sections were examined and subsequent regional analysis revealed that the vast majority of the micro-bleeds were located in the cerebral cortex. Experiments are currently underway to determine the age- and dose-dependency of this effect. Our results suggest that heavy ethanol exposure during the 3rd trimester equivalent can weaken the capillary vasculature in the developing cerebral cortex, causing micro-hemorrhages

in this brain region. We conclude that this effect could be one of the mechanisms underlying the behavioral deficits associated with fetal alcohol spectrum disorders.

Title: *Ex vivo* model of prenatal alcohol exposure: development and confirmation of validity

Authors: ***E. TUNC-OZCAN**[1], A. B. FERREIRA[2], E. E. REDEI[1];
[1]Dept. of Psychiatry and Behavioral Sci., [2]Cell and Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: Fetal Alcohol Spectrum Disorder (FASD) encompasses a continuum of disabilities caused by prenatal alcohol exposure (PE). Hippocampus-based cognitive deficits are among the most debilitating consequences of PE and insulin pathway genes are known to be involved in regulating learning and memory processes in the hippocampus. Currently, no treatment is available for FASD. Development and screening of novel drug targets often relies on *in vitro* studies, which are scarce in FASD research. For this reason, we developed an *ex vivo* model and compared transcript levels of insulin pathway genes between the *ex vivo* primary hippocampal culture and embryonic day 21 (E21) hippocampi. Using our established animal model of FASD, pregnant rats were fed control and ethanol-containing diets from gestational day 8 to 20. Male and female E21 hippocampi were dissected, and male and female E18 hippocampi were cultured together, or separately, for three days (days *in vitro* 3 - DIV3) using standard primary hippocampal culturing techniques. Transcript levels of insulin-like growth factor 2 (Igf2), Igf2 receptor (Igf2r), insulin receptor (Insr), ras-guanine nucleotide releasing factor 1 (Rasgrf1), growth factor receptor-bound protein 10 (Grb10) and pleomorphic adenoma gene-like 1 (Plagl1/Zac1) were measured by quantitative RT-PCR in the fetal hippocampi and from the *ex vivo* primary hippocampal culture in all prenatal treatment groups. When male and female hippocampi were combined by litter, primary hippocampal neurons at DIV3 showed a co-expression pattern of the above genes that was very similar to those obtained from the E21 hippocampus. Furthermore, transcript levels of these genes were affected by PE similarly in the E21 hippocampi compared to the primary hippocampal cultures at DIV3. When male and female

hippocampi from the same litter were handled separately, sex differences in gene expression observed in the fetal hippocampus at E21 were not present in the *ex vivo* model, with the exception of Grb10. PE-induced expression differences were also seen between the female E21 and the cultured hippocampi for Igf2, Rasgrf1 and Zac1. These sex differences are likely due to the developmental events between E18 and E21, and the known size differences between the male and female fetal hippocampus, which is eliminated in the culture. Taken together, primary hippocampal culture could be useful to develop and characterize drug-based interventions to reverse PE-induced hippocampal dysregulation.

Title: DNA methylation, neural stem cells and Fetal Alcohol Spectrum Disorders; implicating the role of MeCP2 regulatory network

Authors: *M. RASTEGAR, V. R. B. LIYANAGE, R. M. ZACHARIAH;
Biochem. and Med. Genet., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Fetal alcohol spectrum disorders (FASD) are intellectual disabilities with facial-growth abnormalities and compromised brain function due to maternal alcohol exposure. FASD are common neurodevelopmental disorders that affect 1-3% of live-born children. Currently, FASD has no cure and the molecular mechanisms by which alcohol deregulates the gene expression program of differentiating neurons are poorly understood. Characterizing the cellular and molecular deficiencies of the affected neurons and identifying clinically relevant drugs to rescue these neurons are the major focus of this study. FASD etiology is thought to be *via* alcohol-gene interactions in differentiating embryonic neural stem cells during brain development. This process is tightly regulated by epigenetic mechanisms and epigenetic factors. One of the best-studied epigenetic mechanisms that control brain development is DNA

methylation. The main protein that binds to the methylated DNA in brain is MeCP2 with key roles in brain development and function, recently linked to FASD. Accordingly, altered MeCP2 levels or loss-of-function mutations cause Rett Syndrome, autism, and X-linked mental retardation. Our initial studies in MeCP2-deficient mouse were proof-of-principle for the role of MeCP2 isoforms in neuronal maturation. We reported the developmental and cell type-specific expression of *Mecp2/*MeCP2 isoforms in brain. We identified and characterized *Mecp2* regulatory elements that are controlled by DNA methylation. We now show that these sequences are involved in *Mecp2*/MeCP2 deregulation by ethanol, associated with altered inactive (5mC: 5-methylcytosine) and active (5hmC: 5-hydroxymethylcytosine) DNA marks. We find that different modes of ethanol exposure [continuous, single time exposure, or withdrawal] either induce or decrease *Mecp2*/MeCP2. In response to ethanol, we show globally altered 5mC and 5hmC levels associated with increased neuronal neurite branching that might be biologically important. MeCP2 is the main 5mC- and 5hmC- binding protein in brain and we show selective deregulation of MeCP2 regulatory network by ethanol. Further, we show altered *Mecp2/*MeCP2 levels by an epigenetic drug (DNA methylation inhibitor) that may have future applications for MeCP2-associated neurodevelopmental disorders. DNA methylation is reversible, thus uncovering deregulation of MeCP2 regulatory network and DNA methylation-mediated effects of ethanol in neurons is critical for possible drug therapy strategies. Our results indicate that targeting MeCP2 network might be a possible intervention-therapeutic avenue to rescue impaired neuronal function caused by ethanol.

Title: Gene expression profiling and genome-wide sequencing of methylated DNA identified dynamic changes in the methylome during early development

Authors: C. MANDAL[1], K. JUNG[2], S. KIM[2], K. PARK[2], J. CHAI[2], Y. LEE[2], *Y.-G. CHAI[3]; [1]Hanyang university, Ansan, Korea, Republic of; [3]Mol. Biol. & Life Sci., [2]Hanyang Univ., Ansan, Korea, Republic of

Abstract: Alcohol (ethanol, EtOH) consumption during pregnancy causes a variety of prenatal and postnatal disorders collectively referred to as fetal alcohol spectrum disorders (FASDs).

Recently, increasing evidence indicates that alcohol may induce epigenetic alterations, in particular aberrant DNA methylation patterns. To better understand the molecular events leading to FASDs, we performed a genome-wide transcriptomic (mRNA-seq) and DNA-methylom analysis (MBD-seq) of ethanol exposed emryoid bodies. Combined transcriptomic and DNA methylomic analysis produced a list of differentiation-related genes dysregulated by ethanol-induced DNA methylation changes. We also short listed 19 transcription factor encoding genes which are regulated through DNA methylation. These findings should help in deciphering the precise mechanisms of alcohol-induced teratogenesis.

Title: The importance of the 6- and 7-positions of tetrahydroisoquinolines as selective antagonists for the orexin 1 receptor

Authors: *Y. ZHANG[1], D. A. PERREY[1], A. M. DECKER[1], J.-X. LI[2], B. P. GILMOUR[1], B. F. THOMAS[1], D. L. HARRIS[1], S. P. RUNYON[1];

Abstract: Selective antagonism of the orexin 1 (OX1) receptor has been proposed as a potential mechanism for treatment of drug addiction. We have previously studied the structure-activity relationships of tetrahydroisoquinoline-based antagonists which normally have di-substitutions at the 6- and 7-positions. Here we aim to elucidate the respective role of 6- and 7-substitution by preparation of a series of either 6-substituted tetrahydroisoquinolines (with no 7-substituents) or vice versa. These compounds were characterized by MS, NMR and HPLC, and then evaluated in calcium-dependent functional assays in RD-HGA16 (Molecular Devices) cell lines stably expressing either the OX1 or OX2 receptor. We found that 7-substituted tetrahydroisoquinolines showed potent antagonism of OX1, with several compounds having Ke values of low nM,

whereas the 6-substituted analogs generally showed modest potency. These results suggest that the 7-position is more important for OX1 antagonism. Several compounds demonstrated insurmountable antagonism at the OX1 receptor and studies on incubation time suggest that these compounds are competitive antagonists with slow dissociation rates. These results will facilitate the development of potent and selective OX1 antagonists as medications for the treatment of drug addiction and related conditions.

Title: Feasibility of targeted intracerebral administration in the cynomolgus monkey

Authors: ***J. DOUVILLE**, F. EMOND, C. FOUCAULT, J.-F. LAFOND, R. ST-JACQUES, C. COPEMAN;
Charles River Labs. Preclinical Services, Montreal, Senneville, QC, Canada

Abstract: Various types of compounds are unable to efficiently cross the blood-brain barrier (BBB), or have too short of a half-life to reach their target across the BBB when administered systemically. Therefore, targeted delivery of drugs directly into specific brain compartments may be indicated. This can be achieved in rodents relatively easily as rats from a given strain are highly homogeneous and stereotaxic coordinates are well established. In large animals, accurate delivery in a given brain structure represents a greater challenge. Documented coordinates are considered approximations, because of marked variability in size and shape of the head. We investigated whether a combination of the published stereotaxic coordinates and cranial landmarks would allow us to develop a reliable approach for accurate intracerebral injection in the cynomolgus monkey. The putamen, the substantia nigra and the lateral ventricles were targeted for this initial project. The scalp was incised, and the position of the bregma relative to the instrumental zero was measured and documented. The coordinates of the areas of interest were located, marked and a burr hole was made to allow insertion of the needle. Various volumes of ink were injected at different rates to evaluate diffusion and reflux in order to determine an optimal administration volume range, size of needle and rate of injection. The animal was euthanized, sequential sectioning of the brain was performed and tissues were

embedded in paraffin and stained with hematoxylin and eosin for histopathological evaluation. The actual localization of the injection sites, ink diffusion and needle tracts was then confirmed by histopathology (substantia nigra and putamen) or by successful collection of cerebrospinal fluid (ventricles), and coordinates to be used were further refined based on the results observed. Once the optimal conditions were established, we proceeded with in-life bilateral injections in the putamen of a limited number of animals followed by an observation period. Clinical signs, body weights, food intake, neurological evaluations, and clinical pathology parameters were monitored for 3 weeks and detailed histopathology of the targeted structures was conducted to characterize any procedure-related effects. Reaching the substantia nigra proved to be more problematic than the other areas, and will require additional refinement of the procedures.

Abstract: Alterations in zinc levels have been associated with various neurological and psychiatric disorders, such as schizophrenia, attention deficit hyperactivity disorder, depression, autism, Parkinson's disease, Alzheimer's disease, seizures and traumatic brain injury. However, the limited uptake of zinc into the brain owing to the presence of the blood-brain barrier, posses a serious challenge in selectively manipulating brain zinc levels for example by specific diets. Thus, in order to manipulate zinc-levels within the central nervous system (CNS) as tool for basic research and as emerging new therapeutic strategy for the prevention and treatment of psychiatric and neurological disorders, new approaches are highly desired. In this study, we

performed *in vivo* experiments investigating the possibility of targeted zinc delivery into the CNS using zinc-loaded polymeric nanoparticles conjugated with glycohexapeptide (g7), which are able to cross the blood-brain barrier. After administration of these nanoparticles, we evaluated the regional and time-dependent distribution of zinc and nanoparticles within the brain. Further, we investigated whether the delivery of zinc or the presence of nanoparticles *per se* alters the expression levels of zinc sensitive genes and proteins such as zinc transporters (ZnT and ZIP family members) and metallothioneins (MTs) and quantified possible toxic effects in terms of cell death. Our results reveal that zinc loaded g7-conjugated nanoparticles offer a promising strategy as a novel non - invasive approach to selectively enhance brain zinc levels within a small amount of time.

Title: Targeted nanoproteinparticle conjugates for direct therapeutic shuttling to the brain

Authors: S. GILMORE, *M. W. MCNERNEY, N. FISCHER, N. BE, C. BLANCHETTE; Biosci. and Biotech. Div., Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: Therapeutic delivery to the brain is challenging due to the limited permeability of the blood-brain barrier (BBB). Traditional therapeutics often cannot permeate the BBB, as it is composed of tightly apposed microvascular endothelial cells with specialized intercellular tight junctions, which severely limit transcellular traffic. To achieve successful passive traversal of the BBB, a compound must satisfy a specific range of physical properties, including low molecular weight, high lipophilicity, and very low levels of serum protein binding, which poses considerable issues in regards to drug design. However, there are active transport mechanisms such as transcytosis, whereby highly specific brain endothelial receptors complex with ligands, which can be exploited for targeted therapeutic delivery. Therefore, successfully delivery of therapeutics across the BBB can be achieved utilizing a platform that leverages this inherent

physiological mechanism. In this work, we examined the potential of using nanolipoprotein particles (NLPs) as a platform for targeted delivery of therapeutic compounds across the BBB. In initial screens of toxicity, the NLP platform was shown to display no signs of cytotoxicity against cultured brain endothelial cells. In addition, in cell uptake experiments, the NLP platform in the absence of any targeting ligands was shown to be rapidly taken up into human brain endothelial cells through endocytosis. To achieve targeted delivery across the BBB, three peptide ligands (TAT, G23 and Angiopep) that were previously shown to cross the BBB through transcytosis in a permeability assay using brain endothelial cells were selected and protocols for conjugation of these ligands to the NLP were developed. We are currently evaluating the effect of these targeting ligands on permeability across the BBB *in vitro* using an established BBB model and *in vivo* using a rat model. In these studies, a fluorophore will be encapsulated in the NLP and used as both a model drug therapeutic, and as a means to monitor BBB crossing through fluorescence detection. Such a platform has the potential to yield a tool providing essential drug delivery capacity relevant to a wide range of devastating neurological ailments. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07-NA27344. Lawrence Livermore National Security, LLC

Title: Guanidinoglycoside conjugation; a novel technology for intranasal delivery of therapeutic proteins to the CNS

Authors: *C. GLASS[1], B. E. THACKER[1], W. TONG[2], K. M. HAMILL[3], C. A. DWYER[2], J. J. PHILLIPS[4], Y. TOR[3], T. SCOTT[5], J. D. ESKO[2];
[1]TEGA Therapeut. Inc, San Diego, CA; [2]Cell. and Mol. Med., [3]Chem. and Biochem., UCSD, San Diego, CA; [4]Neurolog. Surgery and Pathology, Univ. of California, San Francisco, San Francisco, CA; [5]Pharmatek Laboratories, Inc., San Diego, CA

Abstract: Treating central nervous system (CNS) disorders is difficult because the blood brain barrier (BBB) restricts delivery of drugs to the brain. Less than 1% of most drugs reach the CNS

resulting in a lack of available treatments for many CNS diseases such as stroke, neurodegenerative diseases and brain tumors. Many high molecular weight molecules such as antibodies show promise in treating CNS diseases based on *in vitro* systems and animal models; however, high molecular weight substances are severely restricted from crossing the BBB. Intraparenchymal, intraventricular and intrathecal injection/infusion can deliver therapeutics directly to the CNS but these routes are invasive and impractical for long-term recurrent delivery. Intranasal administration, drug delivery across the nasal epithelium into the brain, is an alternative route. The major disadvantage is that limited absorption across the nasal epithelium has restricted the application to compounds that are highly potent, typically hydrophobic and low molecular weight. To address the problem of intranasal protein delivery to the brain, TEGA has developed a patented technology that involves chemically conjugating glycosides to therapeutic agents (proteins and other agents). Glycoside conjugation is a platform technology that facilities the rapid transport of proteins (≥150 kDa) to the brain through the nasal epithelia following intranasal administration. We have conjugated a number of proteins including enzymes and antibodies and assessed them for intranasal CNS delivery. Conjugated iduronidase and sulfamidase, enzymes missing in Hurler's (MPSI) and Sanfilippo syndromes (MPSIIIA), were well tolerated by intranasal administration, and rapidly achieved enzyme activities equal to or greater than wildtype levels in MPSI and MPSIIIA mouse brains, and significantly reduced the levels of toxic substrate. We have also improved the delivery of therapeutic anti-EGFR antibodies for glioblastoma, a deadly malignant brain tumor. Glycoside conjugated antibodies retained their EGFR binding properties and their potency to inhibit cultured glioma progenitor cell growth. In mice, high levels of the conjugated antibody were rapidly achieved in the olfactory bulb, whereas, the unconjugated antibody was ten-fold less. Immunohistological staining revealed the conjugated antibody in the interior granule layer.

Title: Visualizing normal and enhanced distribution of antibodies and antibody fragments in brain extracellular space using *in vivo* integrative optical imaging

Authors: *D. J. WOLAK[1,2], E. BRUNETTE[6], D. B. STANIMIROVIC[6], R. G. THORNE[1,2,3,4,5]; [1]Pharmaceut. Sci., [2]Clin. Neuroengineering Training Program, [3]Neurosci. Council of Canada, Ottawa, ON, Canada

Abstract: The precise factors governing the transport of antibody-based drugs within the CNS are not yet understood, despite their potential use as central immunotherapies. The blood-brain barrier limits drug delivery following systemic administration but a lesser studied barrier that affects both systemic and centrally applied drugs is the tissue hindrance associated with drug diffusion through the tortuous brain extracellular space (ECS). We have used a highly validated method, integrative optical imaging (IOI; Nicholson & Tao. *Biophys J*, 1993), in order to define key protein characteristics that affect their extracellular diffusion in brain tissue (e.g. size, binding). We recently reported that full length IgG (150 kDa) diffusion is ~10-fold lower in brain than in free medium (Wolak, Pizzo & Thorne. *J Control Release*, 2015) and attributed this finding to size-dependent restricted diffusion due to the small (40-60 nm) brain ECS width (Thorne & Nicholson. *PNAS,* 2006) as well as receptor binding (Thorne & Nicholson. *PNAS,* 2008). Here, we investigated extracellular diffusion in brain by carefully studying the variation of diffusional hindrance across antibody tracers of different size as well as the effect of hyperosmolar mannitol solutions on the different tracers. We used *in vivo* IOI to measure the diffusion coefficients of proteins ranging from full length IgG (~150 kDa) to smaller Fab fragments (~50 kDa) to much smaller single domain antibodies (sdAb; ~15 kDa). Free diffusion

(D) was measured in dilute agarose gel and the effective diffusion coefficient (D^*) was measured in the somatosensory cortex of anesthetized rats using an open cranial window. As expected, the larger IgG diffused more slowly [$D = 6.56 \pm 0.22 \times 10^{-7}$ cm^2/s (mean ± SE; $n = 20$)] than the smaller sdAb [$D = 14.5 \pm 0.4 \times 10^{-7}$ cm^2/s ($n = 35$)] in free solution. Comparing free diffusion to diffusion in brain, we observed that IgG experienced much more diffusional hindrance to its distribution in brain than the sdAb (IgG $D/D^* \sim 7.5$; sdAb $D/D^* \sim 4.5$). Co-injection with 0.75 M mannitol significantly reduced the diffusional hindrance of both IgG and sdAb in brain (IgG $D/D^* \sim 4.7$; sdAb $D/D^* \sim 3.5$), but the relative increase in D^* was greater with mannitol for the larger IgG (67%) than for sdAb (31%). We hypothesize that the co-injected mannitol rapidly redistributed water into the ECS from intracellular compartments, enabling the larger IgG to diffuse more effectively through a widening of the ECS. Our results provide the first *in vivo* diffusion measurements for antibody fragments as well as the first quantitative measurements of antibody diffusion in the brain extracellular space using an osmotic approach to enhance distribution.

Title: Lipid DNA-nanoparticles as drug carrier for the treatment of eye diseases

Authors: *S. O. SCHNICHELS[1], J. HURST[1], A. GRUSZKA[1], K. BARTZ-SCHMIDT[1], A. HERRMANN[2], M. S. SPITZER[1], J. DE VRIES[1];
[1]Ctr. for Ophthalmology Tübingen, Tübingen, Germany; [2]Zernike Inst. for Advanced Materials, Groningen, Netherlands

Abstract: Purpose: Currently most eye diseases are treated with multiple daily doses of highly concentrated eye drops. Treatment is severely hindered because only approximately 1-5% of the applied drug stays on the eye long enough to be effective. Due to the high concentration of the drug often systemic and local side effects are caused. Additionally, the repeated application of eye drops generally cause a reduced compliance. Methods: We developed a drug carrier for eye

drops based on lipid-DNA nanoparticles (NPs). This NP can be loaded through several different binding possibilities. To evaluate the NP, they were conjugated to a fluorescent marker and dropped on rat eyes and human corneal tissue. Afterwards the eyes were processed and analyzed for binding. To exclude toxicity our NPs were tested in-vitro and in-vivo. As a first drug kanamycin B was conjugated to the NPs. The uptake of the kanamycin-NPs was tested on human corneal tissue. Additionally, the functionality of pristine and NP-kanamyicn was evaluated in-vitro in a minimum inhibitory concentration test. To prove functionality at the site of action, corneas of eyes treated with our kanamycin-NP or pristine kanmycin were transferred to petrifilms infected with E. coli. Results:The NP showed excellent binding to the cornea epithelium compared to their small molecule counterparts. They were even found up to 4h after application to conscious rats. Most importantly, the NPs also show a high affinity for the human cornea. In addition, our NP did not show any cytotoxicity at the used concentration for our applied NP eye drops neither in-vivo nor in-vitro. Both kanamycin alone and the loaded AB-NPs were able to decrease the amount of colonies compared to the untreated corneas. Even more important, our NPs were still hindering E.coli growth after 30 min of washing, whereas the free antibiotic already lost its effectiveness after 5 min. Conclusion: In conclusion, using this novel carrier system we are able to significantly increase the adherence time of the drug on the eye. Most important is, that the drug tested was still pharmaceutically active. As a consequence, a lower frequency of eye drop administration is feasible which is beneficial for the compliance and treatment of the patient. Additionally, a lower drug concentration can be used, what drastically reduces systemic and local side effects. Another favorable feature of the delivery system is that drugs currently not in use due to their severe side effects could become utilized again.

Title: Guidance of magnetic nanocontainers for treating Alzheimer's disease using an electromagnetic, targeted drug-delivery actuator

Authors: G.-H. YOON[1], F. UL AMIN[1], J. YOON[2], *M.-O. KIM[1];
[1]Col. of Nature Sci., Dept. of Biol., Gyeongsang Natl. Univ., Gajwa 900, Jinju, Korea, Republic of; [2]Mechanical Engin., Gyeongsang national Unverisity, Jin-ju, Korea, Republic of

Abstract: The "impermeability" of the blood-brain barrier (BBB) has hindered effective treatment of central nervous system (CNS) disorders such as Alzheimer's disease (AD), which is one of the most common neurodegenerative disorders. A drug can be delivered to a targeted disease site effectively by applying a strong electromagnetic force to the conjugate of a drug and magnetic nanocontainers. This study developed a novel nanotechnology-based strategy to deliver therapeutic agents to the brain via the BBB as a possible therapeutic approach for AD. First, a novel approach for an electromagnetic actuator for guiding nanocontainers is introduced. Then, we analyzed the *in vivo* uptake in mice experimentally to evaluate the capacity of the nanocontainers. In the mouse model, we demonstrated that magnetic particles can cross the normal BBB when subjected to external electromagnetic fields of 28 mT (0.43 T/m) and 79.8 mT (1.39 T/m). Our study also assessed the differential effects of pulsed (0.25, 0.5, and 1 Hz) and constant magnetic fields on the transport of particles across the BBB in mice injected with magnetic nanoparticles (MNPs) via a tail vein. The applied magnetic field was either kept constant or pulsed on and off. Relative to a constant magnetic field, the rate of MNP uptake and transport across the BBB was enhanced significantly by a pulsed magnetic field. Localization inside the brain was established using fluorescent MNPs. These results using 770-nm fluorescent carboxyl magnetic nanocontainers demonstrated the feasibility of the proposed electromagnetic targeted drug delivery actuator. These results establish an effective strategy for regulating the biodistribution of MNPs in the brain through the application of an external electromagnetic field. This might be a valuable targeting system for AD diagnosis and therapy.

Title: Self-assembling MMP-2 cleavable hydrogel drug delivery systems; neural tissue biocompatibility and response

Authors: *K. M. KOSS[1], M. A. CHURCHWARD[2], K. G. TODD[3], L. D. UNSWORTH[1]; [1]Chem. and Materials Engin., [2]Psychiatry, [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: In the event of neural tissue injury, neurotrophic factor peptide analogues are capable of promoting healing by increasing neurogenesis, promoting neuronal survival and attenuating glial activation. Peptides have been considered as ideal therapeutic agents as they are specific, potent, small, and diffuse readily. However, peptides are also digested and short lived, making their *in vivo* delivery difficult. The self-assembling peptide $(RADA)_4$ is a novel class of peptide that, upon injection, assemble into a 3D hydrogel nanofiber matrix, capable of storing water and molecules. Synthesizing peptide therapeutics onto $(RADA)_4$ can afford protection from circulating proteases and utilizing matrix metalloproteinase-2 (MMP-2) cleavage sequences allows an 'on-demand' and local tissue release strategy. Understanding self-assembly, controlled release of bound therapeutics, biocompatibility, and tissue response is vital for successful clinical application. In this study, $(RADA)_4$-GG-GPQG+IASQ (CS1) and $(RADA)_4$-GG-GPQG+PAGQ (CS2), known for high and low MMP-2 sensitivity, respectively, were investigated. The '+' denotes the scissile bond. Neuropeptides DGGL, a ciliary neurotrophic factor analogue, and MVG, a brain-derived neurotrophic factor secretion stimulant, were tethered to the c-termini. $(RADA)_4$-IKVAV was explored to promote glial adhesion and biocompatibility. Nanofiber matrices were present in all samples, visualized using TEM, suggesting efficient formation of drug delivery matrices. Cleavage of bioactive peptides by MMP-2 was monitored over time, and

showed expected product formation, using MALDI-TOF mass spectrometry, for both the high and low activity cleavage sequences. Microglia seeded onto $(RADA)_4$ matrices retained a ramified morphology, and showed increased adhesion, survival, and proliferation but did not increase markers of inflammation, suggesting good biocompatibility. The MMP-2 cleaved drug fragments promoted neurogenesis in PC-12 cells, observed by neurite extension and increased acetylcholine esterase activity, and these cells increased seeding capacity with the addition of $(RADA)_4$-IKAV. Overall, the $(RADA)_4$ system has been demonstrated as a self-assembling tuneable drug release system with good neural tissue biocompatibility and response. In this system, neurotrophic peptide delivery is balanced to surrounding cell and tissue activity, and may have a greater impact as a potential therapy for many sources of neural tissue injury.

Abstract: Neurotrophic factors, such as the glial cell- derived neurotrophic factor (GDNF), are promising alternatives to treat Parkinson's Disease (PD). However, their short half-life and rapid degradation after *in vivo* administration has limited the clinical use. Recently, the intranasal delivery has appeared as an alternative to release GDNF directly to the brain. The aim of this study was to evaluate the *in vivo* neuroprotective effect of intranasally administered GDNF,

encapsulated in Chitosan-nanostructured lipid carriers (CS-NLCs), in a 6-hydroxydopamine (6-OHDA) rat model. 6-OHDA lesion procedures in rats were performed according to previous protocols and CS-NLCs were prepared by melt-emulsification technique. After the lesion, rats were randomly divided into four groups (5 rats/group): Sham, CS-NLCs-without GDNF, CS-NLCs loaded with GDNF (2.5 µg GDNF/day) and GDNF in PBS solution (2.5 µg GDNF/day) and intranasal administration was done during two weeks. The *in vivo* effectiveness of the intranasal administration of GDNF administration was tested by the amphetamine-induced rotational behaviour test during 7 consecutive weeks and by the cylinder test in three times during the study. At the end of the study, the degree of dopamine denervation in the striatum and substantia nigra compacta (SNc) was analyzed using a Tyrosine Hydroxylase (TH) immunostaining and a correlation analysis was done. CS-NLC-GDNF group showed significantly lower rotations per minute with respect to the basal number of rotations from the 3rd testing session until the end of the study where a reduction of 80% was achieved ($p<0.05$, repeated measures two-way ANOVA). The other groups included showed stable rotational behaviour thorough the 7 weeks of the study. Similar results occurred in the cylinder test where a reduction of forelimb asymmetry ($p<0.05$, repeated measures two-way ANOVA) was found in the CS-NLCs loaded with GDNF group. Also, a significant correlation was observed between rotational and cylinder test performances with both optical density in the striatum and neuronal density in the SNc of the rats. These results demonstrate that the administration of CS-NLCs loaded with GDNF by intranasal route, induces an improvement in the degree of injury in the striatum and SNc of the ipsilateral hemisphere of the lesioned rat brain, and suggest that it could be a promising therapy for the treatment of PD. Title: Changes in birdsong production and electrophysiological activities in HVC after the whole lesion of Nucleus Uvaeformis in adult Bengalese Finches

Authors: *R. WANG[1], F. WU[1], X. ZHANG[2], X. ZHANG[2], S. ZENG[1];

Abstract: Birdsong is a learned bebavior, which has been regarded as the best useful model to study the neural mechanism underlying song learning. High vocal center(HVC) in the telecephalon integrates sensory and motor activity and plays an essential role in birdsong learning and production. The thalamus nucleus Uva, which receives input of auditory information and projects to HVC directly or via telencephalic nucleus interface(Nif) indirectly. Available literature concerning Uva actions in birdsong learning and production is focused on the song behavior changes by injuring Uva, or on the relationship between the firing activities in Uva and HVC. Here we first injured the whole Uva bilaterally in the adult Bengalese Finches(Lonchura domestica). We then compared the song changes before and after lesion. We next made extracellular recording of HVC *in vivo* in normal and Uva injured birds to find out the changes in firing activities within the three types of HVC neurons (interneurons, RA (the robust nucleus of the arcopallium)-projecting or Area X projecting neurons). Finally, we injected fluorescent tracer into the normal HVC, resulting in retrogradely labeled HVC-projecting cells in Uva and Nif. This tracing technique combined with immunohistochemistry for several neurotransmitters or receptors, is allowed us to determine what neurotransmitters are used by HVC projecting cells in Uva and NIf. Our results indicated that: 1) Birdsongs degraded severely and permanently at least 3 months after Uva lesion. Several phrases were deleted (only phrase C was remained), and the amplitude and frequency of the remained phrases largely decreased. These data suggest that Uva is necessary for normal song production; 2) Following Uva lesion, the firing rates in HVC interneuron showed a significant increase, whereas they did not change significantly in RA or Area X -projecting cells, suggesting that HVC activity is inhibited by Uva interneurons; 3) TH (Tyrosine hydroxylase), GABA (γ-aminobutyric acid), NMDAR(N-methyl-d-aspartate receptor) and GABAA receptor are widely distributed in HVC-projecting cells in Uva and Nif. However, the percentage of GABA in Uva was higher than in NIf. These results are useful to further understand the function of Uva in song learning and production.

Title: Intrinsically phasic and tonic excitatory neurons in the avian auditory mesopallium

Authors: ***A. N. CHEN**[1], C. D. MELIZA[1,2];
[1]Neurosci. Grad. Program, Univ. of Virgi, Charlottesville, VA; [2]Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: The caudal mesopallium (CM) is a telencephalic area in the avian auditory pathway where selective, invariant representations of learned conspecific song emerge. Hodological, functional, and gene expression data suggest that CM may be analogous or homologous to superficial neocortical layers, but the intrinsic physiological properties of CM neurons have not been investigated. Using whole-cell recordings from brain slices of juvenile and adult zebra finches (Taeniopygia guttata), we identified several classes of neurons in CM with distinct spike shapes, frequency-current relationships, and adaptation profiles. Many neurons (26%) resembled regular-spiking neurons in the neocortex, with relatively broad action potentials and with spike-frequency adaptation over prolonged depolarizations. A smaller proportion of cells (8%) had narrow spikes and little to no frequency adaptation, characteristics of inhibitory interneurons. However, the majority of neurons (66%) had broad action potentials and exhibited profound adaptation, only firing 1-5 times at the onset of depolarization. Onset-spiking neurons were present in adults, and their properties persisted in the presence of fast synaptic transmission blockers. To our knowledge, intrinsic onset-only responses have not been reported in the mammalian cortex. A subset of neurons were filled with biocytin in order to correlate cell morphology with physiology. Based on responses to complex, broadband current injections, onset- and regular-spiking neurons have different temporal integration properties and are thus likely to fulfill different functions in processing spectrotemporally rich auditory signals.

Title: Multifaceted modulation of auditory signal detection and encoding by norepinephrine: Evidence for differential adrenergic receptor mediation

Authors: *M. IKEDA[1], M. LIMA[2], L. REMAGE-HEALEY[2];
[1]Mol. and Cell. Biol. Grad. Program, [2]Neurosci. and Behavior Grad. Program, Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: In mammalian auditory cortex, norepinephrine enhances auditory detection (measured by signal-to-noise ratio) and frequency tuning for relatively simple stimuli, such as tones and calls. However, the role of norepinephrine in high order processing of complex syntactical auditory stimuli is not clear. Previously, in one region of the songbird auditory cortex, we showed that norepinephrine enhances the signal-to-noise ratio to auditory stimuli by decreasing spontaneous firing activity, similar to the mammalian auditory cortex. Interestingly, norepinephrine also enhances the decoding accuracy of an algorithm that classifies spike trains based on spiking frequency. Here, we further tested whether the enhancement in classification accuracy was due to changes in spike timing and/or changes in the number of spikes. In addition, we tested the effect of adrenergic agonists to determine which adrenergic receptors mediate the effects of norepinephrine. We found that norepinephrine significantly enhanced the performance of a pattern classifier that solely depended on spike timing patterns. In addition, an alpha-2 adrenergic agonist, clonidine, mimicked the effects of norepinephrine on spontaneous firing and signal-to-noise ratio, whereas an alpha-1 adrenergic agonist did not. Interestingly, in contrast to norepinephrine, clonidine did not enhance the performance of either pattern classifier. Together, our findings suggest that norepinephrine enhances both auditory detection and auditory coding by altering spiking pattern and the number of spikes. Moreover, the enhancement in signal detection is likely to be mediated by alpha-2 adrenergic receptors while the change in spike patterning itself may be mediated by other receptor sub-types.

Title: Thalamocortical connections of sensory areas in the nine-banded armadillo (Dasypus novemcinctus)

Authors: *H. A. LAWRENCE, A. BUCK, J. J. PADBERG;
Biol., Univ. of Central Arkansas, Conway, AR

Abstract: In order to identify features of neural organization that may be common across mammalian clades, we are conducting a series of studies examining the sensory areas of a representative species of Xenarthra, a relatively early branch of the mammalian lineage. The nine-banded armadillo (Dasypus novemcinctus) is the only extant xenarthran species found in North America. We are currently exploring the connectional organization of D. novemcinctus by placing electrophysiologically guided injections of fluorescent retrograde neuroanatomical tracers into the sensory cortex, and reconstructing connectional patterns using the Neurolucida imaging software. Labeled cells and terminals in the thalamus resulting from the injections were related to architectonic boundaries as identified based upon cytochrome oxidase (CO) histochemistry or Nissl staining. In CO series, the ventroposterior nucleus is segregated into a medial portion, which is moderate to dense in staining intensity and relatively homogenous, and a lateral portion, which is densely stained and interrupted by small fiber bundles. The ventrolateral nucleus, located dorsal to the ventroposterior lateral nucleus, is lighter staining and homogenous. The lateral geniculate is densely stained and relatively small, while the medial geniculate is densely stained and occupies a large dorsolateral extent of the posterior thalamus. Following injections of .0.3-0.4 μL of tracers (Alexa-Flour 555 conjugated to 10kD dextrans, or Alexa-Fluor 555 conjugated to CTB) placed into the snout representation of primary somatosensory cortex, dense clusters of labeled neurons were identified in the dorso-lateral portion of the medial ventral posterior nucleus, and less dense labeling was observed in the ventrolateral nucleus. This pattern of neuroanatomical organization is consistent with that reported for all other mammalian clades that have been studied, from monotremes to Euarchontoglires, suggesting an origin in a common mammalian ancestor. Furthermore, in this case, unique morphological specializations such as the presence of ossified armor appear to have relatively little impact on the basic mammalian organization of sensory outputs from the thalamus to cortex.

Title: Anatomical and functional convergence of motor and neuromodulatory synapses in mouse auditory cortex

Authors: ***A. NELSON**, R. MOONEY;
Duke Univ., Durham, NC

Abstract: We recently characterized a projection from the secondary motor cortex (M2) to the auditory cortex (ACtx) of the mouse and established that this pathway is an important source of signals that modulate auditory cortical activity in a movement-dependent manner. We hypothesize that this circuit provides motor-related corollary discharge signals to the ACtx and that these signals can be shaped by experience to form associations between the animal's movements and the reafferent sounds resulting from these movements. To better understand how this motor to auditory cortical circuit interacts with neuromodulatory circuits implicated in auditory cortical plasticity, we have begun to explore the relationship between motor cortical synapses and cholinergic synapses in the ACtx. Using intersectional monosynaptic viral tracing methods, we established that cholinergic neurons in the basal forebrain (BF_ACh) innervate all of the auditory cortical cell types that receive input from M2, and that a subset of BF neurons provide input to both M2 and the ACtx. Using anterograde viral tracing methods, we found that BF_ACh and M2 terminals are co-mingled across all layers of the ACtx. Using optogenetic circuit mapping methods in brain slices, we further established that BF_ACh synapses activate both nicotinic and muscarinic receptors on inhibitory and excitatory cells in the ACtx and thus can drive feedforward inhibition onto excitatory cells in the ACtx, further resembling M2 inputs in their functional properties. By using a combination of electrophysiological, pharmacological, and optogenetic methods in brain slices, we also established that BF_ACh and M2 axons provide convergent input onto single auditory cortical neurons. Finally, using *in vivo* multiphoton calcium imaging methods in freely behaving mice, we established that BF_ACh axon terminals in the ACtx display movement-related activity patterns that closely parallel M2 terminal activity patterns. Therefore, motor cortical and cholinergic inputs to the ACtx are coactive during

movement, and these inputs converge postsynaptically to influence single neurons in the ACtx. This functional convergence may be important for gating and modifying corollary discharge signals in the ACtx in a task- and experience-dependent manner.

Title: Thalamocortical innervation pattern in mouse auditory and visual cortex: laminar and cell-type specificity

Authors: *L. MESIK[1], X.-Y. JI[2], B. ZINGG[3], Z. XIAO[2], L. ZHANG[3], H. W. TAO[3];
[1]Unifersity of Southern California, Los Angeles, CA; [2]Southern Med. Univ., Guangzhou, China; [3]USC, Los Angeles, CA

Abstract: Despite many previous studies, the functional innervation pattern of thalamic axons and their target specificity remains to be investigated thoroughly. Here, in primary auditory cortical slices, we examined thalamic innervation patterns for excitatory and different types of inhibitory neurons across laminae, by optogenetically stimulating axons from the medial geniculate body (MGB). We found that excitatory cells and parvalbumin (PV)-expressing inhibitory neurons across layer 2/3 (L2/3) to L6 are directly innervated by thalamic projections, with the strongest innervation occurring in L4. The innervation of PV neurons is stronger than that of excitatory neurons in the same layer, with a relatively constant ratio between their innervation strengths across layers. For somatostatin (SOM) and vasoactive intestinal peptide (VIP) inhibitory neurons, essentially only L4 neurons were innervated by thalamic axons and the innervation was much weaker compared to excitatory and PV cells. In addition, more than half of inhibitory neurons in L1 were innervated, relatively strongly, by thalamic axons. Similar innervation patterns were also observed in the primary visual cortex. Thus, thalamic information can be processed independently and differentially by different cortical layers, in addition to the generally thought hierarchical processing starting from L4. This parallel processing is likely

shaped by feedforward inhibition from PV neurons in each individual lamina, and may extend the computation power of sensory cortices.

Title: Pathway specific effects of isoflurane on synaptic responses in supra- and infra-granular auditory cortex neurons

Authors: ***A. RAZ**[1], B. M. KRAUSE[1,2], S. M. GRADY[1], M. I. BANKS[1];
[1]Dept. of Anesthesiol., Univ. of Wisconsin, Madison, WI; [2]Neurosci. Training Program, Univ. of Wisconsin - Madison, Madison, WI

Abstract: Introduction: The mechanisms underlying loss of consciousness (LOC) under anesthesia remain an enigma. We have previously shown that cortico-cortical (CC; “top-town”) extracellular synaptic responses are preferentially suppressed by isoflurane (ISO) compared to thalamo-cortical (TC; “bottom-up”) responses. This result is consistent with a model in which anesthesia causes LOC by interfering with predictive coding in cortex via selective inhibition of top-down connections. Here, we investigate the mechanism underlying this differential effect by measuring the effect of ISO in clinically relevant concentrations on the post-synaptic responses of cortical supra- and infra-granular (SG, IG) layer neurons to TC and CC stimuli. Methods: The study was approved by the institutional animal care and use committee. Acute auditory TC brain slices were prepared from 4-8 week-old mice. Afferent stimuli were applied using bipolar tungsten electrodes either at the superior thalamic radiation, just rostral to the hippocampus or in layer 1 or 2 (L1/L2) of neocortex, 0.5 - 1 mm rostral to the recording site in auditory cortex.

Cortical neurons, either from layer 5-6 (IG), or from layer 2-3 (SG), were identified visually. Short latency (presumably monosynaptic) TC and CC synaptic responses and responses to polarizing current pulses were recorded under whole cell current clamp. ISO (1%) was dissolved in the aCSF and bath applied to the slice. We compared peak TC and CC EPSP amplitude, as well as resting membrane potential (ERest), membrane resistance (RIn), and spike threshold (VTh) with and without ISO in SG and IG cells. Results: There was no significant effect of ISO on ERest or RIn . VTh increased in both cell types, but the effect was significant only for SG cells (IG: control -33.9±23.8mV ISO -29.5±18.9, p=0.09 paired t-test, n=15 cells; SG: control -34.0±7.4mV ISO -23.0±12.0mV, p=0.01 paired t-test, n=7). Under ISO, TC responses did not decrease significantly: 15.4% (p=0.1 t-test, n=15) and 4.7% (p=0.56 t-test, n=8) decrease in SG and IG responses respectively, whereas CC responses were decreased by 54.8% (p<0.001 t-test, n=15) and 54.7% (p<0.001 t-test, n=8) in SG and IG respectively. Conclusions: Our observation of differential sensitivity of TC versus CC synaptic responses is consistent with previous reports of selective effects of anesthetics on top-down connections in cortex. Because we did not observe changes in RIn, we suggest that the underlying mechanism for this pathway specificity is either selective effects on glutamate release at CC synapses or differential engagement of local inhibitory circuits.

Title: Modulating auditory cortical plasticity through passive exposure to amplitude-modulated noise

Authors: ***M. THOMAS**, M. CISNEROS-FRANCO, L. OUELLET, E. DE VILLERS-SIDANI; McGill University, Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: Cortical representations of the external world are shaped by sensory experience at a young age and preserved through the stabilization of inhibitory networks. These representations are largely thought to remain stable throughout the lifetime, but recent work has shown that sensory deprivation in adulthood, such as dark-rearing, is capable of returning sensory cortices to an immature and disinhibited state. Here, we draw a parallel between sensory deprivation and exposure to continuous white noise. Housing adult rats in white noise, which masks normal environmental sounds without damaging the auditory system, has been found to have a profound disinhibitory effect on the auditory cortex, however the mechanisms behind this effect remain unclear. We argue that similar to sensory deprivation, the prolonged absence of salient auditory signals in noise exposure is the trigger for disinhibition and subsequent induction of cortical plasticity. In the following experiments, we tested this hypothesis by passively exposing adult Long-Evans rats to white noise of different degrees of amplitude modulation. In this manner, we were able to vary the signal-to-noise ratio of the exposure from 0% (no modulation) to 100% (strong modulation). Specifically, we exposed four groups of rats to two weeks of 70 dB broadband noise modulated at a rate of 3 Hz and a depth of 0%, 25%, 50% or 100%. A fifth group of naive rats was housed under standard conditions. At the end of this period, we recorded auditory neuronal responses from the anesthetized rats using multi-electrode arrays and performed immunohistochemical staining on post-mortem tissue slices of the primary auditory cortex. For rats exposed to 0% modulated noise, we observed an increase in cortical plasticity in accordance with previous studies. Evidence of neural disinhibition included a higher spontaneous firing rate, a shorter response latency to pure tones, and sensitization to trains of repeated tones. These variations were significantly less profound in rats exposed to modulated noise, with the magnitude of these changes decreasing with greater depth of modulation. Immunohistochemistry results showed a pronounced increase in excitatory cellular activity as measured by c-fos expression for rats exposed to 0% modulated noise, along with a step-wise decrease in expression for 25%, 50%, and 100% noise-exposed rats. Our results suggest that the absence of auditory signals is a key factor in plasticity following chronic noise exposure. This is an important step in understanding how sensory deprivation leads to cortical disinhibition and will underlie future studies on therapeutic applications of induced sensory plasticity.

Title: Spatial distribution patterns of short term potentiation induced by microelectrode stimulation in the mouse auditory cortex *in vitro*

Authors: *T. TATENO, A. SANO;
Hokaido Univ., Sapporo, Japan

Abstract: All sensory cortical areas, including the auditory areas, are considered to be wired according to the same general schema, often referred to as the canonical model of cortical circuitry. The auditory cortex (AC) *in vivo*, however, is functionally anisotropic; the functional organization along the tonotopic axis is qualitatively different from that orthogonal to this axis. Using *in vitro* preparations of mouse coronal and angled horizontal slices, we previously tested the canonical vs. non-canonical model on the basis of laminar and horizontal conduction velocity. Our results supported a canonical model for the circuits in the slice preparations including AC, by using microstimulation and multi-site recording of planar multielectrode array substrates. In this study, for the next step, by using the similar recording technique, we examined spatial distribution patterns of short term potentiation (for a duration of 10-15 min) induced by local high-frequency stimulation (e.g., 100-Hz short pulses for 1 sec) to mouse AC slices. Each stimulation site on the substrates was selected in the layer 4/5 of AC. The stimulation induced short term potentiation in localized specific sites parallel to the laminar direction from layer 2/3 to 5, and no asymmetry distribution patterns were found. The result is likely to support a canonical model for the circuits in the slice preparations at the spatial resolution (inter-electrode interval=150 μm). These results can provide critical information regarding the extent and spatial patterns of short term plasticity induced by auditory activity in future neural prostheses for AC.

Title: Callosal projections influence neuronal-specific sound-evoked responses in the mouse auditory cortex

Authors: *C. ROCK, A. APICELLA;
Biol., Univ. of Texas San Antonio, San Antonio, TX

Abstract: Auditory information is processed bilaterally in the auditory cortex (AC), and thus interhemispheric communication via the corpus callosum is important for the sound localization processes underlying spatial hearing. However, information is lacking about the specific neuronal microcircuits which are recruited by these callosal projections. A previous study (Kitzes and Doherty, 1994) pairing mono- and binaural sound presentation with electrical stimulation of the contralateral AC showed that three different types of influence are exerted by the callosal projections: suppression, facilitation, or a mixture of both. This assortment of responses is likely due to the heterogenic pool of both pyramidal neurons and interneurons in the AC. In a paper recently published by our lab (Rock and Apicella, 2015) we were able to address this fundamental question of the connectivity patterns of input onto specific neuronal subpopulations in layer 5 of the mouse auditory cortex *in vitro* using optogenetic and electrophysiological methods. We found that callosal projections suppress the activity of corticocortical (CCort) pyramidal neurons, but facilitate firing of corticocollicular (CCol) pyramidal neurons. This difference is mechanistically explained by callosal activation of fast-spiking parvalbumin-expressing interneurons (FS-PARV), which provide selective inhibition to CCort pyramidal neurons. Our results established two distinct previously unknown cortical circuits underlying either callosal suppression (callosal projections → FS-PARV → CCort) or facilitation (callosal projections → CCol) of projecting pyramidal neurons in layer 5 of the AC and attributed a specific function to a genetically defined type of interneuron in interhemispheric communication. In the present study we investigate the preservation of these circuits *in vivo* during sound presentation using extracellular recording and whole-cell patch clamp techniques and optogenetic manipulation of callosal projections and local interneurons in an anesthetized mouse.

Abstract: Faithful representation of rapidly successive acoustic signals in the primary auditory cortex (A1) is central to accurate perception of natural sounds such as human speech and animal vocalizations. However, how cortical stimulus-tracking capacity developmentally emerges remains poorly understood. Using *in vivo* whole-cell recordings right after hearing onset, we found that higher inhibition to excitation (I/E) ratio and longer time course of inhibition remarkably weakened the ability of neurons in developing rat A1 to track repeated stimuli. Surprisingly, only five minutes of passive exposure to sounds presented at ethologically high repetition rates reliably improved cortical stimulus-tracking ability. This unexpected plasticity of spike responses resulted from the significant shortening of the duration of inhibitory inputs, which could last for nearly an hour. Further pharmacological experiments revealed that GABAB instead of GABAA receptors took major responsibility for the elongation and rapid plasticity of inhibitory time course in developing cortex. Thus, our results demonstrated hypersensitivity of developing sensory cortex to the temporal feature of successive stimulus events, and suggested that GABAB-medicated, a novel type of plasticity of inhibition plays a critical role in experience-dependent cortical non-map plasticity and maturation of temporal response properties.

Title: Layer 5 and 6 auditory corticocollicular neurons are differentially distributed with respect to their subcortical targets in the mouse

Authors: *G. YUDINTSEV[1], D. A. LLANO[2];
[1]Neurosci., [2]Mol. and Integrative Physiol., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: The auditory corticocollicular projection has recently garnered much attention due to its ability to alter response properties of cells in the inferior colliculus. However, the basic anatomical organization of this pathway remains poorly understood. Corticocollicular neurons emanate from two distinct bands of the auditory cortex - layer 5 and deep layer 6 - and differ in their firing properties and cellular morphology. In addition, preliminary results from our laboratory in mouse demonstrate significant heterogeneity in the global distributions of layer 5 and 6 corticocollicular projections, with layer 6 cells spanning a broader region of the auditory cortex, extending more anteriorly and ventrally than layer 5, while layer 5 neurons are more concentrated in the primary auditory cortex, as confirmed by parvalbumin and SMI32 immunoreactivity. To further characterize the differences within the corticocollicular system, we ipsilaterally injected two retrograde tracers Cholera toxin B and Fluorogold into the inferior colliculus and the medial geniculate body, respectively. A subset of layer 5 corticothalamic neurons were also found to project to the inferior colliculus, while layer 6 corticocollicular neurons were found in a band that was distinct from layer 6 corticothalamic neurons. These data extend previous findings that suggest that layer 5 and layer 6 corticocollicular projections have different organizations and, presumably, different roles in modifying inferior colliculus function.

Title: Layer 6 corticothalamic neurons modulate the gain and selectivity of columnar sound processing

Authors: *W. GUO[1,2], A. R. CLAUSE[1,3], A. N. BARTH-MARON[1,4], B. G. SHINN-CUNNINGHAM[2], D. B. POLLEY[1,2,3];

Abstract: The cortical column is the canonical unit of information processing in the cerebral cortex. Until recently, intermediate layers of processing between the input and output of the column have remained obscure. Here, we explore sensory response modulation imposed by layer 6 (L6) Ntsr1 neurons, which provide the dominant source of corticothalamic projections but also have abundant connections within the local column. We used a cre-dependent viral construct to selectively express channelrhodopsin-2 (ChR2) in L6 auditory cortex neurons (ACtx) of Ntsr1-cre transgenic mice. We then recorded neural responses in the medial geniculate body (MGB) of the thalamus and all layers of ACtx in response to sound stimulation and/or optogenetic activation of Ntsr1 neurons in awake mice under head restraint. Surprisingly, activation of L6 Ntsr1 neurons induced only weak effects on the responsiveness and sensory tuning in downstream MGB neurons. However, photostimulation of Ntsr1 neurons elicited spiking activity in all layers of ACtx. Analysis of local field potentials and current source densities revealed that Ntsr1 neural activation induced a robust gamma oscillation in deep layers (at 100 - 120 Hz) and superficial layers (at 40 - 50 Hz), immediately followed by a low frequency oscillation (1 - 4 Hz) that persisted for hundreds of milliseconds after the cessation of Ntsr1 spiking. These data suggest that L6 Ntsr1 neurons engage distributed networks of excitatory and inhibitory neurons throughout the column that dynamically transform afferent sensory traces depending on the delay between sensory stimulation and Ntsr1 neuron activity. We tested this hypothesis by quantifying changes in gain and selectivity of single unit responses to pure tone stimuli presented at various delays relative to the onset of L6 Ntsr1 neuron activation. Unlike previous reports in visual cortex, L6 Ntsr1 neuron activation induced weak, additive gain to sensory tuning rather than divisive suppression. Intriguingly, the most pronounced changes occurred immediately after the cessation of the activation, where superficial and middle layer neurons exhibited a strong increase in frequency selectivity, followed by an overall gain in response amplitudes. We observed a group of fast-spiking neurons that specifically responded at the offset of laser stimulation, coinciding with the greatest changes in tuning curve gain or selectivity. Overall, these data suggest that L6 Ntsr1 neurons modulate columnar sound processing in ACtx via local inhibitory circuits, and the direction and strength of the effects critically depend on the relative timing between L6 Ntsr1 neuronal activity and sensory stimuli.

Title: Computational studies of a thalamocortical network containing the thalamic reticular nucleus, using a novel mutual information estimator to measure network performance

Authors: *E. GRIBKOVA, D. A. LLANO;
Dept. of Mol. and Integrative Physiol., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: The dynamics of neural networks that involve thalamocortical (TC) neurons and the thalamic reticular nucleus (TRN) remain vaguely understood. Bursting, a characteristic mode of firing in the thalamus, is observed during some of these events and is primarily influenced by calcium T-currents in TC cells. Applying a Hodgkin-Huxley model framework, consisting of a TC neuron, TRN neuron, external inputs to the TC and TRN cells, and a layer 4 (L4) thalamorecipient neuron, we study bursting in open-loop circuits in this TRN-TC-L4 network with the analysis of T-current variations in the TC cell and how they affect signal transmission from TC to L4. Using a mutual information estimator with an adaptive partition for signals with different time scales, we show that the time constants of the synaptic input to the TC cell, and of the TC to L4 synapse, as well as TC cell calcium T-current conductance all influence mutual information between the input to the TC cell and L4 spiking. In particular, a TC calcium T-current conductance of at least 40 nS is required to enhance the response of the L4 cell to high frequency input at the TC cell, while both synaptic time constants appear to have optimal values of at least 25 ms at which maximal enhancement of the L4 response is observed. These studies suggest that the TRN can enhance mutual information between sensory input to the thalamus and cortical responses, and that mutual information is sensitive to the time constants of both thalamocortical synapses and the external input to the thalamus.

Title: Auditory cortex controls sound driven innate defense behavior through corticofugal projections to inferior colliculus

Authors: X. R. XIONG[1], *F. LIANG[2], B. ZINGG[1], X. JI[5], L. A. IBRAHIM[1], H. W. TAO[3], L. I. ZHANG[4];

Abstract: Defense against environmental threats is essential for animal survival. However, the neural circuits responsible for transforming unconditioned sensory stimuli and generating defensive behaviors remain largely unclear. Here, we show that corticofugal neurons in the auditory cortex (ACx) targeting the inferior colliculus (IC) mediate an innate, sound-induced flight behavior. Optogenetic activation of these neurons, or their projections in the IC, is sufficient for initiating flight responses, while inhibition of these projections reduces sound-induced flight responses. Corticocollicular axons monosynaptically innervate neurons in the cortex of the IC (ICx), and optogenetic activation of projections from the ICx to the dorsal periaqueductal gray is sufficient for provoking flight behaviors. Our results suggest that ACx can both amplify innate acoustic-motor responses and directly drive flight behaviors in the absence of sound input through corticocollicular projections to ICx. Such corticofugal control may be a general feature of innate defense circuits across sensory modalities.

Hosp. in Motol, Prague, Czech Republic; [4]Lab. of Gene Expression, Inst. of Biotechnology, Acad. of Sci., Praha, Czech Republic

Abstract: The auditory cortex (AC) receives the majority of auditory afferent inputs. It is comprised of the primary (A1), secondary and tertiary (belt) regions. Our previous work indicated differences between the sound-evoked spiking patterns of A1 and belt neurons, raising the question as to what extent are incoming sensory signals processed differently by neurons in these two parts. In this study, we investigated the intrinsic electrical properties of layer 5 pyramidal neurons (PNs) in acute AC slices isolated from 30-35-day-old rats. Regular-spiking (RS) cells predominated amongst the PNs in both AC areas. Interestingly, RS cells from A1 showed significantly higher excitability at rest. Their time membrane constants and input resistances were significantly increased compared to those found in RS cells from the belt region. Accordingly, A1 PNs generated action potentials with shorter latencies and lower rheobases. This suggests that A1 and belt neurons could differ in the presence of currents constitutively activated at resting membrane potential (~ -77 mV). We observed Kleak, inwardly-rectifying K+ (IRK) and hyperpolarization/cyclic nucleotide gated cation (HCN) channels participating at resting membrane conductance in AC PNs. No significant differences in amplitudes of Kleak or IRK mediated currents were observed between A1 and belt neurons. In contrast, the densities of HCN-mediated currents (Ih) were nearly doubled in neurons of the belt region compared to those from A1. Single-cell RT-qPCR analysis revealed the prevalence of HCN1and HCN2 mRNAs and minor contributions of HCN3-4 transcripts in both auditory areas. Experimental blockade of Ih hyperpolarized PNs (-2.7 mV vs -4.2 mV for A1 vs belt PNs) and increased their input resistances, suggesting Ih to be the major factor regulating the excitability of belt neurons at rest. Furthermore, Ih generated a depolarization sag in the voltage responses to hyperpolarizing current steps injected into PNs. The activation kinetics of the sag was fast enough to shorten the duration of the after-hyperpolarization phase of action potentials in the belt neurons. Consistently, the jitter of steady-state action potentials evoked by repetitive current stimuli was significantly reduced in belt PNs compared to their A1 counterparts. This suggests that Ih could help to maintain the persistent firing of neurons from the belt region. Our data supports the view that the *in vivo* observed diversity in spiking patterns of A1 and belt neurons could be at least partially explained by differences in their intrinsic electrical properties.

Abstract: Sensory deprivation since birth leads to a variety of structural and physiological brain alterations. This is true for both congenital blindness and congenital deafness, although at different degrees. Several studies have indicated major changes in white matter volume and tracts as measured by diffusion techniques and also in the grey matter occurring outside auditory areas. There are however major discrepancies in the literature concerning those parts of the brain that are modified by hearing loss. In our study, we have concentrated our analysis on auditory and language areas in a large sample of congenitally deaf (CD) individuals who never used hearing aids and were proficient in sign language. They were compared to two groups of hearing subjects, one who acquired sign language (HS) and one who did not (HNS). We analyzed cortical thickness from whole brain MR images with well-defined regions of interests into secondary auditory areas and Broca's area. Our results showed an increased cortical thickness in

Broadmann's area 21 and 22 (secondary auditory cortex) and 44 and 45 (Broca's area) in CD. HS showed also a trend in an increased cortical thickness in language areas compared to HNS. Our results indicate that contrary to congenital blindness, the primary auditory area in congenital deafness does not undergo the same plastic changes.

Title: Differential effects of auditory and visual alpha power in relation to concomitant haemodynamic response

Authors: ***G. Y. BEZGIN**[1], T. BROWN[2], Z. FATIMA[2], A. R. MCINTOSH[2];
[1]Montreal Neurolog. Inst., McConnell Brain Imaging Ctr., Montreal, QC, Canada; [2]Rotman Res. Inst., Baycrest Ctr., Toronto, ON, Canada

Abstract: Sensory-related alpha activity (7-12 Hz) in early auditory and visual cortices has been a subject of debate. Even more obscure and contradictory is available evidence on relation between sensory alpha activity and blood oxygenation metabolism as measured by functional magnetic resonance imaging (fMRI). We addressed both issues with simultaneously acquired electroencephalography (EEG) and fMRI data under an audiovisual reaction time task. Alpha, as well as beta (16-30 Hz) and gamma (32-100 Hz) band powers were assessed in two ways: 1)

overall band power in 1s pre- and 2s post-stimulus epochs, and 2) 1s post- minus 1s pre-stimulus power content. These metrics were correlated across trials with fMRI signal change, involving subtle stimulus-related fluctuations of the latter. Furthermore, these data were also correlated with stimulus response reaction time, as well as EEG signal complexity measured by multiscale entropy (MSE), involving both electrode-based and source-localised EEG activity, wherein the sources were informed by fMRI contrasts. We observed similarities and distinctions between auditory and visual modalities across applied metrics: both exhibited high and significant correlations between all three band powers (alpha in particular: correlation coefficient ranged from 0.76 to 0.96, $p<0.0001$ for all region pairs). The effects of reaction time and response accuracy on band powers were more pronounced in the auditory modality (average increase from $r=0.14$ for inaccurate trials to $r=0.37$ for accurate trials, $p<0.0001$). Visual alpha was systematically suppressed instantaneously after a correct stimulus response (correlation between overall power and post-stimulus modulation: $r=-0.4$, $p<0.001$). Significant correlations between subtle blood-oxygen level dependent (BOLD) fluctuations and stimulus-locked alpha-power were observed in both auditory ($r=0.32$, $p<0.0001$) and visual ($r=0.2$, $p<0.0001$) modalities. MSE was significantly correlated with beta power (visual: $r=0.45$; auditory: $r=0.38$). Overall, this study assesses the relation between fMRI and alpha power in the early auditory cortex and its visual counterpart, exploring effects of response accuracy and lateralisation. Importantly, it emphasises the advantage of using a combined EEG-fMRI setup in conjunction with a simple multisensory perception paradigm, assessed trial by trial - and thus offers a novel paradigm for multimodal experiments acquired with simultaneously combined neuroimaging techniques.

Title: McGurk illusion recalibrates neural representation and perception of subsequent auditory input

Authors: ***C. S. LÜTTKE**, M. EKMAN, M. A. J. VAN GERVEN, F. P. DE LANGE; Donders Inst. Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Observing the mouth of a speaker helps interpreting the auditory signal in a conversation, especially in noisy conditions. Not only does visual input help in interpreting

audiovisual signals, it can also determine how the brain interprets subsequent ambiguous auditory information. Here we examined the influence of McGurk stimuli (where an unambiguous auditory /aba/ and an unambiguous visual /aga/ are merged to the percept of /ada/) on subsequent unambiguous auditory input. In a combined behavioral and fMRI experiment, participants categorized auditory and audiovisual speech stimuli (as /aba/, /ada/ or /aga/). Participants were preselected on the basis of their proneness to the McGurk illusion (on average, >82% illusions). Interestingly, following a McGurk stimulus (during which an auditory /aba/ input, combined with a visual /aga/ input, is interpreted as /ada/), an auditory /aba/ in isolation was more often interpreted as /ada/ (from 16% to 27%, p=0.0009). This effect could not be explained by simple priming effects, as auditory /ada/ in isolation did not influence the interpretation of a subsequent auditory /aba/ (18% vs. 16%, p=0.85). Moreover, perception of auditory /ada/ and /aga/ were unaffected by previous McGurk trials. This phonetic recalibration was also reflected in the auditory cortex. We trained a classifier to distinguish the neural representation of /aba/ and /ada/ in auditory cortex on a separate data set. When the auditory input /aba/ was perceived as /ada/, the classifier categorized the neural activity elicited by the stimulus more often as /ada/. Our results suggest that after experiencing the McGurk effect, the brain may shift the neural representation of an /aba/ sound towards /ada/, culminating in a change in perception of subsequent auditory /aba/ input towards previous perception.

Title: Is the sound-induced double-flash illusion generated in primary visual cortex? Insights into multisensory integration from intracranial EEG recording in humans

Authors: *E. M. YEAGLE[1,2], P. MEGEVAND[3], M. MERCIER[4,5], M. T. KAUFMAN[6], L. CHARTARIFSKY[6], A. K. CHURCHLAND[6], A. D. MEHTA[1,2];

Abstract: A hallmark of cognition is the ability to assemble information from diverse sources, and to use the outcome to guide complex behavior. Here, we leverage a multisensory illusion paradigm to investigate the neural circuits underlying the assembly of information from visual and auditory modalities. In the sound-induced double flash illusion, judgments about a visual flash are influenced in a time-dependent way by auditory beeps. A single flash presented with two beeps often leads to the perception of a second flash, but only when the beeps are close together. Prior fMRI and extracranial EEG studies have localized correlates of this illusion to occipital cortex, but the illusion has not been studied in humans using intracranial recordings. We examined neural responses in this paradigm in three patients with intractable epilepsy, who had been implanted with intracranial electrodes covering occipital cortex in preparation for surgery to treat their seizures. To induce the illusion, subjects were presented with a single flash (16.67 ms) paired with two beeps. The first beep was simultaneous with the flash, while the second occurred after a variable interval (stimulus-onset asynchrony, SOA) of 50-500 ms. Control conditions presented single or double flashes without sound, a single flash paired with a concurrent beep, and a double flash paired with two concurrent beeps. Subjects identified each trial as presenting a single or double flash. As reported for healthy controls, our patients integrated the two modalities: they were more accurate for conditions with concordant visual and auditory stimuli than for visual-only conditions, they perceived the illusion, and they perceived the illusion more often for short SOA trials than for long SOA trials. For neural analysis, we selected the SOA for each subject that most closely produced 50% accuracy. We then compared neural responses on trials when the subject perceived the illusion (reported 2 flashes) to trials when they did not (reported 1 flash). We focused our analysis on early visual cortex. In contrast with earlier findings, we identified no significant difference between illusion and non-illusion trials in early visual cortex, in either the event-related potential or high-gamma power (65-175 Hz). However, preliminary findings suggest that a neural signature of the illusory flash may be present in extrastriate or later visual areas. These recordings may therefore offer greater resolution of the brain areas involved in multisensory integration, pointing to later stages of visual processing than previously believed.

Title: Multisensory learning through passive audio-visual stimulation in six month old infants

Authors: *S. ROHLF[1], B. HABETS[2], B. ROEDER[2];
[2]Biol. Psychology and Neuropsychology, [1]Univ. of Hamburg, Hamburg, Germany

Abstract: The developing brain needs to adapt to the statistical properties of the sensory environment; the detection, binding, and recognition of new sensory information from different modalities is influenced by the likelihood of specific crossmodal combinations. We investigated multisensory learning in infants on a neural level through passive exposure of audio-visual combinations with different probabilities. While recording the EEG six month old infants were presented with two frequently occurring audio-visual standard combinations (70 %) and infrequently occurring audio-visual deviant stimuli. The latter comprised (1) new combinations of the auditory and visual stimuli comprising the standard stimuli (20 %) and (2) an audio-visual combination of new auditory and new visual stimuli (10 %). We expected that infants would learn the frequent standard combinations and expected a deviant response in the event-related potentials (ERPs) for both newly combined as well as new audio-visual stimuli. Results showed a long-lasting ERP deviant response to new audio-visual (200 - 1000 ms) and, importantly, an ERP deviant response to infrequent audio-visual stimulus combinations as well, however with a longer latency (420 -1000 ms). By contrast, a similar effect was found in adults only if audio-visual combinations were task relevant but not under passive exposure. Thus, the present study demonstrates a higher sensitivity of infants for crossmodal environmental statistics as had previous been shown for individual sensory systems.

Title: Cross-modal processing in the auditory and visual cortex: fNIRS study with a double-flash illusion

Authors: S. SHIGARAKI[1], K. HACHISUKA[3], E. OKUNO[3], *T. HIROYASU[2];
[1]Med. Informatics, [2]Doshisha Univ., Kyotnaabe, Japan; [3]Denso Corp., Nisshin City, Japan

Abstract: [Purpose] Hearing and sight are the five human important senses and a brain finally processes these information derived from the senses. In everyday life, information of hearing and sight is not processed separately but is processed interactively. Thus, to clarify the mechanism of sensory information processing, details of cross-modal interactions of hearing and sight should be considered. Auditory and visual interaction is measured using fNIRS(functional Near Infrared Spectroscopy). [Method] Information of behavior and brain functions with a double-flash illusion is analyzed. As the block design, the following three types of stimuli are prepared. We used the block design that has three tasks. Each task has different number of flashes. First task has one flash and two beeps. Second task has one flash and one beep. Last task has two flashes and two beeps. In the task, we applied ten same type of stimuli. In the experiment, fNIRS facility that was manufactured by Hitachi medical was used and cerebral blood flow in the whole brain was measured. The subjects were thirteen healthy adults and they were 22-24 years old. [Results] According to t-test($p<.05$), we measured a number of times in perception of visual stimuli. In this result, the subjects were divided into three groups. One group was defined as the group in which the subjects strongly got illusory impression. Another was defined as the group in which the subjects got weakly illusory impression. The other was defined as the group in which the subjects didn't get an illusory impression. We tested whether a change of cerebral blood flow in a task was very different from in a rest. If a change in cerebral blood flow in a task had been significantly different from in a rest, it was decided that part of brain was active. The subjects who strongly got illusory impression had some active areas of Superior Temporal Sulcus and Intraparietal Sulcus. We hypothesized that a subject got illusory impression to resolve the conflict of auditory and visual information. We tested whether the hypothesis was true or not. The subjects who strongly got illusory impression had some active areas of Superior Temporal Sulcus, which was an integration site, and Intraparietal Sulcus, which was an integration site of somatic and visual sensation. As the result, it was suggested that Intraparietal Sulcus might have a function of the integration site of auditory and visual sensation.

Title: Audio-visual integration for motion perception

Authors: T. OMI[1], W. TERAMOTO[2], S. HIGUCHI[3], S. HIDAKA[4], *Y. SUGITA[1];
[1]Dept. of Psychology, Waseda Univ., Tokyo, Japan; [2]Dept. of Psychology, Kumamoto Univ., Kumamoto, Japan; [3]Advanced Med. Res. Ctr., Iwate Med. Univerisity, Morioka, Japan; [4]Dept. of Psychology, Rikkyo Univ., Niiza, Japan

Abstract: The alternation of sound location induces illusory visual motion when vision cannot provide accurate spatial information. A visual stimulus blinking at a fixed location was perceived to be moving laterally when the flash onset was synchronized to an alternating left-right sound source. This illusory visual motion was strengthened with an increasing retinal eccentricity and occurred more frequently when the onsets of the audio and visual stimuli were synchronized. We investigated brain activity for the sound-induced illusory visual motion with a 7T fMRI. Strong activation was observed in hMT when subjects viewed apparent motion stimuli, but not when they viewed the stimulus blinking at a fixed location. However, the activation was also observed for the stimulus blinking at the fixed location when the flash onset was synchronized to an alternating left-right sound source. These results indicate that the hMT is responsible for the audio-visual integration for motion perception.

Title: Audiovisual speech perception and presence of the McGurk effect in left-hemisphere stroke patients and matched control participants

Authors: *L. C. ERICKSON[1], M. E. FAMA[1], K. A. SPIEGEL[1], E. H. LACEY[1], L. M. SKIPPER-KALLAL[1], S. XING[1], J. P. RAUSCHECKER[1], P. E. TURKELTAUB[1,2]; [1]Georgetown Univ. Med. Ctr., Washington, DC; [2]Res. Div., MedStar Natl. Rehabil. Hosp., Washington, DC

Abstract: Introduction: The McGurk effect is a behavioral measure of audiovisual (AV) speech integration, where the observation of incongruent auditory and visual speech can lead to a percept that is different from either input signal (McGurk and MacDonald, 1976). It is unclear how left-hemisphere (LH) damage impacts AV speech processes. In this study, we examined whether AV speech perception was altered in 34 people with LH strokes compared to 27 matched controls, as tested by the McGurk paradigm. Methods: An adapted McGurk paradigm was created to accommodate language impairments in stroke patients. Stimuli consisted of whole words ("key", "tea", "pea"), and three response options were presented as pictures and written words ("key", "tea", "pea"). For congruent trials, the sound and video matched. For incongruent trials, the "key" video was presented with the auditory "pea" and had 7 timing offsets binned into three types: auditory lead (AL), middle range (MID), and visual lead (VL). For these trials, responses corresponded to the "key" visual input (keyVIS), the "pea" auditory input (peaAUD), and the McGurk "tea" percept (teaMcG). Stroke participants were included if they had a LH stroke at least 6 months prior to the study, no significant brain damage outside the LH, and >80% accuracy on congruent trials. The behavioral analysis included 34 LH stroke patients (age: 59.6 ± 10.6; 10 females; 30 right-handed) and 27 control participants (age: 59.4 ± 13.8; 18 females; 24 right-handed). Results: There were no significant between-group differences or interactions for AL trials (keyVIS: 23.6% stroke vs. 26.4% control; teaMcG: 34.7% stroke vs. 36.2% control; peaAUD: 41.8% stroke vs. 37.4% control) or MID trials (keyVIS: 29.8% stroke vs. 31.7% control; teaMcG: 53.0% stroke vs. 63.0% control; peaAUD: 17.2% stroke vs. 5.3% control). For VL trials, stroke participants reported peaAUD more than controls (p=0.001; 21.8% stroke vs. 5.3% control); however, there were no differences for keyVIS (27.4% stroke vs. 34.6% control) or teaMcG (50.8% stroke vs. 60.1% control). Conclusions: In this preliminary between-group comparison, stroke patients and control participants demonstrated similar patterns of responses to McGurk stimuli. However, when the visual signal was presented first, stroke patients reported

the auditory percept more than controls. We suggest that since the current stroke group has heterogeneous LH damage, it is possible some regions necessary for AV speech integration may be intact in some subjects. Thus, the next stage of analyses will examine individual differences that may relate to AV integration in this task, such as lesion size and location.

Title: The auditory cortex tracks the temporal dynamics of visual speech during silent lip-reading

Authors: *P. MEGEVAND[1,2], M. R. MERCIER[3,4], D. M. GROPPE[1], C. E. SCHROEDER[5,6], N. MESGARANI[7], A. D. MEHTA[1];

Kline Inst., Orangeburg, NY; [6]Neurosurg., [7]Electrical Engin., Columbia Univ., New York, NY

Abstract: Human speech is multisensory by nature: our lips, face and body are set into action when we speak; and being able to see our interlocutor complements and enriches our understanding of what is being said. How does visual speech affect the auditory cortex? According to an influential hypothesis, visual speech could induce phase reset of oscillatory activity in auditory cortex, thus modulating its excitability and optimizing the decoding of auditory speech (Schroeder et al., Trends Cogn Sci 2008). To explore this hypothesis, we recorded the responses of human cerebral cortex to naturalistic auditory and visual speech through intracranial EEG electrodes in patients with drug-resistant epilepsy. Electrodes were

localized by co-registering pre- and post-implantation high-resolution MRI and CT scans. Participants watched and heard short (8-12 second) stories whose ending was cut off; after each story, they indicated whether a written word provided an appropriate ending. Each story was repeated several times, allowing us to measure the degree of phase-locking of the intracranial EEG across repeats of the same story (intertrial coherence, ITC) through time-frequency analysis. We defined auditory cortex as those electrodes that showed increased high-gamma power as well as delta- and theta-band phase-locking to auditory speech. We found that auditory cortex displayed significant phase-locking to visual speech (silent lip-reading) between 1 and 5 Hz, without any concomitant increase in power at these frequencies. We also observed a slight increase in high-gamma power. We then cross-correlated the ITC with mouth opening (approximated by the envelope of the auditory speech signal) and found positive correlations at the same frequencies, indicating that phase-locking in auditory cortex reflected specific characteristics of the visual speech signals. We also found a positive correlation between behavioral performance during silent lip-reading and the 1-to-5-Hz ITC to visual speech in auditory cortex. In order to examine how visual speech signals influence the processing of auditory speech, we compared the amount of phase-locking in auditory cortex when perceiving audiovisual vs. auditory speech and found higher phase-locking to audiovisual speech at 4 and 5 Hz. Our results indicate that oscillatory activity in auditory cortex reflects the slow dynamics of visual speech during silent lip-reading. They support the notion that visual speech gestures influence the oscillations, and hence the response of auditory cortex to speech sounds. More generally, they underscore the possible role of neuronal oscillations in multisensory integration and predictive coding.

Title: Eye can hear clearly now: visual speech increases the sensitivity of auditory cortex to peri-threshold speech-in-noise

Authors: *E. C. LALOR, M. J. CROSSE;
Trinity Col. Dublin, Dublin, Ireland

Abstract: It is well established that viewing a speakers' articulatory movements can improve comprehension of auditory speech, especially in noisy environments (Sumby and Pollack, 1954). It has been suggested that this effect is underpinned by an early integration mechanism where visual speech information increases the sensitivity of auditory cortex to acoustic information and a late integration stage that constrains the possible candidates in a spoken utterance based on visual information about a speaker's articulators (Peelle and Sommers, 2015). Evidence for the early integration mechanism comes from research showing that viewing a speaker's face enhances low frequency cortical entrainment to the speech envelope in auditory cortex (Zion-Golumbic et al., 2013). While this has been shown for the case of a single speaker in quiet and the case of an attended speaker in a two-speaker environment, it has not been shown for the case where the audio speech is degraded by noise to the point of being unintelligible. This is important as the cortical representation of the speech envelope has been shown to be relatively insensitive to background noise for intelligible speech, but to be much reduced when speech become unintelligible (Ding & Simon, 2013). In this study, we examined the impact of visual speech on envelope entrainment for clean speech and speech-in-noise using electroencephalography (EEG). Stimuli consisted of audio-only (A), visual-only (V) and audiovisual (AV) continuous speech segments of ~60 s duration. For speech-in-noise, the audio was embedded in spectrally matched white noise at an SNR of −9 dB, a level where individual words could occasionally be discerned but where the semantic content was essentially unavailable. Word detection and self-reported intelligibility scores were significantly improved in the AV condition relative to the A condition. While only very low levels of cortical entrainment to the envelope were evident for auditory cortex in the A and V conditions, a substantial index of envelope tracking was apparent for the AV condition. These results suggest that, at SNRs where speech is largely unintelligible and cortical entrainment much diminished relative to clean speech, the addition of visual speech information improves speech comprehension by facilitating a dramatic increase in the sensitivity of auditory cortex to the acoustic speech information.

Title: A computational model of content-specific and content-free cross-modal predictions in audiovisual speech

Authors: *I. OLASAGASTI, S. HOVSEPYAN, S. BOUTON, A.-L. GIRAUD;
Dept. of Basic Neurosci., Univ. of Geneva, Geneve, Switzerland

Abstract: Speech processing is inherently multisensory and hierarchical, allowing one sensory system to use predictions about timing and content from the other one to facilitate parsing and decoding. To explore the role of predictions in speech processing, we developed a computational predictive coding model of audiovisual speech integration for the recognition of syllables. Congruent and incongruent audiovisual stimuli (McGurk stimuli) constitute a useful behavioral and electrophysiological model to investigate the mechanisms of audiovisual speech integration. Our model focuses on explaining two basic findings from the electrophysiological literature: that visual stimuli affect brain activity in early auditory cortex in a content unspecific way, and in a content-specific way in higher cortical areas (e.g. Arnal et al., 2009; Hertrich et al., 2009). We modeled audiovisual speech processing using a hierarchical Bayesian inference model in which recognition arises from top-down predictions and bottom-up prediction errors. The model includes amodal recognition units representing individual /aCa/ speech tokens at the top of the model hierarchy (C being a stop consonant). Each unit generates predictions about audiovisual sensory features consistent with the token it represents. The visual stimulus was characterized by lip aperture and the acoustic stimulus by two sensory features: the second formant transitions and voicing. In addition, the units generated predictions about sensory features at two distinct temporal scales broadly related to the syllabic and phonemic levels. Cross-modal predictions included speech-specific information driven by the correlation of lip closure, place of articulation and second formant transitions distinguishing between voiced /aba/, /ada/ and /aga/ (or unvoiced /apa/, /ata/ and /aka/). Cross-modal content-unspecific predictions were driven by the correlation between lip motion and the acoustic speech envelope. This model provides a novel cross-modal predictive coding interpretation of audiovisual integration and specifies two potential ways through which visual information affects speech processing: 1) content-specific information such as place of articulation favors specific speech tokens and their related recognition units, and 2) content unspecific timing information aligns internal rhythms and helps the parsing of continuous speech. The model thus provides a unified account of ‘what’ and ‘when’ predictions across modalities, assigning a specific role to distinct time scales in a well-established model of early audiovisual integration.

Title: Auditory and tactile processing and links to autism spectrum disorder symptoms

Authors: *L. K. BRYANT[1], M. T. WALLACE[1], C. J. CASCIO[2];
[2]Psychiatry, [1]Vanderbilt Univ., Nashville, TN

Abstract: Differences in response to sensory input have long been observed in individuals with autism spectrum disorder (ASD) and are now included among the clinical diagnostic criteria for ASD. Atypical sensory responsiveness manifests itself on a continuum spanning hypo-responsive and hyper-responsive patterns of behavior. It is possible that such altered sensory responsiveness is related to the processing and interpretation of sensory signal strength. However, sensory responsiveness to basic stimulus properties such as intensity has seldom been studied in a manner that allows a complete characterization of the full dynamic response range. Such a characterization would represent an invaluable foundation upon which ASD research could be conducted. We examined auditory and tactile responsiveness to varying levels of stimulus intensity in neurotypical adults using a detection task. A subset of these participants had first-degree relatives with an autism spectrum disorder diagnosis. ASD is highly heritable, and previous studies suggest that siblings of individuals with ASD also exhibit behavioral hypo- and hyper-responsiveness to sensory input. Our preliminary results suggest participants with a first-degree relative with an autism spectrum disorder demonstrate altered auditory and tactile detection thresholds, increased variability in response patterns, and a wider dynamic detection range. Ongoing work includes the correlation of these psychophysical data with self-report data on sensory responsiveness and subclinical autism symptoms, assessment of performance in response to paired audiotactile stimuli, and task adaptation to examine neural signatures of differential auditory and tactile processing using fMRI and EEG methods. This work holds great promise in laying the necessary foundation for studies directed toward better characterizing differences in sensory and multisensory function in autism.

Title: Does sound localization improve with obstructed somatosensory feedback?

Authors: *N. SAVIJA[1], P. DI NOTA[2], G. R. LEVKOV[3], G. A. ESCOBAR[1], K. SMITH[3], J. F. X. DESOUZA[4];
[2]Dept. of Psychology, [3]Dept. of Biol., [4]Ctr. for Vision Res., [1]York Univ., Toronto, ON, Canada

Abstract: This study examines neural integration of the sensory modalities of vision and hearing. The objective is to investigate whether an effect of cross-modal compensation of visual to auditory networks in human participants occurs with the removal of visual input. Using opaque contact lenses, visual input was obstructed during a sound localization task over 8 hours. Individuals were placed in a sound attenuated room, in the centre of a semi-circle consisting of 16 equally distributed speakers. Participants were required to localize sound, and actual and perceived sound locations were recorded at 7 time points across 5 hours. With the absence of somatosensory feedback on the face (i.e. opaque contact lenses versus using a blindfold), this study obtained a model for true blindness. Each participant was exposed to tactile, auditory, and gustatory stimuli. Using a difference score between the actual and perceived speaker location, sound localization was investigated. In the interest of investigating an improvement across time, an analysis of centric and eccentric speaker locations was completed. When speakers were grouped in to four quadrants; (1) left 135-180°, (2) fronto-left 90-135°, (3) fronto-right 45-90°, and (4) right 0-45°, there was a significant main effect of centricity, with participants performing significantly worse on right quadrant trials when compared to fronto-left and fronto-right trials. Additionally, a significant interaction between session and centricity revealed that when looking at each session individually, participants performed worse in quadrant 4 when compared to quadrants 2 and 3, but not compared to quadrant 1, in all sessions except session 4 (after 90 mins of blindness). The preliminary analysis of this study did not exhibit an overall improvement in error reduction for sound localization across time in visually deprived participants. It is possible that the lack of visual calibration (the association of location in space with source of sound), may impact the interaural time and intensity differences, and thus not result in overall reduction of errors across time, particularly in speakers located in the far left and right quadrants, as seen in this study. Although there was no improvement overall across time **for the preliminary results**, the significant main effect of speaker and centricity does not rule out a cross-compensation model for auditory and visual networks **and requires further analysis of the data.**

Title: The multisensory integration of naturalistic musical stimuli

Authors: *M. P. OLSHANSKY[1,3], J. F. X. DESOUZA[1,3,2];
[1]Psychology, [2]Biol., York Univ., Toronto, ON, Canada; [3]Ctr. for Vision Res., Toronto, ON, Canada

Abstract: Multisensory integration is a critical perceptual mechanism, aiding our ability to accurately respond to events in our environment. What has not been examined is the role of attention as well as experience in modulating the multisensory integration of naturalistic stimulus. In the first of two experiments, functional magnetic resonance imaging (fMRI) data was collected from 11 participants in order to investigate the effects of attentional modulation in unisensory (i.e., auditory and visual) and multisensory (i.e., audiovisual) stimuli with a task that directed participants' attention to either auditory or visual features of complex naturalistic stimuli (four acoustic guitar vignettes, 6 seconds each). During unisensory events, our results indicate widespread increases in neural activity during both visual and auditory attention in several cortical regions when compared to passive stimulus presentation. During multisensory events, focused attention to auditory features resulted in significantly more activity in the frontal and parietal regions compared to passive viewing; whereas focused attention to visual features additionally activated the bilateral caudate, insular cortex, and the left thalamus. Building on previous findings (Pynn & DeSouza, 2010), in a comparison between multisensory and unisensory attention, our results reveal significantly greater multisensory enhancement in a frontoparietal network, including regions which are known to processes both attention and multimodal cues. Our results reveal a distributed network of nodes spanning from the parietal lobules to the frontal cortex, which are modulated more strongly by attention during multisensory processing as compared to unisensory processing. In order to assess the effects of expertise on the multisensory integration of naturalistic musical stimuli, our second experiment investigates the effects of musical experience on multisensory integration in a similar paradigm to experiment #1. 22 participants (11 musicians, 11 non-musicians) performed a 2 alternative forced choice task where participants were required to determine which of two brief audio, video, or audiovisual vignettes depicting musical notes being played on a guitar was a higher

pitch. Our preliminary results indicate that unimodal cues were equally reliable for both groups, and visual cues were most reliable for both musicians and non-musicians ($p < 0.05$; both groups) after controlling for task difficulty. Our experiments are some of the first to use naturalistic musical stimuli to investigate the role of endogenous attention and musical experience on multisensory integration.

Title: Visual activation of auditory field maps across Heschl's Gyrus and surrounding cortex

Authors: *B. BARTON, J. H. VENEZIA, K. SABERI, G. HICKOK, A. A. BREWER;
Univ. of California, Irvine, Irvine, CA

Abstract: A primary organizing principle of visual cortical organization is the visual field map (VFM): neurons with visual receptive fields next to one another in visual space are located next to one another in cortex, forming one complete representation of visual space. Similarly, we have shown that auditory cortex is organized into auditory field maps (AFMs): neurons with auditory receptive fields that prefer a unique combination of spectral and temporal acoustic dimensions lie next to similarly specialized neurons. Here we investigate the cross-sensory activation of visual field mapping stimuli within AFMs in the vicinity of Heschl's Gyrus (HG). FMRI and a sparse-sampled traveling wave paradigm measuring tonotopic and periodotopic gradients were used to identify AFMs in four human subjects. Similarly, FMRI and population receptive field (pRF) modeling, standard methods for identifying VFMs, were used to identify visual activation within AFMs within these same subjects. Our results show that 1) there are AFMs within the cortical region surrounding HG and 2) that visual activation extends from the HG maps into these surrounding regions. This pattern of cross-sensory activation of primary and early auditory cortex by simple checkerboard visual stimuli resembles similar patterns of cross-activation in macaque measurements. In addition, this cross-sensory activation in normal subjects might be the basis for the visual reorganization of auditory cortex in congenitally deaf subjects.

Title: Organization of interareal connectivity in mouse cortex

Authors: ***J. A. HARRIS**[1], K. E. HIROKAWA[2], L. NG[2], S. MIHALAS[2], C. GERFEN[3], P. BOHN[2], B. OUELLETTE[2], M. MORTRUD[2], J. D. WHITESELL[2], S. SORENSEN[2], H. ZENG[2]; [1]Allen Inst. For Brain Sci., Seattle, WA; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The mouse cortex is densely interconnected in complex ways. Whether simpler underlying rules exist which govern these connections is currently not well understood. One possibility is that the mouse cortex is organized into a multi-level hierarchy, with anatomical features that differentiate between feedforward and feedback connections. To begin to explore whether this principle applies to mouse cortex, we used data from our Allen Mouse Brain Connectivity Atlas. Long-range axonal projections were mapped from genetically identified cell populations throughout the cortex using Cre driver lines and rAAV expressing Cre-dependent fluorescent protein (e.g. rAAV2/1.pCAG.FLEX.EGFP.WPRE.bGH). Fluorescently labeled axons were imaged by serial two-photon tomography at high throughput, high resolution, and with high sensitivity through the entire brain. Image series were registered into a common 3-D space, allowing for quantitation of signal, determination of spatial location, and relative topographical patterns between brains. Here, we present our analyses of cortical connectivity patterns from a set of 10 cortical areas and Cre driver lines used to selectively label types of projection neurons in layers 2/3 or 5. As a first step, we classified all projection patterns within each cortical target and assessed the frequency of occurrence of each type of pattern. Through this process, we identified ~10 distinct laminar patterns of termination in mouse cortex. The four most common types were; 1) equal density terminations across all layers, 2) preferential terminations in deep layers only, 3) preferential termination in superficial layers only, and 4) preferential termination in layer 1 and deep layers. Additional computational methods to classify termination patterns and analyze connectivity based on layer of origin as well as termination

patterns are used to determine whether there are general governing principles of mouse cortical organization that can be identified based on anatomical connectivity.

Title: Connectivity of Vasoactive Intestinal Peptide expressing inhibitory interneuron in mouse visual cortex

Authors: *E. M. KYUBWA[1,2], J. Z. HUANG[3], E. M. CALLAWAY[1];
[1]Salk Inst. for Biol. Studies, LA Jolla, CA; [2]Bioengineering, UCSD, La Jolla, CA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Understanding how distinct cell types are wired to affect local circuits is important to understanding how cortical circuits function. Inhibitory GABaergic interneurons, although small in number, play a major role in increasing the computational power of cortical circuits. Distinct non-overlapping interneuron populations expressing markers such as Parvalbumin (PV), Somatostatin (SOM), and Vasoactive Intestinal Peptide (VIP) can be targeted using transgenic mouse lines. VIP cells are recruited during particular brain-states and behaviors and preferentially inhibit SOM cells in mouse neocortical layer 2/3. Earlier studies in rat cortex implicated Calretinin (CR) expressing interneurons in similar circuits, but overlap between CR

and SOM in mice led to an emphasis on VIP cells rather than CR. Only about 40% of VIP cells co-express CR (VIP+/CR+) leaving open the possibility that VIP+/CR+ cells might differ from VIP+/CR- neurons in their connectivity or function. To address this question, we take advantage of flp and Cre mouse lines, and an intersectional and subtractive adeno-associated virus (AAV) that expresses ChR2 under the control of flippase and Cre recombinase. We parsed out the VIP population into two groups, VIP+/CR+ and VIP+/CR-, to generate ChR2 expression in each subgroup. We performed *in vitro* slice whole-cell patch recordings simultaneously in SOM cells and pyramidal cells during full field optical stimulation of ChR2. We measured inhibitory postsynaptic currents (IPSC) and postsynaptic charge (IPSQ) and compared the ratios for the SOM/Pyramid pairs. As previously reported in VIP cells, during stimulation of VIP+/CR+ cells IPSCs were high in SOM cells and low in pyramidal cells. The IPSQ ratio in SOM cells and pyramidal cells was high in layer 2/3. During stimulation of VIP+/CR- cells, preliminary data suggest that the ratio of inhibitory input strength for SOM and pyramidal cells is the reverse of what is observed following stimulation of VIP+/CR+ cells; currents are larger in pyramids than in SOM neurons. These results suggest that VIP neurons are a heterogeneous population. We are also investigating other potential postsynaptic targets of VIP+/CR- interneurons to shed light onto the integration of these cells into cortical circuits and to provide further insight into their computational roles.

Title: Characterization and comparison of cortical and geniculate responses in awake and anesthetized mouse

Authors: *S. DURAND, R. IYER, K. MIZUSEKI, S. MIHALAS, C. REID;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The mouse has become one of the main models in the study of vision, but only in the past few years that the vision community has started studying awake mice to better understand the importance of behavior.So far, the most extensive survey studies describing characteristics of V1 and LGN responses have been done in anesthetized mice (Niell and Stryker, 2008 and Piscopo et al., 2013). Our recent work examines how V1 and LGN perform in awake mice.

Using simultaneous recordings with high density silicon probes from hundreds of cells in LGN and V1 of C57BL/6J mice, we analyzed visual response properties to diverse stimuli, including sparse noise and drifting gratings in awake mice, both stationary and running, as well as anesthetized mice. We found that some properties such as orientation tunings are consistent under different states, whereas other properties such as temporal frequency and contrast response curves appear altered. We further divided the cells recorded in putative inhibitory and excitatory cells, based on their spike shape (Niell and Stryker, 2008), and investigated each layer in V1. As seen in the anesthetized mice, putative inhibitory cells show distinct properties such as low orientation selectivity index, low F1F0 index and high receptive field size. Layer 5 putative excitatory cells also had these characteristics compared to other excitatory cells, although to a lesser extent than putative inhibitory cells in all layers. Our overall aim here is to provide a broad overview of visual response properties in V1 and LGN in awake mice that can be useful as a reference for the vision community.

Title: The influence of long-range feedback inputs on single-cell dendritic signaling

Authors: ***A. SHAI**[1,2], C. A. ANASTASSIOU[2], H. ZENG[2], M. E. LARKUM[3], C. KOCH[2]; [1]Bioengineering, Caltech, Pasadena, CA; [2]Allen Inst. for Brain Sci., Seattle, WA; [3]Humboldt Univ., Berlin, Germany

Abstract: Long-range feedback connectivity in the neocortex has been implicated in attention and consciousness [1,2]. What are the physiological effects mediating such top-down and perceptual influences, and what computational role do they play in the cortical network? In this work we study the role feedback axons have on single, layer 5 pyramidal neurons in mouse

primary visual cortex. In particular, we focus our attention on projections arising from anterior cingulate cortex and latero-medial area of the visual cortex. First, we use the method of sCRACM [3] to map the locations of synapses on the dendrites of single cells in V1 [4], and find that inputs arrive in two distinct groups on the dendrites - one in the basal dendrites in layer 5, and the other in the apical tufts, in layers 1 and 2. Then, using an in-vitro optogenetic preparation, we monitor the post-synaptic effects that light-evoked feedback axons have on whole-cell patched cells. We find that direct monosynaptic excitation from frontal regions that form synapses in the upper layers of the cortex manipulate the threshold for dendritic Ca-spikes, even when those synapses fail to elicit any appreciable response at the soma in isolation. Additionally, we characterize the similarities and differences of projections from multiple higher order areas onto single cells in primary visual cortex. We discuss a possible role for such feedback projections in the formation of perceptual representations [5], whereby feedback acts to regulate the frequency of firing in neurons that themselves make long-range projections to other areas of cortex and the thalamus. Title: Cellular taxonomy of the primary visual cortex in mice by single cell RNA-seq

Authors: *B. TASIC, V. MENON, T. N. NGUYEN, T. K. KIM, Z. YAO, K. SMITH, T. DOLBEARE, B. LEVI, T. JARSKY, S. SORENSEN, L. GRAY, D. BERTAGNOLLI, J. GOLDY, N. SHAPOVALOVA, S. PARRY, L. MADISEN, S. SUNKIN, S. MIHALAS, C. DANG, J. PHILLIPS, L. NG, A. BERNARD, C. KOCH, M. HAWRYLYCZ, H. ZENG; Allen Inst. For Brain Sci., Seattle, WA

Abstract: Nervous systems are composed of numerous cell types, but the extent of their diversity is poorly understood. We are pursuing the transcriptomic characterization of individual cells within the visual cortex of adult mice in two phases. For the first phase, we have employed full-length single cell RNA-seq to characterize more than 1600 cells isolated by FACS from a variety of transgenic Cre driver lines. We constructed cellular taxonomy using a purely data-driven "bottom-up" approach refined by machine learning algorithms. We have uncovered at least 49 cell types, of which 23 and 19 types correspond to inhibitory and excitatory neurons, respectively, and 7 types are non-neuronal. Additional analysis reveals that single cell transcriptomic phenotypes are distributed in the gene expression space in a combination of continuity and discreteness; we define cells that congregate well into uniform categories as 'core cells' and define cells that have transcriptional signatures of at least two cell types as 'transitional cells.' In addition, we discover new molecular markers for cell classification, analyze cell type-specific alternative splicing and characterize many transgenic Cre lines for cell type composition. This initial dataset has been used as a guide for other projects at the Allen Institute that are pursuing cellular characterization using other experimental approaches, and will be used for generation of new transgenic mice that will allow specific access to these cell types. To explore this data set, an online interactive scientific vignette application has been developed and can be viewed at: http://casestudies.brain-map.org/celltax. For the second phase of transcriptomic characterization of the primary visual cortex, we are evaluating a variety of different approaches for scaling up the sampling of inhibitory and excitatory neuronal classes in an unbiased manner. We plan to employ pan-excitatory and pan-inhibitory transgenic lines, and to collect an order of magnitude larger number of cells than in the previous phase from layer-specific dissections. This approach will also result in better information on location of specific cell types, as the dissection information will be mapped into the Allen Mouse Common Coordinate Framework. Finally, this information will be integrated with other data modalities (electrophysiological, morphological, etc.) to arrive at a refined cellular taxonomy of this well-defined cortical area.

Title: The effect of the fine structure in connectivity on the collective dynamics in cortex

Authors: *C. A. VAN VREESWIJK[1], S. RAO[2], D. HANSEL[1];
[1]Univ. ParisDescartes, Paris, France; [2]Univ. ParisDescartes, Paris,, France

Abstract: There is increasing evidence for fine-structure in cortical connectivity [1]. Bidirectional connectivity and motifs of 3 or more highly interconnected neurons are more prevalent than expected from purely random connectivity [2]. What is the effect of these excess motifs on the collective dynamics in cortex? To address this question we investigate the dynamics of a network of neurons randomly connected with a rule such that the probability of directional connections is increased compared to the pure chance case (Poisson or Erdös-Renyi connectivity). The network consist of two populations of cells, excitatory (E) and inhibitory (I), and it operates in the 'standard' balanced regime [3]. Combining analytical calculations and extensive numerical simulations we show that excess bidirectional connections between the E cells or between I cells slow down the fluctuations in the neuronal activity. As a result, the autocorrelation of the neuronal activity decay more slowly than in the corresponding Poisson network. Comparing the contributions of E and I connectivity to this effect we show that, remarkably, bidirectional connections between I neurons are more efficacious in slowing down the dynamics. In contrast to bidirectional connections within the same population, bidirectional connections between populations decrease the correlation duration. The Fano factor of the spike count of neurons in sensory cortices decreases when stimuli are presented [4] and varies with the stimulus features [5]. Could the bidirectional connectivity explain these findings ? To investigate this we studied networks of conductance-based spiking neurons modeling V1 with and without an orientation map [6]. We found that bidirectional connectivity affects the Fano factor, both at rest and during stimulation and that the quantitative importance of this effect depends on the synaptic intrinsic dynamics. It is more pronounced when the synapses are slow than when they are fast. Finally, we show that these phenomena are due the small loops that the bidirectionality of the connections induces in the network architecture. Together with the relatively strong synapses these lead to an effective delayed self-coupling of neurons onto themselves, the effects of which are non-negligible because the network operates in the balance regime. Title: Automated creation of generalized leaky integrate-and-fire neuron models at several levels of complexity tuned to *in vitro* electrophysiology data

Authors: *C. M. TEETER, R. IYER, N. CAIN, D. FENG, S. SUNKIN, C. KOCH, S. MIHALAS;
Modeling Analysis and Theory, Allen Inst. For Brain Sci., Seattle, WA

Abstract: For simulations of neural networks there is a tradeoff between the size of the network that can be simulated and the complexity of the model used for the individual neurons. A series of models of increasing complexity were constructed to reproduce the spiking behavior of the database of recorded neurons collected as part of the Allen Cell Types Database. Starting with a leaky integrate-and-fire model, three generalizations were added: a) after-spike currents which represent the slower effects of ion channels activated by an action potential, b) subthreshold voltage and spike-dependent changes in threshold caused by the activation and inactivation of ion channels, and c) voltage and threshold reset rules derived from the electrophysiology data. These rules determine how the threshold and voltage are reset after a spike and depend on the state prior to the action potential. Electrophysiological stimuli were specifically designed to estimate some of the parameters of the generalizations: short square pulse currents to determine the minimal instantaneous threshold, a series of such pulses to determine how the threshold is updated by spikes, and multiple instantiations of frozen noise at different amplitudes for the optimization and testing of the rest of the parameters. Following these initial estimates, some parameters were further tuned to optimize the reproduced spike times generated by a training noise stimulus. The optimization method was based on maximizing the likelihood of a model neuron with intrinsic noise exactly reproducing the spike train observed in the experiment. The model performance was subsequently evaluated on a test stimulus: for different time scales, the fraction of the variance of the neuronal response which was explained by the model was computed. In addition to characterizing the level of complexity that is needed to recreate spiking behavior, we are interested in characterizing sets of predefined cell classes by looking at the relation between model parameters and different cell types, as well as asking if such models can further refine or subdivide these classes.

Allen Inst. For Brain Sci., Seattle, WA

Abstract: The Allen Institute's Cell Types Program seeks to classify cell types in the adult mouse and human neocortex, beginning with a focus on mouse visual cortex and human lateral temporal cortex. The goal is to analyze single neurons based on electrophysiology, transcriptional signatures, dendritic morphology, projection targets and connectivity. Data from these different modalities will be used to derive a cell types taxonomy and to answer such basic questions as: Can every neocortical cell be assigned to a unique type? Is the number of such cell types much smaller than the number of cells? Do they tile the neocortical sheet? How do cell types differ across functionally distinct regions of the neocortex? Are cell types conserved between mice and humans, or do humans have unique cell types? For this purpose, we have established the Allen Cell Types Database. Here we overview the data generation pipeline for neurons from the lateral geniculate nucleus (LGN) and primary visual cortex (V1) of the young adult laboratory mouse. Slices prepared from P45 to P70 mice (an interneuron or cortical layer specific Cre driver line crossed to an Ai14 tdTomato reporter line) are imaged during the cutting process to aid in brain region identification and registration to the Allen Mouse Common Coordinate Framework (CCF). The CCF is a 3-D anatomical framework with 3-D structural annotations and 10 μm resolution. Neurons are then analyzed in various ways including: (i) electrophysiological characterization of their intrinsic firing properties based on somatic patch recordings using a standard stimulation paradigm; (ii) 3-D morphological reconstructions of the dendritic tree based on biocytin fills; (iii) a variety of quantitative abstract point models (generalized, leaky integrate-and-fire or GLIF models) as well as biophysically grounded spatially extended compartmental models that are fitted to the electrical and morphological data for individual neurons; and (iv) the RNA species expressed by these cells using single cell transcriptomics. The data and relevant metadata are publicly available via the Allen Brain Atlas data portal (www.brain-map.org), together with search and visualization tools, and are fully integrated with other Allen Brain Atlas resources.

Title: Genetic labeling strategies for *in vitro* functional analysis of human neocortical cell types and microcircuits

Authors: P. CHONG[1], *J. T. TING[1], T. L. DAIGLE[1], R. P. GWINN[2], C. COBBS[3], E. LEIN[1]; [1]Allen Inst. For Brain Sci., Seattle, WA; [2]Epilepsy Surgery and Functional Neurosurg., [3]The Ben and Catherine Ivy Ctr. for Advanced Brain Tumor Treatment, Swedish Neurosci. Inst., Seattle, WA

Abstract: Understanding the structure and function of the human brain in health and disease represents one of the great scientific challenges of the 21st century. Modern technological advances in molecular neuroscience have enabled extensive breakthroughs in exploring brain function with refined spatial and temporal precision in genetically tractable animal model systems (e.g. mice, rats, fly, worm). Specifically, molecular genetic approaches have enabled precise targeting, lesion, monitoring, and manipulation of cell types and neural circuits in the context of whole animal behaviors, although these techniques have been generally unavailable to study non-genetically manipulable organisms including humans. However, several laboratories have demonstrated the feasibility of performing detailed mechanistic and functional investigations *in vitro* using living tissues from neurosurgical resections, opening the possibility for *in vitro* application of molecular genetic tools to study local brain circuits in human. To advance this approach, we have developed capabilities for electrophysiological, morphological, and transcriptomic analysis of individual human neocortical cells in acute brain slices derived from neurosurgeries. We have also developed capabilities for extended analysis on human brain slice maintained in an incubator for 1-10 days, thereby allowing implementation and exploration of genetic labeling of neocortical cell types using diverse viral transgene expression strategies. Using these preparations, we demonstrate successful human brain slice transduction using Herpes Simplex Virus (HSV), Adeno-associated virus (AAV), and Adenovirus, and conducted a

time course analysis of transgene expression. Furthermore, we have begun to evaluate novel viral vectors for fluorescent labeling of subsets of human neurons for targeted patch clamp recordings as well as viral vectors for optogenetic stimulation to facilitate interrogation of synaptic connectivity in neocortical microcircuits. Collectively, these approaches aim to provide selective molecular genetic targeting and manipulation to identify and study specific features of human neocortical cell types and local circuits.

Title: Standardizing spike sorting: an *in vitro*, in silico and *in vivo* study to develop quantitative metrics for sorting extracellularly recorded spiking activity

Authors: *C. MITELUT[1,2], S. L. GRATIY[2], D. DENMAN[2], J. H. SIEGLE[2], S. DURAND[2], K. GODFREY[2,1], C. LEE[2], R. C. REID[2], M. HAWRYLYCZ[2], C. KOCH[2], N. V. SWINDALE[1], C. ANASTASSIOU[2];

Abstract: Detecting neural dynamics at the single-cell level is central to many experimental investigations of the brain. The most common way of monitoring such dynamics *in vivo* is by recording brain activity from individual electrodes or high-density silicon probes inserted in the brain of the living animal. Extracting, separating and ascribing “spikes” to individual neurons from such recordings, i.e. spike sorting, is challenging given the similar shape of spikes from purportedly different cells [Swindale and Spacek, 2014]; spike sorting becomes significantly more CPU-demanding with increasing numbers of recording sites [Rossant et al 2015]. Additionally, while a number of algorithms and sorting suites have been developed over the past two decades, there are very few realistic ground-truth data-sets to test them against. We developed unique and previously unavailable *in vitro*, in silico and *in vivo* ground truth data-sets to generate quantitative sorting metrics and characterize sorting performance for separate spike sorting stages: spike detection, clustering and manual cleanup. Specifically, we used concurrent intracellular and extracellular recordings from various cell types in rodent slices to obtain realistic single-neuron extracellular spike signatures [Anastassiou et al, in press]. In silico, we

used biophysically and morphologically realistic single-cell representations [Hay et al 2011, 2013; Hu et al 2010; Norenberg et al 2010] to create a cortical patch consisting of ~5,000 synaptically connected spiking cells responding to various external inputs while emulating extracellular depth recordings along the patch. Finally, high-density extracellular recordings were acquired *in vivo* from rodent visual cortex for standardized visual inputs. Using these datasets we determine Receiver Operator Characteristic (ROC) curves for several spike detection thresholds and methods. Following blind spike sorting tests of our data-sets we benchmark speed, resource demands and overall quality of output for several sorting algorithms including: Klustakwik [Rossant et al 2015], SpikeSorter [Swindale and Spacek 2014], Osort [Rutishauser et al 2006]. We develop two sorting metrics, i.e. completeness and purity, and show that the quality of a sorted unit depends not only on its peak-to-peak (PTP) amplitude but also on the sorting algorithms employed. Lastly, we show that several sorting parameters can be determined automatically thus reducing supervision-demand of sorting tasks while preserving the overall quality of output.

Title: Characterizing the mesoscale organization of mouse visual cortex using ultraviolet light

Authors: *J. SIEGLE[1], J. ZHUANG[1], D. J. DENMAN[1], M. T. VALLEY[1], B. P. DANSKIN[1], R. C. REID[1], S. R. OLSEN[1], J. WATERS[1], T. J. BLANCHE[1,2];

Abstract: The mouse retina contains cones that are sensitive to ultraviolet (UV) wavelengths, and mice show behavioral responses to UV light. However, the manner in which UV stimuli are processed at the level of visual cortex has yet to be investigated. We placed mice in an immersive dome environment capable of presenting full-field human-visible (400-700 nm) and UV (350-380 nm) stimuli. In N = 8 Emx1-Cre x Ai96 (GCaMP6s reporter) mice, which express calcium-sensitive fluorescent proteins in cortical excitatory neurons, we mapped the retinotopic organization of visual cortex using through-skull widefield imaging of the dorsal cortical surface.

Checkerboard patterns swept across the visual field in azimuth and elevation led to robust increases in fluorescence (mean maximum ΔF/F across mice = 11.1 ± 4.3%), which were converted into visual sign maps to delineate the borders of V1 and higher visual areas. For both human-visible and UV stimulation, we compared the number of identifiable areas, areal boundaries and retinotopic coverage, and the relative activation strength of each region.

Title: Active somatic and dendritic single-cell models using data from an *in vitro* slice electrophysiology and morphology platform

Authors: ***C. ANASTASSIOU**[1], W. VAN GEIT[2], C. ROSSERT[2], J. BERG[1], T. DESTA[1], D. FENG[1], L. KANARI[2], S. SUNKIN[1], J. SHILLCOCK[2], S. SORENSEN[1], H. PENG[1], A. BERNARD[1], C. DANG[1], M. HAWRYLYCZ[1], S. HILL[2], J. W. PHILLIPS[1], H. ZENG[1], E. MUELLER[2], H. MARKRAM[2], C. KOCH[1];
[1]Allen Inst. for Brain Sci., Seattle, WA; [2]Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland

Abstract: The Allen Institute has recently established the Allen Cell Types Database, with the goal of collecting electrophysiological, morphological, and transcriptional data from individual neurons of the mouse and human brain (e.g., see poster-abstracts by Berg et al and Sorensen et al). As part of this effort, the aim is also to construct and test biophysically and morphologically detailed conductance-based models, emulating the neural response to stereotyped somatic electrophysiological stimuli. Towards this end, in a joint effort between the Allen Institute and EPFL's Blue Brain Project (BBP), experimental (slice electrophysiology and morphology) single-neuron data are used to analyze and construct morphologically detailed compartmental models that faithfully reproduce many aspects of the physiology of these neurons using technology developed by the BBP. Crucially, these single-neuron representations include active dendritic conductances to capture key features of synaptic integration as observed in the mammalian brain. For such active representations to be developed, we use a computational framework based on genetic optimization [Druckmann et al, 2007; Hay et al, 2011]. Specifically,

we instantiate and examine three options for the optimization setup: (1) a soma-centric approach with spatial distribution of active conductances aiming to capture only somatic subthreshold and spiking features (2) a soma- and dendrite-centric approach including dendritic features (such as BAP-speed, BAP-width, input resistance, Vrest as function of apical distance) as measured experimentally (e.g. [Shai et al, *PLoS Computat Biol*, 2015] (3) a soma- and dendrite-centric approach including a Ca-hotzone at the main apical bifurcation and accounting for critical frequency experiments as measured in the literature (e.g. [Shai et al, *PLoS Computat Biol*, 2015]). Each optimization runs in parallel on up to 8192 cores on a Blue Gene Q supercomputer. The accuracy of the resulting models is assessed via a spectrum of metrics (e.g. explained variance, etc.) Crucially, these detailed single-neuron models, along with the electrophysiology and morphology data from the same single-neuron will part of the Allen Institute Cell Types Database and the Human Brain Project Neuroinformatics Platform.

Title: Chromatic responses in the mouse central visual pathway

Authors: *D. J. DENMAN[1], J. H. SIEGLE[1], R. C. REID[1], T. J. BLANCHE[1,2];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Univ. of California, Berkeley, CA

Abstract: The mouse retina contains two cone photopigments: a medium-wavelength opsin (M) with a peak sensitivity at ~520 nm, in the green region of the spectrum, and a short-wavelength opsin (S) with a peak sensitivity at ~360nm, in the UV-A region. These opsins are expressed and co-expressed non-uniformly across the retina, with M-opsin responses dominating dorsal regions and S-opsin responses dominating ventral regions. These chromatic sensitivities are also apparent in bipolar and retinal ganglion cell responses. In spite of this, the mouse dorsal lateral geniculate nucleus (dLGN) and primary visual cortex (V1) have primarily been studied under

photopic conditions using monochromatic stimuli well-suited for the M-opsin, but providing little to no photoexcitation of the S-opsin. We characterized single-cell and population dLGN and V1 responses using high-density silicon array recordings to both monochromatic UV-A and green stimuli. Full-field visual stimuli were presented using an immersive visual stimulation environment and a custom-modified DLP projector capable of generating monochromatic stimuli centered on 360nm or 525nm, under mesopic luminance conditions (2cd/m2 for 525nm, ~3x efficacy for 360nm). Chromatic response clustered into three categories: UV-dominated, green-dominated, and nearly equal UV~green (achromatic). Most recording sites contained a mix of these classes. Chromatic balance was visuotopically organized, with UV-dominant responses more prevalent in the upper visual field and green-dominant more prevalent in the lower visual field. Preliminary results indicate an imbalance toward green in OFF responses, while ON responses were more chromatically balanced. Our results support the existence of chromatic processing without evidence for chromatic opponency in the mouse visual system.

Title: The mechanism of orientation selectivity in Layer 4 in rodent V1

Authors: *D. HANSEL[1,2], G. MATO[3], C. VAN VREESWIJK[1,2];
[1]CNRS, Paris, France; [2]Ctr. for Neurophysics, Physiol. and Pathology, Univ. Paris Descartes, Paris, France; [3]Ctr. Atomico, Bariloche, Argentina

Abstract: Neurons in primary visual cortex (V1) exhibit orientation selectivity (OS). This is true for animals like cats or primates in which V1 has an orientation map (OM) as well as for those without OM (salt-and-pepper organization), e.g. rodents. Whether OS is primarily due to feedforward (FF) connectivity or to recurrent interactions has not been settled. In the former case the presence or absence of an OM hardly matters, but in the latter the spatial organization of preferred orientations (PO) could affect the mechanism. The connectivity in rodent V1 is hotly debated. Unclear is the extent to which connections in adult mice are specific. With specificity, the distribution of the POs of cells projecting to a neuron would be similar to that in cat V1 and the same mechanism could operate in both cases. In contrast, with random connectivity this distribution is flat. Importantly, it has been demonstrated that in mice V1 neural responses are highly selective at eye opening although the connections are not yet specific (Ko etal, 2013). How can OS arise in this case? In a recent theoretical paper (Hansel & van Vreeswijk, 2012) we showed that strong OS emerges naturally in layer 2/3 in V1 if it operates in the balanced excitation/inhibition regime even if the recurrent connectivity is random and FF inputs from Layer 4 (L4) result from selective neurons with random preferred orientations. A question then arises : But how do L4 neurons exhibit OS in rodents ? To address this issue we consider a model comprising two networks, one for L4 and one for the LGN. We assume first circular LGN receptive fields and purely random FF connections. We show that despite the lack of OS in LGN the FF connectivity carries a weak information on the stimulus orientation which can be extracted and amplified by the L4 network if it operates in the balanced regime. We show that the orientation selectivity index (OSI) depends only weakly on the model parameter with typical mean OSI=0.1-0.2 and 0.15-0.3 for the F0 and F1 components of the response. We also find that for realistic parameter values, the F0 component is substantially less tuned for inhibitory neurons than for excitatory neurons but for F1 components tuning is similar in both populations. Additional contributions to the OS in L4 with salt and paper organization can come from LGN neurons if they have elongated center-surround receptive fields, as recently described in experimental studies or in specificity in the LGN projections as in the Hubel & Wiesel mechanism. We show that these three contributions can be unambiguously disentangled experimentally by characterizing how the PO of the neurons varies with the spatial frequency of a drifting grating stimulus.

Title: Generation and analysis of biophysical models of diverse mouse cortical neuron types

Authors: *N. W. GOUWENS, J. BERG, T. DESTA, D. FENG, T. FLISS, K. GODFREY, T. JARSKY, L. NG, S. SORENSEN, S. SUNKIN, Z. ZHOU, A. BERNARD, C. DANG, H. PENG, J. PHILLIPS, H. ZENG, M. HAWRYLYCZ, C. KOCH, A. ARKHIPOV;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The experimental data collected as part of the recently established Allen Cell Types Database contributes to an integrated framework for understanding the components of mouse cortical circuits. In close coordination with these experimental efforts, we have generated biophysically detailed models of individual neurons in that database, providing components for computational studies of neuronal cell types in the context of circuit function. The purpose of these biophysically detailed models, built from matching electrophysiological and morphological data collected from individual neurons recorded in slices, is to characterize the firing properties of different cell types and relate them to generalized biophysical mechanisms governing this firing. We construct the models by importing the reconstructed 3D morphologies of cells into the NEURON simulation environment and placing at the soma a set of 10 active conductances, as well as a mechanism describing intracellular Ca^{2+} dynamics. A leak conductance is also included in all compartments. For each model, the densities of these conductances and parameters of the $[Ca^{2+}]_i$ dynamics are optimized with a genetic algorithm to match a set of 12 electrophysiological features measured from the original cell's responses to step current injection. In most cases, we obtain relatively close matches to the original experimental data, as assessed by features of action potential shape (e.g., peak, depth, and width) and firing pattern (e.g., average firing rate, degree of adaptation) being within one or two experimentally-measured standard deviations or otherwise pre-defined tolerances of a particular feature. We further test the models produced by this procedure by applying all the other stimuli used in the original recordings and comparing the model responses to the recordings. Applying this technique to a diverse set of neurons from the mouse cortex, we analyze how well the resulting models generalize to various stimuli under different circumstances and compare characteristics of the models across subsets of cells (defined by Cre-based labels and location in the cortex). The optimized models are openly accessible online alongside the original experimental data as part of the public Allen Cell Types Database, and source code to run the models can be downloaded from the Allen Software Development Kit.

Title: Characterization of connectivity and synaptic properties of layer 4 neurons in the mouse primary visual cortex

Authors: G. J. SOLER-LLAVINA, *B. R. LEE, H. ZENG;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The connectivity patterns and the synaptic properties among distinct cell types are essential to information flow and processing in the brain. There is a wealth of information regarding cell types and connectivity in many brain regions. However, at the level of resolution relevant to neuronal computation, our understanding of the numbers and kinds of cell types in a given neuronal circuit, their detailed connectivity and the properties of these connections remains incomplete. A goal of the Allen Institute for Brain Science is to create a more comprehensive classification of neuronal types with an initial focus on the mouse primary visual cortex (V1). We seek to create a full connectivity and synaptic properties profile of potential excitatory neurons in layer 4 (L4) of V1 using Cre-driver mouse lines that label sub-populations of cells, in combination with multi-whole cell recordings and optogenetics. In addition to implementing standardized and generalizable paradigms to comprehensively characterize synaptic properties, we aim to gain insight into the following questions: 1) Are patterns of connectivity a property of cell types? 2) Do unitary post-synaptic responses and short-term synaptic plasticity and postsynaptic receptor composition enable further differentiation of cell types? These questions are particularly interesting in the context of L4, which based on classical classification methods, appears to be formed by a homogeneous neuronal population. Our results suggest that there are at least two distinct populations of excitatory neurons coexist in L4 of the mouse V1.

Title: A fine ultra-structural analysis of synaptic terminals formed by different cell types in layer 4 of the primary visual cortex of the mouse

Authors: *A. L. BODOR[1], K. GLATTFELDER[2], S. MIHALAS[2], M. TAKENO[2], N. M. D. COSTA[2];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Layer 4 of the primary visual cortex (V1) provides one of the classical examples of cortical computation. It receives excitatory synapses from multiple sources including the thalamus, other cortical layers and its own recurrent connections. The detailed connectivity between these different partners and dendrites in layer 4 of mouse V1 is however largely unknown. Using serial section electron microscopy we provide a quantitative and detailed morphological analysis of the synapses formed by three different cell types whose axonal arbours innervate layer 4: thalamic, layer 6 corticothalamic neurons and local layer 4 neurons. Different cell types were labeled by immunohistochemistry against VGluT2 (thalamic boutons) or tdTomato expressed in layer 4 (Nr5a line) or layer 6 (Ntsr1 line) neurons. After regions of layer 4 were prepared for electron microscopy, labeled boutons were selected based on random sampling and the physical disector and then reconstructed from serial sections. Thalamic boutons were mostly polysynaptic, targeted mostly spines, and formed the largest synapses, though the distribution of synapse sizes was very broad. Layer 6 cells were highly variable in the number of synapses per bouton, their synapses were the smallest, and while they preferentially targeted spines, approximately 30% of their targets were dendritic shafts. Layer 4 recurrent connections formed mostly one synapse per bouton, the synapses were of a medium size, and like the thalamic boutons, they mostly targeted spines. Our results show that synapses formed by different cell types in layer 4 of mouse V1 display different morphological features. Similar to other animal models of layer 4, thalamic synapses were the largest and layer 6 synapses the smallest, but a notable difference is that rodent synaptic terminals are more polysynaptic. The described differences can also, in principle, be used to classify different cell types based on fine ultra-structural properties.

Title: The functional organization of presynaptic neural networks providing input to individual cortical neurons

Authors: *S. TRENHOLM[1], A. WERTZ[1], K. YONEHARA[1], Z. RAICS[1], M. LEINWEBER[1], D. HILLIER[1], G. SZALAY[2], G. KELLER[1], B. ROZSA[2], K.-K. CONZELMANN[3], B. ROSKA[1,4];
[1]Friedrich Miescher Inst., Basel, Switzerland; [2]Inst. of Exptl. Med., Budapest, Hungary; [3]Ludwig-Maximilians-Universitat, Munich, Germany; [4]Univ. of Basel, Basel, Switzerland

Abstract: Introduction: Many cortical neurons respond selectively to specific cues. For instance, in visual cortex, many neurons preferentially respond to specific orientations or directions of moving images. How this selectivity relates to that of the presynaptic network which spans across cortical layers remains unclear. Methods: Using single-cell-initiated, monosynaptically-restricted, retrograde transsynaptic tracing with rabies viruses expressing GCaMP6s, we imaged, *in vivo*, visual motion evoked activity of individual layer 2/3 pyramidal neurons and their presynaptic neuronal networks across cortical layers in primary visual cortex in mouse. Results: This technique labelled ~400 presynaptic cells connected to individual layer 2/3 pyramidal cells in primary visual cortex. The majority of presynaptic neurons were nearby in primary visual cortex, and cells were labelled across all cortical layers. Longer range connections were also consistently found, including inputs from the thalamus. Next, using *in vivo* calcium imaging we characterized the response properties to moving visual stimuli of the electroporated cell (i.e. the postsynaptic cell) as well as the response properties of the local presynaptic network in primary visual cortex. We found that presynaptic networks connected to individual layer 2/3 pyramidal cells could be classified into different groups based on functional organization. Conclusion: These results reveal the existence of different presynaptic network organization principles belonging to layer 2/3 pyramidal neurons.

Title: Large scale imaging and 3d visualization of long-range circuits in clarity-treated primate visual cortex

Authors: C. CHRISTENSEN[1], F. FEDERER[2], A. GOOCH[1], S. MERLIN[2], V. PASCUCCI[1,3], *A. ANGELUCCI[2];
[1]Scientific Computing and Imaging Inst., Univ. of Utah, Salt Lake City, UT; [2]Ophthalmol Moran Eye Ctr., Univ. Utah, Salt Lake Cty, UT; [3]Pacific Northwest Natl. Lab., Richland, WA

Abstract: Understanding the circuitry of the brain is necessary to understanding brain function. Recently there has been a renaissance in neuroanatomy, thanks to the discovery of cell-type specific tracers, and new methods for high-resolution imaging and 3D reconstruction of large data sets at much greater speed than previously possible. However, the large size and complexity of the primate brain, compared to mouse brain, poses greater challenges to the study of neural circuits. CLARITY tissue clearing (Chung et al. 2013) allows imaging labeled circuits through entire tissue blocks, without the need for tissue sectioning and section-to-section alignment. However, the large primate brain requires long image acquisition times, and software capable of compiling and stitching very large data sets, and tracing through these volumes. Here we have labeled projection neurons between visual cortical areas V1 and V2 in primates, using GFP-expressing AAV9. Tissue blocks were cleared using passive CLARITY technique (PACT; Yang et al. 2014), and imaged in a 2-photon microscope. A 1mm diameter injection site in V2 labeled a field of axons in V1 of about 60mm^3. Imaging a 5mm^3 volume at 1 μm z-resolution took 96 hrs, generating 130 GB of data. Hence, imaging the 60mm^3 V1 block would take 19 days, and produce 1.6 TB of data. To address the challenges posed by handling large data sets we adopted the ViSUS streaming platform for scalable data analysis and visualization (Pascucci et al. 2012). This is designed around an innovative notion of hierarchical space-filling curves that enables selective data access both locally and remotely. Its combination with progressive algorithms enables a dynamic scripting layer that provides on-the-fly computation of derived quantities such as statistics on the data or multiple concurrent maximum intensity projections from arbitrary directions. Remote data access is enabled with a server. Locating the server at the acquisition source allows data conversion so that the 3D images can be viewed during acquisition. View-

dependent, progressive resolution data streaming allows clients fast access to regions of interest while client-side caching amortizes network transfer costs, effectively hiding them from the user. The ease of data access provided by the ViSUS framework facilitates the alignment of 3D volumes while providing interactive access to the full data collection, so that a user can more easily switch among the tasks of data alignment, analysis and annotation. The end result is the presentation of data collections as single, large volumes that can be handled easily and interactively by multiple users in collaboration over a distributed environment.

Title: Morphological classification of genetically-identified neurons in mouse primary visual cortex

Authors: *S. A. SORENSEN, T. DESTA, M. FISHER, A. HENRY, D. SANDMAN, N. THATRA, X. LIU, Z. ZHOU, J. BERG, S. CALDEJON, N. GAUDREAULT, T. LEMON, S. PARRY, J. HARRINGTON, W. WAKEMAN, D. FENG, S. SUNKIN, A. BERNARD, L. NG, C. DANG, H. PENG, J. PHILLIPS, C. KOCH, H. ZENG;
Neurosci., Allen Inst., Seattle, WA

Abstract: The Allen Institute for Brain Science has undertaken a large-scale effort to understand the full diversity of cell types in the mouse brain. We have focused our initial efforts on primary visual cortex (V1) in a range of layer- and interneuron-specific Cre driver mice crossed to TdTomato (tdT) reporter mice. Through a multi-modal characterization of single neurons, including electrophysiological, morphological and transcriptional studies, we aim to identify the crucial features that define a cell type, and to use them to establish a taxonomy of cell types for this brain region. These data will be made publicly available as part of the Allen Institute Cell Types Database. Electrophysiological experiments begin with a whole cell recording targeted to tdT-positive neurons in acute slices maintained *in vitro*. Intrinsic properties are recorded and cells are simultaneously filled with biocytin. For morphological studies, slices are then fixed, and stained for biocytin with an ABC-DAB reaction. Whole mount slices are then imaged with a widefield microscope at 20x (whole slice overview) and 63x (multi-plane image of biocytin-

filled neuron) to allow for regional identification and 3-dimensional reconstruction of individual neurons. Using Vaa3D software (http://www.vaa3d.org), semi-automated reconstructions of the dendrites, soma and the initial part of the axon are obtained for all neurons (>100) that have high data quality and/or value scores. A smaller subset of neurons has a reconstruction of the full axon that appears in the slice. Image and reconstruction data are then used to qualitatively map each reconstructed neuron to a putative morphological cell type and/or a set of correlated features. This analysis reveals the range of morphological types_as it relates to our existing knowledge_represented in this initial dataset. This information also provides a benchmark for data driven approaches to defining morphological cell types (presented in a separate poster by Xiaoxiao Liu et al.). This is a first step toward classifying neurons based on objective measures of their morphology. Morphologically-defined cell types will later be integrated with electrophysiologically- and transcriptionally-defined cell types, in order to generate a comprehensive description of neuronal cell types in mouse V1.

Title: Simulating LFP responses in mouse V1 to sensory inputs using a large-scale, biophysically detailed multi-layer circuit model

Authors: ***S. L. GRATIY**[1], C. MITELUT[2], S. DURAND[1], D. DENMAN[1], J. SIEGLE[1], J. BERG[1], S. SORENSEN[1], A. ARKHIPOV[1], M. HINES[3], A. SHAI[4], J. PHILLIPS[1], H. ZENG[1], R. REID[1], M. HAWRYLYCZ[1], C. KOCH[1], C. ANASTASSIOU[1];

Abstract: Despite enormous progress in characterizing the properties of individual neurons and their connections, the mechanisms underlying processing of sensory stimuli in cortex remains largely unknown. Biophysically detailed models of neuronal circuits are well positioned to address this challenge since they naturally allow for the integration of anatomy, connectivity and physiology while predicting signals across multiple modalities: spikes, extracellular potentials and calcium imaging. With the aim of unraveling the biophysics of computation in mouse V1, we use modeling to explain the laminar LFP response to full-field flash visual stimuli during early stages of cortical processing (<50 ms). We developed a large-scale, biophysically detailed model of a multi-layer circuit in mouse V1 (corresponding to ~0.5 mm2 of cortical surface) utilizing reconstructed single cell morphologies and biophysical properties as well as cell type-specific connectivity rules. Each layer consists of one excitatory and one inhibitory cell-type represented by several different biophysically detailed templates. The model is capable of predicting multi-electrode array recordings such as unit activity and local field potentials [Buzsaki et al, Nat Rev Neurosci, 2012]. Using full-field flash LGN recordings as input to the model we reproduce in silico the stereotypical laminar pattern of LFP recordings [Niell & Stryker, J. Neurosci, 2008] as well as firing activity during resting and stimulus. We aim to 1) compute the laminar LFP profiles of activity of individual neuronal population and then 2) tune connectivity between the populations of different cell-types to match simulations to data. Thereby, we expect to infer the pathways of information processing in mouse V1 at the mesoscopic scale corresponding to that of LFP recordings.

Title: V1 layer 4B neurons projecting to V2 thick stripes in macaque: V1 intra-laminar projections and their relationship to cytochrome oxidase compartments

Authors: *J. T. YARCH, F. FEDERER, A. ANGELUCCI;
Moran Eye Inst., Univ. of Utah, Salt Lake City, UT

Abstract: Neurons in layer 4B of macaque primary visual cortex (V1) send their outputs to functionally different cortical areas and areal compartments. The unique contributions of 4B inputs to different cortical targets may result from differences in their anatomical wiring. Based on dendritic morphology, two 4B cell types have been recognized (spiny stellates, pyramids). Area MT receives 80% of 4B inputs from stellates, while V2 receives 80% of inputs from 4B pyramids (Nassi & Callaway 2007). However, V2 consists of distinct cytochrome oxidase (CO) stripe compartments, and we showed that thick stripes receive ~50% of 4B inputs from stellates (Yarch et al 2013). It is unclear whether 4B cells projecting to different targets also show unique intra-V1 axonal arbor patterns, or even whether such patterns can be used to classify cells. Previous reconstructions of 4B cells randomly filled intracellularly in V1 slices have shown stereotypical axon projection patterns: all 4B cells branch in layers 2/3, 4B and 5, with projections to 2/3 residing in CO blobs irrespective of soma location (Callaway & Wiser 1996). However, the areal targets of these 4B neurons were unknown in these studies. We have characterized the intra-V1 axonal branching patterns of 4B cells projecting to V2 thick stripes to uncover the anatomical foundations for the parallel streams between V1 and V2 (Federer et al. 2009,2013). Small injections of G-deleted-GFP rabies virus were targeted to V2 thick stripes identified by intrinsic optical imaging (3 macaques). GFP filled neurons in V1 L4B (n=19) were fully reconstructed through serial sections. Measurements of total axonal length contributed by each cell in each V1 layer allowed us to classify cells into 2 classes: 1) Class 1 cells (~61% of total) which branch in supragranular (SG, 4B only or 4B and 2/3) and infragranular (IG, mainly 5) layers (as described by Callaway and Wiser, 1996), 2) Class 2 cells (~39%) that only branch in IG layers (not previously described). On average, Class 1 and 2 cells dedicate 63% and 0%, respectively, of their axonal arbor to SG layers. Class 1 and 2 cells are 61% and 71%, respectively, spiny stellates, and both classes have somas that reside in interblobs or at blob borders; 1 soma in our reconstructed sample resided in a blob. For each cell we analyzed bouton positions relative to blobs in all layers. Irrespective of cell class, IG and SG axon branches avoid CO blob columns; instead, they target predominantly interblobs if their soma lies under an interblob, or blob borders if their soma lies under a border. Axon branches of the cell with its soma in a blob avoided blobs. Overall, lateral projections of 4B cells of either class show CO compartment specificity.

Abstract: The Allen Institute has recently established the Allen Cell Types Database, with the goal of collecting electrophysiological, morphological, and transcriptional data from individual neurons of the mouse and human brain. An essential aspect of this database is the investigation of one of the most fundamental neuronal traits - intrinsic electrophysiological behavior. To compare the electrophysiological features of neurons that may contribute to cell classification, a standardized platform has been established for *in vitro* slice recording from mouse brain (with concurrent biocytin cell filling), followed by histological processing, imaging, and morphological reconstruction. Setting quality control parameters, standardized workflows, and increased automation allows for uniform data production across operator or electrophysiology rig. Data is gathered for each cell using a uniform set of electrophysiological stimuli to a) interrogate intrinsic membrane mechanisms that underlie the input/output function of neurons, b) infer aspects of neural response properties *in vivo* using *in vitro* data, and c) construct and test computational firing models, including detailed biophysical and generalized linear models, emulating the neuronal response to stereotyped stimuli. Thus far, the platform has been used to characterize hundreds of mouse neurons, data that are openly accessible via the Allen Brain Atlas web portal. In addition to the electrophysiological and morphological data acquired, each mouse neuron is registered within a common anatomical framework, or 3D reference atlas. The *in vitro* electrophysiology platform has also been applied to the analysis of live human brain slices derived from neurosurgeries at local hospital sites. Overlying neocortical resections are collected from individuals undergoing surgery for tumor removal or intractable epilepsy. By using standardized protocols and procedures, we aim to create a comprehensive, integrated database of cell type features for both human and mouse brain.

Title: Dendritic morphology feature analysis for mouse neuron classification

Authors: ***X. LIU**, S. SORENSEN, C. LEE, Z. ZHOU, B. LONG, S. SUNKIN, H. ZENG, M. HAWRYLYCZ, H. PENG;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Neuronal morphology characterization plays a crucial role in delineating neuronal cell types, as well as understanding neuronal function and connectivity. The Allen Cell Types Database currently contains more than one hundred 3D reconstructions of neuronal morphology generated from bright-field images of mouse neurons filled with biocytin during acute slice electrophysiology experiments. Here we present a study that extracts the most salient dendritic morphology features for distinguishing subtypes of neurons in mouse primary visual cortex. Twenty-one global morphological features were extracted from manually curated dendritic reconstructions. Both a supervised and an unsupervised strategy were deployed to explore neuron taxonomy. In the unsupervised approach, basic linear discriminant analysis was used to discover the hierarchical separations of neuron morphologies. In the supervised approach, neurons were first manually classified by neuroscientists into subgroups based on their shapes and their locations in the brain. We then used a machine learning method called MRMR (minimum redundancy and maximum relevance) to rank the features according to their saliency in terms of distinguishing those subtypes. K-fold cross validations were used to evaluate the classification results. The study provides insights in quantifying the morphological differences among neurons. Specific combinations of salient morphological features that correlate well with anatomical and functional clustering are revealed. The saliency ranks of the features are expected

to evolve as the Allen Cell Types Database grows both in number of samples and diversity of reconstructed neuronal morphologies.

Title: Long range input to layer 1/2 drive distinct excitatory/inhibitory balance in modules within mouse primary visual cortex (V1)

Authors: *P. BISTA, A. BURKHALTER;
Anat. and Neurobio., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Layer 1 (L1) is a unique neocortical layer that is devoid of excitatory neurons, but contains a rich plexus of axons and axon terminals coming from subcortical sources such as thalamus and basal forebrain as well as feedback (FB) inputs from higher cortical areas (Dong et al., 2004; Wang et al., 2012). In addition, L1 contains apical dendrites of Pyramidal cells (Pyr) with cell bodies and basal dendrites in L2-6. Based on the highly polarized dendritic arbor and the stratification of inputs it has been proposed that L1 is an important node in which Pyr couple FB inputs to apical dendrites with FF inputs to basal dendrites in L3/4 (Larkum, 2013). Within the cerebral cortex, the vast majority of interareal FF and FB connections are formed by excitatory Pyr, which in the target area synapse onto Pyr and most often onto parvalbumin-expressing GABAergic interneurons (PV) (Gonchar and Burkhalter, 1999; 2003). In both pathways monosynaptic excitation of Pyr is followed by disynaptic PV-mediated inhibition, which is known as feedforward inhibition (Dong et al., 2004). More recently we have found that inputs from the dorsal lateral geniculate nucleus (dLGN) and several higher visual cortical areas to L1 of V1 terminate in patchy patterns. This raises the question whether inputs to Pyr and PV inside and outside the projection patches vary in absolute and relative strength. To study this

question, we used subcellular Channelrhodopsin-2 assisted circuit mapping (Petreanu et al., 2009) in acute tangential slices of mouse V1, in which PV neurons were genetically labeled with tdTomato. Whole cell patch clamp recordings showed that EPSCs recorded from L2/3 Pyr and PV aligned with patches that receive strong input from the dLGN were 2-3 times more powerful than outside projection patches. Similarly, EPSCs from Pyr and PV recorded inside patches with strong FB input were three times larger than outside patches, suggesting that input density scales with response strength. Inputs to PVs inside and outside of dLGN-projection patches were stronger than inputs to Pyr. A similar asymmetry was found in patches with weak FB input, suggesting that each of these inputs contacts subnetworks that are specialized for the selection of synchronous inputs and the filtering of noise. In contrast, inputs to Pyr and PV inside patches with strong FB projections were balanced. This suggests that activation of Pyr and PV in the same module is input-specific, tilted towards inhibition for dLGN input and similar for intracortical FB connections (Yang et al., 2013). The E/I ratio was balanced for FB input, a circuit mode known to broaden the integration window for coincident inputs and optimize sensory discrimination.

Title: Linking electrophysiology and optophysiology *in vivo*

Authors: *P. LEDOCHOWITSCH[1], M. DUCROS[1], R. LIU[1], M. A. BUICE[1], C. MITELUT[1,2], C. ANASTASSIOU[1], P. SAGGAU[1], T. J. BLANCHE[1,3];

Abstract: Single-unit recordings remain a core technology for *in vivo* electrophysiology. Yet, they offer only limited information about the location, morphology, or genotype of the recorded cells. Compared to traditional micro-wire electrodes, high-density silicon `polytrodes' improve single-unit isolation. Nonetheless, accurate, automated spike sorting remains a tremendous challenge, especially for high channel-count, contiguous electrode arrays. Ground truth data that

tie *in vivo* spike signals to the actual spiking neuron, crucial to validating spike sorting algorithms, are extremely difficult to acquire. On the other hand, ground truth data sets have been gathered through simultaneous polytrode recordings and patching of nearby cells in slice [Anastassiou et al, in press] and *in vivo* [Henze et al, 2001] yet this approach is impractical for an awake *in vivo* preparation where many cells contribute to the neural code as well as to the extracellularly recorded signals. In this work, we present viable and scalable alternatives. We combined high-density electrophysiology with multiphoton Ca^{2+} imaging, and single-cell optogenetics, to identify extracellular electrical signatures of specific neurons. We used high density silicon polytrodes with up to 900 recording sites spaced every 20 μm; resonant scanning, volumetric multiphoton imaging; a high-speed (>300 Hz) spatial light modulator (SLM) for single cell photo-stimulation and aberration correction, GCamP6f transgenic mice, and red-shifted channel rhodopsin derivatives (C1V1, ReaChR). We demonstrate and discuss spike detection and clustering in the presence of photovoltaic artifacts. We present strategies for establishing correspondence between extracellular action potentials and Ca^{2+} spikes. We further show that, with appropriate stimulation parameters, multiphoton-mediated photoactivation can occur in the absence of opsin expression. Our approach provides ground truth *in vivo* data for validating electrical and optical spike sorting algorithms, for optimizing the design of next generation polytrodes, and for quantifying the sampling biases inherent in extracellular recordings.

Title: Local connectivity of long-range projection neurons in mouse primary visual cortex

Authors: ***M. KIM**, M. IACARUSO, P. ZNAMENSKIY, T. MRSIC-FLOGEL;
Biozentrum, Univ. of Basel, Basel, Switzerland

Abstract: Cortico−cortical projections from mouse primary visual cortex (V1) to different higher visual areas convey distinct signals from the visual stimulus (Glickfeld et al., 2013).

However, it is not clear whether neurons projecting to the same target structure are preferentially interconnected, whereby they form functional subnetworks that process similar types of visual information. Here we investigate local synaptic connectivity and intrinsic membrane properties of layer (L) 2/3 and L5 V1 pyramidal cells projecting to either the anterolateral (AL) or the posteromedial (PM) cortical area, using multiple whole-cell patch-clamp recordings in brain slices targeted to neurons labelled with retrograde tracers (Cholera toxin B 488 and 594 injected in AL and PM respectively). We also characterize the visual response properties of these neurons with two−photon calcium imaging in anesthetized mice. We find that (i) AL and PM projection neurons in L2/3 preferentially receive local inputs from neurons projecting to the same long−range target, (ii) neurons projecting to both areas (i.e. double labelled with both retrograde tracers) are more frequent in L5 than in L2/3, (iii) double labelled neurons in L5 receive and provide more local connections than AL and PM projection neurons, (iv) AL projection neurons rarely receive synaptic inputs from other projection neurons in L5, (v) firing frequency of AL projection neurons by somatic current injection is higher than PM projection and double labelled neurons in L5, and (vi) functional tuning properties of these projection neurons in L2/3 are only slightly but significantly different under anaesthesia. Overall, our results indicate that local connectivity of long−range projection neurons in V1 are organized in a projection− and lamina−specific manner.

Title: Construction of a voxel based mesoscopic mouse connectome

Authors: K. D. HARRIS[1], J. HARRIS[2], H. ZENG[2], *S. MIHALAS[2], E. SHEA-BROWN[1]; [1]Applied Mathematics, Univ. of Washington, Seattle, WA; [2]Allen Inst. For Brain Sci., Seattle, WA

Abstract: Construction of a voxel based mesoscopic mouse connectome Kameron Decker Harris, Julie Harris, Hongkui Zeng, Stefan Mihalas, Eric Shea-Brown The long range connections between different areas in a mouse brain have been investigated using a hundreds of injections of an anterograde viral tracing followed by two photon tomographic imaging. For each experiment, injection sites are annotated both volumetric and by ontology, the images are segments and registered in 3D (Allen Connectivity Atlas). This establishes an injection based connectivity, which links the strength of connections to a particular position in the mouse brain from any of the areas which were included in the injection. In the past we used this information with two hypotheses: 1. that the signals sum linearly and 2. that the integral of the connections between different areas are independent of the exact position of the injection within the source region. This data was used to construct a mesoscopic whole brain connectome, which defines the connections between regions which can be as big as a few mm^3. However, the data are available at a finer scale: 100 μm voxel resolution. Our goal is to exploit this increased resolution by fitting a voxel-voxel connection weight matrix using these injection experiments. However, due to the large number of voxels compared to the number of injections, the problem is vastly underdetermined: the full voxel to voxel connectivity would have ~ 10^{12} degrees of freedom, while we are limited to $<10^3$ injections. Evidence from topographic maps suggests that some connection weights may vary smoothly in source and target position. We develop a way to regularize the underdetermined problem with a smoothness assumption and apply it to test data, and to evaluate the validity of this assumption. We pose the regularized inference as a convex optimization problem. This allows us to solve it efficiently for matrices with tens of millions of entries. The accuracy of the resulting weight matrix can be quantified via cross-validation, which also allows us to compare this spatial connectivity to the coarser regional connectivity. We start by applying these techniques to the visual areas. In our ongoing work, we hope to recover topographical correlates of stimuli (such as retinotopy) directly from connectivity as well as obtain a more detailed description of the mesoscale connectome. We also investigate parallel optimization methods which will allow us to solve for whole-brain connectivity matrices at O(100 μm) resolution.

Title: Mechanisms of experience dependent synaptic stabilization in layerII/III excitatory neurons in mouse visual cortex

Authors: *J. SUBRAMANIAN, A. BALCIOGLU-DUTTON, E. NEDIVI;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Changes in sensory experience lead to formation of new synapses and elimination of some pre-existing synapses in corresponding sensory cortices. Excitatory synapse formation is thought to be a multistep process that involves exploratory protrusion of new dendritic spines followed by spine retraction or by recruitment of synaptic proteins and spine stabilization. Conversely, excitatory synapse elimination potentially involves initial synaptic loss, followed by spine retraction. Unfortunately, delineating these steps and their underlying molecular mechanisms *in vivo* has been hampered by the need to independently label the dendritic spine separately from the synapse, and to chronically follow their dynamics at high temporal resolution. Further, how experience drives formation and stabilization of new synapses remains poorly understood. By combining *in utero* electroporation, cranial window implantation and multi-color two-photon microscopy, we were able to simultaneously track the fate of dendritic spines and their synapses in individual layer II/III neurons in mouse visual cortex. We find that excitatory synapse formation and stabilization is a protracted process that occurs over a period of days. Only a small fraction of newly formed spines recruit PSD95, an excitatory post synaptic density protein, and the presence of PSD95 correlates with their stabilization. To gain molecular insight into synapse formation/stabilization, we tested for participation of CPG15, a small protein indirectly implicated in synaptic stabilization and expressed in visual cortex in response to visual experience, by comparing steps in synapse formation in wild type (WT) versus CPG15 knock out (KO) mice. We found that new spine protrusions are similarly initiated in WT and KO animals. However, in the KO mice, newly formed spines were not able to recruit PSD95 and were lost as a consequence. Interestingly, the deficit in excitatory synaptic remodeling in KO mice is dependent on the animals' light experience. In total darkness, where CPG15 expression is down regulated in WT mice, synaptic dynamics were similar between the two genotypes. Our prior studies have shown that inhibitory synapses can also be formed on dendritic spines. To test whether CPG15 regulate inhibitory synapses, we also tracked the dynamics of Gephyrin, a post synaptic protein at inhibitory synapses. In contrast to excitatory synapses, inhibitory synaptic remodeling is not affected by CPG15, thereby, demonstrating distinct molecular requirements for these two processes. Thus, we propose that CPG15 could selectively stabilize excitatory synapses that are active during experience-dependent plasticity.

Title: Correlated turnover of inhibitory boutons during ocular dominance plasticity

Authors: *R. RAJENDRAN, H. SAIEPOUR, A. J. HEIMEL, C. N. LEVELT;
Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: Inhibitory neurotransmission has been suggested to play a major role in adult cortical plasticity. Studies from our lab and others demonstrated that inhibitory synapses on apical tufts of layer 2/3 pyramidal neurons show an increased turnover during ocular dominance (OD) plasticity (van Versendaal et al., 2012, Chen et al, 2012), while this is not the case with excitatory synapses (Hofer et al., 2009). However, it is unclear which inhibitory neuron subtype provides input to these plastic synapses. Parvalbumin (PV) neurons have been strongly implicated in ocular dominance plasticity, and reduction of PV inhibition results in increased plasticity in various brain regions (Kuhlman et al., 2013, Donato et al., 2013). On the other hand studies using optogenetic techniques have shown that Somatostatin (SST) and Vasoactive intestinal polypeptide (VIP) interneurons are necessary and sufficient for adult OD plasticity (Fu et al., 2015). More recently, transplantation of medial ganglionic eminence, which consists of PV and SST but not VIP interneuron populations, in adult visual cortex, reinstates OD plasticity (Davis et al., 2015). While VIP neurons mostly innervate other interneurons, PV and SST interneurons are known to provide dense innervation to layer 2/3 pyramidal neurons. We therefore considered PV and SST as possible candidates to test which interneuron subtype provides inputs to the plastic cohort of inhibitory synapses, on layer 2/3 pyramidal neurons (van Versendaal et al., 2012). PV or SST neurons in binocular primary visual cortex of mice are labeled with GFP, using a viral vector, and labeled boutons imaged through a cranial glass window, using *in vivo* 2-photon imaging. Imaging sessions are repeated every 4 days during baseline, monocular deprivation and recovery (van Versendaal et al., 2012). Boutons are tracked

through all time points and percent turnover rate was determined. We will present data showing how the turnover of boutons from PV- or SST-expressing interneurons correlates with the turnover of inhibitory synapses on layer 2/3 pyramidal neurons during OD plasticity.

Abstract: The visual cortex of adult mice retains the ability to recover upon deactivation after monocular enucleation (ME). Open eye potentiation induces an early but restricted reactivation, leading to the expansion of the binocular zone into monocular territory. The slower and larger impact of cross-modal plasticity facilitates reactivation of the medial monocular cortex by whisker-related inputs (Van Brussel et al., 2011). A dark exposure (DE) period of 10 days prior to ME specifically prevents the late cross-modal reactivation. DE affects GABAergic synaptic transmission differently in binocular and monocular V1, showing that intracortical inhibition is an important regulator of the cross-modal response to unilateral visual deprivation (Huang et al., 2010; Nys et al., in revision). The subpopulation of somatostatin (SOM)-expressing inhibitory interneurons has the potential to play a role in regulating this cross-modal plasticity. These cells do not receive thalamic input and are widespread in infragranular layers where the cross-modal component has a maximal influence in the visual cortex upon loss of the dominant sensory input (Iurilli et al., 2012; Markram et al., 2004; Urban-Ciecko et al., 2015, Van Brussel et al, 2011).

Localized optogenetic SOM-interneuron activation in V1/V2M upon Cre-dependent rAAV2/7 driven stable-step function opsin (SSFO) transduction was performed on 3 consecutive days, prior to ME, combined or not with DE pretreatment. Successful activation/deactivation of the SSFOs by blue/yellow laser pulses was verified by means of extracellular multi-unit recordings. The limitation or potentiation of plasticity by optogenetic stimulation of SOM-interneurons was determined by charting the expression levels of the activity marker zif268. The modulation of SOM-interneurons hampered cross-modal plasticity in all conditions. These observations identify the SOM-interneuron population as an essential cellular component and call for future investigations aiming at elucidating how SOM-specific inhibitory mechanisms direct cross-modal plasticity in adulthood.

Title: Daily *in vivo* imaging of inhibitory and excitatory synapses during the progression of an ocular dominance shift

Abstract: The capacity for dynamic adaptations in response to environmental changes is a key mechanism mediating neuronal plasticity. Inhibitory neurons are known to play a vital role in defining the window for critical period plasticity during development, and it is increasingly apparent that they continue to exert powerful control over experience dependent cortical plasticity in adulthood. During normal visual experience, inhibitory dendrites and synapses are highly dynamic in the binocular visual cortex of the mouse. Monocular deprivation (MD), which induces an ocular dominance (OD) shift, significantly increases the elimination of inhibitory synapses. In contrast, the dynamics of spines, assumed to be a morphological surrogate for excitatory synapses, are not significantly altered after MD on layer II/III pyramidal neurons.

However, after a MD there is a greater likelihood that dynamic spines and inhibitory synapses will occur near each other. This clustering of dynamic events suggests that a subpopulation of dynamic spines may be preferentially affected and is hidden within the larger population of dynamic spines, which as a whole does not appear to be significantly altered by MD. To determine if such a population exists as well as to dissect the progression of an OD shift in greater detail, we utilized a three-color labeling strategy in conjunction with spectrally resolved two-photon microscopy to image all the excitatory and inhibitory postsynaptic sites on individual neurons in the binocular visual cortex of living mice. Daily imaging of the same neurons reveals the structural dynamics of both excitatory synapses, labeled with PSD-95-mCherry, and inhibitory synapses, labeled with teal-gephyrin. We find that under normal visual experience, the majority of dynamic spines lack PSD-95 during daily imaging. With the ability to discern between dynamic spines that do or do not carry an excitatory synapse, we now examine excitatory and inhibitory synapse dynamics and their spatial relations during the progression of an OD shift with high temporal resolution.

Title: Temporal frequency-dependent potentiation of visually-evoked responses in adult mouse visual cortex

Authors: *C. L. LANTZ, E. M. QUINLAN;
Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Repeated visual presentation of sinusoidal gratings induces robust stimulus-selective response potentiation of visually evoked potentials (VEPs) in layer 4 of mouse visual cortex (Cooke, Bear, 2010). Here we use this robust form of experience-dependent synaptic plasticity to survey the plasticity available to different classes of neurons across layers of the visual cortex. Chronically implanted electrode arrays were used to acquire VEPs and single units across all cortical layers in awake adult C57 mice. Visual stimuli (high contrast, low spatial frequency

sinusoidal gratings) reversing at 1 Hz induced an increase in the visually-evoked firing rates in fast spiking inhibitory neurons in layer IV (FS IN; percent change 148 ± 53%) and in regular spiking (RS) neurons in all layers (percent change; layer II/III, 85 ± 23%; layer IV, 109 ± 30%; layer V, 93 ± 43%). However, an increase in the VEP amplitude was observed in layer IV (percent change; 19.2 ± 3 %) and V (17.5 ± 6%) but not layer II/III (1.4 ± 4%). Thus the source of increased neuronal excitability following repetitive visual stimulation at 1 Hz differs across cortical layers. Reversible pharmacological silencing of cortical spiking confirmed an increase in the thalamocortical contribution to the VEP (percent change, layer IV, 32 ± 5%; layer V, 12 ± 5%), and an increase in the corticortical contribution to the VEP in extragranular layers (11.3 ± 5%). In contrast, visual stimuli presented at 10 Hz induced a decrease in visually-evoked firing rates of RS neurons across cortical layers (percent change; layer II/III, -60 ± 5%; layer IV, -39 ± 10%; layer V, -50 ± 15%) and no change in excitability of layer IV FS INs (29 ± 72%). However, VEP amplitudes were increased throughout the visual cortex (layer II/III, 38 ± 12%; layer IV, 43 ± 6%; layer V, 53 ± 19%). This suggests that 10 Hz visual stimulation recruits mechanisms of firing rate homeostasis that are not dependent on enhancing excitability of FS INs. Indeed, NARP-/- mice, which have a deficit in the recruitment of inhibition from FS INs due to reduced excitatory drive, express potentiation of VEP amplitudes in response to 10 Hz but not 1 Hz visual stimulation.

Title: Sensory experience modifies the spatial relationship between orientation and ocular dominance maps in visual cortex

Authors: S. L. CLOHERTY[1], N. J. HUGHES[2], G. J. GOODHILL[2], *M. R. IBBOTSON[1]; [1]Natl. Vision Res. Inst., Melbourne, Australia; [2]Queensland Brain Inst., Univ. of Queensland, Brisbane, Australia

Abstract: Brain structure is influenced by sensory inputs during development and much has been gained by investigating this topic in the mammalian visual cortex. Maps of orientation

preference (OP) and ocular dominance (OD) in the primary visual cortex can be readily manipulated by rearing animals in environments with restricted visual input (e.g. stripe rearing or monocular deprivation). However, in all previous experiments of this type the spatial relationship between OP and OD maps has appeared fixed. However, computational models for map formation based on 'dimension-reduction' predict that the relationship between OP and OD maps is sensitive to visual experience. We have shown that indeed this relationship can be modified by altered visual experience. We reared cats wearing cylindrical lenses over both eyes for 6 hours per day (otherwise in the dark), biasing input in one eye towards vertical orientations, and in the other eye towards horizontal orientations. By doing this we were able to manipulate both the OP and OD maps simultaneously. After ~5 months of rearing we used intrinsic signal optical imaging to measure OP and OD maps in primary visual cortex and compared them to maps from cats reared without lenses (subject to the same light-dark cycle). In our normally-reared cats OP pinwheel centres were most often located in the middle of OD columns, as reported previously. However, in our cross-reared animals we observed a significant shift of OP pinwheel centres away from the middle of OD columns. The shift in OP pinwheels that we observed in our cross-reared animals is well predicted by a computational model for map formation based on dimension reduction. Our results reveal a previously unknown degree of brain plasticity in response to altered sensory input and provide further evidence that the principle of dimension reduction captures essential elements of the mechanisms by which cortical maps develop.

Title: A new effective cell surface proteomics approach for mm3-tissue samples to investigate cross-modal plasticity in mouse visual cortex

Authors: *L. H. ARCKENS[1], N. LOMBAERT[1], J. NYS[1], D. VALKENBORG[2], G. BAGGERMAN[2], K. SMOLDERS[1];

Abstract: The contralateral visual cortex of adult mice reactivates completely upon monocular enucleation (ME) due to a combination of consecutive visual and cross-modal plasticity processes (Van Brussel et al., 2011). However, this response is age-dependent. Adolescent mice clearly lack the late recruitment of cross-modal plasticity mechanisms and therefore fail to fully recover from ME (Nys et al., 2014). A recent 2-D DIGE screen suggested a critical role for cytoskeletal changes. Yet, the importance of plasma membrane proteins (PMPs) like (G-protein coupled) receptors, ion channels and transporters cannot be judged by this in-gel proteomics approach. Here we report a new workflow where biotinylation of acute tissue slices and streptavidin pulldown from mm3-scale tissue is followed by shotgun proteomics. It allowed the selective extraction and identification of >1,600 proteins of which more than 60% is reported to be associated to the plasma membrane. This new approach convincingly outcompetes the traditional approach of PMP extraction by ultracentrifugation, suffering from poor extraction efficiency and high sample consumption. Furthermore, we delivered proof-of concept for neurobiology research that our method allows focusing on PMP proteins located at the synapse, in neuronal projections and in dendritic spines. Upon enrichment, subjecting the samples to a gel-free differential TMT mass spectrometry screening provides a more complete view on the signaling cascades regulating the age factor for cross-modal plasticity. We believe that many research fields outside neuroscience, including cancer, immunology and stem cell research will also greatly benefit from our new plasma membrane proteomics research approach.

Title: Experience-dependent miR-34a triggers critical period plasticity by repressing GAT1

Authors: *Y. KOBAYASHI[1,2], M. D. CAIATI[1], T. K. HENSCH[1,2];
[1]Harvard Univ., Cambridge, MA; [2]Boston Children's Hosp., Boston, MA

Abstract: Controlling GABAergic transmission is pivotal for inducing critical period plasticity, but the underlying molecular mechanisms remain elusive. Here, we show that miR-34a, an experience-dependent microRNA, triggers visual cortical (V1) plasticity by directly repressing the major GABA transporter, GAT1. In mouse V1, miR-34a emerged gradually after eye-opening predominantly in the inhibitory parvalbumin (PV) positive-cells. Dark-rearing delayed this developmental increase concomitant with a post-transcriptional up-regulation of GAT1. Mechanistically, miR-34a directly repressed GAT1 expression through the 3' untranslated region of GAT1 mRNA (Slc6a1). Conditional deletion of miR-34a within PV-cells decreased tonic inhibition in pyramidal cells and accelerated the decay constant of evoked IPSCs, consistent with an elevated expression of presynaptic GAT1. Finally, brief monocular deprivation revealed a lack of visual plasticity at the typical critical period peak (P24-28) in the miR-34a conditional knock-out mice, which was rescued by administration of a selective GAT1 inhibitor, NO711. These data demonstrate a developmental role for the miR-34a/GAT1 axis within PV-cell circuits to optimally delay critical period onset by regulating extracellular GABA levels.

Title: Lynx1 limits dendritic spine turnover in adult visual cortex

Authors: *M. SAJO[1,2,3], G. C. R. ELLIS-DAVIES[2], H. MORISHITA[1,2,3];
[1]Psychiatry, [2]Neurosci., [3]Ophthalmology, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Cortical plasticity is limited after the developmental critical period. This in turn limits recovery from brain disorders and injuries in adults. Identification of the mechanisms that regulate developmental decline in plasticity not only at functional but also at structural level would provide promising targets for robust recovery. In mouse visual cortex (V1), a well-established model of cortical plasticity, it is known that adult wild-type (WT) mice require 4 days of monocular deprivation to elevate the spine gain rate in layer 5 pyramidal neurons (Hofer et al 2009). However, no change was induced in spine loss rate, a juvenile signature of plasticity. Lynx1, an endogenous inhibitor for nicotinic acetylcholine receptors, was recently identified to limit juvenile-like experience-dependent functional plasticity in the adult V1. We hypothesized that the robust juvenile-like spine turnover is masked by the increased expression of Lynx1 in adults. To test this, the spine turnover rate in adult V1 of Lynx1 knock-out (KO) mice was measured by *in vivo* chronic imaging using two-photon microscopy. Dendrites from layer 5 pyramidal neurons were sparsely labeled by mating Lynx1KO mice with Thy1-GFP M line mice. Cranial windows were chronically implanted over the visual cortex. Dendrites in layer 1 of male mice were subjected to longitudinal fluorescent imaging every 4 days before and after monocular deprivation. We found that, in the adult Lynx1KO mice, the baseline spine gain rate was already higher than that of adult WT mice without deprivation, and comparable to the elevated rate in deprived adult WT mice. This spine gain rate remained high after 4 days of deprivation. Strikingly, spine loss rate was also elevated in Lynx1KO mice at the baseline level and remained higher after the deprivation compared to WT matched controls. Collectively, the removal of Lynx1 is not only sufficient to unmask robust spine gain without additional visual deprivation, but also allows an increase in spine loss before and during monocular deprivation. Our data point to the key role of Lynx1 in masking juvenile form of structural plasticity through its action on spine turnover.

Title: Regulation of experience-dependent plasticity in visual cortex following ngr1 deletion within individual cortical layers

Authors: *M. G. FRANTZ[1,2], A. W. MCGEE[3];
[1]Michael Frantz, Los Angeles, CA; [2]Neurosci. Grad. Program, [3]Saban Res. Inst., USC, Los Angeles, CA

Abstract: The neural circuits of cerebral cortex are most sensitive to modification by experience during developmental critical periods. Yet how the duration and closure of critical periods are regulated remains poorly understood. Within the critical period for ocular dominance (OD) plasticity, but not thereafter, a brief four-day monocular deprivation (MD) results in saturating shifts in responses of single units in mouse binocular visual cortex towards the nondeprived eye. However, mice lacking the nogo-66 receptor gene (ngr1) retain this plasticity as adults. How ngr1 contributes to closing this critical period is unclear. To explore the neuronal expression requirements for ngr1 to limit OD plasticity within adult visual cortex, we are characterizing the effects of 4-day MD of adult mice in which we have deleted the ngr1 gene in subsets of cortical neurons by combining a conditional 'floxed' mutant of ngr1 (flx) with one of several driver lines for Cre recombinase. Deleting ngr1 in cortical excitatory neurons with the CamK2a-Cre transgene permits OD plasticity at postnatal day 60 (P60) indistinguishable from the constitutive ngr1 KO mouse. In on-going experiments, we are examining whether ngr1 expression is required by excitatory neurons in one or more layers of cortex to close this critical period. These experiments will improve understanding of where ngr1 operates within visual cortex to close the critical period and how OD plasticity is coordinated between cortical layers.

Title: Bidirectional regulation of matrix metalloproteinase-9 (mmp-9) activity by visual experience in the adult mouse primary visual cortex

Authors: *S. MURASE, Y. GU, E. M. QUINLAN;
Biol., Univ. Maryland, College Park, MD

Abstract: MMP-9, an extracellular zinc-dependent endopeptidase, participates in the activity-dependent remodeling of dendritic structure by degrading components of the extracellular matrix (ECM). We have recently shown that MMP-9 has widespread impact on cortical circuit development, including the regulation of neuronal morphology, synaptic connectivity and excitability. Degradation of the ECM by MMP-9 has also been implicated in the potentiation of excitatory synapse structure and function in the juvenile hippocampus and visual cortex. Structural and functional plasticity are significantly constrained over the course of postnatal development in the mammalian cortex. However, binocular visual deprivation through dark exposure (DE) reactivates synaptic plasticity in the primary visual cortex (V1) of adult rodents, promoting the structural and functional recovery from severe amblyopia. Here we show that the expression and activity of MMP-9 is bidirectionally regulated in adult mouse V1 by visual experience. Dark exposure in adulthood decreases the expression (34±5.6%) and activity (cleavage of β-dystroglycan 40±7.3%) of MMP-9. Subsequent brief exposure (2 hr) to a normal lighted environment (DEL) induces a rapid recovery of MMP-9 expression (115±7.9%) and an increase in MMP-9 activity (317.8±50.4%). Reduction of excitability in dark-exposed V1 with diazepam, an allosteric modulator of ligand-bound $GABA_A$ receptors, which inhibits the rescue of ocular dominance plasticity, decreased the expression and activity of MMP-9 (41±5.1% and 31±11.5%) and blocked the bidirectional regulation of MMP-9 by visual experience. In contrast, treatment of $NARP^{-/-}$ mice with diazepam, which rescues ocular dominance plasticity, enabled the bidirectional regulation of MMP-9 expression and activity by visual experience. Importantly, *in vivo* zymography for MMP-9 activity colocalized with markers for excitatory synapses (VGluT1, 61.2±5.3%; VGluT2, 43±3.3%), and synaptic MMP-9 activity was reduced by DE (63.2±6.1%) and enhanced by DEL (133.6±10.6%). These data support a model in which synapse-specific degradation of ECM is activated by visual experience following DE, which may participate in experience-dependent recovery of structure and function in dark-exposed amblyopes. Title: Environmental enrichment preserves lifelong ocular dominance plasticity in mouse visual cortex

Authors: *F. GREIFZU, S. LÖWEL;
Georg-August Univ. Göttingen, Göttingen, Germany

Abstract: Ocular dominance (OD) plasticity in the primary visual cortex (V1) of standard cage raised mice declines during postnatal development and is absent beyond postnatal day (PD) 110 (Lehmann & Löwel, 2008, PLoS ONE). Using *in vivo* optical imaging of intrinsic signals we have shown that raising mice in an enriched environment (EE) can extend the sensitive phase for OD-plasticity up to PD196 (Greifzu et al., 2014, PNAS). This preserved OD-shift was juvenile-like as it was mediated by reductions in deprived eye responses in V1. Whether EE can preserve OD-plasticity throughout life and if it is continuously the juvenile type of OD-plasticity is not yet known. We therefore raised mice in EE until >PD400 or >PD700 and examined them for OD-plasticity. Indeed, 7 days of MD induced an OD-shift in EE-mice until at least PD809 (oldest mouse tested). In EE-mice >PD400/>PD700, the ODI decreased from 0.25±0.02 (n=5) before MD to 0.07±0.03/0.01±0.04 (n=6/4) after MD ($P<0.01$ for both groups, t-test). In contrast to the younger EE-mice, which showed a juvenile-like OD-plasticity, the old EE-mice displayed an adult OD-shift, mediated by increases in open eye responses in V1. In addition, EE housing could also restore OD-plasticity in standard cage mice which are beyond the sensitive phase for OD-plasticity: transferring mice from standard cages to EE at PD110 allowed OD-plasticity after MD in animals until at least PD922. Taken together, EE preserves lifelong OD-plasticity. In EE-mice around PD200, OD-shifts are mediated by reductions in deprived eye responses (juvenile-like OD-shift), while OD-shifts in EE-mice older than PD400 are mediated by increases in open eye responses in V1 (adult OD-shift). Since in standard cage raised mice, juvenile OD-plasticity is limited to the critical period, which ends around PD40, our results suggest that EE-raising prolongs juvenile OD-plasticity by a factor of about 10 (PD40 vs. PD400).

Title: Effect of synaptic plasticity on orientation selectivity in the primary visual cortex

Authors: *G. MATO[1], S. GONZALO COGNO[2];
[1]CNEA and CONICET, Bariloche, Argentina; [2]Inst. Balseiro, Bariloche, Argentina

Abstract: Orientation selectivity is ubiquitous in the primary visual cortex (V1) of mammals. In cats and monkeys, V1 displays spatially ordered maps of orientation preference. Instead, in mice, squirrels and rats, orientation selective neurons in V1 are not spatially organized, giving rise to a seemingly random pattern usually referred to as a salt-and-pepper layout. The fact that such different organizations can sharpen orientation tuning leads to question the structural role of the intracortical connections; specifically the influence of plasticity and the generation of functional connectivity. In this work, we analyse the effect of plasticity processes on orientation selectivity for both scenarios. We study a computational model of layer 2/3 and a reduced one-dimensional model of orientation selective neurons, both in the balanced state. We analyse two plasticity mechanisms. The first one involves spike-timing dependent plasticity (STDP), and the second one the reconnection of the interactions according to the preferred orientations of the neurons; this last rule gives rise to functional connectivity. We find that under certain conditions STDP can indeed improve selectivity but it works in a somehow unexpected way, that is, effectively decreasing the modulated part of the intracortical connectivity as compared to the non-modulated part. The degree of functional connectivity generated by the plasticity process depends on the selectivity in the initial condition. As in the balanced state the degree of selectivity is inversely proportional to the functional connectivity we have a self stabilizing process that tends to a fixed value of selectivity in the final state. For the reconnection mechanism we also find that increasing functional connectivity leads in fact to a decrease in orientation selectivity if the network is in a stable balanced state. Both counterintuitive results are a consequence of the dynamics of the balanced state. We also find that selectivity can be increased by a reconnection process if the resulting connections give rise to an unstable balanced state for a given Fourier mode. We compare these findings with recent experimental results.

Title: Inhibitory synapses are repeatedly assembled and removed at persistent sites *in vivo*

Authors: *K. L. VILLA[1], K. P. BERRY[1], J. SUBRAMANIAN[1], J. CHA[1], P. T. C. SO[1], Y. KUBOTA[2], E. NEDIVI[1];
[1]MIT, Cambridge, MA; [2]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Brain plasticity allows neural networks to dynamically adapt in response to the environment by remodeling connections between neurons. Recent *in vivo* imaging studies have overturned the idea that adult brains are hard-wired, by demonstrating the capacity for structural remodeling of spines and synapses. Such remodeling events are commonly thought to mediate rearrangements in microcircuit connectivity. Using three-color labeling and spectrally resolved two-photon microscopy, we simultaneously tracked *in vivo* the structural dynamics of all excitatory and inhibitory postsynaptic sites on individual neurons in mouse neocortex, using PSD-95-mCherry and teal-gephyrin as markers of excitatory and inhibitory synapses, respectively. We found that on a daily basis inhibitory synapses on dendritic spines are exceptionally dynamic, largely because many of them disappear and reappear in the same location. In contrast, excitatory synapses on the same spines (dually innervated spines) are extremely stable. We performed post-hoc electron microscopy on dendritic segments which had been imaged for 9 days *in vivo* and found that in some cases, an inhibitory axon can be found at the location of a recently disappeared inhibitory synapse, suggesting that the axon may serve as a placeholder for the rapid reformation of the inhibitory synapse. This reversible type of synapse structural dynamics indicates a fundamentally new role for inhibitory synaptic remodeling - flexible, input-specific gating of stable excitatory connections.

Title: Effective compression of predictive information in retinal ganglion cells learned through STDP

Authors: *A. SEDERBERG[1,2,3], J. N. MACLEAN[2,4], S. E. PALMER[3,4];
[2]Neurobio., [3]Organismal Biol. and Anat., [4]Committee on Computat. Neurosci., [1]Univ. of Chicago, Chicago, IL

Abstract: Prediction is necessary for the brain to overcome delays incurred by sensory processing. A recent study by Palmer et al. (PNAS, 2015) revealed that prediction happens early in visual processing, starting in the retina. This predictive information was highly compressible: a single binary output function could capture nearly all of the predictive information carried by a group of cells. In principle, there are very many (2^(2^N)) ways to partition the 2^N binary states of N neurons into one binary output, and the optimal output rule for compressing predictive information could be any of these. The fact that a perceptron, which can implement a tiny fraction of the total possible rules, achieves near optimal representation of the predictive information in the inputs is surprising. This also suggests that using this predictive information downstream of the retina is biologically plausible. Here, we also show that these near-optimal perceptron rules are learnable. We investigate whether this compression can be learned using spike-timing-dependent plasticity (STDP). In the first part of our study, we demonstrate that STDP can learn predictive rules from model data generated by a Markov process with a structured transition matrix, provided the matrix does not correspond to an exclusive-OR-like operation on the inputs. Eliminating temporal structure of input data during the training period diminishes the similarity between the learned perceptron and the optimal perceptron. In the second part of the study, we use data from retinal recordings as the input and demonstrate the efficacy of STDP for learning the optimally predictive output rule. Networks trained with data generated during the playback of a natural movie capture most of the available predictive information.

Title: Plasticity of binocularity and visual acuity are differentially limited by nogo receptor

Authors: *C.-E. STEPHANY[1], L. L. H. CHAN[2], H. H. M. DORTON[1], S. N. PARIVASH[1], S. QIU[3], A. W. MCGEE[1];

Abstract: The closure of developmental critical periods consolidates neural circuitry but also limits recovery from early abnormal sensory experience. Degrading vision by one eye throughout a critical period both perturbs ocular dominance (OD) in primary visual cortex and impairs visual acuity permanently. Yet understanding how binocularity and visual acuity interrelate has proven elusive. Here we demonstrate the plasticity of binocularity and acuity are separable, and differentially regulated by the neuronal nogo receptor 1 (NgR1). Mice lacking NgR1 display developmental OD plasticity as adults. Furthermore, their visual acuity and OD spontaneously recover after prolonged monocular deprivation throughout the critical period. Restricting deletion of NgR1 to either cortical interneurons or a subclass of parvalbumin-positive interneurons alters interlaminar synaptic connectivity in visual cortex and prevents closure of the critical period for OD plasticity. However, loss of NgR1 in PV neurons does not rescue deficits in acuity induced by chronic visual deprivation. Thus, NgR1 functions with PV interneurons to limit plasticity of binocularity, but its expression is required more extensively within brain circuitry to limit improvement of visual acuity following chronic deprivation.

Title: Understanding the role of fluoxetine in reinstating critical period-like plasticity

Authors: *S. BESHARA[1], J. G. A. PINTO[1], D. G. JONES[3], K. M. MURPHY[1,2];
[1]McMaster Integrative Neurosci. Discovery and Study, [2]Psychology, Neurosci. & Behavior, McMaster Univ., Hamilton, ON, Canada; [3]Pairwise Affinity Inc, Dundas, ON, Canada

Abstract: Fluoxetine has emerged as a novel pharmaceutical therapy for amblyopia because it reinstates critical period-like plasticity and promotes total recovery of visual acuity in adult animals. Translating these results from animal models to clinical therapies, however, has been challenging because of the lack of mechanistic understanding. For example, shifts in the physiological excitatory/inhibitory (E/I) balance are necessary to open and maintain the critical period, but fluoxetine's impact on the E/I balance remains unclear: Fluoxetine reduces intracortical concentrations of the inhibitory neurotransmitter GABA, but it increases the expression of genes associated with inhibitory transmission. Because gene and protein expression are only weakly correlated, we do not know if fluoxetine affects the expression of synaptic proteins that determine the E/I balance and the potential for plasticity. Here, we studied the effect of fluoxetine treatment in adult rats, alone or in combination with visual deprivation (monocular deprivation, MD), on a set of highly conserved pre- and post-synaptic proteins (Synapsin, Synaptophysin, PSD-95, Gephyrin). Synapsin and Synaptophysin contribute to exo- and endo-cytosis of neurotransmitter vesicles, respectively, and support normal patterns of neural firing by affecting neurotransmitter release. The glutamatergic and GABAergic receptor scaffolding proteins, PSD-95 and Gephyrin respectively, interact to regulate the number of excitatory and inhibitory synapses thereby affecting the physiological E/I balance. To test if the effects of fluoxetine and MD were global or localized to the primary visual cortex (V1), we compared the frontal cortex, somatosensory cortex, and V1, contralateral and ipsilateral to the deprived eye. We found that MD caused an overall loss of synaptic proteins and a shift in favor of PSD-95. Surprisingly, fluoxetine alone had no impact on protein expression, but when it was combined with MD it prevented the MD-induced changes. Furthermore we found that these effects were restricted to the contralateral V1. Our results support two conclusions. First, MD causes a homeostatic shift towards greater excitation in the cortical area that lost the greatest amount of neural activity. Second, despite reported changes in gene expression, fluoxetine alone does not change protein expression. Rather, fluoxetine's latent effects are only revealed when it is combined with a strong manipulation of neural activity.

Title: Role of creb on the regulation of ocular dominance plasticity

Authors: ***N. S. PULIMOOD**, A. E. MEDINA;
Pediatrics, Univ. of Maryland Baltimore, Baltimore, MD

Abstract: The transcription factor CREB (cAMP Response Element Binding factor) plays a critical role in neuronal plasticity. In previous years, CREB has been implicated in both LTD and LTP, synaptic phenomena that are crucial for the depression and potentiation components of ocular dominance plasticity (dc-ODP and pc-ODP respectively). However the role of CREB in these *in vivo* processes is poorly known. Here we investigated the role of CREB in pc-ODP and dc-ODP, either by blocking or overexpressing CREB *in vivo* in the visual cortex during a critical period of development. We infected mice with a Herpes Simplex viral vector expressing either a dominant negative form or constitutively active form of CREB (CREB-DN or CREB-CA respectively), and chronically implanted electrodes in the binocular zone of the visual cortex. We then recorded visually evoked potentials in awake animals before and after 5 days of monocular deprivation (MD). This 5 day period allows us to distinguish the contributions of dc-ODP and pc-ODP to visual cortex plasticity. In a naïve animal, there is a temporal aspect to the manifestation of ODP - visual cortical responses to stimulation of the deprived eye depress (dc-ODP) after 3 days of MD, but cortical responses to stimulation of the open eye potentiate (pc-ODP) only after 5 days of MD. In CREB-DN infected animals, after 5-7 days of MD, we find that dc-ODP remains intact, but pc-ODP is disrupted. Moreover, CREB-CA infected mice present pc-ODP after only 2 days of MD. These results show that CREB is required for pc-ODP to occur and that overexpression of CREB may induce pc-ODP early, which together support a critical role of CREB in the temporal manifestation of ocular dominance plasticity.

Title: Arc gates the expression of critical period ocular dominance plasticity in the visual cortex

Authors: *K. R. JENKS[1], E. PASTUZYN[2], J. ICHIDA[1], H. BITO[3], M. BEAR[4], J. SHEPHERD[1];
[2]Neurobio. and Anat., [1]Univ. of Utah, Salt Lake City, UT; [3]Univ. of Tokyo, Tokyo, Japan; [4]MASSACHUSETTS INSTITUTE OF TECHNOLOGY, Cambridge, MA

Abstract: Critical periods in development allow rapid acquisition of new skills and refinement of neuronal circuits involved in sensory processing. Ocular dominance (OD) plasticity in the visual cortex (VC) is well characterized and a useful tool to study the molecular mechanisms that underlie critical periods. In juvenile animals, brief closure of one eye results in a decrease of input from the closed eye and an increase of input from the open eye. In adult animals, this OD plasticity is absent. Expression of the immediate early gene *Arc* is required for many forms of synaptic plasticity, and mice lacking *Arc* exhibit deficits in OD plasticity. Thus, we hypothesize that *Arc* is a permissive factor that gates the critical period of OD plasticity. Moreover, we predict that expression of Arc declines with age, and that this decrease contributes to the loss of OD plasticity in adult animals. To test this hypothesis we examined OD plasticity in transgenic mice overexpressing Arc under an activity-dependent promoter. Visually evoked potentials were recorded in layer 4 of the VC prior to and following monocular deprivation at 1, 3, 6 and 9-month timepoints. Preliminary data show that Arc transgenic mice maintained robust OD plasticity even at 9 months of age, while little plasticity was apparent in wild-type littermate controls. To test if the loss of plasticity in wild type mice correlated with a decrease in Arc expression in VC, we used immunohistochemistry and Western blotting to quantify levels of Arc protein in mice at 1, 3, 6, 9 and 12-month time points. Our data indicates that in wild-type mice, Arc expression peaks at 1 month of age, corresponding to the peak of the critical period. However, Arc levels decreased drastically around 3 month of age, and there was little if any expression in mice at 9 and 12 months. In contrast, the transgenic mice maintained significantly higher levels of Arc at all ages. We will test the sufficiency of Arc in controlling OD plasticity by acutely injecting lentivirus containing the Arc open reading frame and promoter into wild-type adult mouse VC. Our results suggest that decreased expression of important synaptic

plasticity genes in excitatory neurons, perhaps via increased inhibitory network activity, leads to a reduced capacity for plasticity in adult brains. Arc may, therefore, be a novel target to enhance adult plasticity and cognition.

Title: Increased visual cortical thickness in sight-recovery individuals

Authors: *M. J. GUERREIRO, M. V. ERFORT, J. HENSSLER, L. PUTZAR, B. ROEDER; Univ. of Hamburg, Hamburg, Germany

Abstract: Studies in permanently blind individuals have started to shed light onto the consequences of visual deprivation on brain morphology. These studies have shown that congenital or early blindness is associated with increased cortical thickness in a number of occipital brain areas, including the calcarine sulcus, cuneus, lingual gyrus and lateral occipital cortex. In contrast, whether cortical thinning observed in typical brain development is linked to a sensitive phase is not yet known. In the present study, we assessed cortical thickness of occipital brain areas in a group of six cataract-reversal individuals (aged 23-45 years, M = 32.7, SD = 8.5, 3 females) and in a group of six age- and gender-matched normally sighted controls (aged 18-45, M = 31.8, SD = 10.0, 4 females). The results revealed that cataract-reversal individuals exhibited higher cortical thickness than normally sighted controls in the left calcarine sulcus and bilaterally in the superior occipital gyrus and transverse occipital sulcus. Furthermore, occipital cortical thickness in cataract-reversal individuals correlated negatively with behavioral performance in an audio-visual task for which visual input was critical (Putzar et al., 2007), suggesting that the higher the visual cortical thickness, the lower the behavioral performance of cataract-reversal individuals. The present results demonstrate that early sensory experience plays a crucial role in shaping brain structure and suggest that the lack of experience-guided synaptic pruning during a sensitive phase of brain development might be maladaptive in cases of sight restoration.

Title: Transient loss of cross-modal influence in primary visual cortex by experience and inhibition

Authors: *R. HATTORI[1,2], T. K. HENSCH[1,2];
[1]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [2]Neurol., Boston Children's Hosp., Boston, MA

Abstract: Early blind or deaf subjects dramatically rewire their brains to accommodate remaining modalities in visual or auditory brain regions, respectively. How this occurs and to what extent primary sensory areas may process other input remains largely unknown. Using intrinsic flavoprotein imaging and electro-physiological recordings from mice, we show that even primary visual (V1) cortex is weakly multimodal throughout life and that this cross-modal influence shifts dynamically during a critical period in postnatal development. Sound alone is able to evoke weak auditory signals in V1 and the cross-modal audiovisual interactions follow an inverse effectiveness rule (weaker visual responses are preferentially boosted), as in other classically-defined multisensory areas. This in turn impairs orientation and direction selectivity of the visual response. Interestingly, cross-modal auditory input to V1 is developmentally regulated, becoming tightly excluded specifically during a critical period for visual development. Maturation of inhibitory circuits within V1 is known to open this critical period. Using dark-exposure, GAD65 knockout mice or benzodiazepine pharmacology, we found that visual experience or the level of GABA function reversibly masked the cross-modal auditory response. Our results demonstrate that mouse V1 is essentially multimodal and has a mechanism to limit the impact of non-visual inputs during a key moment of developmental plasticity. Tight exclusion of cross-modal noise during the critical period increases signal-to-noise ratio for the primary visual modality and may promote the functional maturation of V1 as “visual” cortex.

Title: Nicotinic modulation of somatostatin interneurons reactivates plasticity in adult visual cortex

Authors: ***M. SADAHIRO**[1,2], M. DEMARS[1,2], P. BURMAN[1,2], H. MORISHITA[1,2,3,4,5];

Abstract: A network of cortical inhibition is critical for experience-dependent plasticity in the visual cortex (V1). Although the role of Parvalbumin (PV)-interneurons on plasticity has been extensively studied, contributions of other GABAergic neurons such as those expressing somatostatin (SST) had largely been largely unexplored. Here we aimed to identify the novel molecular and circuit mechanisms governing the regulation of plasticity through SST-interneurons. Enriched in SST-interneurons, Lypd6 is a positive nicotinic modulator belonging to the same family as Lynx1, a known nicotinic plasticity brake expressed in PV-interneurons. Lypd6 expression in V1 decreased after critical period for ocular dominance plasticity in concert with declining plasticity across development. Transgenic neuronal overexpression of Lypd6 led to prolonged plasticity in the adult V1. Viral overexpression specifically in adult SST-interneurons, but not in pyramidal neurons, reactivated V1 plasticity. This effect required the α2 nicotinic acetylcholine receptor, which is highly enriched in Lypd6-positive SST-interneurons. The Lypd6-based plasticity was normalized by chemogenetic activation of PV-interneurons, highlighting a key role of SST→PV disynaptic inhibitory circuits. These results identify the first molecular and circuit mechanisms of V1 plasticity regulation by SST-interneurons and provide novel therapeutic targets for enhancing brain plasticity as means of functional recovery from neurodevelopmental disorders such as amblyopia. *MS, MD Equal Contribution

Title: Enhancement and suppression of motion signals by static stimuli in the human visual system

Authors: *C. QUAIA, B. M. SHELIGA, L. M. OPTICAN, B. G. CUMMING;
LSR, Natl. Eye Inst., Bethesda, MD

Abstract: Perhaps because static stimuli cannot produce a directional signal, their impact on motion processing has rarely been studied. This leaves open the possibility that static stimuli might significantly influence the processing of motion signals. To address this question we measured reflexive ocular following responses (OFRs) in three human subjects presented with a large (28 deg diameter) drifting 1D grating (either sinusoidal luminance modulation or band-passed white noise) to which we added a static mask (a 1D grating of the same kind). We found that the strength and sign of the interaction varied as a function of the relative orientation and contrast of the two gratings. A parallel static mask had a powerful suppressive effect. By varying independently the contrast of the two gratings, we found that the effect appears divisive: if the relationship between the magnitude of the OFR and the contrast of the moving grating is fitted with a Naka-Rushton function, increasing the contrast of the mask simply increases the semi-saturation constant. When the contrast of the two gratings was fixed, the strength of suppression varied as a function of the spatial frequency of the two gratings, but not simply as a function of their relative frequency. In contrast, the addition of an orthogonal static mask could either suppress or enhance the response to a moving grating. Enhancement was observed when the contrast of the static mask was lower or equal to that of the moving grating; suppression was observed otherwise. Enhancement was only observed when the orthogonal static mask and the moving stimulus were presented to the same eye. Suppression with a parallel mask was instead observed in both uniocular and dichoptic conditions, although stronger in the uniocular case. With noise stimuli we were also able to test the effect of changing the temporal structure of the mask (without adding a directional signal). We found that suppression was strongest when the parallel mask was static, intermediate when it was generated anew in each frame (uncorrelated), and relatively weak when it was present for a single frame (5 ms). In contrast, enhancement was equally strong when the orthogonal mask was static, uncorrelated across frames, or presented for two successive frames only, and still sizeable when presented for a single frame. We thus found

(at least) two mechanisms at work. One is suppressive, binocular, stronger for parallel orientations and prefers static stimuli. The other is facilitatory, monocular, stronger for orthogonal orientations, and insensitive to temporal structure.

Title: Optic flow links BOLD suppressed early visual cortex to areas encoding heading direction as predicted by predictive coding

Authors: *A. SCHINDLER, A. BARTELS;
Ctr. For Integrative Neuroscience, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Along the visual processing stream, information is conveyed in a feed-forward manner, from the analysis of simple visual features, to stages that process complex concepts. However, superimposed on this feed-forward pathway, feedback connections convey higher-level information to cortical areas lower in the hierarchy. A prominent framework for these connections is the theory of predictive coding [1] where high-level areas send stimulus interpretations to areas upstream in the hierarchy, which in turn resend prediction errors. Along these lines a growing body of neuroimaging studies show that predictable stimuli evoke smaller blood oxygen level dependent (BOLD) responses than otherwise matched non-predictable counterparts. The origin of such modulatory feedback signals is however widely unknown. Using functional magnetic resonance imaging (fMRI) in healthy human observers we here re-examine the robust finding of relative BOLD suppression that arises when a visual optic flow stimulus is contrasted to a random motion stimulus with matched low-level features [2, 3]. Using functional connectivity analysis we show a highly specific link between BOLD suppressed early visual cortex and two areas known to encode heading direction: entorhinal cortex (EC) and an area in

precuneus (PreC), bordering retrosplenial cortex (RSC). Our results provide first evidence that BOLD suppression for predictable stimuli are indeed mediated by specific high-level areas as predicted by the theory of predictive coding. **References** 1. Title: Spike-field coupling of the anterior cingulate cortex and frontal eye field in goal-directed eye movements

Authors: *S. BABAPOOR-FARROKHRAN[1], M. VINCK[2], T. WOMELSDORF[3], S. EVERLING[1];
[1]Neurosci., Western Univ., London, ON, Canada; [2]Yale Univ., New Haven, CT; [3]York Univ., Toronto, ON, Canada

Abstract: Although numerous functional imaging studies in human subjects have shown that the frontal eye fields (FEF) and anterior cingulate cortex (ACC) are co-activated during cognitively demanding saccade tasks, single unit and local field potential (LFP) studies in nonhuman primates have shown important differences in the activity between these two areas. Little is known about the coupling of spiking activity and local field potentials in these areas. Here we investigated the spike-field synchrony of ACC and FEF neurons with the corresponding LFPs recorded at the same area while monkeys performed a memory-guided saccade task and a pro/anti-saccade task. During the delay period of the memory-guided saccade task, ACC units exhibited increased low gamma (30-60Hz) coupling prior to ipsiversive saccades whereas FEF units displayed increased high gamma (60-100Hz) synchrony prior to contraversive saccades. This finding supports the saccade-generating role of the FEF for contraversive saccades and suggests a potential inhibitory role of the ACC. Furthermore, ACC and FEF units showed a

different pattern of coupling during the preparatory period of the pro/anti-saccade task. ACC units exhibited an increased theta band (3-8Hz) coupling in pro- vs. anti-saccade trials and no difference across gamma band coupling. Similar to the ACC units, FEF units exhibited increased coupling to the theta band for pro-saccades and an increased gamma band (60-100Hz) coupling of FEF units for anti-saccades compared to pro-saccades. These findings support a role of the theta band in rule maintenance, whereas the gamma band may be more involved in motor-related functions. Taken together, our results indicate that theta and gamma oscillations have different roles in cognitive processes and these frequency bands are modulated differently across ACC and FEF.

Title: How does the visual system recover object motion during self-motion?

Authors: *O. W. LAYTON, B. R. FAJEN;
Rensselaer Polytechnic Inst., Troy, NY

Abstract: To move effectively through dynamic environments, humans must perceive both the direction of self-motion and the trajectories of moving objects. While humans perceive the movement of objects relative to a stationary world (world reference frame), optic flow reflects the motion of objects and the background relative to the moving observer (observer reference frame), not the world. The visual system must not only determine what flow is attributed to self- and object motion, but recover object motion in a world reference frame. The importance of this problem has inspired research on the visual conditions in which object motion is recovered, but the underlying mechanisms in the visual system remain unclear. We present a simple model of primate visual areas MT and MSTd that explains how the visual system dynamically estimates both self-motion and object motion in a world reference frame. The optic flow field, which may consist of motion due to the observer and/or moving objects, activates MT cells tuned to different motion directions. Model MSTd responds to the radial, spiral, or translational pattern

most similar to the global flow and estimates the self-motion direction (Duffy & Wurtz, 1991; Layton & Browning, 2014). The model proposes that MT and MSTd recover object motion in a world reference frame through two interacting processes. First, to enhance the self-motion direction estimate, MSTd cells send feedback to inhibit MT cells that do not signal a motion direction that is consistent with the global flow pattern. This changes the population-coded motion direction of cells responding to the discrepant object motion. Second, model MT neurons tuned to opposing motion directions locally compete with one another (Albright et al., 1984; Heeger et al., 1999). An object passing over a discrepant flow pattern deactivates MT cells responding to the background flow and generates rebound activity in cells tuned to the opponent motion direction through disinhibition. The feedback from MSTd and opponent competition in MT shift the population-coded motion direction of the object toward that in a world reference frame. Model simulations show that object motion estimates are similarly affected as human visual judgments under a range of conditions (Warren & Rushton, 2008; 2009). A number of predictions emerge from our model, including that heading need not be estimated for the trajectory of an object to be recovered in a world reference frame. Our model is compatible with the flow parsing hypothesis (Warren & Rushton, 2005), but proposes specific physiological mechanisms and clarifies how self-motion and object motion estimates interact.

Title: Comparing the specification of facial motion in macaques and humans

Authors: *H. ZHANG[1], A. STACY[2], S. JAPEE[2], L. UNGERLEIDER[2];
[1]NIMH, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Dynamic faces convey a wealth of social information. Both macaques and humans depend on facial motion to facilitate the recognition of facial expression in their social interactions. However, the extent to which the specialization for facial motion is represented in the visual systems across the two species remains unclear. Here, we used fMRI to investigate this issue. Four male macaque monkeys were injected with MION prior to fMRI scanning at 4.7T.

During scanning, they viewed blocks of the following four stimulus categories: dynamic frontal-view neutral monkey faces, dynamic common objects, static frontal-view neutral monkey faces, and static common objects. Twenty human subjects participated in a similar fMRI experiment at 7T, in which they viewed blocks of the identical four stimulus categories, except they viewed human faces. For both monkeys and humans, the static face/object stimuli were extracted from the corresponding dynamic video stimuli, and the motion energy in the dynamic face blocks was equated to that in the dynamic object blocks, using an optic flow algorithm. To localize the face-selective regions in the two species, both monkeys and humans also performed separate localizer runs, in which we contrasted activations evoked by images of static faces and static objects. General linear model analyses were performed on whole brain fMRI data to evaluate the fMRI responses evoked by the four stimulus categories. The contrast of the fMRI response to motion caused by faces (dynamic faces versus static faces) relative to the fMRI responses to motion caused by objects (dynamic objects versus static objects) was used to define the location of the brain areas selective for facial motion. Our results showed that, in all four monkeys, significant activations evoked by facial motion were found in the anterior superior temporal sulcus (STS), within the anterior fundus face patch bilaterally ($p<0.001$). In humans, facial motion activated three separate foci in the right STS ($p<0.001$): anterior STS, middle STS and posterior STS, with the anterior STS focus showing the most significant selectivity for facial motion. Taken together, our results suggest that monkeys and humans share similar neural substrates within the anterior STS for the processing of facial motion.

Abstract: One of the major barriers to modelling the primate visual cortex is the complexity of the network. Since each visual area receives input from many other areas, modelling any

subnetwork without ignoring most of its inputs is difficult. One possible way to mitigate this problem is to develop phenomenological (stand-alone) models of various visual areas, which produce realistic spike patterns, and then use them as inputs to more physiologically detailed models of other areas. We are developing such a phenomenological model of primate area MT and hope to use it, as input to mechanistic models of the other areas to which MT projects (e.g. V1, V2, V4, TEO). We developed the model structure and estimated distributions of its parameters using data from the electrophysiology literature. Each physical location in MT is associated with a probability density function over the model parameters. Our model consists of topographically organized units with lateral interactions [1], which are driven by linear kernels that combine input from several fields. The fields include motion, binocular disparity, contrast, and attention. Some of these (e.g. contrast) can be computed fairly directly from video input. Others (e.g. motion and disparity) are estimated using more sophisticated methods from computer vision. Finally, the attention field is manually defined in each frame of the input videos. These methods produce time-varying spike rates, which we convert to spike trains using a Poisson model with correlations. Our approach is data-driven, in that we simply try to produce statistically realistic spike trains without making any assumptions about mechanisms. On the other hand, it is necessary to extrapolate beyond published data in order for the whole MT model population to respond to a variety of stimuli. 1. Rubin, D. B., Van Hooser, S. D., & Miller, K. Figure: Illustration of the model's fits to a variety of tuning curves from the electrophysiology literature: (A) Effect of directing attention inside (blue curve) versus outside (red curve) the receptive field on the directional tuning curve (compare to Figure 1.B in [2]). (B) Speed-tuning of an MT neuron at low (red curve) and high (blue curve) contrasts (compare to Figure 1.C in [3]). (C, D) Evolution of direction tuning for three oriented moving bars (i.e. 45°, 90°, and 135° angle-difference between the major axis of the moving bar and the direction of motion in blue, red, and green respectively). Direction tuning is represented in polar coordinates. (C) Earliest direction-tuned response for a single MT neuron. (D) Direction tuning for the same MT cell averaged over the last 1,500ms of the stimulus presentation (compare to Figure 2.A,B in [4]). All the results shown in this figure belong to the simulations where we drove our model with laboratory stimuli (e.g. moving bars and random dots) so that we could fit our model to existing tuning curves in the literature. However, we also used natural stereo videos from the computer vision community (i.e. KITTI Dataset) to drive our model.
